50% in the incubator (Sedin, 1995). Other factors, including activity, airflow, and prenatal steroid treatment, also influence the magnitude of transepidermal free water losses (Aszterbaum et al, 1993; Sedin, 1995).

Insensible water losses from the respiratory tract depend mainly on the temperature and humidity of the inspired gas mixture and on the respiratory rate, tidal volume, and dead space ventilation. In a healthy term newborn, the water loss through the respiratory tract is approximately half of the total insensible water loss if the ambient air temperature is 32.5° C and the humidity is 50% (Sedin, 1995). However, the respiratory water loss in critically ill preterm and term infants undergoing mechanical ventilation is zero if the gas mixture is saturated with water at body temperature.

### **Sensible Losses**

Free water loss in the urine is the most important form of sensible water loss. Smaller preterm infants without systemic hypotension or prerenal renal failure usually lose 30 to 40 mL/kg/day water in the urine on the first postnatal day and around 120 mL/kg/day on the third day after birth. In stable, more mature preterm infants born after the 28th week of gestation, urinary water loss is around 90 mL/kg/day on the first postnatal day and 150 mL/kg/day on the third day (Coulthard and Hey, 1985). Owing to their renal immaturity, preterm neonates have a tendency to produce dilute urine, thereby increasing their obligatory free water losses.

Water losses in the stool are less significant, amounting to approximately 10 mL/kg/day in term infants and 7 mL/kg/day in preterm infants during the first week of life (Sedin, 1995). Water losses in the stool increase thereafter and are influenced by the type of feeding and the frequency of stooling.

### **Surgical Losses**

The most commonly encountered surgical water losses occur when a nasogastric tube is placed under continuous suction to provide relief for the gastrointestinal tract in conditions such as necrotizing enterocolitis and postoperative management after abdominal surgery. Because these losses may be substantial, their replacement every 8 to 12 hours is necessary to maintain appropriate water and electrolyte balance. However, free water retention often develops after surgery, so full replacement of the nasogastric free water loss is not usually recommended. The composition of the replacement solution depends on the electrolyte concentration of the fluid loss. Gastric fluid usually contains 50 to 60 mEq/L of sodium chloride, and the sodium loss should also be replaced.

### **Electrolyte Requirements**

Because sodium, potassium, chloride, and bicarbonate have the most profound effects on TBW volume and fluid balance, only the requirements for these electrolytes are considered here.

### **Sodium and its Anions**

In the preterm infant, sodium chloride supplementation should be started only after completion of the postnatal extracellular volume contraction. In general, as long as the infant's fluid balance is stable, daily sodium requirement does not exceed 3 to 4 mEq/kg/day, and provision of this amount usually ensures the positive sodium balance necessary for adequate growth. Extreme prematurity and pathologic conditions associated with delayed transition or disturbance of fluid and electrolyte balance may significantly reduce or increase the infant's daily sodium requirement. Neonates recovering from an acute renal insult and preterm infants with immature proximal tubule functions who are in a state of extracellular volume expansion (Ramiro-Tolentino et al, 1996) may need daily sodium bicarbonate supplementation to compensate for their greater renal bicarbonate losses.

### **Potassium**

In the early postnatal period, neonates, especially immature preterm infants, have higher serum potassium concentrations than older persons. The etiology of the relative hyperkalemia of the newborn is multifactorial and involves developmentally regulated differences in renal function,  $\text{Na}^+$ ,  $\text{K}^+$ -ATPase activity (Vasarhelyi et al, 2000), and hormonal milieu. In general, potassium chloride supplementation should be started only after urine output has been well established, usually during the second day of life. In the majority of cases, potassium requirement is 2 to 3 mEq/kg/day. However, after the completion of the postnatal volume contraction, preterm infants may need more potassium because of their increased plasma aldosterone concentrations, prostaglandin excretion, and disproportionately high urine flow rates as well as the use of diuretics.

## **Clinical Conditions Associated with Fluid and Electrolyte Disturbances**

### **Extreme Prematurity**

Infants born between 23 and 27 weeks of gestation are at particular risks for acute abnormalities of the fluid and electrolyte status in the immediate postnatal period. Their transepidermal water loss is much higher than that in more mature preterm neonates (see Fig. 30-4), and it is difficult to maintain their water balance unless the excessive losses are prevented. It should be kept in mind that such an infant, when cared for in an open warmer without the use of a plastic heat shield, may lose 150 to 300 mL/kg/day of free water through the skin during the first 3 to 5 days of life. Although the insensible water loss primarily affects the extracellular volume, the intracellular compartment ultimately shares the loss of free water as osmotic pressure in the extracellular compartment rises. As water leaves the cells, intracellular osmolality rises and cell volume diminishes. In the central nervous system, as described earlier, these changes stimulate the generation of idiogenic osmols, resulting in selective increases in intracellular osmolality

and a tendency toward normalization of neuronal cell volumes. This protective mechanism has significant clinical implications for the rate at which hypernatremia should be corrected, and the decrease in serum sodium concentration should not exceed 12 mEq/L/24 hours, especially in the infant in whom the hypernatremia has been chronic (>12 hours).

Because serum sodium concentration is a reliable clinical indicator of extracellular tonicity, monitoring of this parameter every 6 to 8 hours during the first 2 to 3 postnatal days coupled with daily measurements of body weight provide valuable information and appropriate guidance for the fluid and electrolyte management of the extremely immature preterm neonate, especially in the absence of prenatal steroid exposure and if the infant is not cared for in a humidified incubator. Serum osmolality should be directly measured in patients in whom calculated serum osmolality is more than 300 to 320 mOsm/L.

Because immature neonates cared for in an incubator with an ambient air humidity of 50% to 80% require significantly less free water as well as less frequent measurements of serum electrolyte and osmolality (Sedin, 1995), open radiant warmers should be used only for critically ill, extremely labile preterm infants requiring frequent hands-on medical management. In these cases, the use of a protective plastic heat shield decreases excessive evaporative losses, and total daily fluid intake may be started at 80 to 100 mL/kg/day with 5% dextrose in water. Daily fluid intake is then increased by 10 to 30 mL/kg/day every 6 to 8 hours if the serum sodium concentration rises from the baseline, the goal being to keep serum sodium concentration below 150 mEq/L. As skin integrity improves during the course of the second to third days, serum sodium concentration starts to fall. At this time, a significant stepwise limitation of total fluid intake is obligatory to allow a complete contraction of the extracellular volume to occur and to minimize the possibility of free water overload with its attendant risks for the development of ductal patency, pulmonary edema, and worsening lung disease.

Potassium chloride supplementation may be started as soon as urine output has been established and the serum potassium concentration is below 5 mEq/L. Extremely premature infants are at risk for the development of both oliguric and nonoliguric hyperkalemia, so the serum potassium concentration should be monitored closely, and supplementation discontinued if warranted by changes in serum potassium values or in renal function. Critically ill, extremely immature neonates often receive excess sodium with volume boluses, medications, and the maintenance infusion of their arterial lines. Therefore, extra sodium supplementation usually should not be started during the first few postnatal days so as to prevent a rise in total body sodium concentration and thus in extracellular volume.

Many critically ill preterm infants, however, retain their originally high extracellular volumes even when sodium and water intakes are restricted, and such neonates also tend to lose more bicarbonate in the urine. Interestingly, proximal tubular bicarbonate reabsorption may be appropriate even in the very LBW infant despite the immaturity of their renal functions, as long as extracellular volume contraction takes place (Ramiro-Tolentino et al, 1996). Therefore, the

presence of the extracellular volume expansion appears to be an important factor in the renal bicarbonate wasting in these infants. The diagnosis of functional proximal tubular acidosis in such cases should not rely solely on the finding of an alkaline urine pH, because the distal tubular function is usually mature enough to acidify the urine once serum bicarbonate has decreased to its new threshold. Provided that liver function is normal, daily supplementation of bicarbonate in the form of sodium acetate, potassium acetate, or both normalizes blood pH and serum bicarbonate in these infants and also increases urine pH, aiding in the diagnosis. Once extracellular volume contraction occurs, these neonates generally achieve a positive bicarbonate balance (Ramiro-Tolentino et al, 1996), and supplementation becomes unnecessary.

Other general guidelines in the fluid and electrolyte management of the immature preterm infant during the first week of life are (1) daily calculation of fluid balance and estimation of sodium balance, (2) testing of all urine samples for glucose, albumin, and hemoglobin as well as osmolality or specific gravity, and (3) the daily measurements of serum electrolytes and creatinine, plasma glucose, and blood urea nitrogen. The frequency of testing and the addition of other tests, including the measurement of serum albumin concentration and osmolality, depend on the clinical status, severity of underlying disease, and fluid and electrolyte disturbance of the given patient.

### **Respiratory Distress Syndrome**

There is a well-established relationship between fluid and electrolyte balance and respiratory distress syndrome. Surfactant deficiency results in pulmonary atelectasis, elevated pulmonary vascular resistance, poor lung compliance, and decreased lymphatic drainage. In addition, preterm infants have low plasma oncotic and critical pulmonary capillary pressures and suffer pulmonary capillary endothelial injury from mechanical ventilation, oxygen administration, and perinatal hypoxia (Dudek and Garcia, 2001; Sola and Gregory, 1981). These abnormalities alter the balance of the Starling forces in the pulmonary microcirculation, leading to interstitial edema formation with further impairment in pulmonary functions.

In the pre-surfactant era, an improvement in pulmonary function occurred only during the third to fourth postnatal day. This improvement was usually preceded by a period of brisk diuresis characterized by small increases in glomerular filtration rate and sodium clearance and a larger rise in free water clearance (Costarino and Baumgart, 1991). Although the exact mechanism of the diuresis is not known, it is likely that improving endogenous surfactant production and capillary integrity promoted the recovery of the pulmonary capillary endothelium and lymphatic drainage. The ensuing changes in Starling forces then favored reabsorption of the hypotonic interstitial lung fluid into the circulation, and a delayed "physiologic diuresis" took place.

Currently, with the routine use of surfactant and the more common use of prenatal steroids, the pulmonary compromise and its consequences are less severe. However, because significant improvements in lung function take place only after the majority of the excess free water

is excreted (Costarino and Baumgart, 1991), daily fluid intake should still be restricted to allow for the extracellular volume contraction to take place. If this principle is not followed and a positive fluid balance occurs, preterm infants with hyaline membrane disease are at higher risk for a more severe course of acute lung disease and for presenting with a higher incidence of patent ductus arteriosus, congestive heart failure, and necrotizing enterocolitis as well as a higher incidence and greater severity of the ensuing chronic lung disease.

Antenatal administration of steroids and postnatal use of surfactants have clearly altered the course and clinical presentation of hyaline membrane disease (Ballard and Ballard, 1995; Ishisaka, 1996; Kari et al, 1994). Antenatal steroid administration accelerates maturation of organs including those involved in the regulation of fluid and electrolyte balance (Ballard and Ballard, 1995), while the use of exogenous surfactant decreases pulmonary capillary leak and edema formation (Carlton et al, 1995). Furthermore, surfactant administration does not alter the rate and timing of ductal closure (Reller et al, 1993) although it may affect the pattern of shunting through the ductus arteriosus in the acute period (Kaapa et al, 1993; Kluckow and Evans, 2000). Thus, these interventions generally enhance extracellular volume contraction and aid in the stabilization of fluid and electrolyte homeostasis in preterm neonates with hyaline membrane disease. However, maintenance of a negative water and sodium balance during the first few days of life remains the cornerstone of fluid and electrolyte management in these infants (Tammela, 1995; Van Marter et al, 1990).

On the basis of the events in the pathophysiology of pulmonary edema formation in infants with hyaline membrane disease previously described, the use of furosemide has long been suggested to promote a negative fluid balance and directly inhibit pulmonary epithelial transport processes involved in edema formation in the lungs (Green et al, 1988; Yeh et al, 1984). However, furosemide induces only short-term improvements in pulmonary function in these patients, and no beneficial effects on long-term morbidity or mortality has been documented. Moreover, prophylactic use of the drug during the first postnatal days may lead to intravascular volume depletion with hypotension, tachycardia, and decreased peripheral perfusion as well as to acute and chronic disturbances in serum electrolytes and, thus, osmolality (Green et al, 1988; Shaffer and Weismann, 1992; Yeh et al, 1984). Furthermore, its chronic administration may be associated with an increased incidence of patent ductus arteriosus (Green et al, 1983). Therefore, the use of furosemide during this period should be restricted to patients with oliguria of renal origin whose intravascular volume appears to be adequate.

### **Chronic Lung Disease**

Low gestational age and birth weight, lack of antenatal steroid administration, severe hyaline membrane disease with oxygen toxicity, volu- and barotrauma, air leak, inflammation, patent ductus arteriosus, and insufficient nutrition are among the known etiologic factors for the development of bronchopulmonary dysplasia. In addition, a high

fluid and salt intake during the first weeks of life have been shown to increase the incidence and severity of chronic lung disease. Therefore, careful fluid and electrolyte management during the first weeks of life is of great importance in decreasing the incidence and severity of this condition (see Chapter 49).

### Shock and Edema

In the uncompensated phase of shock, blood pressure is low, cardiac output may be low, normal, or high, effective circulating blood volume is usually decreased, transcapillary hydrostatic pressure is elevated, and capillary integrity and lymphatic drainage are impaired, resulting in edema formation and increased interstitial compliance. The latter condition further enhances fluid accumulation in the interstitium. The changes in the effective circulating blood volume also trigger the release of antidiuretic hormones, including the catecholamines, renin-angiotensin-aldosterone, and vasopressin, resulting in retention of sodium and free water. The specific cause of shock (infection, asphyxia, myocardial insufficiency, hypovolemia, etc.) may independently contribute to this chain of events, further compromising fluid and electrolyte balance. In affected infants, treatment is directed at normalizing tissue perfusion and oxygen delivery by restoring effective intravascular volume, cardiac output, and renal function with the use of vasopressor and inotropic support, as well as with the judicious use of volume expanders while monitoring blood pressure, cardiac output, and changes in organ blood flow (see Chapter 31). In shock refractory to this management, early initiation of low-dose glucocorticoid and mineralocorticoid replacement may help break the vicious cycle by improving capillary integrity and thus effective circulating blood volume, and by potentiating the cardiovascular response to vasopressors and inotropic agents (Seri et al, 2000).

### Patent Ductus Arteriosus

A patent ductus arteriosus significantly increases morbidity and mortality, especially in the very LBW preterm infant. Several conditions, including severe hypoxemia, unstable cardiovascular status, acute deterioration, metabolic acidosis, and increases in extracellular volume and ductal prostaglandin synthesis, have been recognized to promote the patency of the ductus arteriosus (Hammerman, 1995; see also Chapter 56). Accordingly, clinical management aimed at preventing the occurrence of ductal patency involves interventions that keep the cardiovascular status and oxygenation stable, restrict fluid intake, and maintain low levels of local prostaglandin synthesis by the administration of indomethacin (Clyman, 1996). Pharmacologic ductal closure with indomethacin is indicated only during the first two postnatal weeks, because ductal sensitivity to prostaglandins rapidly diminishes thereafter (Clyman, 1996; Van Overmeire et al, 2000).

In the sick preterm infant, indomethacin administration almost always has clinically significant, although mostly transient, renal side effects. Ibuprofen may cause less severe renal dysfunction (Van Overmeire et al, 2000) and cerebral vasoconstriction (Patel et al, 2000). However,

further trials are necessary before ibuprofen can be used in this setting, especially since ibuprofen displaces bilirubin from albumin. If not recognized and treated promptly, the untoward renal actions of the inhibition of prostaglandin synthesis may alter the infant's fluid and electrolyte balance and could potentially reduce the effectiveness of the therapy. Under physiologic circumstances in the immediate postnatal period, renal prostaglandin production is increased to counterbalance the renal actions of vasoconstrictor and sodium- and water-retaining hormones released during labor and delivery (Bonvalet et al, 1987; Gleason, 1987). Thus, compared with the renal function of the adult kidney in euolemia, the neonatal kidney is more dependent on the increased production of vasodilatory and natriuretic prostaglandins, rendering it more sensitive to the vasoconstrictive and sodium- and water-retaining actions of cyclooxygenase inhibition.

In the indomethacin-treated neonate, the unopposed renal vasoconstriction and sodium and water reabsorption lead to decreases in renal blood flow and glomerular filtration rate and to increases in sodium and free water reabsorption. These side effects occur despite the diminishing left-to-right shunt through the closing ductus. Characteristic clinical findings include a rise in serum creatinine level, oliguria, and hyponatremia (Cifuentes et al, 1979). Hyponatremia occurs because the free water retention caused by the unopposed renal actions of high plasma vasopressin levels is out of proportion to the sodium retention induced by angiotensin and noradrenaline. This pattern of renal response can most likely be explained by the fact that in a preterm infant, function of the distal tubule is more mature than that of the proximal tubule (Lumbers et al, 1988), leading to an expanded but somewhat hypotonic extracellular space. Therefore, treatment must focus on maintaining an appropriately restricted fluid intake and avoiding extra sodium supplementation. As the prostaglandin inhibitory effects of indomethacin diminish after the last dose, renal prostaglandin production returns to normal, and the retained sodium and excess free water are rapidly excreted, especially with the improvement in the cardiovascular status as the ductus closes. Similar but somewhat milder changes in renal function have been observed with the use of ibuprofen (Van Overmeire et al, 2000).

Because furosemide increases prostaglandin production, the drug may be used to attenuate the renal side effects of indomethacin if the intravascular volume is judged to be adequate (Yeh et al, 1982). However, furosemide administration may increase the incidence of ductal patency (Green et al, 1983), so routine use of the drug may not be prudent in preterm infants treated with indomethacin, because of the theoretical risk of reopening the ductus arteriosus (Seri, 1995). In cases of hemodynamic instability or to avoid the potential effect of furosemide on ductal closure, dopamine infusion may be used to support the cardiovascular status and attenuate the indomethacin-induced oliguria (Cochran et al, 1989; Seri et al, 1984, 1993). However, there is controversy regarding the efficacy and clinical significance of these interventions (Baenziger et al, 1999; Fajardo et al, 1992; Seri, 1995).

### Growing Premature Infant with Negative Sodium Balance

The 2- to 6-week-old growing preterm neonate who is without significant chronic lung disease and is not undergoing diuretic treatment may present with hyponatremia (serum sodium concentration 125 to 129 mEq/L) due to a relative sodium deficiency (Sulyok et al, 1979, 1985). Despite the low total body sodium and high activity of sodium retaining hormones, such an infant continues to lose sodium in the urine mainly because of the immaturity of the renal function. Although the infant is usually in a positive sodium balance, it is insufficient to keep up with the increased sodium demand of their growth. The treatment of this condition is to provide extra sodium supplementation in the form of sodium chloride (usually 2 to 4 mEq/kg/day) to keep serum sodium values higher than 130 mEq/L.

### Surgical Conditions

Surgery has a major effect on metabolism and fluid and electrolyte balance in the newborn. Preterm infants with acute or chronic lung disease are especially sensitive and respond to the procedure with significant catabolic responses, increases in capillary permeability with the attendant shift of fluid into the interstitial space, and retention of sodium and free water (John et al, 1989). The retention of sodium and free water is secondary to the decrease in effective circulating blood volume and to the increased plasma levels of sodium- and water-retaining hormones, including catecholamines, renin-angiotensin-aldosterone, and vasopressin.

Preoperative management has a significant effect on outcome and should be aimed at maintaining adequate effective circulating blood volume as well as cardiovascular and renal functions. In preterm infants who have evidence of absolute or relative adrenal insufficiency (Watterberg, 2002), the provision of stress doses of steroids may be necessary. In the postoperative period, maintenance of the integrity of the cardiovascular system through the judicious use of volume expanders and pressor support, prompt correction of any acute acid-base disorder, meticulous replacement of ongoing surgical and nonsurgical fluid and electrolyte losses, close monitoring, and intense and effective communication between the neonatal and surgical teams are essential to ensure a successful outcome. As capillary integrity improves, reabsorption and excretion of the expanded interstitial fluid volume takes place, with normalization in the secretion of hormones regulating fluid and electrolyte balance. At this time, the provision of maximized nutritional support becomes essential to restore the anabolic state and growth of the infant.

## ACID-BASE BALANCE

### Physiology of Acid-Base Balance Regulation

Like adults, newborns must maintain their extracellular pH, or hydrogen ion concentration, within a narrow range. A normal pH is essential for intact functioning of all enzymatic processes and, therefore, the intact functioning of all organ systems of the body. Newborns are subjected to many stresses that may affect their acid-base balance. In addition, infants, especially if they are premature, have a limited ability to compensate for acid-base alterations. Therefore, acid-base disturbances are common in the neonatal period. An understanding of the principles of acid-base regulation is essential for proper diagnosis and treatment of these disturbances.

matic processes and, therefore, the intact functioning of all organ systems of the body. Newborns are subjected to many stresses that may affect their acid-base balance. In addition, infants, especially if they are premature, have a limited ability to compensate for acid-base alterations. Therefore, acid-base disturbances are common in the neonatal period. An understanding of the principles of acid-base regulation is essential for proper diagnosis and treatment of these disturbances.

In the healthy human, the normal range of ECF hydrogen ion concentration is 35 to 45 mEq/L. As pH is defined as the negative logarithm of hydrogen ion concentration ( $\text{pH} = -\log [\text{H}^+]$ ), these values of hydrogen ion concentration correspond to a pH range of 7.35 to 7.45. Acidosis is a shift downward in pH to less than 7.35, and alkalosis is a shift upward in pH to more than 7.45. Alterations in normal pH are resisted by complex physiologic regulatory mechanisms. The main systems that maintain pH are the body's buffer systems, the respiratory system, and the kidneys. Some of these systems respond immediately to sudden alterations in hydrogen ion concentration, whereas others respond more slowly to changes but maintain the overall balance between acid and base production, intake, metabolism, and excretion over the long term.

The systems that respond immediately in the physiologic regulation of acid-base balance include the various intracellular and extracellular buffers as well as the lungs. A buffer is a substance that can minimize changes in pH when acid or base is added to the system. The extracellular buffers, which include the bicarbonate-carbonic acid system, phosphates, and plasma proteins, act rapidly to return the extracellular pH toward normal. The intracellular buffers, which include hemoglobin, organic phosphates, and bone apatite, act more slowly, taking several hours to reach maximum capacity.

The most important extracellular buffer is the plasma bicarbonate-carbonic acid buffer system, in which the acid component (carbonic acid [ $\text{H}_2\text{CO}_3$ ]) is regulated by the lungs, and the base component (bicarbonate [ $\text{HCO}_3^-$ ]) is regulated by the kidneys. The buffer equation is

At equilibrium, the amount of dissolved carbon dioxide [ $(\text{CO}_2)_d$ ] exceeds that of  $\text{H}_2\text{CO}_3$  by a factor of 800:1; thus, for practical purposes,  $(\text{CO}_2)_d$  and  $\text{H}_2\text{CO}_3$  can be treated interchangeably. The fact that  $\text{CO}_2$  excretion can be controlled by the respiratory system markedly improves the efficiency of this buffer system at physiologic pH. The enzyme carbonic anhydrase allows rapid interconversion of  $\text{H}_2\text{CO}_3$  to  $\text{H}_2\text{O}$  and  $\text{CO}_2$ . If the hydrogen ion ( $\text{H}^+$ ) concentration increases for any reason, hydrogen combines with  $\text{HCO}_3^-$ , driving the buffer reaction toward greater production of  $\text{H}_2\text{CO}_3$  and  $\text{CO}_2$ . Carbon dioxide crosses the blood-brain barrier and stimulates central nervous system chemoreceptors, leading to increased alveolar ventilation and decreased concentration of extracellular  $\text{CO}_2$ . This respiratory compensation begins within minutes after a pH change and is complete within 12 to 24 hours. A similar compensation occurs in response to a decrease in  $\text{H}^+$  concentration, with a decreased  $\text{HCO}_3^-$  concentration leading to decreased alveolar ventilation and a resultant increase in extracellular  $\text{CO}_2$ .

The relationship of the two components of the bicarbonate-carbonic acid buffer system to pH is expressed by the Henderson-Hasselbalch equation

$$\text{pH} = \text{pK} + \log \frac{[\text{HCO}_3^-]}{[\text{H}_2\text{CO}_3]}$$

Because  $\text{H}_2\text{CO}_3$  is in equilibrium with the dissolved  $\text{CO}_2$  in the plasma, and because the amount of dissolved  $\text{CO}_2$  depends on the *partial pressure* of  $\text{CO}_2$ , the equation can be modified as

$$\text{pH} = \text{pK} + \log \frac{[\text{HCO}_3^-]}{0.03} \times P_{\text{aCO}_2}$$

Both the original equation and the modified equation are clinically difficult to use. Therefore, the modified Henderson-Hasselbalch equation can be rewritten as the Henderson equation, without logarithms for an easier clinical use

$$[\text{H}^+] = 24 \times \frac{P_{\text{aCO}_2}}{[\text{HCO}_3^-]}$$

This last equation clearly points out the clinically most important aspect of acid-base regulation by the bicarbonate-carbonic acid buffer system, that the change in the *ratio* of  $P_{\text{aCO}_2}$  to  $\text{HCO}_3^-$  concentration, and not in their absolute values, determines the direction of change in  $\text{H}^+$  concentration and thus in pH. The status of the plasma bicarbonate-carbonic acid buffer system can be easily monitored by serial blood gas measurements, making understanding of this buffer system important in clinical care.

The system that responds more slowly in the physiologic regulation of acid-base balance is the renal system. There must be a long-term balance between net acid increase due to intake and production and net acid decrease due to excretion and metabolism. Although formula and protein-containing intravenous fluids have small amounts of preformed acid, most of the daily acid load results from metabolism. A large amount of the acid produced is in the form of the *volatile*  $\text{H}_2\text{CO}_3$  that can be excreted in the lungs. *Nonvolatile* or *fixed* acids are also produced, which must be excreted through the kidneys. Nonvolatile acids normally are sulfuric acid produced in the metabolism of the amino acids methionine and cysteine as well as smaller contributions from phosphoric acid, lactic acid, hydrochloric acid, and incompletely oxidized organic acids. In addition to excretion of nonvolatile acids, however, the kidneys play a role in long-term acid-base regulation by controlling renal  $\text{HCO}_3^-$  excretion.

Two regions of the kidney act to achieve urinary acidification, the proximal tubule and the collecting tubule. The proximal tubule acidifies the urine by two mechanisms. The first mechanism is the reabsorption of any  $\text{HCO}_3^-$  already present in the blood that is being constantly filtered through the glomeruli. The proximal tubule reabsorbs 60% to 80% of all filtered  $\text{HCO}_3^-$  and performs this role through an exchange of  $\text{Na}^+$  for  $\text{H}^+$  across the luminal membrane of the proximal tubular cells via the  $\text{Na}^+/\text{H}^+$  exchanger. The excreted  $\text{H}^+$  combines with filtered  $\text{HCO}_3^-$ , producing  $\text{H}_2\text{CO}_3$  through the activity of carbonic anhydrase in the cellular brush border. The  $\text{H}_2\text{CO}_3$  is then quickly converted to  $\text{CO}_2$ , which crosses into the tubular cell, where  $\text{HCO}_3^-$  is

regenerated and reabsorbed back into the blood stream, probably in exchange for chloride ( $\text{Cl}^-$ ). The regenerated  $\text{H}^+$  ion reenters the cycle at the  $\text{Na}^+/\text{H}^+$  exchanger.

The second mechanism by which the proximal tubule acidifies urine is by the production of ammonia ( $\text{NH}_3$ ). Inside the tubular cell,  $\text{NH}_3$  is produced by the deamination of glutamine. The  $\text{NH}_3$  is secreted into the tubular lumen, where it combines with and “traps” free  $\text{H}^+$  to form ammonium ( $\text{NH}_4^+$ ).

The remaining urinary acidification occurs mostly in the collecting tubule.  $\text{H}^+$  secretion in this region of the kidney is sufficient to combine with or *titrate* any remaining filtered  $\text{HCO}_3^-$  or any filtered anions, such as phosphate and sulfate. Hydrogenated phosphate and sulfate anions produce the *titratable acid* of the urine. The collecting tubule also takes up  $\text{NH}_3$  from the medullary interstitium and secretes it into the urine, where again it can combine with and trap  $\text{H}^+$  as  $\text{NH}_4^+$ . This urinary  $\text{NH}_4^+$  can act as a cation and be excreted with urinary anions such as  $\text{Cl}^-$ ,  $\text{PO}_4^-$ , and  $\text{SO}_4^-$ , thereby preventing loss of cations such as  $\text{Na}^+$ ,  $\text{Ca}^{++}$ , and  $\text{K}^+$ . Total acid secretion in the kidney can be represented by

and under normal conditions should equal the net production of acid from diet and metabolism that is not excreted in the form of  $\text{CO}_2$  through the lungs.

In adults, the steady state for renal compensation for respiratory alkalosis is reached within 1 to 2 days and for respiratory acidosis within 3 to 5 days. Newborns are able to compensate for acidemia through the previously described renal mechanisms, although the renal response to acid loads is limited, especially in premature infants born before 34 weeks of gestation. Reabsorption of  $\text{HCO}_3^-$  in the proximal tubule and distal tubular acidification are also decreased, with a fairly rapid gestational age-dependent maturation of these functions after birth (Jones and Chesney, 1992).

To accomplish the tight regulation of pH necessary for survival,  $\text{H}^+$  ions generated in the form of the volatile acid  $\text{H}_2\text{CO}_3$  are excreted by the lungs as  $\text{CO}_2$ .  $\text{H}^+$  ions generated in the form of nonvolatile acids are buffered rapidly by extracellular  $\text{HCO}_3^-$  and more slowly by intracellular buffers.  $\text{HCO}_3^-$  is then replenished by the kidneys via the reabsorption of much of the filtered  $\text{HCO}_3^-$  and by the excretion of  $\text{H}^+$  in the urine as  $\text{NH}_4^+$  and titratable acids.

## Disturbances of Acid-Base Balance in the Newborn

### General Principles

The plasma bicarbonate-carbonic acid buffer system is the reference base for acid-base equilibrium, and the status of this system can be monitored with blood gas measurements. Therefore, the blood gas measurement should be the starting point for the evaluation of any acid-base disorder. In the blood gas measurement, the pH and  $P_{\text{aCO}_2}$  levels are directly measured, and from these the  $\text{HCO}_3^-$  level is calculated.

The whole blood buffer base, defined as the conjugate sum of the  $\text{HCO}_3^-$  and non- $\text{HCO}_3^-$  buffer systems, is the

TABLE 30-4

## Expected Compensatory Mechanisms Operating in Primary Acid-Base Disorders

Acid-Base Disorder	Primary Event	Compensation	Rate of Compensation
Metabolic acidosis Normal anion gap	↓ [HCO <sub>3</sub> <sup>-</sup> ]	↓ PCO <sub>2</sub>	For 1 mEq/L ↓ [HCO <sub>3</sub> <sup>-</sup> ], PCO <sub>2</sub> ↓ by 1-1.5 mm Hg
Increased anion gap	↑ acid production ↑ acid intake	↓ PCO <sub>2</sub>	For 1 mEq/L ↓ [HCO <sub>3</sub> <sup>-</sup> ], PCO <sub>2</sub> ↓ by 1-1.5 mm Hg
Metabolic alkalosis	↑ [HCO <sub>3</sub> <sup>-</sup> ]	↑ PCO <sub>2</sub>	For 1 mEq/L ↑ [HCO <sub>3</sub> <sup>-</sup> ], PCO <sub>2</sub> ↑ by 0.5-1 mm Hg
Respiratory acidosis Acute (<12-24 hr)	↑ PCO <sub>2</sub>	↑ [HCO <sub>3</sub> <sup>-</sup> ]	For 10 mm Hg ↑ PCO <sub>2</sub> , [HCO <sub>3</sub> <sup>-</sup> ] ↑ by 1 mEq/L
Chronic (3-5 days)	↑ PCO <sub>2</sub>	↑ [HCO <sub>3</sub> <sup>-</sup> ]	For 10 mm Hg ↑ PCO <sub>2</sub> , [HCO <sub>3</sub> <sup>-</sup> ] ↑ by 4 mEq/L
Respiratory alkalosis Acute (<12 hr)	↓ PCO <sub>2</sub>	↓ [HCO <sub>3</sub> <sup>-</sup> ]	For 10 mm Hg ↓ PCO <sub>2</sub> , [HCO <sub>3</sub> <sup>-</sup> ] ↓ by 1-3 mEq/L
Chronic (1-2 days)	↓ PCO <sub>2</sub>	↓ [HCO <sub>3</sub> <sup>-</sup> ]	For 10 mm Hg ↓ PCO <sub>2</sub> , [HCO <sub>3</sub> <sup>-</sup> ] ↓ by 2-5 mEq/L

Modified from Brewer ED: Disorders of acid-base balance. *Pediatr Clin North Am* 37:430-447, 1990.

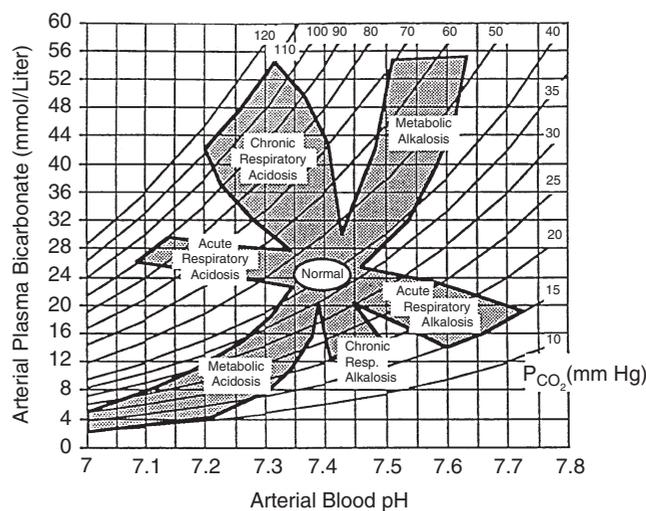

other important blood gas value used in evaluating acid-base disturbances. The difference between the observed whole blood buffer base of any blood gas sample and the expected normal buffer base of that sample is called the *base excess* or *base deficit*. The base excess and base deficit give an accurate measure of the amount of strong base and acid, respectively, that have been added to the ECF. For example, a base excess of 10 mEq/L indicates the addition of 10 mEq of base per liter (or loss of 10 mEq of H<sup>+</sup> per liter). A base deficit of 10 mEq/L indicates the addition of a similar amount of strong acid (or loss of base).

Acid-base disorders are classified according to their cause as being either *metabolic* or *respiratory*. *Metabolic acidosis* occurs as a result of the accumulation of increased amounts of nonvolatile acid or decreased amounts of HCO<sub>3</sub><sup>-</sup> in the ECF. *Metabolic alkalosis* occurs as a result of increased amounts of HCO<sub>3</sub><sup>-</sup> in the ECF. *Respiratory acidosis* is due to hypoventilation and decreased excretion of volatile acid (CO<sub>2</sub>), whereas *respiratory alkalosis* is due to hyperventilation and increased excretion of volatile acid (CO<sub>2</sub>).

Acid-base disorders are also classified according to the number of conditions causing the disorder. When only one primary acid-base abnormality and its compensatory mechanisms occur, the disorder is classified as a *simple acid-base disorder*. When a combination of simple acid-base disturbances occurs, the patient has a *mixed (or complex) acid-base disorder*. Because secondary physiologic regulatory mechanisms often compensate for the alteration in pH caused by primary disturbances, it sometimes is difficult to differentiate simple from mixed disorders or even a simple disorder from its resulting compensation. One important principle that allows determination of primary acid-base disturbance is that the compensatory regulatory mechanisms do not completely normalize the pH.

Nomograms, such as the one shown in Fig. 30-6, can help in the diagnosis of the primary disturbance. The nomo-

gram describes the 95% confidence limits of the expected compensatory response to a primary abnormality in either PaCO<sub>2</sub> or HCO<sub>3</sub><sup>-</sup>. Table 30-4 summarizes the expected respiratory and metabolic compensatory mechanisms for primary acid-base disorders (Brewer, 1990). If the compensation in a given patient differs from that predicted in Fig. 30-6 or Table 30-4, the patient either has not had enough time to compensate for a simple acid-base disturbance or has a mixed acid-base disorder. Furthermore, the complete correction of an acid-base disturbance occurs only when the

**FIGURE 30-6.** Acid-base nomogram illustrating the 95% confidence limits for compensatory responses to primary acid-base disorders. (From Cogan MG, Rector FC Jr: *Acid-base disorders*, In Brenner BM, Rector FC Jr [eds]: *The Kidney*. Philadelphia, WB Saunders, 1986.)

underlying process responsible for the abnormality has been effectively treated.

For identification of the primary disturbance, the analysis of blood gas values must be considered in light of the patient's history and physical findings and with an understanding of expected compensatory responses. Further laboratory evaluation is indicated if the problem is not immediately obvious or if the response to therapy is not as expected. The evaluation of the acid-base disturbance should always involve efforts to determine the underlying cause of the disturbance, because adequate treatment requires correction of the underlying disorder, if possible.

### Metabolic Acidosis

Metabolic acidosis is a common problem, particularly in the critically ill newborn. Metabolic acidosis occurs when the drop in pH is caused by the accumulation of acid other than  $\text{H}_2\text{CO}_3$  by the ECF, resulting in loss of available  $\text{HCO}_3^-$ , or by the direct loss of  $\text{HCO}_3^-$  from body fluids. Cases of metabolic acidosis are divided into those with an *elevated anion gap* and those with a *normal anion gap*.

The anion gap reflects the unaccounted-for acidic anions and certain cations in the ECF. The unmeasured anions normally include the serum proteins, phosphates, sulfates, and organic acids, whereas the unaccounted-for cations are the serum potassium, calcium, and magnesium. Thus, in clinical practice, the anion gap is estimated using the formula

$$\text{anion gap} = [\text{Na}^+]_{\text{serum}} - ([\text{Cl}^-]_{\text{serum}} + [\text{HCO}_3^-]_{\text{serum}})$$

The normal range of the serum anion gap in newborns is 8 to 16 mEq/L, with slightly higher values in very premature newborns. Accumulation of strong acids due to increased intake or production or to decreased excretion results in an increased anion gap acidosis, whereas loss of  $\text{HCO}_3^-$  or accumulation of  $\text{H}^+$  results in a normal anion gap acidosis. A decrease in serum potassium, calcium, and magnesium concentrations, an increase in serum protein concentration, or a falsely elevated serum sodium concentration may also result in an increased anion gap in the absence of metabolic acidosis. In clinical practice, although a serum anion gap value greater than 16 mEq/L is highly predictive of lactic acidosis and a value less than 8 mEq/L is highly predictive of the *absence* of lactic acidosis, an anion gap value between 8 and 16 mEq/L cannot be used to differentiate between lactic and nonlactic acidosis in the critically ill newborn (Lorenz et al, 1999). Therefore, the measurement of serum lactate is indicated when one suspects lactic acidosis and the anion gap is in the normal range.

An increased anion gap metabolic acidosis in the newborn is most commonly due to lactic acidosis secondary to tissue hypoxia, as seen in asphyxia, hypothermia, severe respiratory distress, sepsis, and other severe neonatal illnesses. Other important, but much less common causes of an increased anion gap metabolic acidosis in the neonatal period are inborn errors of metabolism, renal failure, and intake of toxins (Table 30-5). Table 30-6 lists inborn errors of metabolism that can manifest as increased anion gap metabolic acidosis in the newborn period.

TABLE 30-5

### Common Causes of Metabolic Acidosis

Increased Anion Gap	Normal Anion Gap
Lactic acidosis due to tissue hypoxia	Renal bicarbonate loss
+ Asphyxia, hypothermia, shock	+ Bicarbonate wasting due to immaturity
+ Sepsis, respiratory distress syndrome	+ Renal tubular acidosis
Inborn errors of metabolism	+ Carbonic anhydrase inhibitors
+ Congenital lactic acidosis	Gastrointestinal bicarbonate loss
+ Organic acidosis	+ Small bowel drainage: ileostomy, fistula
Renal failure	+ Diarrhea
Late metabolic acidosis	Extracellular volume expansion with bicarbonate dilution
Toxins (e.g., benzyl alcohol)	Aldosterone deficiency
	Excessive chloride in intravenous fluids

In the syndrome of late metabolic acidosis of prematurity, first described in the 1960s, otherwise healthy premature infants at several weeks of age demonstrated mild to moderate increased anion gap acidosis and decreased growth. All the infants were receiving high-protein cow's milk formula, and they demonstrated higher net acid excretion compared with controls. This type of late metabolic acidosis is now rarely seen, probably because of the use of special premature infant formulas and changes in regular formulas with decreased casein-to-whey ratios and lower fixed acid loads.

A normal anion gap metabolic acidosis most commonly occurs in the newborn as a result of  $\text{HCO}_3^-$  loss from the extracellular space through the kidneys or the gastrointestinal tract. Hyperchloremia develops with the  $\text{HCO}_3^-$  loss because a proportionate rise in serum chloride concentration must occur to maintain the ionic balance or to correct the volume depletion in the extracellular compartment. The most common cause of normal anion gap metabolic acidosis in the preterm newborn is a mild, developmentally regulated, proximal renal tubular acidosis with renal

Galactosemia
Hereditary fructose intolerance
Type I glycogen storage disease

$\text{HCO}_3^-$  wasting. In infants with this disorder, the serum  $\text{HCO}_3^-$  usually stabilizes at 14 to 18 mEq/L in the early postnatal period. The urinary pH is normal once the serum  $\text{HCO}_3^-$  falls to this level, because the impairment in proximal tubular  $\text{HCO}_3^-$  reabsorption is not associated with an impaired distal tubular acidification of similar magnitude (Jones and Chesney, 1992). The diagnosis of this temporary cause of acidosis can be established by the recurrence of a urinary alkaline pH when serum  $\text{HCO}_3^-$  is raised above the threshold after  $\text{HCO}_3^-$  or acetate supplementation. Even term newborns have a lower renal threshold for  $\text{HCO}_3^-$ , with normal plasma  $\text{HCO}_3^-$  levels in the range of 17 to 21 mEq/L. In most infants, plasma  $\text{HCO}_3^-$  increases to adult levels over the first year as the proximal tubule matures. Other common causes of normal anion gap metabolic acidosis seen in neonatal intensive care units are gastrointestinal  $\text{HCO}_3^-$  losses often due to increased ileostomy drainage, diuretic treatment with carbonic anhydrase inhibitors, and dilutional acidosis with rapid expansion of the extracellular space through the use of non- $\text{HCO}_3^-$  solutions in the hypovolemic newborn.

The presence of metabolic acidosis in the newborn should be suspected from the clinical presentation and the history of predisposing conditions, including perinatal depression, respiratory distress, blood or volume loss, sepsis, and congenital heart disease associated with poor systemic perfusion or cyanosis. Metabolic acidosis is confirmed by blood gas measurements. The cause of metabolic acidosis is often readily discernible from the history and physical examination; specific laboratory evaluation of electrolytes, renal function, lactate, and serum and urine amino acids may be undertaken, depending on the diagnosis that is suspected clinically. Fig. 30-7 shows a simple flow diagram outlining an approach to diagnosis of metabolic acidosis in the newborn.

The morbidity and mortality of metabolic acidosis depend on the severity of the acidosis and the responsiveness of the underlying pathologic process to clinical management. Because experimental data suggest that even a very low pH is compatible with neurologically intact survival (von Planta et al, 1993), and because a clear benefit

of buffer therapy in the management of metabolic acidosis has not been demonstrated (Basir et al, 1996; Brewer, 1990; Nudel et al, 1993), indications for the use of buffers in newborns remain uncertain. At present, the judicious use of temporizing buffer therapy aimed at increasing the arterial pH to 7.25 to 7.30 in cases of severe acidosis is recommended and practiced by most neonatologists to avoid the complications of acidosis per se (Brewer, 1990; von Planta et al, 1993). These complications include arteriolar vasoconstriction followed by dilation, depression of cardiac contractility, systemic hypotension, pulmonary hypertension, pulmonary edema, and arrhythmias. This practice is supported by findings on the cardiovascular effects of sodium bicarbonate in preterm newborns with an arterial pH of less than 7.25 and term newborns with an arterial pH of less than 7.30 (Fanconi et al, 1993). The use of sodium bicarbonate in this study induced an increase in myocardial contractility and a reduction in afterload.

Sodium bicarbonate is the most widely used buffer in the treatment of metabolic acidosis in the neonatal period. Bicarbonate should not be given if ventilation is inadequate, because its administration results in an increase in  $\text{P}_a\text{CO}_2$  with no improvement in pH and an increase in intracellular acidosis. Therefore, sodium bicarbonate should be administered slowly and in its diluted form only to newborns with documented metabolic acidosis and adequate alveolar ventilation. Once a blood gas measurement has been obtained, the dose of sodium bicarbonate required to correct the pH can be estimated with the use of the formula

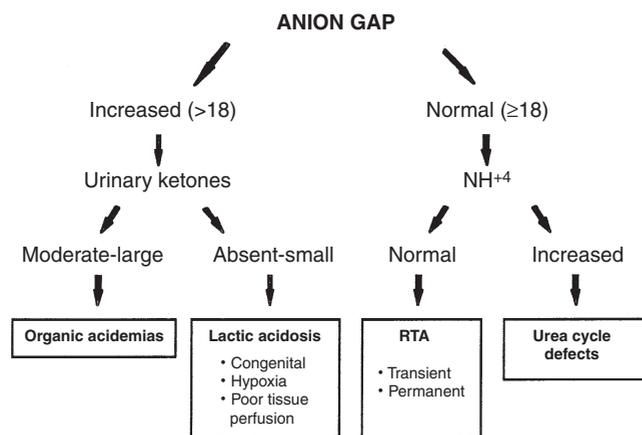

$$\text{dose of NaHCO}_3 \text{ (mEq)} = \text{base deficit (mEq/L)} \times \text{body weight (kg)} \times 0.3$$

Sodium bicarbonate is confined mostly to the ECF compartment, and the 0.3 value in the formula represents its volume of distribution. Most clinicians would use half of the calculated total correction dose for initial therapy to avoid overcorrection of metabolic acidosis. Subsequent doses of sodium bicarbonate are then based on the results of further blood gas measurements.

In certain clinical situations, tromethamine (Tham) may be used as an alternative buffer to sodium bicarbonate. The theoretical advantages of tromethamine over sodium bicarbonate in the treatment of metabolic acidosis of the newborn include its more rapid intracellular buffering capability, its ability to lower  $\text{P}_a\text{CO}_2$  levels directly, and the lack of an increase in the sodium load (Schneiderman et al, 1993). Tromethamine lowers  $\text{P}_a\text{CO}_2$  by covalently binding  $\text{H}^+$  and thus shifting the equilibrium of the reaction

to the left resulting in a decrease in  $\text{CO}_2$  and an increase in  $\text{HCO}_3^-$ . Because the end-product (chelated tromethamine) is a cation that is excreted by the kidneys, oliguria is a relative contraindication to the repeated use of this buffer. Tromethamine administration also has been associated with the development of acute respiratory depression, most likely secondary to an abrupt decrease in  $\text{P}_a\text{CO}_2$  levels as well as from rapid intracellular correction of acidosis in the cells of the respiratory center (Robertson, 1970). Furthermore, because hypocapnia is associated with decreases in brain blood flow and a higher incidence of white matter damage, especially in the immature preterm

**FIGURE 30-7.** Flow diagram summarizing a diagnostic approach in cases of increased anion gap and normal anion gap metabolic acidosis in the newborn. TRA, renal tubular acidosis.

neonate, close monitoring of  $P_a\text{CO}_2$  is of paramount importance when tromethamine is being used. Finally, when large doses of tromethamine are administered, hyponatremia (Seri et al, 1998b), hypoglycemia, hyperkalemia, an increase in hemoglobin oxygen affinity, and diuresis followed by oliguria may occur. Because the solution is hyperosmolar, and because rapid infusion of tromethamine may also lower blood pressure and intracranial pressure (Duthie et al, 1994), slow infusion is recommended.

Despite these disadvantages, tromethamine has a major advantage over sodium bicarbonate in that it acts to increase pH by also lowering  $P_a\text{CO}_2$ . Therefore, *tromethamine is the recommended buffer therapy in life-threatening situations of combined metabolic and respiratory acidosis*. Some centers also use tromethamine as initial therapy for neonatal resuscitation until adequate ventilation is documented by blood gas measurements. The suggested initial dose is 1 to 2 mEq/kg or 3.5 to 6 mL/kg given intravenously using the 0.3 M solution, with the rate of administration not exceeding 1 mL/kg/min. Once a blood gas measurement has been obtained, the dose of tromethamine required to raise the pH can be estimated using the formula

$$\text{dose of tromethamine in mL} = \text{base deficit (mEq/L)} \\ \times \text{body weight (kg)}$$

A third buffer, dichloroacetate, has been successfully used in critically ill adults as an alternative to sodium bicarbonate and tromethamine. Dichloroacetate enhances cardiac output and increases oxidation of pyruvate and lactate through the stimulation of pyruvate dehydrogenase activity (Brewer, 1990). Because only limited experimental information regarding its effectiveness in the newborn period is available, however, its use cannot be recommended at this time (Nudel et al, 1993).

Regardless of the buffer used, care should be taken to avoid overtreatment, to minimize adverse effects of the buffer itself and of rapid swings in pH, and to direct therapy toward the underlying problem. In most conditions, correcting the pH to 7.25 to 7.30 is adequate. In addition, the recommendations for buffer treatment in metabolic acidosis, although widely practiced, are largely empiric without the backing of substantial experimental evidence.

Finally, during the correction of metabolic acidosis, particular attention should be paid to ensure an appropriate potassium balance. Because potassium moves from the intracellular space to the extracellular space in exchange for  $\text{H}^+$  when acidosis occurs, the presence of a total body potassium deficit may not be appreciated during metabolic acidosis. Hypokalemia may become evident only as the pH increases and potassium returns to the intracellular space. Furthermore, intracellular acidosis cannot be completely corrected until the potassium stores are restored. Therefore, close monitoring of serum electrolytes and, if necessary, potassium supplementation are important during the correction of metabolic acidosis in the sick newborn.

### Respiratory Acidosis

Respiratory acidosis occurs when a primary increase in  $P_a\text{CO}_2$  develops secondary to impairments in alveolar ventilation that result in an arterial pH of less than 7.35.

Primary respiratory acidosis is a common problem in the newborn, and causes include hyaline membrane disease, pneumonia due to infection or aspiration, patent ductus arteriosus with pulmonary edema, chronic lung disease, pleural effusion, pneumothorax, and pulmonary hypoplasia. The initial increase in  $P_a\text{CO}_2$  is buffered by the non- $\text{HCO}_3^-$  intracellular buffers without noticeable renal compensation for at least 12 to 24 hours (see Table 30-4). Renal metabolic compensation reaches its maximum levels within 3 to 5 days, and its effectiveness in the newborn is influenced mainly by the functional maturity of proximal tubular  $\text{HCO}_3^-$  transport.

Management of respiratory acidosis is directed toward improving alveolar ventilation and treating the underlying disorder. In the sick newborn, adequate ventilation must often be provided by mechanical ventilation. In severe respiratory acidosis, tromethamine, because it lowers  $\text{CO}_2$ , may be used to raise pH. Tromethamine, however, produces only a transient decrease in  $P_a\text{CO}_2$ , and toxic doses would quickly be reached if it were used to buffer all the  $\text{CO}_2$  produced by metabolism over a sustained period. Therefore, tromethamine should be used only as a temporizing measure in severe respiratory acidosis until alveolar ventilation can be improved.

### Metabolic Alkalosis

Metabolic alkalosis is characterized by a primary increase in the extracellular  $\text{HCO}_3^-$  concentration sufficient to raise the arterial pH above 7.45. In the newborn, metabolic alkalosis occurs when there is a loss of  $\text{H}^+$ , a gain of  $\text{HCO}_3^-$ , or a depletion of the extracellular volume with the loss of more chloride than  $\text{HCO}_3^-$ . It is important to understand that metabolic alkalosis generated by any of these mechanisms can be maintained only when factors limiting the renal excretion of  $\text{HCO}_3^-$  are also present.

Metabolic alkalosis can result from a *loss of  $\text{H}^+$*  from the body, from either the gastrointestinal tract or the kidneys, that induces an equivalent rise in the extracellular  $\text{HCO}_3^-$  concentration. The most common causes of this type of metabolic alkalosis in the newborn period are continuous nasogastric aspiration, persistent vomiting, and diuretic treatment. Less common causes of  $\text{H}^+$  losses are congenital chloride-wasting diarrhea, certain forms of congenital adrenal hyperplasia, hyperaldosteronism, posthypercapnia, and Bartter syndrome.

Metabolic alkalosis can also result from a *gain of  $\text{HCO}_3^-$* , such as occurs during the administration of buffer solutions to the newborn. In the past, a metabolic alkalosis was intentionally created when sodium bicarbonate or tromethamine was used to maintain an alkaline pH to decrease pulmonary vasoreactivity in infants with persistent pulmonary hypertension, a practice not recommended anymore. Currently, however, iatrogenically produced metabolic alkalosis is primarily unintentional and due to chronic excessive administration of  $\text{HCO}_3^-$ , lactate, citrate, or acetate in intravenous fluids and blood products. Because excretion of  $\text{HCO}_3^-$  is normally not limited in the newborn, metabolic alkalosis resulting from  $\text{HCO}_3^-$  gain alone should rapidly resolve after administration of  $\text{HCO}_3^-$  is discontinued. However, if the alkalosis is severe and urine output is limited, inhibition

of the carbonic anhydrase enzyme by the administration of acetazolamide may enhance elimination of  $\text{HCO}_3^-$ .

Metabolic alkalosis can also result from a *loss of ECF* containing disproportionately more chloride than  $\text{HCO}_3^-$ , so-called contraction alkalosis. During the diuretic phase of normal postnatal adaptation, preterm and term newborns retain relatively more  $\text{HCO}_3^-$  than chloride (Ramiro-Tolentino et al, 1996). The obvious clinical benefits of allowing this physiologic extracellular volume contraction to occur, especially in the critically ill newborn, clearly outweigh the clinical importance of a mild contraction alkalosis that develops after recovery. No specific treatment is needed in such cases, because with the stabilization of the extracellular volume and renal function after recovery, acid-base balance rapidly returns to normal. Contraction alkalosis due to other causes, however, may need treatment as discussed subsequently.

For metabolic alkalosis to persist, *factors limiting the renal excretion of  $\text{HCO}_3^-$*  must be present. The kidneys are usually effective in excreting excess  $\text{HCO}_3^-$ , but this ability can be limited under certain conditions, such as decreased glomerular filtration rate, increased aldosterone production, and the more common clinical situation of volume contraction-triggered metabolic alkalosis with potassium deficiency. In the last-mentioned condition, there is a direct stimulation of  $\text{Na}^+$  reabsorption coupled with  $\text{H}^+$  loss in the proximal tubule, and an indirect stimulation of  $\text{H}^+$  loss in the distal nephron by the increased activity of the renin-angiotensin-aldosterone system. Contraction alkalosis responds to administration of saline to replete the intravascular volume and potassium supplementation. In the other disorders, however, the primary problem of reduced glomerular filtration rate or elevated aldosterone must be treated for the alkalosis to resolve.

One of the most commonly encountered clinical scenarios of chronic metabolic alkalosis actually occurs most often in the form of a mixed acid-base disorder in a preterm infant with chronic lung disease on long-term diuretic treatment. Such a newborn initially has a chronic respiratory acidosis that is partially compensated by renal  $\text{HCO}_3^-$  retention. Prolonged or aggressive use of diuretics can lead to total-body potassium depletion and contraction of the extracellular volume, thus exacerbating the metabolic alkalosis. By stimulating proximal tubular  $\text{Na}^+$  reabsorption and thus  $\text{H}^+$  loss, distal tubular  $\text{H}^+$  secretion, and renal ammonium production, the diuretic-induced hypokalemia contributes to the severity and maintenance of the metabolic alkalosis in such a patient. Furthermore, metabolic alkalosis per se worsens hypokalemia, because potassium moves intracellularly to replace hydrogen as the latter shifts into the extracellular space. Although the serum potassium concentration may be decreased, the serum levels in the newborn do not accurately reflect the extent of total-body potassium deficit because potassium is primarily an intracellular ion, with around 98% of the total body potassium being in the intracellular compartment. In addition, the condition is often accompanied by marked hyponatremia and hyponatremia. Hyponatremia occurs in part because sodium shifts into the intracellular space to compensate for the depleted intracellular potassium. If the alkalosis is severe, alkalemia ( $\text{pH} > 7.45$ ) can supervene and result in hypoventilation. In this situation,

potassium chloride, and not sodium chloride supplementation, reverses hyponatremia and hyponatremia, corrects hypokalemia and metabolic alkalosis, and increases the effectiveness of diuretic therapy. Because chloride deficiency is the predominant cause of the increased pH, ammonium chloride or arginine chloride also corrects the alkalosis. These agents do not affect the other electrolyte imbalances such as the hypokalemia, so they should not be the only therapy given.

It is important to keep ahead of the potassium losses in infants receiving long-term diuretic therapy, rather than to attempt to replace potassium after intracellular depletion has occurred. Because the rate of potassium repletion is limited by the rate at which potassium moves intracellularly, correction of total body potassium deficits can take days to weeks. In addition, there is also a risk of acute hyperkalemia if serum potassium levels are driven too high during repletion, particularly in newborns in whom an acute respiratory deterioration may occur, with worsened respiratory acidosis and the subsequent movement of potassium from the intracellular to the extracellular space. The routine use of potassium chloride supplementation and close monitoring of serum sodium, chloride, and potassium levels are therefore recommended during long-term diuretic therapy to prevent these common iatrogenic problems.

### Respiratory Alkalosis

When a primary decrease in  $\text{P}_a\text{CO}_2$  results in an increase in the arterial pH beyond 7.45, respiratory alkalosis develops. The initial hypocapnia is acutely titrated by the intracellular buffers, and metabolic compensation by the kidneys returns pH toward normal within 1 to 2 days (see Table 30–4). Interestingly, this is the only simple acid-base disorder in which, at least in the adult, the pH may completely be normalized by the compensatory mechanisms (Brewer, 1990). The cause of respiratory alkalosis is hyperventilation, which in the spontaneously breathing newborn is most often caused by fever, sepsis, retained fetal lung fluid, mild aspiration pneumonia, or central nervous system disorders. In the neonatal intensive care unit, the most common cause of respiratory alkalosis is iatrogenic secondary to hyperventilation of the intubated newborn. Because findings suggest an association between hypocapnia and the development of periventricular leukomalacia (Okumura et al, 2001; Wiswell et al, 1996) and chronic lung disease (Garland et al, 1995) in ventilated preterm infants, avoidance of hyperventilation during resuscitation and mechanical ventilation is of utmost importance in the management of the sick preterm newborn. The treatment of neonatal respiratory alkalosis consists of the specific management of the underlying process causing hyperventilation.

## Cardiovascular Compromise in the Newborn Infant

Nick Evans and Istvan Seri

When oxygen delivery is inadequate to meet oxygen demand, the organs fail, and if the situation is not corrected, irreversible damage and, ultimately, death result. Oxygen delivery to the organs depends on many factors but, most fundamentally, on the oxygen content of the blood and the volume of blood flowing to those organs. Because *oxygen content* is determined primarily by the hemoglobin concentration and oxygen saturation with less contribution from the dissolved oxygen ( $O_2$  content =  $[Hgb \times 1.39 \times O_2 \text{ saturation}] + [PaO_2 \times 0.0031]$ ), it is relatively easily evaluated and monitored in the newborn intensive care unit. However, reliably measuring *organ blood flow* (tissue perfusion) at the bedside is difficult because it depends on cardiac output and end-organ vascular resistance.

In clinical practice, tissue perfusion is routinely assessed by monitoring heart rate, blood pressure, capillary refilling time, acid-base status, and urine output. However, Doppler ultrasound and near infrared spectroscopy data have shown that these parameters are relatively poor indicators of acute changes in organ blood flow in preterm neonates immediately after birth (Kluckow and Evans, 1996 and 2000b; Lopez et al, 1997; Pladys et al, 1999; Tyszczyk et al, 1998). This observation may herald the need for a shift in thinking about the pathophysiology, diagnosis, and treatment of neonatal circulatory compromise especially *in the preterm neonate during the period of immediate postnatal adaptation*, and should lead us to incorporate blood flow and its relationship to systemic blood pressure.

### **PATHOPHYSIOLOGY AND PATHOGENESIS OF NEONATAL SHOCK**

#### **Cardiac Output and Its Determinants**

Cardiac output is the product of stroke volume and heart rate and is determined by the amount of blood returning to the heart (*preload*), the strength of myocardial contractility, and the resistance against which the heart must pump (*afterload*). If myocardial function is intact, cardiac output depends solely on preload and afterload according the relationships described by the Starling curve.

*Low cardiac output and thus low systemic blood flow* can result from various combinations of the following three factors: low cardiac preload, poor myocardial

contractility, and high cardiac afterload. Decreases in preload lead to diminution in stroke volume and cardiac output. Low circulating blood volume is the main cause of the decreases in preload. It can be due to loss of circulating blood volume after hemorrhage (absolute hypovolemia), or the circulating volume may be inadequate for the vascular space, as in vasodilatory shock (relative hypovolemia). Because preload is also augmented by the negative intrathoracic pressure generated at each spontaneous inspiration, the positive intrathoracic pressure associated with excessive positive-pressure mechanical ventilation may reduce venous return and, hence, preload and cardiac output.

The strength of myocardial contractility depends on the filling volume and pressure as well as on the maturity and integrity of the myocardium. Thus, decreases in preload (hypovolemia, cardiac arrhythmia) as well as prematurity (especially extreme immaturity), hypoxic insults, and infectious (viral or bacterial) agents all negatively affect the ability of the myocardium to contract, leading to decreases in cardiac output.

If cardiac afterload (i.e., systemic vascular resistance) is too high, the ability of the myocardium to pump against the increased resistance may become compromised, and cardiac output will fall (Osborn et al, 2002; Roze et al, 1993). Such increases in afterload may be associated with the enhanced endogenous catecholamine release during the period of immediate postnatal adaptation. High afterload can also be a problem in hypovolemia, hypothermia, and when inappropriately high doses of vasopressor inotropic agents are being administered to a patient with intact cardiovascular adrenoceptor responsiveness. High afterload can affect either ventricle, and if the output of one of the ventricles is reduced, the function of the other ventricle is also affected. For instance, if the right ventricular output is low owing to high pulmonary vascular resistance, the amount of blood getting through the lungs to the left ventricle is reduced, leading to low systemic blood flow with blood pooling in the systemic venous system.

Finally, during transition to extrauterine life, shunts through a persistently patent ductus arteriosus, foramen ovale, or both may compromise circulation (Kluckow and Evans, 2000b). Particularly in the preterm infant, normal postnatal closure of these fetal channels can fail. As the right-sided pressures fall, blood shunts left to right, from the systemic circulation back into the pulmonary circulation. This situation may occur soon after birth, especially when surfactant is administered. It may have greater impact on the circulatory status than has been traditionally appreciated (Evans and Iyer, 1994; Kluckow and Evans, 2000a) and is thought to contribute to the occurrence of pulmonary hemorrhage after administration of surfactant.

#### **Systemic Blood Pressure**

Systemic blood pressure is the product of systemic blood flow and systemic vascular resistance. Although there may be an association between low blood pressure and central

nervous system injury in the preterm neonate, blood pressure only weakly correlates with blood flow in this patient population during the period of immediate postnatal adaptation (Kluckow and Evans, 2000b). Thus, in preterm infants during the first postnatal day, blood pressure may be low because resistance is low in the presence of normal or even high blood flow, or blood pressure may be normal or high because resistance is high in the presence of normal or low blood flow.

### **Organ Blood Flow Autoregulation**

Even very immature preterm neonates appear to be capable of autoregulation of cerebral blood flow (Seri et al, 1998; Tyszczyk et al, 1998). However, organ blood flow autoregulation is impaired in a subset of preterm neonates in whom changes in blood pressure are mirrored by changes in cerebral blood flow, and these babies are at higher risk for cerebral injury (Tsuji et al, 2000). Factors that impair organ blood flow autoregulation include birth asphyxia, acidosis, infection, tissue hypoxia and ischemia, and sudden alterations in arterial carbon dioxide tension. Whether the impairment of autoregulation in the preterm neonate immediately after birth is the cause of the cerebral injury or a consequence of a preceding ischemic insult remains to be clarified.

## **Pathogenesis of Neonatal Shock**

### **Conditions Affecting All Babies**

#### ***Hypovolemia***

Hypovolemia is probably overdiagnosed in neonatology; it is a relatively uncommon primary cause of circulatory compromise, especially during the first postnatal days. Among preterm newborns, there is no evidence that hypotensive babies as a group are hypovolemic (Wright and Goodhall, 1994). However, when hypovolemia occurs, it can be difficult to detect clinically.

Hypovolemia in the newborn can be due to several conditions. *Intrapartum fetal blood loss* is usually caused by an open bleed from the fetal side of the placenta and therefore is likely to be detected. More difficult to diagnose is the closed bleeding of an acute fetomaternal hemorrhage or an acute fetoplacental hemorrhage. The latter can occur in delivery situations in which the umbilical cord comes under some pressure (breech presentation or nuchal cord). Because the umbilical vein is occluded before the artery, blood continues to be pumped into the placenta, and if the cord is clamped early, this blood remains trapped in the placenta. This scenario probably happens to some degree in all babies with tight nuchal cords who, as a group, have lower hemoglobin levels. A tight nuchal cord may also cause severe circulatory compromise. *Postnatal hemorrhage* may occur from any site and is frequently associated with endothelial damage induced by perinatal infection or severe asphyxia and the ensuing disseminated intravascular coagulation. Finally, *acute abdominal surgical problems and conditions associated with the nonspecific inflammatory response syndrome* and subsequent increased capillary leak with loss

of fluid into the interstitium can lead to significant decreases in the circulation blood volume.

### **Sepsis**

Although clinical evidence of circulatory compromise is a feature of many infectious processes in the newborn, the hemodynamics in neonatal septic shock have not been systematically studied. In older subjects, two distinct hemodynamic patterns occur. “Warm shock” is characterized by loss of vascular tone, increased systemic blood flow and low blood pressure, and “cold shock” by increased vascular tone, low systemic blood flow, and, eventually, falling blood pressure. Cold shock has been well described in the newborn (Meadow and Rudinsky, 1995), but the warm shock phase is more difficult to recognize clinically unless the blood pressure is being closely monitored. The mediators of neonatal warm septic shock remain unclear; in adult sepsis, however, in addition to dysregulated cytokine release, nitric oxide and deficiency of vasopressin seem to play a role. The significance of this observation to newborn sepsis remains unclear but it may have relevance to the late inotrope unresponsive hypotension seen in preterm babies (Ng et al, 2001; Seri et al, 2001).

### **Severe Respiratory Distress and Pulmonary Hypertension**

Term babies with severe respiratory failure have a high incidence of low ventricular output (Evans et al, 1998). The low output state is most common in the early course of the disease, resolving spontaneously with time, clinical improvement, or both. The causes of such circulatory compromise are probably multifactorial but include postnatal cardiovascular adaptation, the negative effects of excessive positive-pressure ventilation, and the systemic effect of raised pulmonary vascular resistance as previously described.

### **Heart Disease**

Circulatory compromise can result from primary heart disease, either congenital or acquired. Structural heart defects that produce a ductus-dependent systemic circulation, such as the hypoplastic left heart syndrome, critical coarctation, and critical aortic stenosis, classically manifest as acute circulatory compromise with pallor, tachypnea, impalpable pulses, and hepatomegaly as the duct starts closing. The presentation is often initially misdiagnosed as sepsis.

Acquired heart diseases that can manifest as circulatory compromise include primary cardiomyopathies and post-asphyxial myocardial dysfunction. Studies have shown a high incidence of ischemic changes on electrocardiography (ECG), raised blood cardiac enzyme levels, and low cardiac output in babies after intrapartum asphyxia (Tapia-Romero et al, 2000). There is more detail on structural heart disease and cardiomyopathies in the chapters on congenital heart disease.

## Circulatory Compromise in the Extremely Preterm Infant

### Transitional Circulatory Compromise

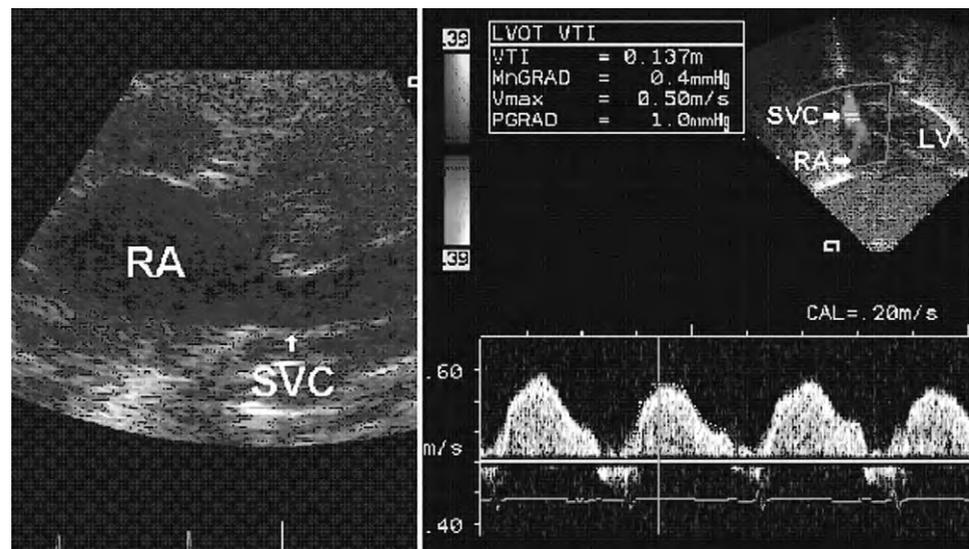

The transitional circulatory changes in the first 12 to 24 hours after birth are a period of unique circulatory vulnerability for the extremely preterm infant. During normal postnatal adaptation, pulmonary vascular resistance falls, systemic vascular resistance rises when the placenta is removed from the circulation, the ductus arteriosus closes, and the foramen ovale is closed by the reversal of the atrial pressure gradient. As these changes occur, the left ventricle has to double its output. Given that very preterm infants' cardiovascular systems are adapted to the low-resistance intrauterine environment and that their myocardium is immature, it is not surprising that these babies often have difficulties during this critical period. However, because blood pressure is not an accurate reflection of systemic and organ blood flow in this patient population during the immediate postnatal period, it is important to recognize that successful treatment of hypotension may not necessarily ensure normalization of organ blood flow. Furthermore, blood pressure in the low-normal to normal range does not necessarily translate into normal organ blood flow and tissue perfusion in these patients. Indeed, it is only when mean blood pressure is higher than 40 mm Hg during the first postnatal day in the preterm neonate born before 30 weeks of gestation that the systemic blood flow can definitely be assumed to be normal (Osborn et al, 2004).

Another special characteristic of the process of cardiovascular adaptation in this patient population is that early shunts through the preterm ductus arteriosus and foramen ovale are not balanced and, thus, can produce left-to-right shunts of significant clinical importance. The immediate postnatal physical constriction of the ductus is characterized by great variation, but if constriction fails, very large shunts can occur within a few hours of birth, leading to high, not low, pulmonary blood flow as previously thought. These abnormal hemodynamic changes

may be further augmented by the administration of surfactant.

In the transitional circulation of the preterm infant, neither ventricular output will consistently reflect systemic blood flow because of the shunts across the ductus arteriosus and foramen ovale. Consequently, measurement of either ventricular output can overestimate systemic blood flow by more than 100% in some cases (Evans and Kluckow, 1996). Superior vena cava (SVC) flow can be used as a marker of total systemic blood flow, and serial measurement of SVC flow has been used to describe the natural history of systemic blood flow changes in preterm neonates in the early postnatal period (Fig. 31-1). These studies have found that at least one third of preterm neonates born before 30 weeks of gestation have a period of low systemic blood flow, mostly during the first 12 hours of life (Kluckow and Evans, 2000b). Gestational age is the predominant predictor of the low-flow state; 70% of babies born before 26 weeks of gestation having a period of low systemic flow, compared with about 10% of those born at 29 weeks. A larger-diameter ductus arteriosus (Evans and Iyer, 1994) and the need for a higher mean airway pressure have also been shown to be associated with low SVC flow. As mentioned earlier, the correlation between SVC flow and blood pressure is statistically significant but weak, in that some babies have low flow and normal blood pressure and others have low pressure and normal flow. The low-flow state can persist for up to 24 hours but usually improves after thereafter. There is a strong relationship between recovery from the low-flow state and subsequent intraventricular hemorrhage (IVH) (Kluckow and Evans, 2000b; Osborn, 2003). The finding that IVH occurs after systemic blood flow has improved indicates the involvement of a hypoperfusion-reperfusion cycle in the pathogenesis of this injury. Follow-up for up to 3 years of 96 of the 126 patients enrolled in the first phase of these studies identified the low-flow state as a significant risk factor for poor neurodevelopmental outcome (Hunt et al, 2002).

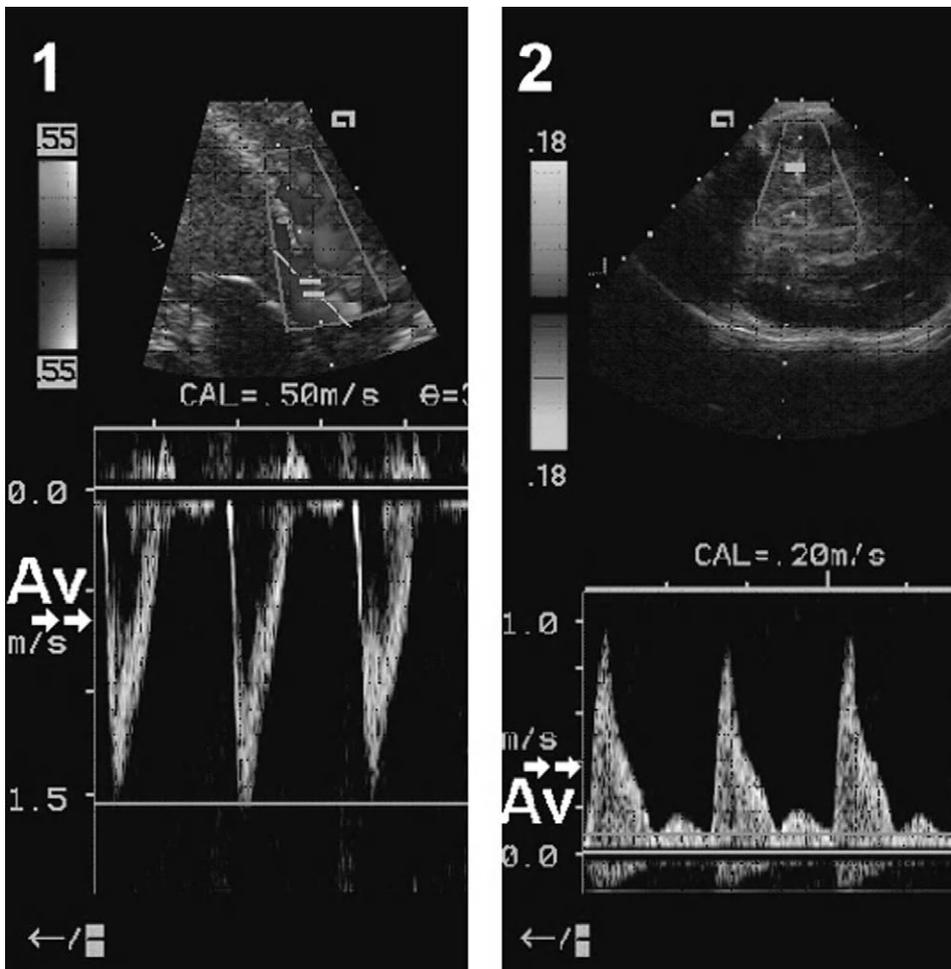

**FIGURE 31-1.** Assessment of superior vena cava (SVC) flow with measurement of the diameter from the low parasternal sagittal view (left) and measurement of the velocity time (VTI) integral (area under the Doppler envelope) (right). LV, left ventricle; RA, right atrium. (From Kluckow M, Evans N: Superior vena cava flow in newborn infants: A novel marker of systemic blood flow. *Arch Dis Child Fetal Neonatal Ed* 82:F182-F187, 2000.)

As for the pathogenesis of the abnormal circulatory adaptation of the very premature neonate, there is indirect evidence that the sudden increase in the systemic vascular resistance after separation from the placenta combined with myocardial immaturity plays an important role in the development of the low-flow state afflicting primarily the more immature patient population. Because the preterm myocardium is adapted to a low-resistance intrauterine environment and is characterized by reduced contractile elements and a limited ability to respond to an increase in afterload (Hawkins et al, 1989; Takahashi et al, 1997), it struggles to cope with the sudden increase in vascular resistance immediately after birth. The situation is compounded by both shunts out of the systemic circulation through the fetal channels and the negative circulatory effects of positive-pressure ventilation. In some babies, the result is a critically low systemic circulation. Then, as treatment and endocrine, neuroendocrine, and other compensatory responses to stress are initiated, the cardiovascular system adapts, and systemic blood flow improves. However, if the low-flow state is severe, a reperfusion injury may occur during the period of cardiovascular stabilization, especially in the extremely vulnerable immature central nervous system.

### Persistent Hypotension in Preterm Infants

Although the above-described transitional problems may or may not manifest as low blood pressure, there are a group of preterm babies in whom a persistent hypotension develops that is resistant to conventional inotropic support (Ng et al, 2001; Seri et al, 2001). Although this condition is well recognized, the underlying systemic hemodynamic changes are not well defined. Affected babies are more likely to be extremely preterm (<27 weeks in gestational age), have been critically ill or suffered a degree of perinatal asphyxia, or both. The problem may be apparent on the first postnatal day but typically persists beyond that time and may represent a state of vasodilatory shock with normal to high systemic blood flow and possibly supranormal cardiac output (Fig. 31-2) (Lopez et al, 1997). There are striking analogies between this presentation in preterm neonates with the vasodilatory shock as described in adults, particularly the lack of responsiveness to vasopressor inotropic agents (Landry and Oliver, 2001). Potential mechanisms of the uncontrolled vasodilation include dysregulated cytokine release, excess nitric oxide synthesis, vasopressin deficiency, overactivation of the potassium-adenosine triphosphate ( $K_{ATP}$ ) channels in the vascular smooth muscle cell membrane in response to tissue

**FIGURE 31-2.** Doppler velocity in the ascending aorta (1) and middle cerebral artery (2) in a preterm infant, born at 27 weeks of gestation, with septic shock due to *Pseudomonas* septicemia. The baby had a mean blood pressure of 20 mm Hg despite vasopressor and inotropic support. The high flow velocity can be seen from the normal average maximum velocity marked by the arrows (*Av*). The calculated left ventricular output was about 600 mL/kg/min (normal 150 to 300 mL/kg/min).

hypoxia, and down-regulation of the cardiovascular adrenergic receptors (Seri et al, 2001).

### Summary

The circulation of the very preterm infant exists in a state of precarious balance. The peripheral circulation is balanced between overconstriction, which may compromise systemic blood flow, and overdilation, which may result in vasodilatory shock. Data now suggest that the former situation dominates in the first 24 hours and the latter becomes increasingly important after that time. This suggestion creates a difficult therapeutic dilemma, because the correct approach for a circulatory compromise due to vasoconstriction is counterproductive if the underlying abnormality is vasodilation, and vice versa. Therefore, accurate diagnosis of the type of the circulatory failure is imperative.

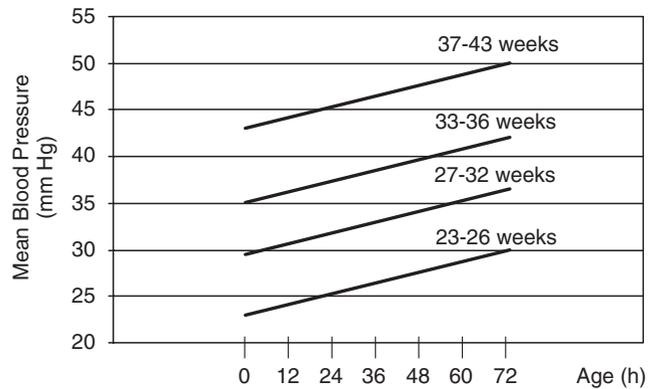

### DIAGNOSIS OF CIRCULATORY COMPROMISE

What the “gold standard” for the diagnosis of circulatory compromise should be is far from clear. Conventionally, blood pressure has been and still is used as that standard. As mentioned earlier, data now suggest that this approach may not be appropriate and that sole reliance on blood pressure will lead to inaccurate and sometimes significantly delayed diagnosis of circulatory compromise, especially in the very preterm infant immediately after birth. On the other hand, many clinicians believe that over-reliance on blood pressure measurement will lead to overdiagnosis of shock. The other commonly used clinical signs of circulatory compromise, such as increased heart rate, slow skin capillary refill time, increased core-peripheral temperature difference, low urine output, and acidosis, have limited value in aiding the diagnosis of circulatory compromise in the preterm or term infant (Osborn et al, 2004).

### Heart Rate and Blood Pressure

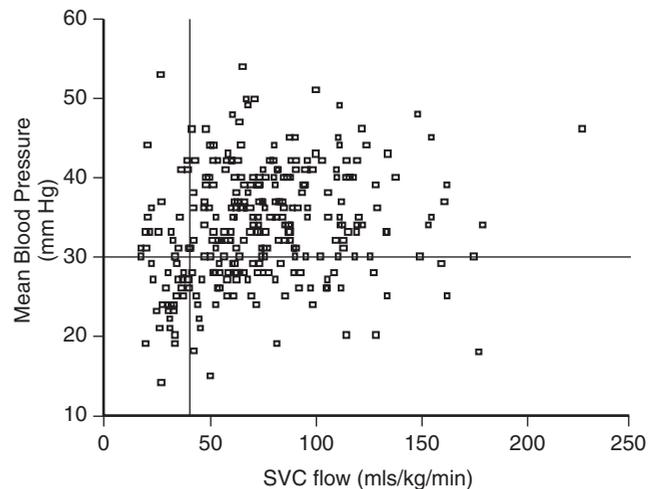

Heart rate is accurately and routinely monitored in neonates requiring admission to the newborn infant care unit. Because many factors other than those regulating the cardiovascular system affect heart rate, it has a limited yet widely utilized role in the diagnosis of circulatory compromise.

In babies with invasive intra-arterial access, continuous and accurate measurement of blood pressure is possible. The accuracy of the noninvasive oscillometric method is less certain. Normal ranges for blood pressure in babies of different gestations have been defined in the literature, and it is clear that gestation and postnatal age are the dominant influences on blood pressure (Lee et al, 1999; Nuntnarumit et al, 1999). The nomogram in Figure 31–3, constructed from data of Nuntnarumit and colleagues (1999), shows the 10th percentile for mean blood pressure for babies of different gestations at different postnatal ages. A simple rule of thumb is that the number of the mean blood pressure in mm Hg should be higher than the number of weeks of the baby’s gestation at the time of birth (Lee et al, 1999).

**FIGURE 31-3.** Gestational age- and postnatal age-dependent normogram for mean blood pressure values in neonates during the first 3 days of life. The normogram is derived from continuous arterial blood pressure measurements obtained from 103 neonates with gestational ages between 23 and 43 weeks. Each line represents the lower limit of 80% confidence interval of mean blood pressure for each gestational age group. Thus, 90% of infants for each gestational age group are expected to have a mean blood pressure equal to or greater than the value indicated by the corresponding line (the lower limit of confidence interval). (From Nuntnarumit P, Yang W, Bada-Ellzey HS: Blood pressure measurements in the newborn. *Clin Perinatol* 26:981-996, 1999.)

How accurately blood pressure defines the state of the systemic circulation in preterm neonates, however, is less clear. As mentioned earlier, there is only a weak relationship between mean blood pressure and measures of systemic blood flow in preterm neonates immediately after birth (Fig. 31–4). Thus, if blood pressure alone is

**FIGURE 31-4.** The relationship between superior vena cava (SVC) flow and mean blood pressure (MBP) during the first 24 hours in a cohort of 126 babies born before 30 weeks of gestation. Normal values are marked by the line. The 30-mm Hg value is chosen arbitrarily for MBP because the change in normal MBP with gestation cannot be marked. Although there is a relationship between the two measures ( $r = 0.21$ ;  $P = .023$ ), it is not strong, with some babies having normal pressure and low flow and others having low pressure and normal flow. (From Kluckow M, Evans N: Low superior vena cava flow and intraventricular hemorrhage in preterm infants. *Arch Dis Child Fetal Neonatal Ed* 82:F188-F194, 2000.)

used to guide treatment, some of these babies may not be treated appropriately. Available data indicate that only when mean blood pressures in very preterm babies are  $\leq 20$  mm Hg and  $\geq 40$  mm Hg does blood pressure become a more accurate indicator of abnormal and normal systemic blood flow, respectively. Thus, in the extremely preterm neonate with mean blood pressures between 20 and 40 mm Hg in the immediate postnatal period, the state of systemic blood flow is unclear, and the situation can be clarified only with Doppler flow measurements (Osborn et al, 2004).

### Capillary Refill Time

Although capillary refill time is a widely used clinical sign, there is little validation of its accuracy. A capillary refill time of less than 3 seconds is traditionally accepted as normal. In older infants in a pediatric intensive care setting, there is little relationship between capillary refill time and measures of systemic blood flow (Tibby et al, 1999). A similar lack of tight relationship has been found in preterm neonates born before 30 weeks of gestation; only when capillary refill time exceeds 5 seconds does it have any degree of specificity (Osborn et al, 2004).

### Core-Peripheral Temperature Difference

As with capillary refill, there is little data to support the accuracy of core-peripheral temperature difference in older babies (Tibby et al, 1999). In preterm neonates born before 30 weeks of gestation, no relationship has been found between this measure and systemic blood flow in the immediate postnatal period (Osborn et al, 2004).

### Low Urine Output and Hyperkalemia

A strong relationship has been documented in very preterm babies between low systemic blood flow and subsequent low urine output and hyperkalemia (Kluckow and Evans, 2001). However, there is a time delay between the development of the circulatory compromise and the recognition of oliguria or hyperkalemia, making these signs somewhat less valuable for the early diagnosis of shock.

### Lactic Acid, pH, and Base Excess

In a large series, pH and base excess was found to have little relationship with low systemic blood flow in preterm babies immediately after birth. This finding is likely explained by the lack of a strong relationship among pH, base excess, and lactic acid levels (Deshpande and Platt, 1997). Although the lactic acid concentration has been proposed as a measure of circulatory compromise, there is little evidence to support its accuracy. One study found that there also was no relationship between lactic acid level and SVC flow measured at two different time points during the first postnatal day (Kluckow and Evans, 1999). At both times, lactic acid level had a stronger relationship

with the events of the preceding hours than with what was going on at the time of its measurement. Thus, as with urine output and hyperkalemia, by the time lactic acidosis develops and is detected, the initiating event may not be present anymore. In support of this assumption is the finding that a rising lactate level is more predictive of adverse outcome than a high early level that then falls (Deshpande and Platt, 1997).

### Organ Blood Flow

Much of the attention in the newborn has focused on measuring blood flow to the brain. Several methodologies have been studied, including Doppler velocity measurements, xenon clearance, and near-infrared spectroscopy (Tsuji et al, 2000; Tyszczyk et al, 1998). Because peripheral arteries tend to be too small for size measurement, Doppler studies in such vessels tend to be limited to parameters of velocity, from which it is not possible to derive blood flow. Consequently, peripheral artery Doppler ultrasonography tends to be more useful for assessing changes over time frames in which it is unlikely that vessel size will have changed (Seri et al, 1998). Xenon clearance is not practical outside a research setting. Near-infrared spectroscopy, which uses changes in oxygenation over time, or the difference between oxygenated and deoxygenated hemoglobin, to assess flow, has been very useful as a research tool (Tsuji et al, 2000; Tyszczyk et al, 1998). Whether it can be implemented in the clinical arena remains unclear.

### Echocardiographic Systemic Blood Flow Measures

In the mature circulation, systemic blood flow is the cardiac output. Although the outputs of the two ventricles are the same, cardiac output is traditionally measured from the left ventricular output. In the clinical practice, Doppler ultrasonography offers a noninvasive method to measure cardiac output. Measuring blood flows directly in the pulmonary artery and ascending aorta enables us to evaluate outputs from the right and left ventricles, respectively (Alverson et al, 1982; Evans and Kluckow, 1996; Walther et al, 1985). Unfortunately, in the transitional circulation of the newborn infant, neither ventricular output will consistently reflect systemic blood flow because of the shunts across the fetal channels. Because SVC flow measures blood flow returning from the upper body and brain, which must be the same as the blood flow going out to this area of the body, and because SVC lends itself well to Doppler flow studies in the early postnatal period, SVC flow has been introduced to evaluate systemic blood flow in preterm babies in the early postnatal period (see Fig. 31-1) (Kluckow and Evans, 2000).

Measurement of ventricular output is exceedingly difficult in the preterm infant because of atelectasis and multiple shunts. In addition, Doppler flow measures rely on a level of ultrasonographic technology and echocardiographic skill that are often not available 24 hours a day in many neonatal intensive care units. However, this may change in the future as increasing numbers of neonatologists are developing these skills (Evans, 2000).

## Summary

The mainstay of the diagnosis of neonatal circulatory compromise has been a combination of blood pressure measurement and evaluation of the previously described clinical parameters. However, none of these parameters has sufficient accuracy to be used on its own to evaluate systemic blood flow and tissue perfusion. Therefore, the addition of echocardiographic hemodynamic assessment to blood pressure monitoring and thorough continuous clinical evaluation of the patient are necessary to better understand changes in organ blood flow and tissue perfusion, especially in preterm neonates during the vulnerable period of immediate transition to extrauterine life. The goal should be to maintain normal systemic blood flow in the presence of an acceptable blood pressure, with use of the normal range for blood pressure that controls for gestation and postnatal age. If there is no immediate access to echocardiography, the clinician must rely on blood pressure monitoring while keeping in mind the limitations of this approach.

## TREATMENT

Selection of the most appropriate treatment strategy for neonatal shock requires identification of its pathogenesis (Seri, 2001). As described previously, the most common etiologic factors of neonatal cardiovascular compromise are (1) inappropriate peripheral vasoregulation resulting in vasodilation or vasoconstriction and (2) the dysfunction of the immature myocardium (Gill and Weindling, 1993; Osborn et al, 2002; Seri, 1995). Absolute hypovolemia is a much less frequent primary cause of neonatal hypotension, especially in preterm infants in the immediate postnatal period.

### Volume Administration

The findings that hypotensive neonates as a group are not hypovolemic, that low blood pressure is frequently associated with normal or even high ventricular output and low index of resistance (Pladys et al, 1999) and that dopamine is more effective than volume administration in normalizing blood pressure (Lundstrom et al, 2000) provide evidence that absolute hypovolemia is an uncommon primary cause of neonatal hypotension. Therefore, particularly in the preterm infant in the immediate postnatal period, fluid resuscitation should be minimized. Furthermore, because myocardial dysfunction frequently contributes to the development of neonatal hypotension (Gill and Weindling, 1993) and because aggressive volume administration in this patient population is associated with higher pulmonary, cardiovascular, gastrointestinal and central nervous system morbidity and mortality (Kavvadia et al, 2000; Lundstrom et al, 2000; Van Marter et al, 1990), judicious use of fluid administration is indeed of utmost importance.

Concerning the type of fluid administration, isotonic saline has been shown to be as effective as 5% albumin in raising the blood pressure (Oca et al, 2003; So et al, 1997). In addition, albumin may cause an impairment of gas exchange, may induce a fluid shift from the intracellular

compartment (Ernest et al, 1999), and may be associated with increased mortality (Nadel et al, 1998). Therefore, unless evidence of serum or blood loss or hypoalbuminemia is present, volume support in hypotensive preterm infants should be provided in the form of 10 to 20 mL/kg of isotonic saline (Seri, 2001). However, it is important to mention that, owing to the unbalanced nature of normal saline, its administration in large amounts over a short time may worsen the metabolic acidosis. If the limited volume administration is ineffective, pharmacologic cardiovascular support with dopamine, dobutamine, or both should be initiated (Seri, 1995 and 2001; Osborn et al, 2002).

If there is an identifiable volume loss, the kind of fluid lost should be replaced. In cases of blood loss, transfusion with packed red blood cells after the initial bolus of crystalloid or colloid or with packed red blood cells suspended in fresh frozen plasma with a hematocrit around 55% may be used. In cases of greater transepidermal water losses, administration of larger amounts of free water without an increase in sodium supplementation is indicated.

## Dopamine And Dobutamine

Dopamine and dobutamine were introduced into the management of neonatal hypotension in the early and middle 1980s, respectively, without appropriately designed randomized and blinded clinical trials of their effectiveness. Thus, we have only indirect evidence that the use of these sympathomimetic amines improves neonatal mortality or morbidity. A few studies have extended their focus beyond the dopamine- and dobutamine-induced heart rate and blood pressure changes by examining the drugs' effects on neonatal myocardial contractility and organ blood flow (Lundstrom et al, 2000; Osborn et al, 2002; Roze et al, 1993; Seri et al, 1998, 2002; Zhang et al, 1999). However, there is still only limited information available about the effects of dopamine and dobutamine on tissue oxygen delivery and consumption (Wardle et al, 1999) and systemic blood flow in the newborn (Osborn et al, 2002).

### Hemodynamic Effects

Dopamine, an endogenous catecholamine, is the sympathomimetic amine most commonly used in the treatment of hypotension in preterm infants (Seri, 1995; Noori et al, 2003). It exerts its cardiovascular actions via the dose-dependent stimulation of the cardiovascular dopaminergic,  $\alpha$ - and  $\beta$ -adrenergic and serotonin receptors. In addition, by stimulating epithelial and peripheral neuronal dopaminergic and adrenergic receptors, the drug exerts significant renal and endocrine effects independent of its cardiovascular actions. Although dopamine affects all three major determinants of cardiovascular function (preload, myocardial contractility, and afterload), the drug-induced increases in myocardial contractility (Lundstrom et al, 2000; Zhang et al, 1999) and peripheral vascular resistance (afterload) (Lundstrom et al, 2000; Roze et al, 1993; Zhang et al, 1999) are the most important factors in raising systemic blood pressure and improving the cardiovascular status.

The original dose range recommendation for dopamine, 2 to 20  $\mu\text{g}/\text{kg}/\text{min}$ , was based on pharmacodynamic data obtained in healthy adults. However, changes in cardiovascular adrenergic receptor expression by critical illness (Hausdorff et al, 1990) as well as the dysregulated production of local vasodilators during severe illness decrease the sensitivity of the cardiovascular system to dopamine, resulting in the emergence of hypotension resistant to “conventional” doses of the drug (Ng et al, 2001). Thus, with the advancement of the disease process, larger doses of dopamine and other sympathomimetic amines may be needed to generate the same magnitude of cardiovascular response. Dopamine administration should therefore be tailored to the drug’s pharmacodynamic effects in the given patient at the bedside, rather than driven by the conventional dose recommendations based on data obtained in healthy adults. Indeed, although many neonatologists do not increase the dose of dopamine beyond 20  $\mu\text{g}/\text{kg}/\text{min}$ , there is no evidence that, when required to normalize blood pressure, higher-dose dopamine treatment with or without additional administration of epinephrine has detrimental vasoconstrictive effects. However, there are no data available on changes in cardiac output and organ blood flow in response to high-dose catecholamine treatment in vasopressor-resistant neonatal shock, so close attention should be paid to signs of inappropriate vasoconstriction when this therapy is applied.

Unlike dopamine, dobutamine is a relatively cardioselective sympathomimetic amine with significant  $\alpha$ - and  $\beta$ -adrenoreceptor-mediated direct inotropic effects and limited chronotropic actions (Ruffolo, 1987). Dobutamine administration is usually also associated with a variable drop in total peripheral vascular resistance and, at least in adults, with improvements in coronary blood flow and myocardial oxygen delivery. Furthermore, unlike dopamine, dobutamine increases myocardial contractility exclusively through the direct stimulation of the myocardial adrenergic receptors. Because myocardial norepinephrine stores are immature and rapidly depleted in the newborn, and because dobutamine may decrease afterload, newborns with primary myocardial dysfunction and elevated peripheral vascular resistance are most likely to benefit from dobutamine treatment (Martinez et al, 1992; Osborn et al, 2002; Noori et al, 2004). Interestingly, though addition of dobutamine to dopamine in preterm infants with RDS was effective in increasing blood pressure, it was associated with supranormal cardiac output states and low systemic vascular resistance (Lopez et al, 1997). Whether the benefits of supranormal cardiac output, through provision of adequate tissue oxygen delivery throughout the body, outweigh the risks of sustained hypercontractility, which potentially results in myocardial injury, remains to be investigated.

Some randomized studies have demonstrated that dopamine is more effective than dobutamine in raising blood pressure in the preterm infant. A meta-analysis of the findings confirmed that dopamine was more successful than dobutamine in treating hypotension and found that fewer infants in the dopamine-treated groups experienced treatment failure (Subdehar and Shaw, 2000). However, there was no difference in incidence of short-

term adverse neurologic outcome between the two groups, and in the absence of long-term outcome data, no firm recommendations could be made regarding the first choice of drug to treat hypotension in preterm infants in the immediate postnatal period.

Because of the weak relationship between blood pressure and systemic blood flow in *very preterm neonates during the immediate postnatal period*, an increase in blood pressure does not necessarily guarantee that tissue perfusion has improved along with the blood pressure. Indeed, a randomized trial comparing the effects of dopamine and dobutamine on blood pressure and SVC blood flow found that, although dopamine is more effective in improving blood pressure, it is less effective in improving systemic blood flow in the very low-birth-weight neonate on the first postnatal day (Osborn et al, 2002). These findings may be explained by the difficulties extremely low-birth-weight neonates face during the immediate postnatal adaptation, when their immature myocardium struggles to maintain appropriate systemic blood flow against the suddenly increased peripheral vascular resistance. Under these circumstances, high doses of dopamine may further increase afterload without effectively improving myocardial function, and systemic blood flow may not improve or may worsen. Therefore, if there is evidence of peripheral vasoconstriction, especially in very low-birth-weight neonates during the first postnatal day, high-dose dopamine treatment should be attempted only if systemic blood flow can be monitored, because this treatment approach may result in further impairment in systemic blood flow despite improvements in blood pressure. At present, the neonatologist must rely on monitoring blood pressure and the indirect measures of cardiovascular function and must accept lower-end blood pressure values for gestational and postnatal age if evidence of vasoconstriction is present with higher doses of dopamine, while decreasing the dose of the drug below 10  $\mu\text{g}/\text{kg}/\text{min}$ , at which significant  $\alpha$ -adrenoreceptor stimulation is less likely (Seri, 1995; Noori et al, 2003). A combination of dobutamine and low- to medium-dose dopamine may achieve the most important goals of treatment by maintaining blood pressure and systemic blood flow in acceptable ranges, if monitoring of both cardiovascular parameters is possible. In summary, since both hypotension and low systemic blood flow may be associated with impairment of neurodevelopmental outcome, the primary goal of management of the hypotensive, very preterm neonate should be the correction of both measures of cardiovascular function.

The vasodilatory dopamine receptors are expressed primarily in the renal, mesenteric, and coronary circulation (Seri, 1995). Dopamine has been shown to selectively reduce renal vascular resistance (Seri et al, 1998, 2002) and raise glomerular filtration rate (Seri et al, 1993) in preterm infants as early as the 23rd week of gestation. However, dopamine decreases mesenteric vascular resistance in preterm infants only after the first postnatal day (Hentschel et al, 1995; Seri et al, 1998, 2000), and the effect may be variable (Zhang et al, 1999). Similarly, there are some differences in the reported magnitude of the drug-induced increases in ventricular function, cardiac output, and systemic vascular resistance (Clark et al, 2002; Lundstrom

et al, 2000; Roze et al, 1993; Zhang et al, 1999). These differences may be best explained by variations in the intravascular volume status, the postnatal age, the developmentally regulated expression of cardiovascular adrenergic and dopaminergic receptors, and the severity of adrenoreceptor down-regulation among the different populations of critically ill preterm infants studied. It is important to note that none of the studies found evidence for a direct effect of dopamine on cerebral blood flow (Lundstrom et al, 2000; Seri et al, 1998, 2000; Zhang et al, 1999). Thus, dopamine administration appears to be devoid of potentially harmful selective hemodynamic effects in the brain. Finally, in addition to increasing afterload, dopamine may increase pulmonary vascular resistance in some preterm neonates (Liet et al, 2002). However, because the drug-induced increases in systemic blood pressure are not associated with impaired oxygenation in the majority of the preterm infants (Wardle et al, 1999), there is no evidence for consistent increases in extrapulmonary right-to-left shunting during dopamine treatment, especially in term neonates with persistent pulmonary hypertension.

There are no data available on the direct renal, cerebral, or pulmonary hemodynamic effects of dobutamine in the newborn (Noori et al, 2004). However, one nonrandomized study comparing the effects of dopamine and dobutamine on blood pressure and mesenteric blood flow in preterm infants found that the two drugs increased blood pressure and were equally effective in decreasing mesenteric vascular resistance (Hentschel et al, 1995). Dobutamine does not stimulate the dopaminergic receptors, so a  $\beta$ -adrenoreceptor-induced selective vasodilation may be responsible for the observed mesenteric vasodilation in the dobutamine-treated patients.

### Epithelial and Neuroendocrine Effects

Independent of the cardiovascular effects already described, dopamine exerts direct renal and endocrine (Seri, 1993 and 1995) actions in the newborn. Via its direct effects on sodium, phosphorus, and water transport processes and  $\text{Na}^+$ ,  $\text{K}^+$ -ATPase activity in the renal tubules, dopamine increases excretion of sodium, phosphorus, and free water and may raise the hypoxic threshold of renal tubular cells during episodes of hypoperfusion and hypoxemia. Via its renal vascular and epithelial actions, dopamine also potentiates the diuretic effects of furosemide (Tulassay and Seri, 1986) and theophylline (Bell et al, 1998). Although dopamine has the theoretical potential to attenuate the renal side effects of indomethacin, published data for this issue are contradictory. Differences in the level of maturity, disease severity, ductal shunting, intravascular volume status, and indomethacin dose may be responsible for the conflicting results.

Among its endocrine actions, the dopamine-induced decreases in plasma prolactin and thyrotropin levels may be of clinical importance. The decrease in plasma prolactin may attenuate the preterm infant's propensity to edema formation. The inhibition of thyrotropin release, on the other hand, necessitates the postponement of routine neonatal thyroid screening until after dopamine administration has been discontinued. The potential

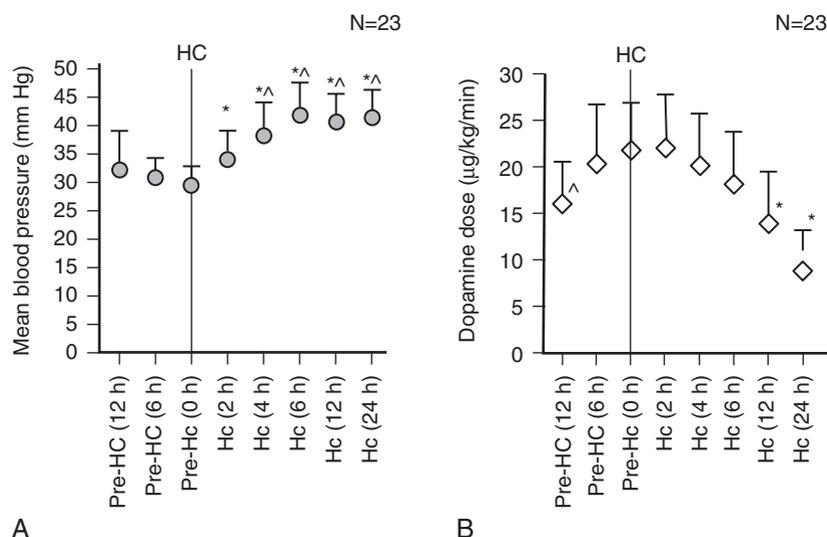

effects on long-term neurodevelopmental outcome and immunologic function of the drug-induced alterations in the neuroendocrine function have not been investigated in the preterm or term neonate. Because dobutamine does not directly stimulate the dopaminergic receptors, its administration is devoid of neuroendocrine effects.

### Other Sympathomimetic Amines and Hormones

Despite the lack of peer-reviewed publications of controlled studies in the neonatal patient population, both epinephrine (Campbell and Byrne, 1998; Seri and Evans, 1998) and norepinephrine (Derleth, 1997) have been used in the treatment of hypotension in preterm infants. It is not known whether there is a difference in the cardiovascular response or side effects between the combined use of epinephrine and dopamine and the use of increasing doses of dopamine beyond 20  $\mu\text{g}/\text{kg}/\text{min}$  with or without dobutamine. No detrimental vasoconstrictive effects have been reported for either high doses of epinephrine with or without dopamine or norepinephrine in these preliminary publications; this finding is best explained by the decreased cardiovascular sensitivity of these critically ill preterm infants to catecholamines, necessitating the high sympathomimetic support in the first place. In addition to sympathomimetic amines, arginine-vasopressin has been reported to improve cardiovascular function in a small number of newborns with vasodilatory shock after cardiac surgery (Rosenzweig et al, 1999).

### Corticosteroids

There is some limited evidence that brief corticosteroid treatment may stabilize the cardiovascular status and decrease the need for pressor support in the critically ill newborn with vasopressor-resistant hypotension. During the course of critical illness, down-regulation of adrenergic receptors may lead to gradual desensitization of the cardiovascular system to catecholamines, resulting in the need for escalation of vasopressor support. The finding that glucocorticoids regulate the expression of cardiovascular adrenergic receptors and some components of the second messenger systems (Hausdorff et al, 1990) explains the effectiveness of brief steroid treatment in stabilizing the cardiovascular status and reversing vasopressor resistance. In addition to regulating cardiovascular adrenergic receptor expression via their "genomic" effects, steroids exert certain "non-genomic" actions (Wehling, 1997), such as the inhibition of catecholamine metabolism and the production of vasoactive factors, including nitric oxide. Moreover, physiologic doses of mineralocorticoids and pharmacologic doses of glucocorticoids have been shown to instantly improve intracellular availability of calcium (Wehling, 1997), resulting in enhanced myocardial and vascular smooth muscle cell responsiveness to catecholamines. Indeed, some data suggest that hydrocortisone treatment in preterm infants with vasopressor-resistant hypotension is associated with significant increases in blood pressure within 2 hours of its administration (non-genomic effects) and that decreases in vasopressor requirement occur only after 8 to 12 hours of the first dose of the drug (genomic effects) (Fig. 31-5; Seri

**FIGURE 31-5.** Effect of hydrocortisone (HC) on mean blood pressure (mean  $\pm$  SD; **A**) and the dose of dopamine (mean  $\pm$  SD; **B**) during the first 24 hours of hydrocortisone treatment in 23 preterm neonates with pressor-resistant shock. The mean blood pressure and dopamine requirement during 12 hours before and the first 24 hours after the first dose of hydrocortisone are shown. Before hydrocortisone administration, blood pressure remained low, despite significantly increased dopamine doses (**B**; ^,  $P < .05$  vs. baseline [0 h]). However, mean blood pressure increased significantly by 2 hours after the first dose of hydrocortisone (**A**; \*,  $P < .05$  vs. baseline [0 h]) and continued to rise until 6 hours of hydrocortisone therapy, remaining stable thereafter (**A**; \*,  $P < .05$  vs. baseline [0 h]; ^,  $P < .05$  vs. HC [2 h]). The dose of dopamine significantly decreased at 12 and 24 hours of hydrocortisone therapy (**B**; \*,  $P < .05$  vs. baseline [0 h]). (From *Seri I, Tan R, Evans J: Cardiovascular effects of hydrocortisone in preterm neonates with pressor-resistant hypotension. Pediatrics 107:1070-1074, 2001.*)

et al, 2001). However, there is growing concern about the potential short-term and long-term side effects of systemic steroid administration.

### Supportive Measures

Maintenance of a normal arterial pH and serum ionized calcium concentrations is necessary for the optimum cardiovascular response to catecholamines. Because some clinicians believe that a metabolic acidosis in which pH is less than 7.25 may compromise myocardial function in the preterm infant (Fanconi et al, 1993), it has been recommended that the arterial pH be maintained above this range in cases of acidosis with a significant metabolic component.

### SUMMARY

Sustained stabilization of the cardiovascular status with provision of appropriate blood pressure, cardiac output, tissue perfusion, and oxygenation remains a difficult task in most critically ill hypotensive newborns. Treatment of these patients requires the ability to monitor the most important measures of cardiovascular function (blood pressure and systemic blood flow) as well as a thorough understanding of the pathogenesis and pathophysiology of neonatal shock and the mechanisms of actions, pharmacodynamics, and potential side effects of the sympathomimetic amines and other medications used in the management of neonatal shock.

# Care of the Extremely Low-Birth-Weight Infant

Eric C. Eichenwald

Few medical specialties have experienced the amount of progress in medical care and impact on overall patient survival than neonatology over the past two decades. Improvements in technology, greater use of prenatal glucocorticoids and surfactant replacement therapy, better regionalization of perinatal and high-risk neonatal care, and a more comprehensive understanding of the physiology of the immature infant have all contributed to dramatic increases in survival of very preterm infants. Care of premature infants with birth weights between 1000 and 1500 g has become almost routine in most newborn intensive care units (NICUs) in the United States.

The newest frontier in neonatology is the care of extremely low-birth-weight infants (ELBW) (birth weight <1000 g), sometimes referred colloquially as “micro-preemies.” These infants present one of the greatest medical and ethical challenges to the field. Although they represent a small percentage of overall births and NICU admissions, ELBW infants are often the most critically ill and at the highest risk for mortality and long-term morbidity of any NICU patient. They also contribute disproportionately to overall hospital days and consume a large percentage of NICU personnel time, effort, and costs of care. Care of these infants is in constant evolution, owing to new discoveries in both basic and clinical research as well as to growing clinical experience. In this chapter, I review some of the special challenges in and practical aspects of the management of the ELBW infant. The reader is referred to specific chapters throughout the text for a more comprehensive review of specific problems and conditions.

## EPIDEMIOLOGY

The percentage of babies born preterm in the United States has risen slowly over the past two decades (Martin et al, 2002). In the year 2000, preterm (<37 weeks of gestation) births accounted for 11.6% of all births, and births of infants before 28 weeks of gestation for just below 1%. There is a significant racial disparity in the incidence of extreme preterm birth, the African-American ELBW birth rate being nearly double that of the Hispanic and non-Hispanic white populations. Associated with this increase in frequency of preterm births is the greater availability of assisted reproductive technologies. These technologies result in a higher incidence of LBW infants, due in part to the higher frequency of multiple gestations (Schieve et al, 2002). Twins, triplets, and higher-order

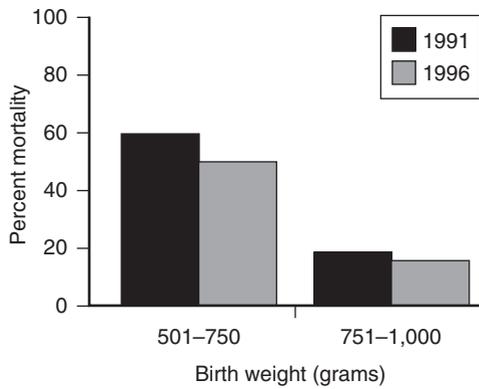

multiple gestations currently represent almost a quarter all LBW deliveries in the United States (Martin et al, 2002), and contribute to the ELBW population. Multiple gestations add to the potential morbidity of extremely premature birth because of a higher frequency of intrauterine growth restriction (IUGR) and other medical complications of pregnancy.

Several studies have shown increased survival in the smallest and most premature infants over the past decade (Figs. 32–1 through 32–3) (Horbar et al, 2002; Lemons et al, 2000). See also Chapter 1 for a complete discussion of these changes.)

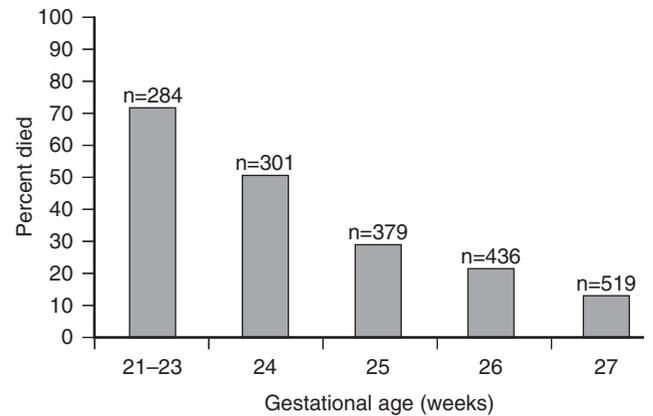

Improved survival has been accompanied by a change in the incidence of several major morbidities among survivors (Figs. 32–4 and 32–5). Little change in the frequency of severe intracranial hemorrhage or necrotizing enterocolitis was observed in the National Institute of Child Health and Development (NICHD) cohort of infants born in institutions participating in the Neonatal Research Network between 1991 and 1996 (Lemons et al, 2001). In contrast, the Vermont-Oxford NICUs reported a reduction in the incidence of severe intracranial hemorrhage in the early part of the 1990s, which has remained static into the late 1990s (Horbar et al, 2002). The incidence of chronic lung disease (defined as oxygen requirement at 36 weeks of postmenstrual age) rose slightly from 1991 to 1996 in the NICHD cohort, likely related to the greater survival of infants in the lowest weight group. With the current trends in survival and in hospital morbidity, the absolute number of extremely premature infants who survive to NICU discharge and are diagnosed with a major morbidity in the neonatal period has increased (Fig. 32–6). A significant percentage of these infants continue to suffer from neurodevelopmental and neurosensory disability into childhood (Wood et al, 2000).

## PERINATAL MANAGEMENT

Short-term outcomes of extremely premature infants are improved if they are delivered in a high-risk center rather than being transported after birth (Arad et al, 1999; Chien et al, 2001; Cifuentes et al, 2002; Towers et al, 2000). Therefore, if clinically feasible, the pregnant woman who seems likely to deliver an extremely premature infant should be transferred to a high-risk perinatal center for the expertise in obstetrical and neonatology management. Upon arrival, she should be evaluated for factors that may have predisposed to preterm labor and assessed for the status of the fetal membranes and the presence or absence of chorioamnionitis. In addition, best obstetrical estimate of gestational age (by date of last menstrual period and early ultrasonographic dating, if available), ultrasonographic assessment of fetal size and position, and the presence of other medical or obstetrical complications (preeclampsia, placenta previa, abruptio placentae) should be documented. Specimens for rectovaginal cultures to detect the presence of group B streptococcus should also be obtained on admission (Schrag et al, 2002), and treatment with penicillin (or vancomycin for the penicillin-allergic patient) initiated until culture results

**FIGURE 32-1.** Mortality in extremely low-birth-weight infants cared for in the National Institute of Child Health and Human Development Neonatal Research Network Centers in 1991 to 1996. (Adapted from Lemons J, Bauer C, Oh W, et al: *Very low birth weight outcomes of the National Institute of Child Health and Human Development Neonatal Research Network, January 1995 through December 1996. Pediatrics 197:1-8, 2001.*)

**FIGURE 32-3.** Mortality before discharge, by gestational age as estimated by best obstetrical estimate, among infants born at 21 to 27 weeks of gestation in National Institute of Child Health and Human Development Neonatal Research Network Centers between January 1, 1995, and December 31, 1996. (Adapted from Lemons et al, 2001.)

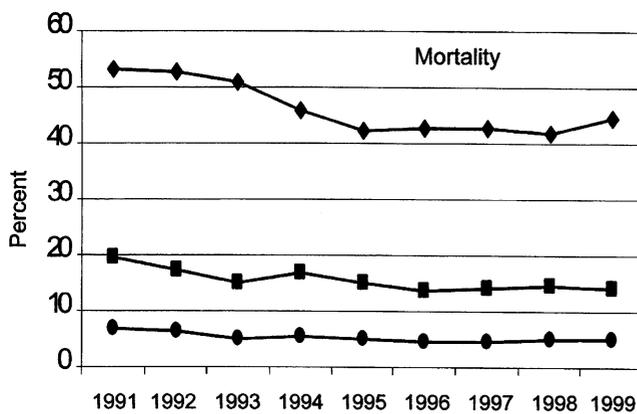

are available. There is widespread agreement that prenatal glucocorticoids should be offered to any woman in whom delivery at 24 to 34 weeks of gestation threatens; treatment at earlier gestational ages is controversial and of unclear benefit. Although unlikely to arrest labor for an extended period, tocolytic agents (ritodrine, terbutaline, magnesium sulfate) should be considered for women with preterm uterine contractions without evidence of chorioamnionitis.

Premature rupture of the fetal membranes (PROM) occurs in 30% to 40% of women who deliver prematurely (Mazor et al, 1998). If PROM is diagnosed without evidence of chorioamnionitis, consideration should be given to use of prophylactic antibiotic therapy (ampicillin or erythromycin) for the mother. Several studies have shown that such therapy prolongs the latency period, reduces the incidence of chorioamnionitis and endometritis, and improves neonatal outcome (Gibbs and Eschenbach, 1997;

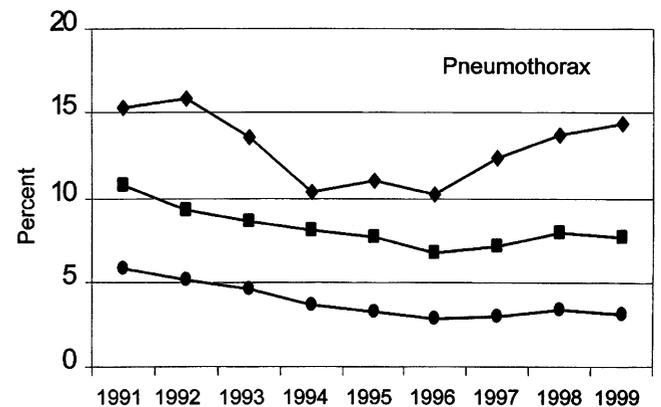

Mazor et al, 1998; Mercer et al, 1997). Tocolytic and antibiotic therapy in the setting of PROM may prolong latency by 48 to 72 hours in many extremely preterm pregnancies in which delivery threatens, allowing administration of a complete course of glucocorticoids to the mother. (See also Chapters 42 and 47.)

### PRENATAL CONSULTATION

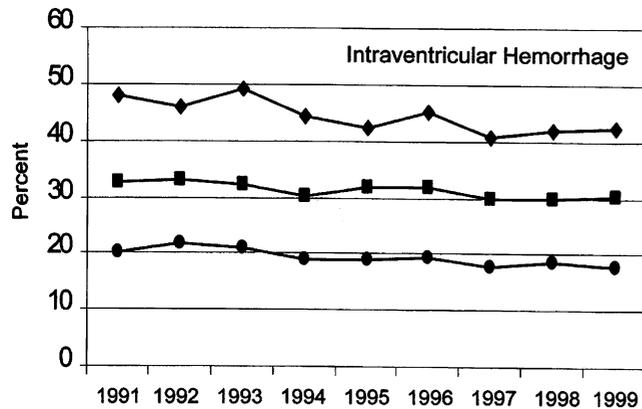

If possible, all parents who are at risk for delivery of an extremely premature infant should meet in consultation with a neonatologist before the infant's birth, preferably jointly with a perinatologist caring for the mother (Finer and Barrington, 1998). There are several goals of this consultation. First, the neonatologist and perinatologist should inform the parents about the proposed management of the pregnancy and delivery of the infant, including

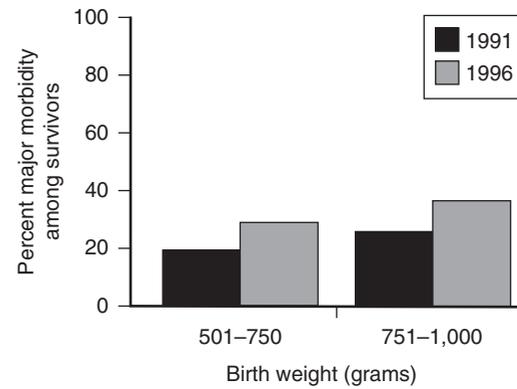

**FIGURE 32-2.** Mortality for infants 501 to 1500 g, 1991 to 1999, by birth weight category from 362 Vermont-Oxford Network centers. *Diamonds* indicate 501 to 750 g birth weight; *squares*, 750 to 1000 g; and *circles*, 1000 to 1500 g. (From Horbar J, Badger G, Carpenter J, et al: *Trends in mortality and morbidity for very low birth weight infants, 1991-1999. Pediatrics 110:143-151, 2002.*)

**FIGURE 32-4.** Incidence of pneumothorax for infants 501 to 1500 g by birth weight category from 362 Vermont-Oxford Network centers, 1991 to 1999. *Diamonds* indicate 501 to 750 g birth weight; *squares*, 750 to 1000 g; and *circles*, 1000 to 1500 g. **FIGURE 32-6.** Incidence of major morbidity (including severe intracranial hemorrhage, chronic lung disease, and proven necrotizing enterocolitis) among surviving extremely low-birth-weight infants cared for in National Institute of Child Health and Human Development Neonatal Network Research Centers in 1991 to 1996. (Adapted from Lemons et al, 2001.)

a discussion of the advantages of administration of glucocorticoids to the mother, the possible need for cesarean delivery, and delivery room care and resuscitation of the baby. Second, the parents should be informed about the potential risks of both the extent of prematurity and the

proposed therapeutic interventions (Tables 32-1 and 32-2). Third, the neonatologist should investigate the parents' beliefs and attitudes about delivery of an extremely premature infant and the potential for long-term morbidity. This outline for prenatal consultation is especially impor-

Data from Lee S, McMillan D, Ohlsson A, et al: Variations in practice and outcomes in the Canadian NICU network: 1996-1997. *Pediatrics* 106:1070-1079, 2000.

tant if delivery is expected at the borderline of viability (23 to 24 weeks of gestation).

Data are sparse about the process and results of prenatal consultation with parents of an extremely preterm infant. Some studies suggest that significant incongruity exists among the attitudes of obstetricians, nurses, neonatologists, and parents about active delivery room resuscitation and treatment of extremely premature infants (Streiner et al, 2001; Zupancic et al, 2002). Reuss and Gordon (1995) have shown that the obstetrical judgment of fetal viability was associated with an 18-fold increase in survival for infants with a birth weight less than 750 g, indicating that obstetrical attitudes and decisions influence outcome. Obstetricians and nurses tend to overestimate, and parents tend to underestimate, mortality and morbidity in premature infants (Doron et al, 1998; Haywood et al, 1994). Parents report being more in favor of intervening irrespective of gestational age or condition at birth compared with health care professionals (Streiner et al, 2001). In a survey by Ballard and colleagues (2002), the majority of neonatologists responded that they would respect parents' wishes about resuscitation of a borderline viable infant. In practice, when parental preferences about active resuscitation are known before delivery of

an extremely preterm infant, neonatologists report that they would alter their management of the infant in the delivery room accordingly (Doron et al, 1998), indicating the important role for prenatal consultation. However, parental attitudes likely are strongly influenced by physician recommendations about aggressive resuscitation conveyed during the prenatal consultation.

The earliest gestational age at which resuscitation should be initiated remains controversial among neonatologists (Finer et al, 1999), making firm recommendations for the actual content of prenatal consultation difficult. Most studies that describe the outcome of premature infants are based on birth weight rather than gestational age and thus confound the effects of extremely preterm birth with those of intrauterine growth restriction. However, both parents and physicians are usually faced with making decisions based on the anticipated gestational age at delivery. Data from several studies suggest that in terms of survival and potential for long-term disability, encouragement of active management is appropriate for pregnancies expected to deliver at 25 weeks of gestation or later (Piecuch et al, 1997; Wood et al, 2000). The risk of death and severe morbidity is significantly higher before 25 weeks of gestation (El-Metwally et al, 2000). Mortality approaches 80% for

infants delivered at 23 completed weeks of gestation, with the majority of survivors suffering from neurodevelopmental sequelae (Vohr et al, 2000; Wood et al, 2000). These data should be shared with parents during prenatal consultation, and appropriate guidance given for decision-making about the pregnancy, delivery, and resuscitation of the infant.

## GENERAL PRINCIPLES OF CARE SPECIFIC TO THE EXTREMELY LOW-BIRTH-WEIGHT INFANT

### The First Hours

The first few hours after admission to the NICU are critical for the ELBW infant, although there are significant variations in practice among hospitals and practitioners. Careful adherence to details in the delivery room and during the first few hours after birth is essential to help avoid some of the immediate and long-term complications of the ELBW infant. All NICUs should have a consistent approach to the initial care of these fragile infants in the

delivery room and upon admission to the NICU. A suggested treatment guideline for the first few hours after birth is presented in Table 32–3, and screening guidelines for common complications are shown in Table 32–4.

### Delivery Room

At delivery, strict attention to maintenance of body temperature by means of rapid, gentle drying of the infant and the use of adequate heat sources is paramount to avoid cold stress. Use of a polyethylene occlusive skin wrap immediately after delivery may also help prevent initial evaporative heat losses (Vohra et al, 1999). Many ELBW infants need some form of assisted ventilation immediately after birth. If positive-pressure ventilation is required, it should be provided with low inspiratory pressure to prevent overdistention of the lungs, which can result in air leak and other lung injury, and adequate positive end-expiratory pressure (PEEP) to maintain lung

**TABLE 32-3**

**Treatment Guidelines for Initial Management of Extremely Low-Birth-Weight Infants**

Delivery room	Ensure good thermoregulation “Gentle” ventilation as required Avoid hyperventilation and hyperoxia Administer surfactant (if prophylaxis approach)
NICU admission	Obtain weight Administer surfactant within first hour (if rescue approach) Establish vascular access: Peripheral intravenous catheter Umbilical arterial catheter Umbilical venous catheter (central, double-lumen) Start intravenous fluids as soon as possible with dextrose solution Limit evaporative water losses (humidified incubator) Minimize stimulation Avoid hyperventilation and hyperoxia Obtain specimens for complete blood count with differential, blood culture, blood glucose measurement Give antibiotics as indicated Give parents information about their child
First 24 to 48 hours	
Cardiovascular	Monitor blood pressure; give vasopressors as required Maintain vigilance for presence of patent ductus arteriosus Obtain echocardiogram as indicated
Respiratory	Give additional surfactant doses as indicated Maintain low tidal volume ventilation Avoid hyperventilation and hyperoxia Extubate infant and start on continuous positive airway pressure when possible
Fluid Management	Obtain weight every 12 to 24 hours Monitor serum electrolyte, blood glucose, and calcium concentrations every 4 to 8 hours Limit evaporative water losses Administer skin care
Hematologic	Obtain second blood count Administer transfusion support as indicated Monitor bilirubin; give phototherapy as indicated
Infection	Consider discontinuing antibiotics if blood culture results negative at 48 hours
Nutrition	Start amino acid solution/parenteral nutrition
Neurologic	Minimize stimulation Perform screening head ultrasonography
Social	Arrange to meet with family

TABLE 32-4

**Recommended Screening for Common Complications of Extremely Low-Birth-Weight Infants**

Intraventricular hemorrhage (IVH): Germinal matrix hemorrhage Intraventricular hemorrhage IVH with ventricular dilation or intraparenchymal bleeding Periventricular white matter disease	Head ultrasonography (HUS) on day 1-3; repeat on day 7-10 Repeat HUS weekly until findings normal Repeat HUS every 3 to 7 days until stable/resolved Repeat HUS every 3 to 7 days until stable/resolved Consider measurement of resistive indices for progressive ventricular dilatation HUS at day 30; repeat at 36 weeks of postmenstrual age or at discharge Consider magnetic resonance imaging if HUS findings equivocal
Retinopathy of prematurity (ROP):	Perform ophthalmologic examination (OE) exam at 4 to 6 weeks of postnatal age Repeat every 2 weeks if no ROP Repeat weekly if ROP present Repeat twice weekly for pre-threshold disease or rapidly progressive ROP
Absence of ROP	Repeat OE every 2 weeks
Presence of ROP	Repeat OE weekly
Presence of prethreshold disease or rapidly progressive ROP	Repeat OE twice weekly
Audiology screening	Hearing screen no earlier than 34 weeks of postmenstrual age but prior to discharge home

volume. Hyperventilation and hyperoxia also should be avoided. The use of room air for resuscitation of these infants has been proposed to protect them from hyperoxia and damage to the lungs by oxygen free radicals. This issue is under active investigation (Lefkowitz, 2002), but most centers continue to use either 100% or blended oxygen for initial resuscitation. (See also Chapter 28.)

Some centers routinely intubate all ELBW infants in the delivery room for respiratory support, and prophylactic surfactant administration (Egberts et al, 1997; Kendig et al, 1998). Soll and Morley (2001) have reported on their meta-analysis of eight randomized trials of the use of natural surfactant as prophylaxis versus as a rescue strategy for established respiratory distress syndrome (RDS) in the ELBW infant. Administration of exogenous surfactant before 15 minutes of age resulted in a reduction in rates of neonatal mortality, air leak, and the combined outcome of bronchopulmonary dysplasia (BPD) or death compared with a selective rescue approach. However, no trials comparing prophylactic administration with very early rescue administration of exogenous surfactant (within the first 30 to 60 minutes) have been performed (see Chapter 46). In some centers, ELBW infants are observed briefly after birth, and if respiratory distress develops, they are intubated and hand-ventilated for transfer to the NICU. Exogenous surfactant is given within 1 hour of birth, after endotracheal tube position and the presence of RDS are confirmed on chest radiograph. This strategy assures uniform distribution of surfactant to both lungs and allows initial stabilization and more intensive monitoring of the infant during its administration. Other centers report success with intubation and immediate administration of surfactant during resuscitation, and still others try to avoid mechanical ventilation in ELBW infants by applying continuous positive airway pressure (CPAP) immediately in the delivery room (Lindner et al, 1999).

If intubation is required, both oral and nasal routes for endotracheal tube placement are equally effective and have similar complication rates (Spence and Barr, 2002).

Preference is usually institution specific, although successful placement of a nasal endotracheal tube takes longer.

### Admission to the Neonatal Intensive Care Unit

All infants should be weighed upon admission; frequent determination of subsequent weights is an invaluable tool in managing fluid intake. In many centers, ELBW infants are initially placed in a radiant warmer for easier access (i.e., for surfactant administration and catheter placement). Because of the very high transepidermal fluid losses in these infants, intravenous fluids with a 5% to 10% dextrose solution should be started immediately after admission, and efforts made to ameliorate evaporative water losses by increasing the relative humidity surrounding the infant. A plastic heat shield used in concert with the radiant warmer may decrease transepidermal water losses; alternatively, a polyethylene “tent” with an infusion of warmed humidified air may be used. Several studies suggest that fluid management is improved by utilization of a humidified incubator instead of a radiant warmer, because of smaller water losses (Gaylord et al, 2001; Meyer et al, 2001). Exposure to high humidity may raise the rate of skin colonization with gram-negative organisms, although no increase in the rate of nosocomial infections was observed in several randomized trials comparing incubators with radiant warmers (Flenady and Woodgate, 2002). However, temperature regulation for the smallest infants in the first few days may be more difficult in an incubator than in a servo-controlled radiant warmer because of rapid drops in air temperature as the incubator doors are opened to care for the infant (Meyer et al, 2001). (See also Chapter 29.)

### Vascular Access

Close monitoring of blood pressure, arterial blood gases, and serum chemistries during the first few days after birth is required in most sick ELBW infants, so it is advantageous

to insert an umbilical arterial catheter for reliable access in infants who require assisted ventilation. Infusion of half-normal saline with 0.5 units of heparin per milliliter at a low rate (0.8 to 1 mL/hr) is usually enough to maintain catheter patency. Although using a saline solution rather than a dextrose-water solution in the umbilical arterial line may complicate fluid and electrolyte management, this disadvantage is offset by the advantage of reliable measurement of blood glucose levels, which are frequently required, without disturbing the infant. Placement of a central umbilical venous catheter (tip at the inferior vena cava–right atrial junction) at the same time the umbilical arterial catheter is placed also provides the clinician with reliable venous access for infusion of fluids, medications, and blood products. Use of a double-lumen umbilical venous catheter often obviates insertion of a peripheral intravenous line over the first few days after birth and helps preserve intravenous sites and skin integrity.

The length of time that umbilical catheters are left in place varies by hospital. In most centers, umbilical lines are generally discontinued after 7 to 10 days because of the potential for catheter-related infection and vascular complications, although it is unusual for arterial access to be needed beyond a few days after birth. Before the umbilical venous catheter is removed, insertion of a percutaneous central venous catheter with its tip at the junction of the superior or inferior vena cava and the right atrium, dedicated to infusion of parenteral nutrition (see later), is advisable. Such a catheter helps maintain intravenous access for nutritional purposes without raising the risk of catheter-related infections and reduces the need to establish and maintain peripheral intravenous lines (Janes et al, 2000; Parellada et al, 1999). The incidence of com-

plications of percutaneous central catheters, including catheter-related infections, is lower if a limited number of NICU personnel insert and maintain the lines.

### Skin Care

The skin of an infant born at 23 to 26 weeks of gestation is extremely immature and is ineffective as an epidermal barrier. Poor epidermal barrier function in the extremely preterm infant leads to disturbances in temperature regulation and water balance as well as breakdown in skin integrity that may increase the risk of infection. The stratum corneum, which is responsible for epidermal barrier function, does not become functionally mature in the fetus until about 32 weeks of gestation (Rutter, 2000). However, acceleration of the maturation process occurs after birth, so most extremely premature infants have a mature epidermal barrier by about 2 weeks of postnatal age. Until that time, full-thickness skin injury can occur in the ELBW infant from seemingly innocuous causes, such as local pressure from body positioning, removal of adhesives, and prolonged exposure to products containing alcohol or iodine. Such injury can lead to larger transepidermal water losses, an even greater risk of nosocomial infection, and significant scarring.

Because of these risks, preservation of skin integrity should be incorporated into the care of the extremely preterm infant (Table 32–5). Limited use of adhesives and extreme care upon their removal, frequent repositioning of the infant to avoid pressure points on the skin, and use of soft bedding or a water mattress are the minimum requirements. Hydrocolloids (e.g., DuoDerm) applied to

**TABLE 32-5**

#### Practical Guidelines for Skin Care of Extremely Low-Birth-Weight Infants

Interventions	Guidelines
Adhesive application	<ul style="list-style-type: none"> <li>Increase adhesive tack by applying to dry, clean skin surface</li> <li>Avoid alcohol for skin cleansing</li> <li>Use smallest amount of tape possible</li> <li>Use a hydrocolloid or pectin-based layer on the skin, before application of heavy adhesive</li> <li>Avoid using adhesive over areas of skin breakdown</li> <li>Avoid adhesive bonding agents (e.g., benzoin)</li> <li>Use hydrophilic gel or pectin-based adhesives preferentially</li> </ul>
Adhesive removal	<ul style="list-style-type: none"> <li>Avoid adhesive removers and solvents</li> <li>Use warm, wet cotton ball to periodically saturate hydrogel adhesives (avoid over-drying and over-saturation)</li> <li>Facilitate removal of adhesive with mineral oil, petrolatum, and emollients if reapplication is not necessary</li> </ul>
Emollient application	<ul style="list-style-type: none"> <li>Infants born at &lt;27 weeks may benefit from emollient use</li> <li>Avoid multidose containers (e.g., large jars)</li> <li>Use non-perfumed, non-irritating hydrophilic emollients</li> <li>Recognize potential for emollients to interfere with adhesive and conductive properties of monitoring devices</li> </ul>
Emollient removal	<ul style="list-style-type: none"> <li>Wipe off gently with a soft cloth/gauze if site is contaminated</li> <li>Avoid repeated attempts to thoroughly cleanse the skin (undesired friction effect)</li> <li>Remove emollients before attaching thermistors or other monitoring devices</li> </ul>

the baby in areas where adhesive tape may come in prolonged contact with the skin (i.e., umbilical catheter or endotracheal tube fixation) to prevent direct application of tape to the baby may be useful because it is more easily removed than standard adhesive tape. Polyurethane adhesive dressings (Tegaderm) or hydrogels (Vigilon) may also be used to protect areas of skin friction and superficial wounds.

Prophylactic application of preservative-free emollient ointments (Aquaphor) to protect the skin of the ELBW infant has been studied (Lane and Drost, 1993; Nopper et al, 1996). Several small studies demonstrated smaller transepidermal water losses, improved skin condition, and lower risk of suspected or proven nosocomial infection with prophylactic application of emollient ointments. However, one report documented an increase in rate of systemic yeast infections in a single NICU coincident with a change to use of prophylactic emollients in ELBW infants; they returned to baseline after such use was discontinued (Campbell et al, 2000). Data are insufficient to recommend routine use of prophylactic emollients; however, their selective use in ELBW infants at risk for significant skin breakdown may be effective as an adjunct to other types of local skin care already described.

### **Mechanical Ventilation**

A high percentage of ELBW infants require some level of assisted ventilation to survive. Data from animal models of RDS indicate that positive-pressure ventilation with large tidal volumes damages pulmonary capillary endothelium, alveolar and airway epithelium, and basement membranes. This mechanical damage results in leakage of fluid, protein, and blood into the airways, alveoli, and interstitial spaces, leading to inhibition of surfactant activity and further damage to the lungs. These data suggest that a ventilator strategy that avoids large changes in tidal volume may reduce ventilator-induced lung injury in ELBW infants. The optimal mode, timing, and application of ventilatory support used in the initial management of the ELBW infant to meet this goal remain controversial. However, the objectives of all strategies of assisted ventilation in the ELBW infant should be similar—(1) to provide the lowest level of ventilatory support possible that will both support adequate oxygenation and ventilation and prevent atelectasis and (2) to try to reduce acute and chronic lung injury secondary to barotrauma, volutrauma, and oxygen toxicity (Clark et al, 2000).

### **Conventional Mechanical Ventilation**

Most NICUs continue to use pressure-limited time-cycled conventional ventilators for the initial respiratory management of the ELBW infant. Synchronized intermittent mandatory ventilation (SIMV) is the preferred mode of conventional ventilation for the ELBW infant. In the premature infant, SIMV, in which the inspiratory cycle is synchronized with the patient's own effort, is better in terms of oxygenation, ventilation, work of breathing, and blood pressure variability than conventional IMV (Cleary et al, 1995; Hummler et al, 1996; Jarreau et al, 1996).

Technologic limitations in the ability of some ventilators to synchronize breaths with very weak inspiratory efforts may prevent use of SIMV in the smallest infants. With further advances in ventilator design, other modes of patient-triggered ventilation, including volume-guarantee, assist-control, and pressure support, have become available to the clinician. These designs are under investigation but have not been proven to produce better pulmonary outcomes than SIMV in the ELBW infant (Donn and Sinha, 1998; Herrera et al, 2002).

Currently accepted conventional ventilatory strategies in the ELBW infant stress avoidance of excessive tidal volumes by limiting peak inspiratory pressures and provision of adequate PEEP to maintain lung volume (Thome et al, 1998). This strategy helps prevent repeated cycles of atelectasis and lung overdistention, a risk factor for ventilator-induced lung injury (Dreyfuss and Saumon, 1998). Hyperventilation ( $\text{PaCO}_2 < 35$  mm Hg) has been associated with a higher risk for the development of BPD (Garland et al, 1995; Van Marter et al, 2000) as well as neurodevelopmental sequelae in ELBW infants (Wiswell et al, 1996).

In response to this suggestion of worse pulmonary outcome in hyperventilated infants, a strategy of “minimal ventilation,” or permissive hypercapnia, has been proposed for conventional ventilation in ELBW infants. In the largest study to date of this ventilatory strategy, Carlo and associates (2002) randomly assigned 220 infants with birth weights between 501 and 1000 g to receive either minimal ventilation (target  $\text{PaCO}_2 > 52$  mm Hg) or routine ventilation (target  $\text{PaCO}_2 < 48$  mm Hg). No difference in the rate of BPD, death, or other major short-term morbidities was seen between the two groups. Potential risks of a high  $\text{PaCO}_2$  include increases in both cerebral perfusion and pulmonary vascular resistance and lower pH. Without clear data to support the benefit and safety of permissive hypercapnia, most centers target their conventional ventilatory strategy to maintain  $\text{PaCO}_2$  between 45 and 55 mm Hg in the first several days of mechanical ventilation in the ELBW infant.

In infants whose lung disease prevents extubation in the first several days after birth, changes in lung dynamics over the first 1 to 2 weeks often necessitate a change in ventilatory strategy. In the early stages of chronic lung disease, increased airway resistance and decreased lung compliance may require higher values for mean airway pressure, peak inspiratory pressure, PEEP, and inspiratory time than are usually used in initial ventilatory management. Once the need for more prolonged mechanical ventilation is established, many centers tolerate higher target  $\text{PaCO}_2$  values in the attempt to limit further ventilator-induced lung injury.

### **High-Frequency Ventilation**

Considerable interest has been generated over the past 15 years in the application of high-frequency ventilation (HFV) in newborns who have respiratory failure because this technique allows ventilation with very small tidal volumes. Results of studies using HFV in animal models of RDS have been promising in the prevention of lung

injury, but those of clinical studies of this ventilatory technique have not. Despite many clinical trials, controversy continues to surround the indications for HFV in ELBW infants, whether HFV is more effective than other modes of ventilation for RDS, whether HFV reduces adverse outcomes (specifically BPD), and whether HFV is more likely to have significant long-term complications than conventional mechanical ventilation.

Early trials of HFV before surfactant replacement therapy demonstrated no pulmonary advantage of HFV over conventional mechanical ventilation and suggested an increase in rates of air leak and intracranial abnormalities in the HFV-treated infants (HIFI Study Group, 1989). Later trials in ELBW infants who were treated with surfactant also failed to demonstrate any reduction in the incidence of BPD in the HF-treated infants (Johnson et al, 2002; Rettitz-Volk et al, 1998; Thome et al, 1999).

A rigorously controlled trial of HFV as the primary mode of assisted ventilation compared with conventional mechanical ventilation was the first to suggest a small advantage to the early use of HFV in reduction of BPD or death without an increase in the incidence of short-term complications in ELBW infants. Courtney and associates (2002) compared high-frequency oscillatory ventilation (HFOV) with synchronized IMV in a randomized trial that enrolled 500 ELBW infants. These investigators found a small but significant decrease in the incidence of BPD in survivors, requirement of fewer doses of exogenous surfactant, and shorter time to successful extubation in the HFOV-treated group. No differences in other complications of prematurity were observed between the two groups.

These results suggest that when used in experienced hands according to strict protocol, HFV may confer some protection from lung injury in ELBW infants. Whether this same advantage is gained when HFV is used under usual clinical circumstances in less experienced centers and whether the incidence of other complications may be affected by mode of ventilation remain unclear. Some NICUs with the most experience with HFV use it routinely as the initial mode of ventilation for ELBW infants. Most centers continue to use conventional ventilation with low tidal volumes and reasonable ventilation goals as the initial mode of ventilation for ELBW infants, reserving HFV for infants in whom conventional ventilation and surfactant fail. This latter practice seems advisable, given the potential risks of HFV, including inadvertent lung overdistention, impaired cardiac output, and increased central venous pressure that may lead to intracranial hemorrhage.

### **Continuous Positive Airway Pressure**

In a classic study comparing the incidence of BPD between NICUs, Avery and colleagues (1987) reported that the NICU with the lowest incidence used CPAP more frequently and more aggressively than the other units. Van Marter and associates (2000) confirmed these observations.

Theoretically, early CPAP may protect the very immature lung from injury due to positive pressure tidal breaths, by preserving surfactant function, increasing alveolar volume and functional residual capacity, enhancing alveolar stability, and improving ventilation-perfusion

matching. It also may stimulate the growth of the immature lung. In some NICUs, CPAP, delivered via nasal prongs or nasopharyngeal tube at 5 to 7 cm H<sub>2</sub>O, is used as the initial mode of assisted ventilation for ELBW infants, starting almost immediately in the delivery room (Lindner and Vobeck, 1999). CPAP used this way has been reported in retrospective studies to decrease the need for mechanical ventilation (Gittermann et al, 1997; Poets and Sens, 1996), the need for surfactant treatment, and the incidence of BPD (Aly, 2001; de Klerk and de Klerk, 2001; Lindner and Vobeck, 1999). Alternatively, CPAP may be used after prophylactic or rescue surfactant therapy is given during a brief period of intubation and positive-pressure ventilation (Verder et al, 1999). Although results of these observational studies are promising, it is important to note that early CPAP has not been compared with mechanical ventilation with surfactant administration as the initial mode of assisted ventilation for the ELBW infant in a randomized fashion, nor have long-term follow-up data been reported.

### **Post-Extubation CPAP for Respiratory Distress Syndrome and Apnea**

CPAP is commonly used in the ELBW infant after extubation to stabilize functional residual capacity and reduce the frequency of apneic spells after the lung disease has improved. All ELBW infants should be extubated as soon as they have recovered from acute RDS and should be given a trial of CPAP to protect them from further barotrauma. When used in combination with methylxanthine therapy, CPAP decreases the need for re-intubation due to progressive respiratory distress or apnea (Davis and Henderson-Smart, 2003). Methylxanthine (aminophylline or caffeine) treatment before extubation has also been shown to lower the incidence of apnea and the need for re-intubation in premature infants. Although almost universally used in ELBW infants as a treatment for apnea of prematurity, methylxanthines have not been rigorously studied in this population, and their use may need to be reassessed as follow-up data become available (Schmidt, 1999). Many ELBW infants benefit from prolonged use of CPAP by nasal prongs after extubation, especially those with frequent or severe episodes of apnea and bradycardia resistant to methylxanthines, and some centers are now providing assisted ventilation through nasal prongs in order to avoid intubation (Khalaf et al, 2001). However, the smallest and least mature infants may need prolonged mechanical ventilation because of frequent, severe apneic spells unresponsive to other therapies.

### **Adjunctive Therapies to Prevent Bronchopulmonary Dysplasia**

#### **Vitamin A Supplementation**

ELBW infants have low stores of vitamin A. Because of the role of vitamin A in promoting lung healing, its deficiency has been linked to a higher risk for development of BPD. In a large multicenter trial, vitamin A supplementation (5000 IU given intramuscularly 3 times a week for 4 weeks) reduced biochemical evidence of vitamin A

deficiency and decreased the incidence of BPD by 12% without adverse effects in ELBW infants who required mechanical ventilation or supplemental oxygen at 24 hours of age (Tyson et al, 1999). Given these efficacy data and apparent safety, vitamin A supplementation as described should be administered to all ELBW infants starting at 24 hours after birth.

### Superoxide Dismutase

One of the proposed contributory mechanisms in the development of BPD in ELBW infants is lung damage from oxygen free radicals. Preterm infants have inadequate antioxidant defenses and may not be able to induce antioxidant enzymes in response to oxidative stress (Davis, 1998). Exogenously administered superoxide dismutase (SOD), an important intracellular enzyme that dismutates the superoxide radical into hydrogen peroxide, has been studied as a potential therapy to prevent oxygen toxicity in the ELBW infant. No difference in the incidence of BPD was seen in a small randomized, masked study of recombinant human SOD administered intratracheally in ELBW infants who were treated with surfactant for RDS (Davis et al, 1997); no acute toxicity of the therapy was observed. Although SOD is apparently safe, available data do not support its use for the prevention of BPD in the ELBW infant outside clinical trials.

### Systemic Corticosteroids

Inflammation also plays an important role in the pathogenesis of BPD; therefore, pharmacologic doses of systemic corticosteroids have been widely used for prevention and treatment of BPD in ELBW infants. Several studies have examined early (<96 hours of age) administration of corticosteroids, usually dexamethasone, to prevent the development of BPD in infants at risk (Garland et al, 1999; Rastogi et al, 1996; Stark et al, 2001). A meta-analysis of studies in which corticosteroids were used to prevent rather than treat established BPD suggested that early corticosteroid treatment in ELBW infants results in more rapid extubation and a lower incidence of BPD (Halliday and Ehrenkranz, 2001), although no effect on mortality was observed. However, a higher incidence of short-term complications, including hyperglycemia, hypertension, poor growth, and intestinal perforations and bleeding, was observed in the corticosteroid-treated infants (Garland et al, 1999; Stark et al, 2001). More importantly, long-term follow-up data suggest that exposure to corticosteroid for prevention or treatment of BPD raises the risk of neurological sequelae in treated infants, including poor head growth, cerebral palsy, and developmental impairment (American Academy of Pediatrics, 2002).

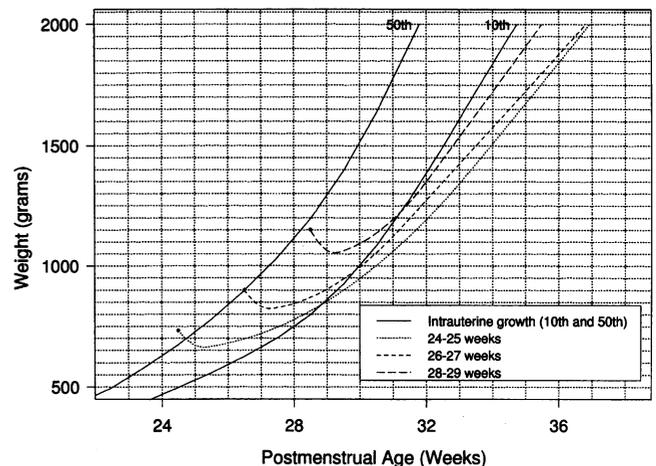

The apparent higher risk of long-term sequelae without an effect on overall mortality has tempered enthusiasm for systemic corticosteroid treatment to prevent or treat BPD in ELBW infants. Studies are currently under way to examine the effect of lower doses of dexamethasone, the use of alternative corticosteroids that may have a different side effect profile (Andre et al, 2000), and replacement hydrocortisone (Watterberg et al, 1999) on the develop-

ment of BPD as well as long-term outcome. Until further data become available, it seems prudent to avoid routine use of systemic corticosteroids in ELBW infants. An American Academy of Pediatrics (2002) statement on postnatal corticosteroids to treat or prevent chronic lung disease in preterm infants summarizes current recommendations as follows: "Outside of the context of a randomized, controlled trial, the use of corticosteroids should be limited to exceptional clinical circumstances (e.g., an infant on maximal ventilatory and oxygen support). In those circumstances, parents should be fully informed about the known short- and long-term risks and agree to treatment."

### Nutritional Management

Provision of adequate nutrition is central to effective care of ELBW infants (see Chapters 68 and 69). These infants are born with limited nutrient reserves, immature pathways for nutrient absorption and metabolism, and higher nutrient demands. In addition, medical conditions associated with extreme prematurity both alter requirements for and complicate the adequate delivery of nutrients. The goals of nutritional management of the ELBW infant are preservation of endogenous body stores, achievement of postnatal growth similar to intrauterine weight accretion and body composition, and maintenance of normal physiologic and metabolic processes concomitant with minimizing complications and side effects. However, few ELBW infants are able to meet these goals despite the use of central parenteral nutrition and caloric supplementation of enteral feedings, so significant growth failure is commonplace (Fig. 32-7) (Berry et al, 1997; Ehrenkranz et al, 1999).

Medical problems of ELBW infants often preclude initiation of enteral feedings for several days to weeks. The experience of the NICHD Neonatal Network centers is likely representative of the problems in nutritional management of these infants (Ehrenkranz et al, 1999).

**FIGURE 32-7.** Average body weight versus postmenstrual age in weeks for 1660 very low-birth-weight infants plotted against the 50th and 10th percentiles for intrauterine growth. (From Ehrenkranz R, Younes N, Lemons J, et al: Longitudinal growth of hospitalized very low birth weight infants. *Pediatrics* 104: 280-289, 1999.)

In these centers, the mean age to first enteral feeding in the 500- to 1000-g weight group ranged from 6 to 9 days; mean age at which full enteral feedings were reached ranged from 21 to 34 days. Not surprisingly, the smallest and least mature infants were introduced to feedings and reached full enteral feedings later than larger, maturer infants did. Even after recommended enteral dietary intakes are reached, ELBW infants continue to have a cumulative energy and protein deficit, which in part explains their later growth failure (Embleton et al, 2001).

### Early Parenteral Nutrition

Protein losses in ELBW infants receiving a glucose infusion alone begin immediately after birth and can approach 1.5 g/kg/day in the first 24 to 72 hours. Fortunately, these losses can be offset by early administration of an amino acid solution, even at low caloric intakes. Several studies have demonstrated the safety of early administration (within 24 hours after birth) of an amino acid solution, with no abnormal elevations of ammonia or blood urea nitrogen even in the most immature infants (Rivera et al, 1993; Van Goudoever et al, 1995). To prevent early protein deficit, ELBW infants should be given a source of parenteral protein as soon as possible after birth. (See also Chapter 69.)

In most centers, parenteral nutrition is used exclusively during the first few days after birth and then gradually reduced as enteral feedings are introduced. Longer duration of parenteral nutrition is associated with the development of a number of complications, including cholestasis, osteopenia, and sepsis. For example, the risk of an episode of late-onset sepsis in premature infants is 22-fold higher if parenteral nutrition is continued for more than 3 weeks compared with its use for 1 week or less (Stoll et al, 2002b).

### Early Enteral Feedings

The structural and functional integrity of the gastrointestinal tract depends on the provision of enteral feedings. Withholding enteral feedings at birth imposes risks for all the complications of luminal starvation, including mucosal thinning, flattening of the villi, and bacterial translocation. Early initiation (within the first few days after birth) of low volumes of milk (trophic feedings, or “gut priming”) has been studied in several small trials in premature infants (McClure and Newell, 2000; Schanler et al, 1999a). Trophic feedings are not meant to give the infant significant nutrition but rather to promote continued functional maturation of the gastrointestinal tract. Documented benefits of trophic feedings include higher plasma concentrations of gastrointestinal hormones, a more mature gut motility pattern, lower incidence of cholestasis, increased calcium and phosphorus absorption, and better as well as sooner tolerance of enteral feedings. Trophic feedings have not been associated with a higher risk of necrotizing enterocolitis or other adverse outcomes; therefore, there is no clinical advantage to delaying initiation of feedings in the medically stable ELBW infant. (See also Chapter 68.)

Feeding intolerance, indicated by gastric residuals that exceed 25% to 50% of the volume fed, abdominal

distention, or microscopic blood in the stool, is very common in ELBW infants and may be difficult to differentiate from early stages of necrotizing enterocolitis. Feeding intolerance may preclude the advance of enteral nutrition for days to weeks, complicating nutritional management and prolonging the need for parenteral nutrition. Numerous feeding strategies to avoid episodes of feeding intolerance have been employed in the ELBW infant, including very slow increase in enteral volume (<10 mL/kg/day), use of dilute rather than full-strength milk, continuous versus bolus tube-feeding, and use of prokinetic agents. None of these feeding strategies has been found to be clearly superior, although bolus feedings may decrease episodes of gastric residuals compared with continuous tube feedings and may allow a more rapid advance to full enteral volumes as well as promote better growth.

Episodes of feeding intolerance also are reduced in ELBW infants fed human milk rather than premature formulas (Schanler et al, 1999b). Other benefits of giving human milk in ELBW infants are a more rapid advance to full enteral volumes and the immunologic effects, with a reduction in the risk of necrotizing enterocolitis and late-onset sepsis. Human milk must be fortified with calcium, phosphorus, sodium, protein, and other minerals to provide adequate nutrition in the ELBW infant. In addition to commercially available human milk fortifiers, which increase the caloric density to approximately 24 calories per ounce, human milk may be fortified further to higher caloric densities with medium chain triglycerides, glucose polymers, and added protein.

Premature infants who are fed fortified human milk may grow more slowly than infants fed premature formulas (Schanler et al, 1999b), perhaps because of the variability in fat and caloric content of pumped breast milk or changes in the nutrient composition of human milk with fortification that affect fat absorption. Despite the potential for slower growth in infants fed human milk, its use should be strongly encouraged in ELBW infants because of the immunologic and other nutritional benefits. Further research on how best to fortify human milk is necessary to promote the best rate of growth in ELBW infants. (See also Chapter 68.)

### Management and Prevention of Infection

Bacterial and fungal infections are an important cause of illness and death among ELBW infants. In addition to the immediate morbidity and mortality, local and systemic inflammation caused by infections may increase the risk for development of other complications of prematurity, including BPD and brain injury. ELBW infants are frequently exposed to perinatal and delivery complications that raise their risk of early-onset (<7 days) infections. The need for prolonged intravenous access, exposure to parenteral nutrition, and mechanical ventilation also subject the ELBW infant to a high risk of late-onset (>7 days) nosocomial infections. The frequent infections seen in the ELBW population are related to immaturity of both humoral and cellular immunity (see Chapter 35). In addition to the judicious use of antimicrobial therapy, environmental controls, nursery surveillance, and modulation of the immature

immune response have been proposed as possible interventions to prevent infections in extremely premature infants.

### Early-Onset Infections

The incidence of early-onset bacterial infections in very LBW (VLBW) infants is approximately 1% to 2%, with a mortality of approximately 40% to 50% (Stoll et al, 2002a; see also Chapter 39). The major risk factor for the development of perinatally acquired bacterial infections is PROM with chorioamnionitis, which frequently complicates premature deliveries. However, a significant percentage of extremely premature births may be associated with intrauterine infection before membrane rupture (Goldenberg et al, 2000); in one study, 41% of premature infants with early-onset sepsis were born less than 6 hours after membrane rupture (Stoll et al, 2002a).

Because the clinical signs of perinatally acquired infection are nonspecific, the index of suspicion and the concern about the possibility of intrauterine infection should always be high in the presence of premature birth. All ELBW infants should be evaluated for infection at birth by means of a complete blood count with differential and blood culture, and empiric antibiotic therapy with ampicillin and an aminoglycoside should be initiated. A white blood cell count less than 5000 cells/ $\mu$ L, a ratio of immature to total neutrophils ratio greater than 0.2 to 0.3, and neutropenia (absolute neutrophil count less than 1000 cells/ $\mu$ L) are all suggestive of infection but may also be seen in infants with other conditions, including maternal preeclampsia and hypertension. The duration of initial antibiotic therapy depends on the results of the blood culture, blood counts, the clinical course, and the perinatal history. If the blood culture is negative for bacterial growth at 48 to 72 hours and the infant has improved clinically, consideration should be given to discontinuation of antibiotics. Prolonged exposure to antibiotic therapy increases the likelihood of colonization with multiple antibiotic-resistant organisms and the development of fungemia, so should be reserved for those infants with documented infection or a very high index of suspicion of infection based on clinical or historical factors.

The distribution of pathogens causing early-onset sepsis in VLBW infants has changed, likely because of a greater use of intrapartum antibiotics for prevention of group B streptococcal infections and treatment of preterm PROM. As the rate of infections from group B streptococci has diminished with intrapartum antibiotic prophylaxis, the rate of documented infections from gram-negative organisms has risen (Table 32–6) (Stoll et al, 2002a). In a further change of the epidemiology of early-onset infections in premature infants, possibly related to greater use of intrapartum antibiotics, the frequency of infections due to ampicillin-resistant *Escherichia coli* strains has increased (Joseph et al, 1998; Stoll et al, 2002a). Current recommendations for empiric antibiotic therapy of the ELBW infant at risk of early-onset sepsis have not changed, but continued surveillance of the epidemiology and antibiotic resistance patterns of isolates within individual units is warranted. In infants with severe illness that may be caused by sepsis, broadening initial antibiotic coverage to include a third-generation cephalosporin should be considered.

**TABLE 32–6**

### Distribution of Pathogens among 84 Cases of Early-Onset Sepsis\*

Organism	No.	%
Gram-negative organism:	51	60.7
<i>Escherichia coli</i>	37	44.0

\*Occurring in 5447 infants born between September 1, 1998, and August 31, 2000. Data from Stoll B, Hansen N, Fanaroff A, et al: Changes in pathogens causing early onset sepsis in very low birth weight infants. *N Engl J Med* 347:240-247, 2002.

### Late-Onset Infections

Nosocomial infection is a common complication of intensive care of the ELBW infant. The incidence of late-onset sepsis in ELBW infants who survive beyond 3 days of age is 25% to 50%, depending on gestational age and birth weight, with the median age at onset of the first episode approximately 2 weeks (Fanaroff et al, 1998; Stoll et al, 2002b). The overall mortality rate is approximately 20% but may be as high as 80%, depending on the organism causing sepsis. Risk factors for the development of late-onset sepsis include prolonged hyperalimentation and lipid use, the presence of a central venous catheter, longer duration of mechanical ventilation, and delay in initiation of enteral feedings (Stoll et al, 2002b). These practices and procedures are common events that may be unavoidable in the care of ELBW infants. However, large variations have been observed among NICUs in the rate of late-onset infections in premature infants (Brodie et al, 2000; Stoll et al, 2002b), suggesting that individual NICU practices may affect the incidence of nosocomial infections.

The most common cause of late-onset infections in ELBW infants is coagulase-negative *Staphylococcus* (CoNS). The most significant risk factor for the development of CoNS infection is the use of a fat emulsion (e.g., Intralipid) infusion (Freeman et al, 1990). Infection with CoNS is almost never fatal but is associated with significant morbidity, such as more days of ventilator use and prolonged hospital stay (Gray et al, 1995). Other organisms that cause late-onset infections in ELBW infants are associated with a much higher morbidity and mortality. The distribution of pathogens associated with the first episode of late-onset sepsis among 1313 infants

TABLE 32-7

**Distribution of Pathogens Associated with the First Episode of Late-Onset Sepsis\***

Organism	No.	%

\*In National Institute of Child Health and Development Neonatal Research Network institutions, September 1, 1998, through August 31, 2000.

Data from Stoll B, Hansen N, Fanaroff A, et al: Late-onset sepsis in very low birth weight neonates: Experience of the NICHD Neonatal Research Network. *Pediatrics* 110:285-291, 2002.

in a cohort of VLBW babies over a 2-year period is shown in Table 32-7.

Presenting features of late-onset sepsis include increased apnea, feeding intolerance, abdominal distention or guaiac-positive stools, increased respiratory support, and lethargy and hypotonia (Fanaroff et al, 1998). Because these symptoms are nonspecific, ELBW infants are frequently evaluated for infection and treated with empiric antibiotic therapy. In one study, both use of vancomycin and antifungal therapy were inversely related to birth weight; approximately three-quarters of infants with a birth weight less than 750 g were treated with vancomycin during their hospital stay, and approximately one-third treated with antifungals (Stoll et al, 2002b). Central catheters should be removed immediately to ensure adequate treatment of infants in whom sepsis is diagnosed, except for that due to CoNS (Benjamin et al, 2001).

Endotracheal tube colonization with multiple organisms is common in infants who require prolonged mechanical ventilation. In general, such colonization should not be treated with antibiotics unless there is evidence of pneumonia or significant inflammation indicative of tracheitis. Prospective surveillance of common isolates and antimicrobial resistance patterns within individual NICUs can help guide empiric antibiotic therapy in the ELBW infant being evaluated and treated for presumed sepsis. However, indiscriminate use of broad-spectrum antibiotics in the absence of true infection can alter antimicrobial resistance patterns (Goldmann et al, 1996), raising the risk of late-onset infections and complicating therapy.

**Prevention of Nosocomial Infection**

Because of the frequency and potential severity of late-onset sepsis in ELBW infants, several strategies to prevent infection have been proposed. Using these practices as a guideline, Horbar and colleagues (2001) observed a decrease in the CoNS infection rate from 22% to 16.6% over a 2-year period in VLBW infants in six study NICUs. Some NICUs routinely screen ELBW infants by stool or respiratory secretion cultures for the presence of multiple antibiotic-resistant organisms and isolate infants found to be colonized. Clusters of infections with unusual organisms should prompt surveillance cultures of infants, potential NICU environmental sources, and NICU staff (Foca et al, 2000). Restriction of broad-spectrum antibiotic use by hospital policy or treatment guidelines may limit local spread of resistant organisms (Goldmann et al, 1996). Strict adherence to hand-washing before and after every patient contact and avoidance of overcrowding within NICUs also help decrease the incidence of infection. Use of alcohol-based hand gels at the bedside may improve compliance with hand hygiene (Harbarth et al, 2002).

In addition to practice and environmental controls, prophylactic use of antibiotics and modulation of the immune response of ELBW infants have been studied as methods to reduce the incidence of late-onset sepsis. Low-dose vancomycin given continuously via hyperalimentation solutions (Baier et al, 1998; Spafford et al, 1994), or intermittently via peripheral vein (Cooke et al, 1997), has been shown to reduce the incidence of CoNS in premature infants at risk. Concern about emergence of vancomycin-resistant organisms and the low mortality associated with CoNS infections has prevented widespread use of this approach. In another study, prophylactic intravenous fluconazole given for 6 weeks lowered the incidence of fungal colonization and invasive disease in ELBW infants without associated complications or the emergence of resistant organisms (Kaufman et al, 2001). Such an approach might be advisable for NICUs with a high incidence of fungal infections in their ELBW population but needs considerably more study. Approaches that have been used with success in adult immunocompromised patients, such as antibiotic lock technique for central catheters and antiseptic-impregnated central catheters, are promising but have not yet been adequately studied in premature infants.

Prophylactic intravenous administration of polyclonal immunoglobulin (IVIG) to prevent late-onset sepsis has been extensively studied in premature infants. Several trials have shown a decrease in the incidence of documented sepsis by a small but significant amount in premature infants treated with prophylactic IVIG and no effect on mortality or other complications of prematurity (Lacy and Ohlsson, 1995). The costs associated with this therapy to achieve the small decrease in infection rates, as well as the increased exposure to blood products, have limited its use; whether selective prophylactic IVIG treatment of ELBW infants at highest risk for sepsis is warranted is unclear. However, IVIG therapy in addition to antibiotic therapy may be of benefit in reducing mortality in infants with established sepsis (Jenson and Pollock, 1997). Development of more targeted polyclonal or monoclonal  $\gamma$ -globulin preparations for specific organisms that cause sepsis in premature newborns may alter the use of IVIG in the future (Lamari et al, 2000).

Another promising strategy under investigation for modulation of the immature immune response to help prevent infections in premature infants is treatment with hemopoietic colony stimulating factors, including granulocyte colony-stimulating factor (G-CSF) and granulocyte-macrophage colony-stimulating factor (GM-CSF) (Modi and Carr, 2000). Most studies of these factors have been conducted in neutropenic, small-for-gestational-age infants or infants delivered to women with preeclampsia. Treatment with G-CSF in neutropenic infants resulted in an increase in neutrophil counts and reduced the incidence of sepsis (Kocherlakota and La Gamma, 1998). Prophylactic treatment with GM-CSF in premature infants with normal neutrophil counts prevented the development of neutropenia in episodes of sepsis, but whether this type of therapy to address cellular immune deficiency in ELBW infants will reduce the incidence of infection without additional complications remains unclear (Miura et al, 2001; Modi and Carr, 2000).

### Developmental and Parental Care

ELBW infants are particularly vulnerable to the potentially noxious stimuli of the NICU environment, including light, noise, frequent disturbances, and painful procedures. The ELBW infant reacts to the noisy and well-lit environment of many NICUs with greater variability of blood pressure, ventilatory requirements, and oxygen saturation as well as behavioral disorganization, which may have both short-term and long-term effects on outcome (Jacobs et al, 2002). Modification of the NICU environment to limit exposure of ELBW infants to such stresses—by lowering ambient light and reducing noise, clustering caregiving periods and procedures to allow periods of uninterrupted sleep, and using positioning aids to promote containment—is an intuitive part of their care. Whether individualized, developmentally supportive care or other developmental interventions started in the NICU improve long-term outcome in ELBW infants remains unclear (Feldman and Eidelman, 1998).

In addition to environmental modifications, NICUs should promote parental involvement with their infants, even when they are critically ill. Open visitation rules and encouragement of parental caregiving when appropriate may help parents bond with their baby. Skin-to-skin (kangaroo) care, in which the infant is placed unclothed on the mother or father's bare chest, was originally developed in nonindustrialized countries to maintain temperature regulation in premature infants. It is now used in many NICUs to promote parental attachment. Kangaroo care may have a positive effect on infant state organization and respiratory patterns, increase the rate of infant weight gain, improve maternal milk production, and have long-term benefits in infant development and parents' perceptions of their babies (Feldman et al, 2002). Kangaroo care can be initiated in ELBW infants within the first 2 weeks after birth, when they are more medically stable.

### FUTURE DIRECTIONS

In this chapter I present just some of the special needs of the ELBW infant. The medical care of the ELBW infant is a complex combination of knowledge of developmental physiology, evidenced-based interventions, and clinical

experience. Wide variability in approach to care of these infants exists among practitioners and NICUs, as does variability in outcomes. Nevertheless, NICUs involved in treating ELBW infants should develop a coherent approach to the medical as well as ethical aspects of their care. Future research should focus on identification of best practices to narrow the variability in approach to care and with the goal to prevent long-term disability. As more of these tiny infants survive, it is the responsibility of neonatologists to stay abreast of clinical improvements and the short-term and long-term consequences of established and newly proposed medical interventions so as to provide the best care for these vulnerable infants and to keep parents informed and involved.

## Pharmacologic Principles and Practicalities

Robert M. Ward and Ralph A. Lugo

The rapid application of new drug therapy in the neonatal intensive care unit (NICU) has made pharmacology in the newborn increasingly complex. Accompanying that complexity is the realization that even though drug treatment of newborns may be curative, it may also induce significant problems. Potential morbidity and mortality associated with drug treatment of newborns must be recognized and weighed against the expected benefits.

Drug therapy of newborns follows basic principles of pharmacology superimposed on dynamic, developmental changes during the newborn period. Patients cared for in the NICU are exposed to a wide variety of drugs, many of which are incompletely studied in newborns. Therapeutic drug monitoring is often an integral part of this drug exposure in the NICU. The effective use of drug concentration measurements requires a working knowledge of pharmacokinetics and thoughtful consideration of when such measurements are appropriate and helpful.

### PERINATAL DRUG EXPOSURE

Repeated warnings about fetal drug exposure were issued to physicians and the public after recognition of the teratogenic effects of thalidomide in the 1960s. Despite these warnings, drug exposure of the human fetus and newborn increased during subsequent decades and remains extensive today. The average number of drugs ingested during pregnancy rose from 3 in the 1950s to 11 in the 1970s (Ward and Green, 1988). Virtually all drugs administered to the pregnant woman reach the fetus, but careful interpretation of the significance of this exposure is needed because fetal drug concentrations and effects vary widely, from insignificant to life-threatening (Ward and Green, 1988; Ward et al, 1980).

For hospitalized newborns, a similar pattern of increasing drug exposure is evident. Serial observations from the same NICU reveal almost a doubling of the average number of drugs administered to newborns in less than a decade, from 3.4 per patient during 1974 and 1975 (Aranda et al, 1976) to 6.2 per patient during 1977 through 1981 (Aranda et al, 1982a). Unfortunately, drug exposure among NICU patients is disproportionately greater in the most susceptible (and least studied) patients—the most immature newborns and newborns with multiple organ dysfunction (Aranda, 1983).

### DRUG-INDUCED ILLNESS

The extensive exposure of newborns to drugs in the NICU is not benign. During their NICU hospitalization, 30% of newborns sustain one or more adverse drug reactions, of which 14.7% are fatal or life threatening (Aranda et al, 1982b). The causes of this NICU “epidemic” of drug-related morbidity and mortality are complex. Pharmacologic studies in pediatric patients are difficult because of a variety of problems from ethics to study design (Ward and Green, 1988). The difficulty of studying therapeutics in the newborn has created a situation in which a plethora of drugs is administered with a paucity of pharmacologic data. For the smaller and more immature newborns who are now surviving, there are no gestational age–appropriate pharmacologic data about efficacy, dose-response, and kinetics for most drugs they receive.

Furthermore, drug-induced illness is seldom considered in newborns. Failure to recognize drug-induced illness in the newborn often leads to further pharmacologic treatment as the first approach to correct unrecognized drug-induced problems. This fact may reflect an expectation that drug therapy is usually effective and safe. The observations of Aranda and colleagues suggest the opposite. Prudent management of newborns must recognize and weigh the potential benefits of unstudied drug therapy against potential drug-induced morbidity and mortality. Some examples from the history of drug-induced mortality and morbidity in newborns should serve as a reminder of how more harm than good may accrue from uncontrolled or unstudied drug therapy in the NICU.

### Lessons from Chloramphenicol

Chloramphenicol was released for use in the 1940s, and reports of its efficacy for treatment of *Salmonella* infections included pediatric patients. The manufacturer recommended dosages of 50 to 100 mg/kg per day for patients  $\leq 15$  kg. In 1959, when Sutherland reported three cases of sudden death in newborns treated with high dosages of chloramphenicol (up to 230 mg/kg per day), the drug was considered “well tolerated and non-toxic.” Later the same year, Burns and colleagues (1959) reported the disturbing results of a controlled trial of the following four prophylactic treatment regimens for newborn sepsis: (1) no treatment, (2) chloramphenicol alone, (3) penicillin and streptomycin, and (4) penicillin, streptomycin, and chloramphenicol. The groups that received chloramphenicol (100 to 165 mg/kg per day), in regimens 2 and 4, had overall mortality rates of 60% and 68%, respectively, whereas groups receiving regimens 1 and 3 had mortality rates of 19% and 18%, respectively. The deaths of these newborns demonstrated the stereotyped sequence of symptoms and signs caused by chloramphenicol, designated the *gray syndrome*, which consisted of abdominal distention with or without emesis, poor peripheral perfusion and cyanosis, vasomotor collapse, irregular respirations, and death within hours of the onset of these symptoms. Weiss and coworkers (1960) attributed the gray syndrome in newborns to high concentrations of

chloramphenicol secondary to its prolonged half-life in newborns who received dosages of more than 100 mg/kg per day, which are usually used in older children. They recommended maximum dosages of 50 mg/kg per day in term infants younger than 1 month, half that dose for premature infants, and careful monitoring of chloramphenicol blood concentrations.

The discovery and explanation of chloramphenicol toxicity in newborns illustrate several important aspects of neonatal pharmacology. Because chloramphenicol was considered well tolerated in older children and adults, it was regarded as nontoxic for newborns. Chloramphenicol was so effective in newborns that higher dosages were used without pharmacokinetic study. Higher doses were administered to newborns despite recognition that its clearance required glucuronide conjugation, which was known to be immature in newborns. The unexpected finding that chloramphenicol in doses of 100 to 165 mg/kg per day could be lethal to newborns was demonstrated because the study conducted by Burns and colleagues (1959) included appropriate control groups. In fact, because the mortality rate from the most effective antibiotic treatment regimen was equivalent to that of no antibiotic treatment, these investigators discontinued prophylactic use of antibiotics in the nursery.

Similar pharmacologic comparisons are needed for other drugs used in newborns. Even more, thoughtful consideration should be given to clinicians' response to therapeutic failure. Fewer drugs and lower dosages may be safer and more effective than additional drugs in higher dosages.

### REDUCTION AND PREVENTION OF MEDICATION ERRORS IN NEWBORN CARE

Drug treatment is one of the most common approaches used in the care of sick newborns. At Primary Children's Medical Center 35-bed NICU in Salt Lake City, Utah, with an average of 785 patient-days per month, patients receive an average of 8700 (range 6990 to 11,290) doses of medications, pharmacy-formulated intravenous solutions, and aerosols each month (unpublished observations, 1994). These are usually prepared by pharmacists and administered by nurses, respiratory therapists, and (rarely) physicians. In such a large and complex system that produces so many drug treatments per month, errors are virtually inevitable despite several levels of prospective and redundant reviews by nurses, pharmacists, and NICU unit secretaries involved in the drug treatment process. At Primary Children's NICU, the medication error rate averages 0.04% for nurses and pharmacists and 0.07% for physicians (unpublished observations, 1994). Many errors are inconsequential, whereas others have serious adverse effects. Medication errors incur significant costs, ranging from the obvious ones such as direct patient injury, prolonged hospital stays, and additional corrective treatments to the more subtle costs associated with monitoring and regulation of medication use within hospitals (ASHP, 1995).

In a study of 393 malpractice claims reported to the Physician Insurers Association of America, the second

most common cause of malpractice claims was drug errors (Physician Insurers Association of America [PIAA], 1993). Among 16 medical specialties with two or more claims, pediatric practice ranked sixth in the number of claims, yet it had the third highest average cost per indemnity. The medications most frequently involved in all claims were antibiotics, glucocorticoids, narcotic or non-narcotic analgesics, and narcotic antagonists. In pediatric practice, the medications most frequently involved were vaccines (diphtheria-pertussis-tetanus) and bronchodilators (theophylline). In the PIAA review (1993), the five most common causes of drug errors were as follows:

- Incorrect doses
- Medications that were inappropriate for the medical condition
- Failure to monitor for drug side effects
- Failure of communication between physician and patient
- Failure to monitor drug levels

The primary opportunity for prevention of these five most common errors rests with the prescribing physician. Additional information as well as additional time for communication and documentation may be needed.

Prescriptions and drug orders are a means of communicating, yet clinicians often devote too little attention to making them legible, clear, and unambiguous (ASHP guidelines, 1993). Physicians should keep the following recommendations in mind to ensure that their medication orders communicate more effectively:

- Write out instructions rather than use abbreviations.
- Avoid vague instructions (e.g., "take as directed").
- Specify exact dosage strengths.
- Avoid abbreviations of drug names (e.g., MS could mean morphine sulfate or magnesium sulfate).
- Avoid trailing zeroes; use leading zeroes.
- Ensure that prescriptions and signatures are legible, even if it means printing the prescriber's name that corresponds to the signature.

The process for ordering, preparing, dispensing, and administering medications in an ICU with acutely ill patients is often complicated and may contribute directly to errors. The frequency of those errors, however, may be reduced in almost every NICU. Although complex and expensive computerized systems may help reduce medication errors, caregivers can take steps that are completely within their control to reduce medication errors without waiting for changes in the entire pharmacy process within the hospital (ASHP guidelines, 1993).

### PRINCIPLES OF NEONATAL THERAPEUTICS

A thorough understanding of factors that affect drug concentrations helps in the planning of accurate therapy and the identification of the causes of therapeutic failure. Many of these factors are not chosen consciously in a therapeutic plan but have tremendous impact on its effectiveness. Pharmacokinetics and pharmacodynamics in newborns follow the same general principles that govern drug actions in patients of any age: diagnosis, drug selection

and administration, absorption, distribution, metabolism, and excretion. When applied to the newborn, these principles must accommodate several unique physiologic and pharmacologic features of the newborn, as outlined in Table 33–1 and discussed in detail here.

## Diagnosis

Effective treatment begins with an accurate diagnosis and accurate assessment of symptoms. Although this principle applies to all areas of therapeutics, treatment in newborns presents special diagnostic challenges because the small size and fragility of such patients may preclude useful, but inordinately invasive, diagnostic procedures. For example, many small immature newborns with chronic lung disease are given treatment for “bronchospasm” after decreased air entry associated with desaturation and abnormal breath sounds is observed. Relief of these symptoms with aerosolized bronchodilators may be interpreted as confirmation of the diagnosis. Although this interpretation may be correct, increased humidity, chest physiotherapy, or movement of the endotracheal tube bevel away from a pliable tracheal wall during an aerosol treatment may also account for the

improvement. Evaluation of ineffective therapy should include reconsideration of the diagnosis.

## Absorption

Although most types of drug therapy for acute problems involve *intravenous administration* to ensure drug delivery to the site of action, this route may *not* be reliable in newborns (Roberts, 1984). Drugs are often injected away from newborns, “up the IV line” through a Y-site injection port, with the expectation that the preset flow rate will deliver the drug over an appropriate infusion time. Intravenous infusion rates for very-low-birth-weight (VLBW) infants may be less than 2 mL/hour, sometimes divided between two infusion sites. Consequently, a drug injected away from the infant may infuse so slowly that it does not reach the circulation for several hours and then enters over a prolonged period. Gould and Roberts (1979) estimated that as much as 36% of the total daily dose may be discarded when the intravenous solution tubing is changed. Infusion solution filters may also prevent drug delivery by direct adsorption of the drug or by allowing a heavier drug to settle in the filtration chamber and mix slowly with the infusion solution. For drug therapy in which the driving force for tissue entry is a concentration gradient between the circulation and the tissue (e.g., in meningitis), sustained low drug concentrations may provide suboptimal therapy.

*Intramuscular administration* of drugs to newborns is suboptimal and is generally used when there is difficulty maintaining intravenous access. Absorption of drugs from an intramuscular injection site is directly related to muscle perfusion. Patients with hypothermia or shock are unlikely to absorb intramuscular doses effectively. Intramuscular administration of drugs may sclerose tissue or create large intramuscular collections of the drugs, which are absorbed slowly, producing a “depot effect” in which serum concentrations rise slowly over a prolonged period. Intramuscular administration of drugs to newborns, especially for multiple doses, should be avoided because it may not deliver effective drug concentrations to the site of action and may cause disfiguring sterile abscesses in the limited muscle mass of small newborns.

Even though *oral administration* of drugs is preferred for treatment of chronic illnesses in newborns, this route is not well studied. In adults, less drug is usually absorbed from the stomach than from the intestinal tract because of the smaller surface area. Delayed gastric emptying postpones achievement of peak serum drug concentrations and prolongs the absorption phase while elimination continues. Many newborns experience gastroesophageal reflux associated with delayed gastric emptying, which may alter drug bioavailability. Passive venous congestion of the intestinal tract from elevated right atrial pressures decreases drug absorption in adults and may do so in premature infants with severe bronchopulmonary dysplasia complicated by cor pulmonale (Peterson et al, 1980). The administration of medications to newborns in small volumes of formula or during continuous gastric feedings may also alter drug absorption.

**TABLE 33–1**

### Pharmacologic Principles and Pitfalls in Management of the Very-Low-Birth-Weight Infant

- I. Diagnosis:
  - A. Limited diagnostic procedures
- II. Absorption:
  - A. Intravenous:
    1. Drug injection away from patient
    2. Uneven mixing of drugs and intravenous fluids
    3. Delayed administration due to very low flow
    4. Part of the dose discarded with tubing changes
  - B. Intramuscular:
    1. Poor perfusion limits absorption
    2. Danger of sclerosis or abscess formation
    3. Depot effect
  - C. Oral:
    1. Poorly studied
    2. Affected by delayed gastric emptying
    3. Potentially affected by reflux
    4. Passive venous congestion may occur with chronic lung disease, decreasing absorption
- III. Distribution (affected by):
  - A. Higher (85%) total body water (versus 65% in adults)
  - B. Lower body fat, i.e., about 1% body weight (versus 15% in term infants)
  - C. Low protein concentration
  - D. Decreased protein affinity for drugs
- IV. Metabolism:
  - A. Half-life prolonged and unpredictable
  - B. Total body clearance decreased
  - C. Affected by nutrition, illness, and drug interaction
  - D. Affected by maturational changes
- V. Excretion:
  - A. Decreased renal function, both glomerular filtration rate and tubular secretion

The possible effects of feeding patterns on drug absorption and action must be considered when enteral drug therapy fails.

### Distribution

In pharmacokinetics, *distribution* is the partitioning of drugs among various body fluids, organs, and tissues. The distribution of a drug within the body is determined by several factors, including organ blood flow, pH and composition of body fluids and tissues, physical and chemical properties of the drug (e.g., lipid solubility, molecular weight, and ionization constant), and the extent of drug binding to plasma proteins and other macromolecules (Ward et al, 1980).

Important differences among premature infants, children, and adults affect the distribution of drugs. Total body water varies from 85% in premature newborns to 75% in term newborns to 65% in adults (Boreus, 1982). Conversely, body fat content varies from 1% or less in premature infants to 15% in term newborns (Mirkin, 1978). These differences change the distribution of many drugs, especially polar, water-soluble drugs such as the aminoglycosides. Protein binding of drugs in the circulation is decreased in the premature newborn because of a smaller total amount of circulating protein and lower binding affinity of the protein itself. With rare exceptions, only the free (not bound to protein) drug molecules “are active,” that is, cross membranes, exert pharmacologic actions, and undergo metabolism and excretion. Clinical measurements of serum or plasma drug concentrations usually reflect total circulating drug concentrations, which consist of both free and protein-bound drug. Thus, total circulating drug concentrations in the newborn, which are low by adult standards, may represent free drug concentrations that are equivalent to those of the adult because of the decreased protein binding in the newborn.

### Metabolism

Many drugs require metabolic conversion before elimination from the body. *Biotransformation* of a drug usually produces a more polar, less lipid-soluble molecule that can then be eliminated rapidly by renal, biliary, or other routes of excretion. Drug biotransformation is classified into two broad categories, (1) nonsynthetic (phase I) reactions, which include oxidation, reduction, and hydrolysis, and (2) synthetic or conjugation (phase II) reactions, which include glucuronidation, sulfation, and acetylation. Although the liver is considered the major organ responsible for drug biotransformation, many other organs carry out drug metabolism.

For most drugs in the newborn, the half-life is prolonged and total body clearance is decreased. Important variations occur, however, among drug classes and among individuals. Glucuronide conjugation of bilirubin is usually low at birth unless this enzyme has been induced in utero through maternal exposure to drugs, cigarette smoke, or other inducing agents (Ward et al, 1980). In contrast, conjugation through sulfation is usually active at

birth. Various factors after birth, such as nutrition, illness, and drug interactions, may hasten or retard the maturation of enzymes and organs responsible for drug metabolism in the newborn. Maturation changes in hepatic blood flow, drug transport into hepatocytes, synthesis of serum proteins, protein binding of drugs, and biliary secretion—alone and in combination—confound accurate predictions about drug metabolism after birth, leading to empiric dose adjustments (Morselli et al, 1980). These factors must be studied again in the very immature, very-low-birth-weight infant.

### Excretion

Another major pathway for drug elimination from the body is renal excretion of metabolized and unchanged drug. Neonatal renal function is diminished both in absolute terms and when normalized to body weight or surface area. The neonatal glomerular filtration rate averages about 30% of the adult rate per unit surface area. Glomerular function rises steadily after birth, whereas tubular function matures more slowly, causing a glomerular and tubular imbalance (Aperia et al, 1981). The postnatal increase in glomerular function reflects greater cardiac output, reduced renal vascular resistance, redistribution of intrarenal blood flow, and changes in intrinsic glomerular basement membrane permeability (Morselli et al, 1980). The dynamics of neonatal renal function markedly influence drug excretion. The rate of change of renal function and its susceptibility to hypoxemia, nephrotoxic drugs, and underperfusion confound predictions of drug elimination rates in newborns, which must be measured empirically.

## PHARMACOKINETIC PRINCIPLES

*Pharmacokinetics* describes the time course of changes in drug concentrations within the body. Although rates of change are often described with differential equations, concepts useful at the bedside are emphasized here. More detailed mathematical discussions of pharmacokinetics can be found elsewhere (Gibaldi and Perrier, 1982; Greenblatt and Koch-Weser, 1975a, 1975b; Notari, 1980).

### Compartment

In pharmacokinetics, *compartment* refers to fluid and tissue spaces into which drugs penetrate. These compartments may or may not be equivalent to anatomic or physiologic fluid volumes. In the simplest case, the compartment may correspond to the vascular space and equal the volume of a real body fluid, blood. Large or quite polar molecules may be confined to this central compartment until they are eliminated by excretion or metabolism. Many drugs, however, diffuse reversibly out of the central compartment into tissues or other fluid spaces, referred to generically as peripheral or tissue compartments. Such compartments are seldom sampled directly, but their involvement in kinetic processes may be recognized from the graphic or mathematical description of the kinetics of a drug.

## Apparent Volume of Distribution

The apparent volume of distribution might be better termed “volume of dilution,” because it is a mathematical description of the volume (L or L/kg) required for dilution of a dose (mg or mg/kg) to produce the observed circulating drug concentration (mg/L or  $\mu\text{g/mL}$ ). (To simplify cancellation of units, concentrations are expressed here as mg/L, which is the same as  $\mu\text{g/mL}$ , the more conventional unit for drug concentrations.)

$$\text{Concentration (mg/L)} = \frac{\text{Dose (mg/kg)}}{\text{Apparent volume of distribution (L/kg)}}$$

For many drugs, the volume of distribution does not correspond to a specific physiologic body fluid or tissue—hence the term “apparent.” In fact, the volume of distribution for drugs that are bound extensively in tissues may exceed 1.0 L/kg, a physiologic impossibility that emphasizes the arithmetic, nonphysiologic nature of the apparent volume of distribution. The calculation of distribution volume is described later.

## First-Order Kinetics

Removal of most drugs from the body can be described by first-order (exponential or proportional) kinetics, in which a constant proportion or percentage of a drug is removed over time, rather than a constant amount over time. For drugs exhibiting first-order kinetics, the higher the concentration, the greater the amount removed. The following equations describe the concentration (C) of a drug whose first-order kinetics have a rate constant, k (minute<sup>-1</sup>), at time (t) and an initial concentration of C<sub>0</sub>.

In differential form, the change in C with time is

$$\frac{dC}{dt} = -kC$$

In exponential form, C at time t is

$$C_t = C_0 e^{-kt}$$

If integrated, C at time t is expressed as the natural logarithm (ln)

$$\ln C_t = \ln C_0 - kt$$

The last equation fits the equation of a straight line, so that a graph that plots  $\ln C_t$  versus t has an intercept of  $\ln C_0$  at t = 0 and a slope of -k, the rate constant for the change in concentration, which can be used to calculate the half-life and dosages. Multiple rate constants in more complex equations are distinguished with the letter k and numbered subscripts or with Greek letters.

## Half-Life

The drug half-life ( $t_{1/2}$ ) is the time required for a drug concentration to decrease by 50%. Half-life is a first-order kinetic process because the same proportion, 50%, of the drug is removed during equal periods. Half-life can be determined mathematically from the elimination rate constant, k, as

$$t_{1/2} = \frac{\text{natural logarithm } 2}{k} = \frac{0.693}{k}$$

Figure 33-1 illustrates a graphic method for determination of half-life. Drug concentrations measured serially are graphed on semilogarithmic axes, and the best-fit line is determined either visually or by linear regression analysis. In this illustration of first-order kinetics, the concentration decreases 50% (from 800 to 400) during the first hour and decreases another 50% (from 400 to 200) during the second hour. Thus, the half-life is 1 hour. More drug is removed during one half-life at higher concentrations, although the proportion removed remains constant. The exponential equation for this graph is

$$C = 800e^{-0.0116t}$$

where k = 0.0116/minute and C<sub>0</sub> = 800, allowing a mathematical calculation of half-life using the equation previously described:

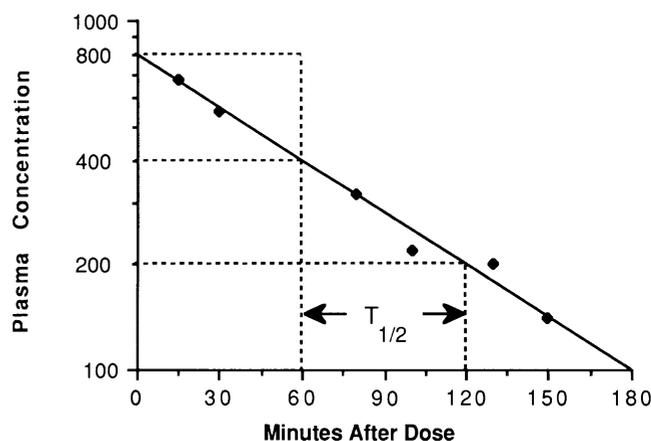

$$t_{1/2} = \frac{0.693}{k(\text{minute}^{-1})} = \frac{0.693}{0.0116/\text{minute}} = 60 \text{ minutes}$$

## Multicompartment, First-Order Kinetics

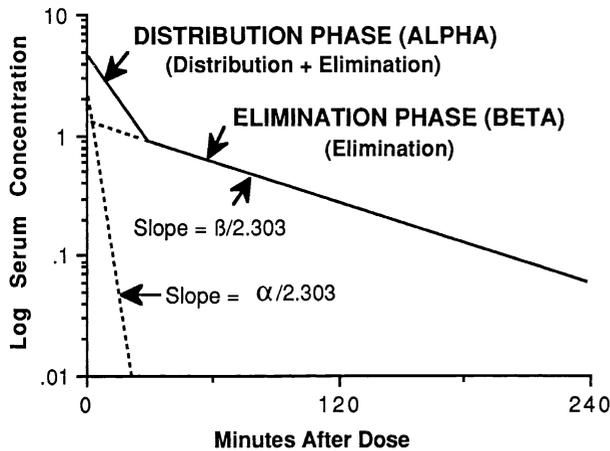

The rate of removal of many drugs from the circulation is biphasic. The initial rapid decrease in concentration is the distribution ( $\alpha$ ) phase, often lasting 15 to 45 minutes, which is followed by a sustained slower rate of removal, the elimination ( $\beta$ ) phase. Such biphasic processes are best visualized from semilogarithmic graphs of concentration versus time. When such semilogarithmic graphs show kinetics that best fit two straight lines, the kinetics are described as *biexponential*, or *two-compartment*, and first-order (Fig. 33-2). Two exponential terms are needed to describe such changes in concentration, as

$$C = Ae^{-\alpha t} + Be^{-\beta t}$$

In this equation, the rate constant for distribution is designated  $\alpha$  to discriminate it from the rate constant for terminal elimination ( $\beta$ ), where A and B are the time = 0

**FIGURE 33-1.** Apparent single-compartment, first-order plasma drug disappearance curve illustrating graphic determination of half-life from best-fit line of serial plasma concentrations.

**FIGURE 33-2.** Multicompartment serum drug disappearance curve.

intercepts for the lines describing distribution and elimination, respectively. Division by 2.303 converts logarithms to natural logarithms.

After an intravenous dose, drug loss from the vascular space during the distribution phase occurs through both distribution and elimination (see Fig. 33-2). The rate constant of distribution ( $\alpha$ ) can be determined by plotting the difference between the total amount of drug lost initially and the amount of drug lost through elimination (Greenblatt et al, 1975a). This produces the line with the steeper slope (equal to  $\alpha/2.303$ ) below the serum concentration graph in Fig. 33-2. The single slope of the distribution phase and of the terminal elimination phase does not imply that distribution or elimination occurs through a single process. The observed rates usually represent the summation of several simultaneous processes, each with differing rates, occurring in various tissues.

When the time course of drug elimination is observed for prolonged periods, a third rate of elimination, or  $\gamma$  phase, may be observed that is usually attributed to elimination of drug that has reequilibrated from deep tissue compartments back into the plasma. Such kinetics are designated *three-compartment* and *first-order*. The kinetics of a drug are expressed with the smallest number of compartments that accurately describes its concentration changes over time.

### Apparent Single-Compartment, First-Order Kinetics

When a semilogarithmic graph of concentration versus time reveals a single slope with no distribution phase, the kinetics are characterized as *apparent single-compartment, first-order* (see Fig. 33-1). This may occur when a drug remains entirely within the vascular space or central compartment or when a drug passes very rapidly back and forth between the circulation and peripheral sites until it is metabolized or excreted by first-order kinetics. The adjective *apparent* is used because careful study often shows that distribution does occur even though the kinetic curve has only a single slope. Single-compartment kinetics implies that the drug rapidly and completely

distributes homogeneously throughout the body, which rarely occurs clinically.

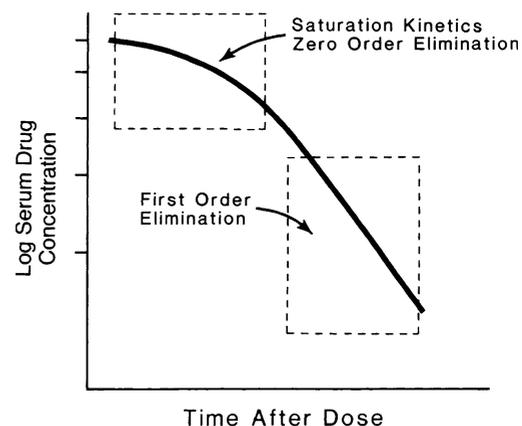

In many pharmacokinetic studies in newborns, blood samples are not obtained early enough to allow calculation of the distribution phase, and the kinetics are described as single-compartment. If sampling begins after the distribution phase, the concentration time points may fit a single-compartment, first-order model, which determines the elimination rate constant ( $\beta$ ). The kinetics cannot be assumed, however, to fit a single-compartment model from such a limited study. The most accurate approach to kinetic analysis, *noncompartmental analysis*, makes no assumptions about the number of compartments (Gibaldi and Perrier, 1982; Notari, 1980).

### Zero-Order Kinetics

Some drugs demonstrate *zero-order kinetics*, in which a constant amount of drug, rather than a constant proportion or percentage, is removed over time, rather than a constant proportion or percentage. This relationship can be expressed as

$$\frac{dC}{dt} = -k$$

It is important to understand when zero-order kinetics occurs, how to recognize it, and how it affects drug concentrations. Zero-order kinetics is sometimes referred to as “saturation kinetics” because it may occur when excess amounts of drug completely saturate enzymes or transport systems so that they metabolize or transport only a *constant amount* of drug over time. Zero-order processes produce a curvilinear shape in a semilogarithmic graph of concentrations versus time (Fig. 33-3). When drug concentrations are high from inappropriate dosing or a drug overdose, kinetics may be zero-order, followed by first-order kinetics at lower concentrations. For drugs exhibiting zero-order kinetics, small increments in dose may cause disproportionately large increments in serum concentration. Certain drugs administered to newborns exhibit zero-order kinetics at therapeutic doses and concentrations and must be recognized for their potential accumulation (Table 33-2).

**FIGURE 33-3.** Representation of saturation, or zero-order (serum concentration-dependent), and first-order (serum concentration-independent) pharmacokinetics.

**Target Drug Concentration Strategy**

Drug treatment of newborns commonly uses the *target drug concentration strategy* (Table 33-3), in which drug therapy corrects a specific problem by producing an effective concentration of free drug at a specific site of action (Sheiner et al, 1978). The target site of drug action is usually inaccessible for monitoring of concentrations.

The requirements for effective and accurate application of the target drug concentration treatment in adults have been discussed by Spector and colleagues (1988). When applied to newborns, these requirements highlight the special problems of drug therapy in these patients and the special circumstances in which clinical drug concentration monitoring is appropriate. Some of these requirements are as follows:

- An available analytic procedure for accurate measurement of drug concentrations in small volumes of blood
- A wide variation in pharmacokinetics among individuals with the knowledge that population-based kinetics do not accurately predict individual kinetics
- Drug effects are proportional to plasma drug concentrations
- A narrow concentration range between efficacy and toxicity (narrow therapeutic index)
- Constant pharmacologic effect over time, in which tolerance does not develop
- Clinical studies that have determined the therapeutic and toxic drug concentration ranges

**Therapeutic Drug Monitoring**

Table 33-3 illustrates the basic assumptions of therapeutic drug monitoring, that total plasma drug concentrations correlate with dose as well as with circulating unbound drug concentrations and unbound drug concentration at the site of action. Clinical measurements of

drug concentrations usually include both bound and unbound drug, and the active portion is that portion that is unbound (see discussion of distribution). The two broad indications for monitoring drug concentrations are (1) attainment of effective concentrations and (2) avoidance of toxic concentrations. As Kauffman (1981) has pointed out, drug concentration ranges are not absolute reflections of effective therapy. Patient response, not a specific drug concentration range, is the endpoint of therapy.

Although concentrations of aminoglycoside antibiotics, such as gentamicin, are monitored frequently in newborns, toxicity is rare in newborns compared with its occurrence in adults (McCracken, 1986). Because of the limited evidence of toxicity in newborns, it is more important to measure aminoglycoside concentrations to achieve effective concentrations for treatment of culture-proven infections than to avoid toxicity. In newborns with serious therapeutic problems, measurement of serum drug concentrations should be used to achieve effective concentrations as well as to avoid toxicity. When the desired concentration range and kinetic parameters are known, doses may be estimated to reach that concentration with single bolus doses or bolus doses followed by continuous infusions.

**Kinetic Dosing**

The following equations can be used both to guide dosing and to derive kinetic parameters for individual patients.

Where C = concentration and Vd = volume of distribution:

$$\text{Dose} = \Delta C \cdot Vd = [C_{\text{desired}} - C_{\text{initial}}] \cdot Vd$$

$$(\text{mg/kg}) = (\text{mg/L}) (\text{L/kg}) = (\text{mg/L}) (\text{L/kg})$$

This equation may be used to estimate dosage changes needed to increase or decrease concentration. For the first dose, the starting concentration is zero; for doses after the first, the calculation of distribution volume should use the change ( $\Delta$ ) in concentration from the preceding trough to the peak associated with that dose. To reach a desired concentration rapidly, a loading dose can be administered followed by a sustaining infusion. The equation for calculation of infusion doses to maintain a constant concentration is shown below.

Where C = concentration, Vd = volume of distribution, and k = rate constant of elimination,

$$\text{infusion rate} = k \cdot Vd \cdot C$$

$$(\text{mg/kg})(\text{min}^{-1}) = (\text{min}^{-1}) (\text{L/kg}) (\text{mg/L})$$

TABLE 33-3

**Target Drug Concentration Strategy**

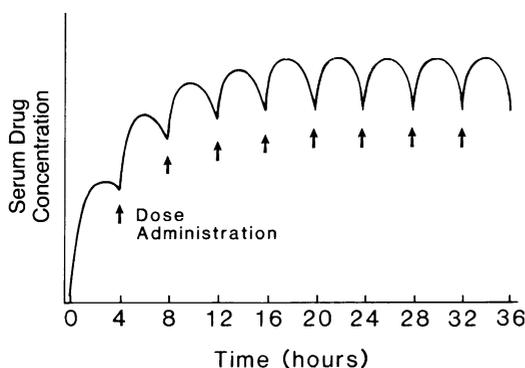

Drug dose ↔ Plasma total drug concentration ↔ Plasma unbound drug concentration ↔ Target site unbound drug concentration ↔ Desired pharmacologic effect

Steady state is reached when tissue concentrations are in equilibrium and the amount of drug removed equals the amount of drug infused. The time needed to reach a steady state depends on the elimination half-life and is *not* shortened by the administration of a loading dose.

### Repetitive Dosing and the “Plateau Principle”

During the typical course of drug therapy, drug doses are administered before complete elimination of previous doses, and the kinetics are more complex (Greenblatt et al, 1975b). During repeated administration, the peak and trough levels after each dose increase for a time. *Steady-state*, or *plateau*, concentrations are reached when the amount of drug eliminated equals the amount of drug administered during each dosing interval. During repetitive dosing, the steady-state concentrations achieved are related to the half-life, dose, and dosing interval relative to the half-life (Greenblatt et al, 1975b).

Fig. 33-4 illustrates a hypothetical concentration-time curve for a drug with a half-life of 4 hours administered orally every 4 hours, so the dosing interval corresponds to one half-life. Several important principles of pharmacokinetics are illustrated in this figure, with the mathematics described in detail elsewhere (Greenblatt et al, 1975b). Drug concentrations rise and fall with drug administration (absorption) and elimination. For dosing intervals of one half-life, accumulation is 88% complete after the third dose, 94% complete after the fourth dose, and 97% complete after the fifth dose. At steady state, the peak and trough concentrations between doses are the same after each dose. If a drug is administered with a dosing interval equal to one half-life, the steady-state peak and trough concentrations are two times those reached after the first dose. If the dosing interval is shortened to half of a half-life, the concentration decreases less before the next dose, more total drug is administered per day, and the steady-state peak and trough concentrations are considerably higher (3.4 times the peak and trough concentrations after the first dose). Thus, the shorter the dosing interval-to-half-life ratio, the higher the drug accumulation. As noted during infusions, the *length of time* required to reach steady-state concentrations depends primarily on the elimination half-life, not the dosing interval.

**FIGURE 33-4.** Representation of multiple dosing with accumulation of serum drug levels to steady-state concentration.

### Clearance

*Clearance* of drugs, as for creatinine, describes the volume of blood from which all the drug is removed per unit of time. Clearance is proportional to organ blood flow and the intrinsic capacity of organs to metabolize or remove drug from the circulation. In its simplest form, clearance is proportional to the flow to a single organ ( $Q$ ) and to the arterial-venous difference in drug concentrations compared with the amount of drug in the circulation, expressed as

$$CL = Q \cdot \frac{C_{\text{arterial}} - C_{\text{venous}}}{C_{\text{arterial}}}$$

Total body clearance usually reflects the combined clearance of multiple organs with different enzyme activities and different rates of blood flow. Clearance can be measured by the rate of appearance of drug outside the body (such as urinary creatinine clearance) or by the rate of disappearance of drug from the circulation compared with the circulating concentration. For calculations, *clearance* ( $CL$ ) is defined as the dose divided by the area under the plasma-concentration versus time curve ( $AUC$ ) and by the rate of drug input per  $C_{ss}$  average, where rate of input is the dose/dosing interval ( $\tau$ ) and  $C_{ss}$  is the steady-state concentration. For a drug administered by continuous infusion, this is simply the infusion rate ( $\text{mg/kg}\cdot\text{hr}^{-1}$ ) divided by  $C_{ss}$  as follows:

$$CL = \frac{\text{dose}}{AUC} = \frac{\text{dose}/\tau}{C_{ss}} = \frac{\text{infusion rate}}{C_{ss}}$$

Once clearance is known, this equation can be rearranged to solve for the dose necessary to achieve any desired steady state concentration, as

$$\begin{aligned} \text{Infusion rate} &= C_{ss} \cdot CL \\ (\text{mg/kg}\cdot\text{hr}^{-1}) &= (\text{mg/L}) (\text{mL/kg}\cdot\text{hr}^{-1}) \end{aligned}$$

Clearance changes significantly for some drugs during fetal and infant development because the activity of metabolic enzymes increases with advancing gestational and postnatal age. Values for clearance and volume of distribution at different stages of preterm development are available for a few drugs and can be used to estimate the dosages needed to achieve and maintain “therapeutic” concentrations associated with desired clinical responses.

Studies of the kinetics of fentanyl illustrate the developmental changes in its kinetics and how they may be used to calculate dosages to reach and maintain concentrations associated with effective analgesia. Analgesia has been associated with a serum fentanyl concentration of 1 to 2 ng/mL (Santeiro et al, 1997). If analgesic treatment is initiated with a continuous infusion of fentanyl, five half-lives are needed to reach a steady state. The fentanyl half-life ranges from 3 hours in term newborns to 12.7 hours in premature newborns (Koehntop et al, 1986; Santeiro et al, 1997). Because of this prolonged half-life, the patient may be inadequately treated for a long time, unless a loading dose is administered to reach an effective concentration more rapidly. In general, initiation of analgesic treatment and increases in infusion dosages of analgesics should

begin with a loading dose based on the estimated volume of distribution in the central compartment (circulation) and desired concentration. Use of a loading dose shortens the time to reach higher effective analgesic concentrations but also increases the likelihood of toxicity, as has been reported with digoxin.

Limited data are available regarding the gestational age-related changes in fentanyl clearance, but two studies show that it increases with advancing gestational age (Koehntop et al, 1986; Santeiro et al, 1997) and with increasing age after birth (Gauntlett et al, 1988; Santeiro et al, 1997). The linear graph of clearance versus gestational age from 38 neonates who began treatment within 47 hours after birth was used to derive mean rates of clearance at different gestational ages as shown in Table 33–4.

Other investigators studied single-dose fentanyl kinetics during anesthesia and found an apparent central volume of distribution of fentanyl in neonates of 1.45 L/kg (Koehntop et al, 1986). Note that this distribution volume is smaller than the steady-state volume of distribution of 5.1 L/kg also calculated after a single dose of fentanyl (Koehntop et al, 1986). In turn, the apparent steady-state volume of distribution after a single bolus dose of a lipophilic drug is usually smaller than that associated with continuous drug infusions, during which tissues throughout the body become saturated with drug. The steady-state distribution volume for fentanyl during continuous infusions was calculated as 17 L/kg (Santeiro et al, 1997). It should be noted that because fentanyl is a lipid-soluble drug, it distributes rapidly from the central compartment into the peripheral tissue compartment. This much larger distribution volume likely reflects the period during the infusion when drug is leaving the circulation to penetrate peripheral tissues, such as fat. Because it may take 15 to 60 hours to achieve a steady-state concentration (5 half-lives) after a fentanyl infusion is begun or the infusion rate is increased, one may have to repeat the bolus dose in order to maintain effective plasma concentrations in the central compartment. The best approach is to repeat the calculated loading dose until the desired clinical effect is achieved. This also illustrates why, for sedation specifically, dosing should be adjusted to achieve the desired clinical effect. Clearance calculations, however, can guide the starting dosages to achieve effective sedation, as illustrated later.

The kinetic parameters for fentanyl in premature infants reported by Koehntop and associates (1986) can be used to calculate a loading and infusion dose to reach a

fentanyl concentration of 2 ng/ml (Saarenmaa et al, 2000) in a premature at a gestational age of 33 weeks of (note that ng/ml is equivalent to  $\mu\text{g/L}$ ) as

$$C (\mu\text{g/L}) = \frac{\text{load dose } (\mu\text{g/kg})}{V_{d\text{central}} (\text{L/kg})}$$

$$\begin{aligned} \text{load dose } (\mu\text{g/kg}) &= 2 (\mu\text{g/L}) \cdot 1.45 (\text{L/kg}) \\ &= 2.9 \mu\text{g/kg} \end{aligned}$$

$$\begin{aligned} \text{infusion rate } (\mu\text{g/kg} \cdot \text{hr}) &= C (\mu\text{g/L}) \cdot \text{CL} (\text{mL/kg} \cdot \text{hr}) \\ &= 2 \mu\text{g/L} \cdot 11.4 \text{ mL/kg/min} \\ &\quad \cdot 1 \text{ L/1000 mL} \cdot 60 \text{ min/hr} \\ &= 1.4 \mu\text{g/kg} \cdot \text{hr} \end{aligned}$$

Two studies have observed rises in fentanyl clearance with increasing postnatal age (Gauntlett et al, 1988; Santeiro et al, 1997). This postnatal rise in clearance of fentanyl likely relates either to maturation of cytochrome P450 3A4 (the enzymes responsible for fentanyl metabolism) activity or to increased hepatic blood flow after birth, because fentanyl has a high hepatic extraction rate. For drugs, like fentanyl, with a high hepatic extraction ratio, the rate-limiting factor in clearance is the flow of blood to the liver (Saarenmaa et al, 2000). Some researchers have observed that increased intra-abdominal pressure reduces fentanyl clearance, a finding that is likely to be a consequence of reduced hepatic blood flow (Gauntlett et al, 1988; Koehntop et al, 1986). Clinical changes known to increase or decrease fentanyl clearance should be used to adjust starting dosages, but dosing should be adjusted primarily for the desired clinical effect.

## PHARMACOKINETIC PRACTICALITIES

### Dose Adjustments

Gentamicin and phenobarbital can be used to illustrate the practical application of the principles of pharmacokinetics and therapeutic drug monitoring already discussed. The calculations may be carried out at the bedside with standard arithmetic calculators.

#### Gentamicin

Assume that optimal gentamicin concentrations are

$$\text{Peak} = 6\text{--}10 \mu\text{g/mL}$$

$$\text{Trough} = 0.5\text{--}2 \mu\text{g/mL}$$

Gentamicin peak concentration was 5.0  $\mu\text{g/mL}$ ; 18 hours later, the trough was 2.5  $\mu\text{g/mL}$  after the fourth 2.5 mg/kg dose was administered intravenously to an edematous premature newborn. It is apparent that the distribution volume is greater than predicted because the peak concentration is lower than anticipated, and the half-life is longer than anticipated because the trough is higher than expected. The times of drug infusion and blood sampling were confirmed (an important step), so the half-life is 18 hours, because the concentration decreases 50% from 5.0 to 2.5  $\mu\text{g/mL}$  in 18 hours. (This assumes that the kinetics are linear and first-order.)

**TABLE 33–4**

#### Fentanyl Development Kinetics

Gestational Age (wk)	Clearance at 0–47 hours after birth (mL/[min · kg])
29	9.6
33	11.4
37	13.2
41	15.0

Data from Saarenmaa E, Neuvonen PJ, Fellman V: Gestational age and birth weight defects of plasma clearance of fentanyl in newborn infants. *J Pediatr* 136:67, 2000.

$$\begin{aligned} Vd \text{ (mL/kg)} &= \frac{\text{Dose (mg/kg)}}{\Delta C \text{ (}\mu\text{g/mL)} \cdot 1 \text{ mg/1000 } \mu\text{g}} \\ &= \frac{2.5 \text{ mg/kg} \cdot 1000 \text{ } \mu\text{g/mg}}{(5.0 - 2.5) \text{ (}\mu\text{g/mL)}} \\ &= 1000 \text{ mL/kg} \end{aligned}$$

To ensure a trough concentration of 2.0  $\mu\text{g/mL}$  or less, doses are administered every two half-lives or every 36 hours. When two half-lives have passed after the fourth dose, the gentamicin concentration should be about 1.25  $\mu\text{g/mL}$  (50% of 2.5  $\mu\text{g/mL}$ ). Increasing the concentration from the 1.25  $\mu\text{g/mL}$  trough to >6  $\mu\text{g/mL}$  requires a concentration difference of  $\geq 4.75 \mu\text{g/mL}$ . With a distribution volume of 1000 mL/kg, a dose of 4.75 mg/kg should raise the concentration from a trough of 1.25  $\mu\text{g/mL}$  to a peak of 6.00  $\mu\text{g/mL}$ . In one half-life, this concentration will decrease to 3.0  $\mu\text{g/mL}$ , and in two half-lives or 36 hours, to 1.5  $\mu\text{g/mL}$ . Another 4.75-mg/kg dose will raise the peak concentration to 6.25  $\mu\text{g/mL}$ , which will fall to 3.12  $\mu\text{g/mL}$  in one half-life and to 1.6  $\mu\text{g/mL}$  in two half-lives. The variation between the peak and trough concentrations after the last dose is within the measurement error for gentamicin and should achieve the optimum concentrations defined previously.

### Phenobarbital

Seizures that were hard to control developed in a 3.6-kg asphyxiated newborn. Seizures continued after two 20 mg/kg phenobarbital doses until an additional 10 mg/kg dose was administered. A maintenance dose of 7 mg/kg per day was started 24 hours after the loading doses were administered. At 10 days, this child was increasingly somnolent. The phenobarbital level measured in a blood specimen drawn 2 hours after administration of the oral maintenance dose was 50  $\mu\text{g/mL}$ . Additional doses were withheld, and the phenobarbital concentration was checked daily; the results were as follows:

- 24 hours: 40  $\mu\text{g/mL}$
- 48 hours: 31  $\mu\text{g/mL}$
- 72 hours: 25  $\mu\text{g/mL}$
- 96 hours: 21  $\mu\text{g/mL}$

The maintenance dose (7 mg/kg) was resumed immediately after the 21  $\mu\text{g/mL}$  concentration was measured and produced a concentration of 30  $\mu\text{g/mL}$ . These concentrations and dosages can be used to calculate the volume of distribution and a dose to maintain the phenobarbital concentration between 20 and 30  $\mu\text{g/mL}$  as

$$\begin{aligned} Vd \text{ (L/kg)} &= \frac{\text{Dose (mg/kg)}}{\Delta C \text{ (}\mu\text{g/mL} = \text{mg/L)}} \\ &= \frac{7.0 \text{ (mg/kg)}}{(30 - 21) \text{ (mg/L)}} \\ &= \frac{7 \text{ (mg/kg)}}{9 \text{ (mg/L)}} \\ &= 0.78 \text{ L/kg} \end{aligned}$$

Half-life can be determined from inspection, because the concentration decreased from 50 to 25  $\mu\text{g/mL}$  in 72 hours. Thus, it should take 72 hours for the concentration to decrease by one half-life from 30 to 15  $\mu\text{g/mL}$ . The concentration will decrease approximately 5  $\mu\text{g/mL}$  every 24 hours, or one third of a half-life. Dividing the half-life into fractions is an approximation because it estimates the change in concentration as linear rather than exponential. To be more accurate, the concentration decreases 59% in half of one half-life. Although this approximation violates certain principles of pharmacokinetics, it allows estimation of the change in concentration for each one third of a half-life as one third of the change during one half-life. Thus, the concentration decreases about 5  $\mu\text{g/mL}$  in 24 hours. The following approach can be used to estimate the daily phenobarbital dose needed to return the concentration to 30  $\mu\text{g/mL}$ , a change in concentration of 5  $\mu\text{g/mL}$ :

$$\begin{aligned} \Delta C \text{ (mg/L)} &= \frac{\text{Dose (mg/kg)}}{Vd \text{ (L/kg)}} \\ 5 \text{ (mg/L)} &= \frac{\text{Dose (mg/kg)}}{(0.78) \text{ (L/kg)}} \\ 3.6 \text{ mg/kg} &= \text{Dose (mg/kg)} \end{aligned}$$

### DRUG EXCRETION IN BREAST MILK

The excretion of drugs in breast milk remains a source of confusion and concern for many physicians and families. Newer analytic techniques and more thorough pharmacokinetic studies have improved the available data in this area of neonatal pharmacology. The available data regarding drug exposure of the newborn through human milk have been organized, in decreasing levels of concern, from drugs that are associated with adverse effects on the infant during nursing to those that are of concern pharmacologically to those that have not been associated with problems during nursing. The list of drugs clearly contraindicated during nursing is surprisingly short (AAP, 2001).

### SUMMARY

The extensive drug exposure of the sick newborn in the NICU is dangerous because of the frequency of adverse, sometimes fatal, drug reactions. Unfortunately, in the rapidly changing fetus and newborn, drug therapy is often empiric owing to a lack of gestational age-appropriate kinetic data. Methods appropriate for the study of therapeutics in newborns present unique difficulties, but a review by Ward and Green (1988) may provide assistance for investigators. Drug therapy of newborns requires practical application of the principles of pharmacokinetics and pharmacodynamics—which describe the processes of drug absorption, distribution, metabolism, and excretion—to the estimation and individualization of dosages.

## Neonatal Pain Management in the 21st Century

Theresa J. Di Maggio  
and Mary Ann E. Gibbons

In the last decade of the 20th century, the pool of resources and information available to support medical and surgical teams in neonatal pain management has expanded rapidly. Concurrently, the U.S. Department of Health and Human Services and the Joint Commission on Accreditation of Healthcare Organizations (JCAHO) have partnered with various professional organizations and mandated health care providers to look across the continuum of life at the complex nature of the pain experience so as to create new foundations for care. Organizations have commissioned interdisciplinary teams to incorporate regulatory directives and results of scientific investigation into institutional practice guidelines and standards for care. These guidelines include a patient's right to regular and systematic assessments of pain, interventions to relieve pain, evaluation of effectiveness of interventions, attention to long-term pain management needs, deleterious effects of unmanaged pain, and educational needs of families and staff who provide care (American Pain Society, 2001; Bell, 1994; Carrier and Walden, 2001; Joint Commission on Accreditation of Healthcare Organizations [JACHO], 2004).

Despite these initiatives, surveys of physicians and nurses continue to suggest that pain in the neonatal population is underassessed and undermanaged (Anand et al, 1996; Franck, 1987; Porter et al, 1997). Several investigations have substantiated the effectiveness of analgesia and comfort measures in attenuating acute pain responses and promoting long-term development; yet routine use of medications and comfort measures during performance of treatments remains inadequate in most NICUs (Anand et al, 1999; Fitzgerald et al, 1989; Guinsburg et al, 1998; Pokela, 1994). Concern about results of these studies is compounded by reports that infants born at 27 to 31 weeks of gestation may experience as many as 134 painful procedures in the first 2 weeks of life (Stevens et al, 1999a).

Finally, research and investigation have cautioned caregivers about the consequences of untreated and unmanaged pain. Several researchers have linked the stress induced by the pain response to the secondary development of adverse sequelae in multiple organ systems. Acute effects include elevations of cortisol, catecholamines, and lactate, hypertension, tachycardia, respiratory instability, glucose instability, and changes in cerebral blood flow. Chronic pain may affect growth, immune function, recovery, and discharge. In addition, a growing body of evidence has drawn attention to the potential deleterious effects of "growing up in a NICU envi-

ronment," and the impact of repeated handling, stress, and pain on long-term memory, social and cognitive development, and neural plasticity (Anand, 1998; Anand et al, 1987, 1989; Evans, 2001; Fitzgerald et al, 1989; Pokela, 1994; Porter et al, 1999; Taddio et al, 1995a).

### COMPLEXITIES OF EFFECTIVE PAIN ASSESSMENT IN INFANTS

The broad spectrum of challenges to overcome the quest for effective pain management for the neonatal population cannot be underestimated. Despite efforts to dispel old myths about pain perception and safe, effective management strategies, remnants of conventional beliefs continue to interfere with progress in this area. To ensure that pain is managed reasonably and ethically, caregivers must be educated about infant pain physiology, neural development, and the differences in response patterns of term and preterm infants (Franck, 1997).

By 20 weeks of gestation, the fetus is served by a highly differentiated and fully functional sensory system. At this time, the pain experience is a dynamic process that links the nervous system to organ systems throughout the body, producing complex, measurable responses within those organ systems when stimulated. Pain perception may be more intense than in the adult, for several reasons. The large number of nociceptive nerve endings in the skin and mucous membranes of the fetus far exceed that in adults (Anand et al, 1987). Ascending pathways between the peripheral nervous system (PNS) and the spinal cord are rich in excitatory neurotransmitters, which potentiate pain transmission, but poor in mediating neurotransmitters, which blunt the pain response.

Although development of the complex structures of the central nervous system (CNS) parallels that in the PNS and a vast supply of neurons pervues the cortex itself, differentiation of structure and function in the cortex is a slower process and compromises preterm infants' ability to integrate and assimilate pain information (Anand et al, 1987, 1989). Their response patterns, both physiologic and behavioral, are less organized, less robust, less coordinated, and more difficult to interpret. They may become more easily disorganized with stress or may adapt to pain more readily. As many as 50% of premature infants do not exhibit crying behaviors during painful procedures (Evans et al, 1997; Johnston et al, 1993, 1995, 1999). Studies have also demonstrated that with repeated exposure to painful procedures, infants may lose the ability to distinguish between painful and nonpainful stimuli and maintain hypersensitive states for protracted periods of time. This hypersensitivity persists even if non-noxious stimuli are introduced (Evans, 2001; Fitzgerald et al, 1989). In addition, local tissue injury resulting from repeated heelsticks and invasive procedures trigger increased proliferation of nerve endings in surrounding tissues, particularly when this damage occurs early in gestation. As a result scars, old IV sites and surrounding tissues may remain hypersensitive well beyond the neonatal period (Fitzgerald et al, 1989; Reynolds and Fitzgerald, 1995). Pain assessment is most challenging in preterm infants who are

exposed to the NICU environment for long periods (Johnston and Stevens, 1996).

### NEONATAL PAIN SCORING TOOLS

A review of current literature substantiates the importance of selecting a valid, reliable, and clinically useful pain scoring tool that is easily implemented at the bedside and allows for consistency in use and interpretation as part of clinical care. Caregivers are urged to keep in mind that the focus of these scoring tools is assessment of procedural pain, and their use may leave gaps in effective assessment for infants who are paralyzed, asphyxiated, or experiencing chronic pain. In addition, discriminating between pain and distress or agitation in the neonate is difficult, and a trial of therapies, both pharmacologic and nonpharmacologic, may occasionally be helpful. Assessments should be initiated on admission and then performed at regular intervals throughout the infant's hospitalization (JCAHO, 1999).

Scoring tools may use a unidimensional approach (e.g., The Neonatal Facial Coding System; Grunau et al, 1998), in which one specific behavior or group of related behaviors is evaluated, or a multidimensional approach (e.g., Neonatal Infant Pain Scale [NIPS]; Lawrence et al, 1993) in which complex behavioral and physiologic information is assessed simultaneously. With all gestational age groups, cry has been identified as the least reliable indicator of pain, and changes in facial expression, such as brow bulge, eye squeeze, nasolabial furrow, taut lips, and open mouth, as the most reliable (Grunau and Craig, 1987; Guinsburg et al, 1997; Stevens et al, 1993). Because of the complex nature of the pain experience, the infant's limited cognitive abilities, and the various ways that changes in physiologic parameters can be interpreted, the current recommendation has been to approach pain assessment with a multidimensional scoring tool. Such a tool adequately captures changes in both behavioral and physiologic domains (APS, 2001; Craig et al,

1993; Franck et al, 2000). A variety of pain scoring tools are available for use in the neonatal population. A few multidimensional tools that have been well studied and used extensively in the neonatal population are reviewed here.

The *CRIES* scoring system was established as a neonatal postoperative pain scoring tool and has been proven to be both clinically reliable and valid (Krechel and Bildner, 1995) (Table 34-1). *CRIES* is an acronym for an assessment approach that is comprised of five indicators, three behavioral and two physiologic. Each indicator is evaluated on a scale of 0 to 3. The total score ranges from 0 to 10, with a score of 4 or higher indicating pain. Although initially established as a tool to assess postoperative pain, *CRIES* has been useful in the broader range of neonates and is now widely used clinically.

The *Premature Infant Pain Scoring Tool (PIPP)* is a seven-indicator, multidimensional tool originally developed to assess acute pain in term and preterm infants (Stevens et al, 1996) (Table 34-2). Scoring with the *PIPP* is unique, in that special consideration is given to the infant's gestational age in addition to physiologic and behavioral indices. Each indicator is evaluated on a scale of 1 to 4, with a total score range of 21 for more premature infants and 18 for term and older infants. Given the complexities of pain appreciation and interpretation in premature infants, this tool may provide more accurate assessment and effective management for this group of patients. It is also the most tested neonatal pain scoring tool available. Because of its focus on acute pain experiences, additional study is needed with regard to its application to postoperative and more chronic pain situations.

The *Distress Scale for Ventilated Newborn Infants (DSVNI)* is another multidimensional, procedure-focused scoring tool that has been designed specifically for assessment of the ventilated infant (Sparshott, 1996). Although the *CRIES* and *PIPP* can be used in the ventilated population, their use does require the observer to make more subjective assessments about cry and changes in facial expression,

TABLE 34-1

#### CRIES: Neonatal Postoperative Pain Assessment Score

Indicator	Scoring Criteria		
	0	1	2
Crying	No cry, or cry not high pitched	High-pitched cry, but consolable	High-pitched cry, inconsolable
Requires oxygen for saturation >95%	No oxygen required from baseline	Oxygen requirement <30% from baseline	Oxygen requirement >30% from baseline
Increased vital signs*	Heart rate and blood pressure are both unchanged or at less than baseline	Heart rate or blood pressure is increased by <20%	Heart rate or blood pressure is increased by >20%
Expression†	None (no grimace)	Grimace only is present	Grimace and nonaudible grunt present
Sleeplessness‡	Continuously asleep	Awakens at frequent intervals	Awake constantly

\*Measure blood pressure last so as not to awaken infant.

†Grimace consists of lowered brow, eyes squeezed shut, deepening nasolabial furrow, and open lips and mouth.

‡Based on infant's state during preceding hour.

TABLE 34-2

## Premature Infant Pain Profile (PIPP)

Process	Indicator	Description of Score				Score
		0	1	2	3	
Chart	Gestational age	≥36 wks	32 wks-35 wks 6 days	28 wks-31 wks 6 days	≤28 wks	—
Score 15 seconds before event	Behavioral state	Active/ awake Eyes open Facial movements	Quite/ awake Eyes open No facial movements	Active/ sleep Eyes closed Facial movements	Quiet/ sleep Eyes closed No facial movements	—
Record baseline heart rate (—): Observe infant 30 seconds after event	Maximum heart rate	0-4 beats/min increase	5-14 beats/min increase	15-24 beats/min increase	≥25 beats/min increase	—
Record baseline oxygen saturation (—): Observe infant 30 seconds after event	Minimum oxygen saturation	0-2.4% decrease	2.5%-4.9% decrease	5%-7.4% decrease	≥7.5% or decrease	—
Observe infant 30 seconds after event	Brow bulge	None (0-9% of time)	Minimum (10%-39% of time)	Moderate (40%-69% of time)	Maximum (≥70% of time)	—
Observe infant 30 seconds after event	Eye squeeze	None (0-9% of time)	Minimum (10%-39% of time)	Moderate (40%-69% of time)	Maximum (≥70% of time)	—
Observe infant 30 seconds after event	Nasolabial furrow	None (0-9% of time)	Minimum (10%-39% of time)	Moderate (40%-69% of time)	Maximum (≥70% of time)	—
<b>Total score</b>						—

## Scoring guidelines:

1. Score the corrected gestational age before beginning.
2. Assess baseline heart rate and oxygen saturation:
  - a. For procedural pain, assess before the event.
  - b. If pain is already present, review the chart for earlier baseline.
3. Score behavioral state by observing the infant for 15 seconds immediately before the event.
4. Observe the infant for 30 seconds immediately after the event.

Adapted from Stevens B, Johnson C, Petryshen P, Taddio A: Premature infant pain profile: Development and initial evaluation. Clin J Pain 12:13-22, 1996.

because view of the infant may be obscured by an artificial airway. The DSVNI is more detailed and complex, but it may be more helpful in infants with special assessment needs.

## MANAGEMENT OF PAIN IN INFANTS

Effective pain management is a systematic approach that combines judicious use of pharmacologic and nonpharmacologic interventions. Because pain expression can be influenced by multiple contextual factors, management strategies should be comprehensive and should include the following aspects (Walden, 2001; Franck et al, 2001):

- Decrease in the number of painful interventions and noxious stimuli that infants are exposed to as part of bedside care
- Minimization of handling before invasive procedures
- Performance of procedures when the infant's state is most protective
- Timing of medication administration around necessary interventions

- Optimization of skill levels of staff performing procedures
- Use of an interdisciplinary team to evaluate the effectiveness of interventions
- Listening to family assessments and suggestions

## Nonpharmacologic Interventions

The complimentary effects of nonpharmacologic interventions have been well described in the literature. Additional information about various therapeutic modalities, including alternative therapies, massage, and music, are available on the selected reading list. A few of the more research-based interventions are discussed here.

### Developmental Care

Als and colleagues (1994) reported the positive effects of an individualized, developmentally supportive approach to care of the preterm neonate. Review of current literature universally supports integration of this philosophy into pain

management plans. This approach emphasizes the importance of assessing the individual strengths and limitations of an infant's development and then incorporating these cues into a caregiving approach that supports the infant at rest and protects the infant when handled. Highlights include protection from environmental stressors, promotion of self-regulatory behaviors, support during stressful interventions, and gentle, supportive handling. Suggested benefits include earlier time to extubation, earlier progression to oral feeds, better developmental outcomes, shorter time to discharge, and reduced hospital cost; however, these interventions have never been tested in a randomized, controlled fashion.

### **Sucrose Pacifiers**

Research-based evidence supports the use of single-dose sucrose as nonpharmacologic pain intervention in term and preterm infants (Stevens et al, 2000). Meta-analysis of four studies confirmed that a single dose of sucrose administered orally can reduce the time infants spend crying after completion of a painful procedure; this effect is thought to be mediated by the endogenous release of opioids stimulated by the sweet taste. Consensus has not been reached regarding dosage and method of administration. Beneficial effects have been documented in preterm infants after oral administration of 2 mL of 12% to 25% dextrose solution 2 minutes before painful procedures as well as with pacifiers dipped in 24% sucrose solutions and administered 2 and 5 minutes prior to painful procedures. Some concern has been raised about the potential for increased risk of necrotizing enterocolitis as a result of repeated administration of hyperosmolar dextrose solutions to the premature gut. Although no adverse effects were reported for use of the approaches in these studies, caregivers are urged to review the corresponding literature before incorporating this approach into guidelines for pain management practice.

### **Positioning**

Supportive positioning and containment have been effective in reducing procedural distress and promoting self-regulation (Porter et al, 1998). Facilitated tucking, a technique in which caregivers use their own hands to contain an infant's limbs close to the trunk, has also been shown to reduce pain responses in preterm infants (Corff et al, 1995) and can be used regularly throughout the course of bedside care.

### **Pharmacologic Interventions**

The severity of the pain, etiology, available administration routes, and consideration of potential side effects should all be evaluated for selection of an analgesic. Once medication administration has begun, careful monitoring for side effects can decrease potential adverse events related to administration of pain medications to infants. A key component of effective pain management is reassessment after a pain intervention. Evaluating the success or failure of a pain intervention and the need for modification of the pain regimen is essential.

## **Nonopioid Analgesics**

### **Acetaminophen**

Acetaminophen is the most widely administered analgesic in patients of all ages. Acetaminophen inhibits the production of cyclooxygenase in the central nervous system and peripherally blocks pain impulse generation (Arana et al, 2001). Neonates are able to form the metabolite that results in hepatocellular damage (Arana et al, 2001); however, it is inappropriate to withhold acetaminophen in newborns because of concerns of liver toxicity. The immaturity of the newborn's cytochrome P-450 system may actually decrease the potential for toxicity by reducing production of toxic metabolites (Collins, 1981).

Current recommendations are for less frequent oral dosing, every 8 to 12 hours in preterm and term neonates, because of slower clearance times, and higher rectal dosing due to decreased absorption (Arana et al, 2001; van Lingen et al, 1999). Typical oral dosages for acetaminophen are 10 to 15 mg/kg/dose every 6 to 8 hours for neonates and 10 to 15 mg/kg/dose every 4 to 6 hours for infants. Administering 10 mg/kg may be inadequate for pain control as this dose is based on antipyretic dose-response studies. The maximum dose is 75 mg/kg/24 hours for infants, 60 mg/kg/24 hours for term and preterm neonates more than 32 weeks of postconceptional age, and 40 mg/kg/24 hours for preterm neonates 28 to 32 weeks of postconceptional age (Berde, 2002).

Rectally administered acetaminophen has a longer half-life, but absorption is highly variable because it depends on the individual infant and placement of the suppository. It should also be noted that the suppository may contain all of the drug in the tip and therefore should be divided lengthwise if a partial dose is desired. The analgesic effect of acetaminophen is additive when the agent is administered with opioids; this co-administration may enable a decrease in the opioid dose and therefore in corresponding opioid side effects.

### **Nonsteroidal Anti-inflammatory Drugs**

Nonsteroidal anti-inflammatory drugs (NSAIDs) inhibit prostaglandin synthesis by inhibiting the action of cyclooxygenase. Cyclooxygenase enzymes are responsible for the breakdown of arachidonic acid to prostaglandins. NSAIDs have significant adverse effects, including decreased glomerular filtration rate and platelet dysfunction. These adverse effects are particularly worrisome for neonates and infants. NSAIDs are not generally recommended in neonates because of concerns about intestinal perfusion.

### **Indomethacin**

Indomethacin has been widely used to promote closure of the patent ductus arteriosus (PDA) (Chapter 56) and also to prevent intraventricular hemorrhage (see also Chapter 64).

### **Opioid Analgesics**

Opioids provide the most effective treatment for moderate to severe pain in patients of all ages. There is a wide range of interpatient pharmacokinetic variability. Opioid dosing

depends on the severity of the pain as well as the age and clinical condition of the infant. Opioids should be used in infants younger than 2 months only in a monitored setting such as an intensive or intermediate care unit (Yaster et al, 2003). Some clinicians propose a more conservative recommendation, restricting use of opioids to monitored settings for any infant younger than 6 months.

### **Morphine**

Morphine, the “gold standard” for pain management, is widely used in neonates. In older children and adults, morphine is metabolized in the liver and forms an active metabolite, morphine-6-glucuronide (M6G), and a second metabolite, morphine-3-glucuronide, that may be antianalgesic under some circumstances. However, little is known about the relative concentration of these metabolites in preterm infants. There is a potential for late respiratory depression due to a delayed release of morphine from less well perfused tissues and the sedating properties of the metabolite M6G (Anand et al, 2000).

Clearance or elimination of morphine and other opioids is prolonged in infants owing to the immaturity of the cytochrome P-450 system at birth. Hepatic function reaches adult levels at 1 or 2 months of age. The rate of elimination and clearance of morphine in infants 2 months and older is similar to that in adults. Chronologic age seems a better indicator than gestational age of how an infant metabolizes opioids (Scott et al, 1999; Yaster et al, 2003).

Infants are at greater risk of respiratory depression because of their immature responses to hypoxia and hypercarbia. There is an increase in unbound or free morphine available to reach the brain as a result of the reduced concentration of albumin and  $\alpha_1$  acid glycoproteins (Houck, 1998).

Hypotension, bradycardia, and flushing constitute the response to the histamine release and rapid intravenous administration of morphine. Histamine release may cause bronchospasm in infants with chronic lung disease, although this is not commonly seen (Anand et al, 2000).

There is a wide range of interpatient pharmacokinetic variability. For nonventilated infants, the initial opioid dose is approximately one fourth to one third the recommended dose for older children. For example, 0.03 mg/kg of morphine IV can be used as a starting dose (AHCPR, 1992). For ventilated infants, 0.05 to 0.1 mg/kg of morphine IV is an appropriate starting dose. Titration to the desired clinical effect is required in adjusting both the dose and the frequency of administration.

### **Fentanyl**

Fentanyl is 80 to 100 times more potent than morphine. Fentanyl causes less histamine release than morphine, making it a more appropriate choice for infants with hypovolemia, hemodynamic instability, or congenital heart disease. Another potential clinical advantage of fentanyl is its ability to reduce pulmonary vascular resistance, which can be of benefit for infants who have undergone cardiac surgery, have persistent pulmonary hypertension, or need extracorporeal membrane oxygenation (Anand et al, 2000).

Fentanyl must be administered over a minimum of 3 to 5 minutes to avoid chest wall rigidity, a serious side effect observed after rapid infusion. Chest wall rigidity, which can result in difficulty or inability to ventilate, can be treated with naloxone or a muscle relaxant such as pancuronium or vecuronium.

Fentanyl is highly lipophilic. It has a quick onset and relative short duration of action. Owing to fentanyl's short duration of action, it is typically used as a continuous infusion for postoperative pain. In infants 3 to 12 months of age, total body clearance of fentanyl is greater than that of older children, and the elimination half-life is longer owing to its increased volume of distribution (Singleton et al, 1987). Fentanyl has been demonstrated to have a prolonged elimination half-life in infants with increased abdominal pressure (Gauntlett et al, 1988; Koehntop et al, 1986).

A rebound transient increase in plasma fentanyl levels is a phenomenon known to occur after discontinuation of therapy in neonates. It is a result of fentanyl's accumulation in fatty tissues, which may prolong its effects after continued use. Therefore, caution must be exercised in the use of repeated doses or a continuous infusion.

### **Oral Opioids**

Oral methadone can be used to wean infants from long-term opioid use. Methadone is widely used in neonates and children, although there are limited data on its efficacy and pharmacokinetics in this population (Chana and Anand, 2001; Suresh and Anand, 1998). The respiratory depressant effect of methadone is longer than its analgesic effect. Methadone is metabolized very slowly, and its half-life is very long.

Codeine is prescribed at 0.5 mg to 1 mg/kg orally every 4 hours as needed. Most pharmacies supply acetaminophen and codeine in a set formula, consisting of acetaminophen 120 mg and codeine phosphate 12 mg per 5 ml with alcohol 7%. The dose prescribed is limited by both the appropriate dose of codeine and the safe dose of acetaminophen.

Oxycodone dosing is 0.05 mg/kg to 0.15 mg/kg orally every 4 to 6 hours as needed. The liquid form is not universally available.

### **Mixed Agonist-Antagonist Drug**

Nalbuphine is a mixed agonist-antagonist drug; therefore its administration to infants of opioid-addicted mothers may precipitate withdrawal. This agent is equianalgesic with morphine. Nalbuphine has a ceiling effect for analgesia. Additional studies are needed on the safety and efficacy of nalbuphine use in infants.

### **Sedatives-Benzodiazepines**

Sedatives-benzodiazepines should not be used in place of an appropriate pain medication as this class of medication has no analgesic effect. Benzodiazepines are administered to decrease irritability and agitation in infants and to provide sedation for procedures. In ventilated infants,

benzodiazepines can help avoid hypoxia and hypercarbia from breathing out of “sync” with the ventilator. For painful procedures, an analgesic must be used in conjunction with the benzodiazepine.

## Topical Anesthetics

### EMLA Cream

For infants 37 weeks of gestation and older, EMLA (eutectic mixture of local anesthetics) cream to desired area and then cover with an occlusive dressing for 1 hour before the procedure. Longer application times provide deeper local anesthetic penetration but may potentially lead to toxicity. There is a slight risk of methemoglobinemia with use of EMLA cream in infants and G6PD-deficient patients. A rare occurrence, methemoglobinemia can occur when hemoglobin is oxidized by exposure to prilocaine. EMLA should not be used in patients with methemoglobinemia or infants younger than 12 months who are also receiving methemoglobinemia-inducing drugs, such as acetaminophen, sulfonamides, nitrates, phenytoin, and class I antiarrhythmics. (Refer to Table 34–3 recommended maximum doses of EMLA cream by age and weight) A study of 30 preterm infants found that a single 0.5-g dose of EMLA applied for 1 hour did not lead to a measurable change in methemoglobin levels (Taddio et al, 1995b).

## Procedural Pain

Some invasive procedures are obviously considered painful. Routine care performed in a neonatal unit, such as diaper changing and bathing, may not typically be thought of as painful but can be distressing to the neonate as indicated by changes in oxygen saturation and heart rate. Nonpharmacologic treatment should be routinely employed for stressful procedures, and pharmacologic treatment should be used for painful procedures. Infants are beginning to receive adequate pain management for postoperative pain, but unfortunately, little progress has been made in managing procedural pain for such patients.

## Circumcision

The Circumcision Policy Statement of the American Academy of Pediatrics (AAP) states that analgesia must be provided to infants undergoing circumcisions. EMLA

cream, dorsal penile nerve block, and subcutaneous ring block are all possible options. AAP reports that subcutaneous ring block may provide the best analgesia (Circumcision, 1999).

Subcutaneous ring block has been found to be more effective than EMLA or dorsal penile nerve block in other studies (Lander et al, 1997). Dorsal penile nerve block has been found to be more effective than EMLA, but this method is not always available (Lee and Forrester, 1992).

EMLA has been established as superior to placebo for pain relief during circumcision (Bennini, 1993; Taddio, 1997). An effective method for applying EMLA in preparation for circumcision is to apply one third of the dose to the lower abdomen, extend the penis upward gently, pressing it against the abdomen, and then apply the remainder of the dose to an occlusive dressing placed over the penis. This dressing is then taped to the abdomen so the cream surrounds the penis. Another method is to apply the cream and then place plastic wrap (Saran Wrap) around the penis in a tubelike fashion to help direct the urine stream out and away from the cream.

Acetaminophen is ineffective for the management of severe pain associated with the circumcision procedure but does provide some analgesia in the postoperative period. Acetaminophen has been found to decrease pain 6 hours after circumcision (Howard et al, 1994).

## Blood Sampling and Monitoring

Heelsticks are routinely performed to obtain blood samples in neonates. The most appropriate method for relieving pain from a heelstick is yet to be determined. Heels should be warmed to aid blood sampling. EMLA does not relieve the pain of a heel lance (Stevens et al, 1999b; Taddio et al, 1998). Shah and colleagues (1997) demonstrated that neonates experiencing venipuncture had lower pain scores than those who underwent heelstick for blood sampling. In healthy neonates, venipuncture should be used preferentially over heelstick.

The pain of arterial puncture can be decreased by infiltrating around the site with 0.1 to 0.2 mL of 0.5 or 1% lidocaine using the smallest-gauge needle possible (Franck and Gregory, 1993). Buffering the lidocaine with sodium bicarbonate is recommended to decrease the burning caused by lidocaine. EMLA may reduce the pain of arterial puncture.

**TABLE 34–3**

### EMLA Cream: Recommended Maximum Dose by Age and Weight

Age and Body Weight	Maximum Total EMLA Dose	Maximum Application Area	Maximum Application Time
Birth–3 mo or <5 kg	1 g	10 cm <sup>2</sup>	1 hr
3–12 mo and >5 kg	2 g	20 cm <sup>2</sup>	4 hr

EMLA, eutectic mixture of local anesthetics.

Data Taketomo CK, Hodding JH, Kraus DM (eds): Pediatric Dosage Handbook, 2001–2002, p 595.

## Mechanical Ventilation

Because intubation can raise both blood pressure and intracranial pressure, a short-acting benzodiazepine such as midazolam can be beneficial. Midazolam can be used for infants with stable cardiovascular function; fentanyl can be used as an alternative for infants with compromised cardiovascular function (McClain and Anand, 1996). Any infant who is pharmacologically paralyzed during mechanical ventilation should receive adequate sedation. In addition, the infant should receive pain medication if pain is suspected from the infant's condition or because of the procedures being performed.

## Other Invasive Procedures

Placement of a central venous line requires topical anesthesia with EMLA or infiltration of the skin with lidocaine. Additionally, a parenteral opioid such as fentanyl is typically required.

The pain of a lumbar puncture is compounded by both the needle puncture and the distress caused by the body position required for the procedure. EMLA has been shown to decrease the pain of lumbar puncture in children (Halperin et al, 1989). Chest tube insertion requires an intravenous opioid, adequate local analgesia, or both.

## Antagonizing Pain Management

Small incremental doses of naloxone may make it possible to reverse respiratory depression without adversely affecting analgesia. Naloxone, 1 to 10  $\mu\text{g}/\text{kg}$  given as an IV push (IVP) or subcutaneously (SC), is recommended for infants with mild somnolence. For apnea or respiratory arrest, an initial dose of 10  $\mu\text{g}/\text{kg}$  IVP or SC followed by 1  $\mu\text{g}/\text{kg}$  titrated to effect is recommended to avoid sudden hemodynamic effects. After the administration of naloxone, the infant must be observed, because the duration of naloxone is significantly shorter than the duration of an opioid. Naloxone can lead to seizures in opioid-dependent patients.

The use of flumazenil for reversal of benzodiazepines has not been investigated in infants.

## Physical Dependence, Tolerance, and Addiction

A clear distinction must be made between opioid or benzodiazepine dependence, tolerance, and addiction. Physical *dependence* is demonstrated by the need to continue the administration of the drug to prevent signs or symptoms of physical withdrawal. *Tolerance* is a reduction in the drug effects after repeated administration, or the need to increase the dose to achieve the same clinical effect. *Addiction* is compulsive drug-taking behavior (Gutstein and Akil, 2001). Infants are not capable of being addicted to a drug.

## Weaning Considerations

Baseline pain and weaning scores should be obtained prior to beginning the weaning process, and infants should be reassessed every 2 to 4 hours for signs of with-

drawal. In addition, when an opioid dosage is being tapered, the infant must be assessed for the presence of pain a minimum of every 4 hours. If an infant is receiving both an opioid and a benzodiazepine, it is prudent to taper and stop only one class of medication at a time. Typically, a weaning schedule is 10% of the total initial dose per day, or 20% of the initial dose every other day. Many patients can tolerate a relatively large initial decrease in dose, but subsequent decreases may need to be smaller. Environmental stressors should be eliminated or reduced whenever possible. It should be noted that the potential onset of withdrawal symptoms varies according to the half-life of the opioid or benzodiazepine and the half-life of active metabolites, which may be much longer than that of the parent compound (Tobias, 2000).

CHAPTER  
**35**

## Immunology of the Fetus and Newborn

Calvin B. Williams and F. Sessions Cole

Understanding the contribution of the newborn infant's immunologic response to neonatal disease requires a review of the complex immunologic environment of pregnancy and the developmentally regulated changes in fetal and neonatal immunity. The contrasting functions of the fetal, neonatal, and maternal immunologic responses, that is, preservation of fetal well-being as an allogenic graft versus adequate immunologic protection in a nonsterile extrauterine environment, are regulated by a host of incompletely understood developmental and genetic mechanisms. The diversity and importance of these mechanisms are suggested by the heterogeneity and frequency of the infectious problems encountered in newborns. Differences in immunologic responsiveness between adults and newborns should not be considered defects or abnormalities. Just as the ductus arteriosus, a cardiopulmonary necessity in the intrauterine environment, closes at different rates in different infants, human fetal and newborn infant immunologic response mechanisms are developmentally and genetically programmed to change from graft preservation to identification and destruction of invading pathogens at different rates.

Fortunately, systemic antimicrobial chemotherapy can control microbial invasion and permit adaptation of the infected infant's immunologic system to an extrauterine existence exposed to multiple potential pathogens. However, antibiotics coupled with advances in support technology do not ensure survival of infected infants: Significant infectious morbidity and mortality persist in newborn infants (Polin and Harris, 2001; Shah et al, 1999).

### MATERNAL AND PLACENTAL IMMUNOLOGY

#### Maternal Immunologic Response During Pregnancy

The survival of the fetal allogeneic graft in the uterus requires multiple adaptive immunologic mechanisms. Both tolerogenic and inflammatory mechanisms are at work

during the different stages of reproduction (Mellor and Munn, 2000). Ovulation, copulation, and fertilization all induce changes in uterine physiology that alter immunologic responses and favor acceptance of the fetal allograft. For example, progesterone induced by ovulation can decrease the proliferation of T cells and inhibit the function of antigen-presenting cells (Ehring et al, 1998; Miyaura and Iwata, 2002). Prostaglandin (PE)  $E_2$ , which is present at high concentration in seminal fluid, has also been shown to inhibit lymphocyte activation and modify cytokine release in favor of interleukin (IL) 10 (Denison et al, 1999). IL-10 inhibits the production of IL-12, thereby favoring Th2 responses and tolerance. These and other data imply that a maternal shift from Th1-type immune responses to Th2-type responses may play a role in maternal tolerance to the fetal allograft (Mellor and Munn, 2000).

In contrast to PGE<sub>2</sub> and progesterone, which promote T-cell tolerance, other factors in seminal fluid, such as transforming growth factor- $\beta$ 1 (TGF- $\beta$ 1) have a pro-inflammatory effect (Tremellen et al, 1998). TGF- $\beta$ 1 stimulates production of granulocyte-macrophage colony stimulating factor (GM-CSF), which then acts by recruiting macrophages, dendritic cells, and neutrophils to the endometrial stroma. This pre-implantation inflammatory cascade may play a role in the tissue remodeling needed to prepare the endometrium for the fetal allograft (Norwitz et al, 2001). GM-CSF also has embryotrophic effects that promote fetal growth and viability. Knockout mice lacking GM-CSF have normal implantation rates but have 15% to 25% smaller litters (Robertson et al, 1999). In summary, the pregravid or gravid uterus is not ignored by the immune system, as suggested by the original notions of "immunologic privilege" (Billingham, 1964; Medawar, 1953; Simmons, 1969; Simmons and Russell, 1967). Instead, an orchestrated series of specific pro-inflammatory and tolerogenic mechanisms support implantation and fetal allograft survival.

Fetal antigenic maturity in eliciting a maternal immunologic response has been well documented (Beer and Billingham, 1976; Billington, 1987). Major histocompatibility complex (MHC) class I proteins are expressed at high levels on murine trophoblasts in early gestation (Chatterjee-Hasrouni and Lala, 1982; Philpott et al, 1988). The high frequency of alloreactive T cells in the maternal circulation (10% to 30%) makes it certain that maternal T cells will encounter fetal MHC class I alloantigens (Mellor and Munn, 2000). In the nonpregnant host, this high frequency of precursors results in potent T-cell responses to tissue allografts. The lack of such responses to fetal alloantigens has been studied in murine lineages genetically

engineered to express a transgenic T-cell receptor restricted by MHC class I antigens (Jiang and Vacchio, 1998; Tafuri et al, 1995). These studies demonstrate that MHC class I expression on murine fetal trophoblasts results in the elimination of alloreactive class I-restricted maternal T cells and in induced unresponsiveness of the antigen-specific cells remaining.

Extrapolation of these data to humans is complicated by the fact that human trophoblasts do not express the conventional MHC class I molecules HLA-A or HLA-B. They do express HLA-C, but only during the first trimester (King et al, 1996a). Instead of these conventional MHC molecules, extravillous fetal cytotrophoblasts express HLA-G, a nonclassic MHC class I molecule (Kovats et al, 1990). HLA-G exhibits relatively little polymorphism (Klein et al, 1998), and the expression of this molecule is primarily limited to fetal tissue (Kovats et al, 1990; McMaster et al, 1995). On the cell surface, HLA-G is a trimolecular complex containing the HLA-G heavy chain in a complex with  $\beta$ -2 microglobulin and a short peptide in the antigen-binding groove. The peptides bound by HLA-G are similar to those bound by other class I molecules (Lee et al, 1995). In an ex vivo assay, investigators used a blocking monoclonal antibody to demonstrate that HLA-G was important in protecting the fetus from maternal natural killer (NK) cell-mediated cytotoxicity (Rouas-Freiss et al, 1997). Several receptors on human NK cells that bind HLA-G or a fragment of HLA-G bound to HLA-E (another nonclassic MHC molecule) have now been described (Llano et al, 1999; Ponte et al, 1999; Rajagopalan and Long, 1999; Soderstrom et al, 1997). Biochemical data suggest that ligand binding by certain receptors results in the inhibition of NK cell activity. In this regard, it is intriguing that virtually all human placental NK cells at term express the inhibitory receptor KIR2DL4, whereas circulating maternal NK cells do not (Ponte et al, 1999).

The lack of expression of MHC class II proteins by murine and human trophoblast cells contributes to maternal unresponsiveness to fetal antigens. MHC class II molecules are necessary for CD4<sup>+</sup> T cell responses, which contribute both effector and regulatory functions needed for graft rejection. MHC class II gene silencing in trophoblasts is partially the result of the transcriptional repression of class II transactivator (CIITA), a necessary transcription factor for class II gene expression (Morris et al, 1998; Murphy and Tomasi, 1998). Lack of CIITA may be the reason that attempts to force expression of MHC class II molecules in trophoblast cells in vivo have been largely unsuccessful (Mellor and Munn, 2000). Thus, it is an oversimplification to view the fetal tissues at the maternal-fetal interface as antigenically immature. Instead, tightly regulated expression of nonclassic MHC genes and silencing of several classic MHC genes help create an environment that favors survival of the fetal allograft.

Considerable evidence now supports the notion that the maternal-fetal interface is an immunologically active site, rather than an inert, impermeable barrier. Fetal cells enter the maternal circulation, where they may play a role in maternal T-cell tolerance. In mice, maternal splenic T cells show awareness of paternal alloantigens (Tafuri et al, 1995). In humans, fetal genetic microchimerism can be

detected for years after parturition (Bianchi et al, 1996; Evans et al, 1999; Lo et al, 1996). Clearly, the placenta does not function as an impermeable barrier to cellular traffic (Medawar, 1953). However, several interesting features of the maternal-fetal interface document that this is a unique immunologic environment. Fas ligand (FasL) is expressed in both maternal and fetal components of the uteroplacental unit throughout gestation. Activated T cells express the Fas receptor, which delivers a death signal when bound by FasL. Implicit in these observations is the hypothesis that expression of FasL limits the reciprocal migration of activated fetal and maternal T cells. This idea is strengthened further by experiments examining the homozygous matings between *gld* mice, which make a nonfunctional FasL. Pregnant *gld* mice demonstrate leukocyte infiltration and necrosis at the decidual-placental interface, with many resorption sites and small litters (Hunt et al, 1997). In humans, the placenta restricts access of cytotoxic cells to the fetus (Beer et al, 1994; Sargent, 1993). However, evidence from infants with severe combined immunodeficiency (SCID) suggests that maternal T lymphocytes can cross the placenta and engraft in fetal bone marrow (Thompson et al, 1984). Whether aberrant regulation of maternal-fetal effector cell traffic plays a role in specific fetal or neonatal diseases, for example, intrauterine growth restriction, is poorly understood (Beer and Billingham, 1973; Beer et al, 1972).

In addition to FasL, placental products progesterone and prostaglandin E<sub>2</sub> both suppress Th1 responses (Abe et al, 1997; Piccinni et al, 1995). The Th1 cytokines interferon- $\gamma$  (IFN- $\gamma$ ) and tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ) have been shown to inhibit the growth of trophoblasts as well as embryonic and fetal development (Haimovici et al, 1991). Th1 cytokines terminate normal pregnancy when injected into pregnant mice (Chaouat et al, 1990). When peripheral blood mononuclear cells from women with a history of recurrent spontaneous abortion were stimulated with trophoblast antigen extracts, the mononuclear cells produced high levels of factors that were toxic to mouse embryos. These factors, which included IFN- $\gamma$  and TNF- $\alpha$ , were not seen in the control group, which produced IL-10 instead (Polgar and Anderson, 1995; Yamada et al, 1994). Finally, the local production of TGF- $\beta$  and IL-10 provide additional lymphocyte immunosuppression. Although the placenta is not a physical barrier to immunologic recognition, it does seem reasonable to conclude that specific apoptotic mechanisms limit the trafficking of activated T cells, and the general cytokine milieu at the maternal-fetal interface favors the development of tolerogenic Th2 responses.

This body of evidence supports the hypothesis that tolerogenic mechanisms are important at the normal maternal-fetal interface. However, *scid* mice that lack an antigen-specific immune response are fertile even when bred with mice that carry the beige (*bg*) mutation that selectively impairs NK cell function (Croy, 1993; Croy and Chapeau, 1990; Roder and Duwe, 1979). Clark and associates (1994) reported that *scid/scid* mice bred with a different genetic background (CB-17) did not have a high rate of successful syngeneic pregnancies. The possibility of a TNF- $\alpha$ -induced vasculopathy triggered by an unidentified infectious agent was raised in these studies. These observations suggest that

either multiple redundant systems contribute to successful pregnancy outcome or placental function does not require induction by immune recognition of lymphoid or cytokine functions (Croy, 1993; Ossa et al, 1994).

The placenta also regulates maternal-fetal and fetal-maternal transfer of immunologically important factors (Gitlin et al, 1964; Gurka and Rocklin, 1987; Hunziker and Wegmann, 1986; Jacoby et al, 1984). To accomplish these complex functions, the placenta has a wealth of cell populations that provide considerable regulatory diversity. The hemochorial placenta of the human is a chimeric organ. Fetal villi covered with invasive trophoblasts erode into layers of maternal epithelium, stroma, and vessel endothelium. In addition to the various cell types of the decidua, there are multiple immunologically competent cells in the placenta, as noted previously. The importance of these cell types has been emphasized by the immunotrophism model, which suggests that maternal immunologic recognition of fetal antigens induces production of cytokines that are necessary for placental growth, and by the important roles of IL-1, IL-6, TNF- $\alpha$ , and other immunoregulatory cytokines in the initiation of parturition (Guilbert et al, 1993; Romero et al, 1992, 1994; Tangri et al, 1994).

Besides local production of factors that regulate fetal and maternal well-being, the placenta can regulate passage of maternal immunologic effectors to the fetus (Tongio et al, 1975). For example, although maternal immunoglobulin (Ig) G is transported efficiently beginning at 20 weeks of gestation, maternal antibody can also be bound and degraded by the placenta (Swinburne, 1970; Wegmann et al, 1980). On the basis of observations in rabbits and mice, there is considerable antibody-binding capacity in the placenta: Radiolabeled maternal antibody is internalized and degraded by the placenta in 4 to 6 hours. Failure of this placental function may be due to elevated concentrations of maternal antibody that cannot be cleared by the placenta. Alternatively, specific antibodies may escape placental clearance and accumulate in the fetus because of a poorly understood lack of recognition of these antibodies. As understanding of the diverse immunologic functions of the placenta improves, more specific immunoregulatory clinical information will be derived from this important organ.

The fact that pregnant women are healthy and display all the appropriate immunologic defense mechanisms suggests strongly that pregnancy-induced systemic maternal immunosuppression is not necessary for successful pregnancy (Gill, 1992). The availability of genetically homogeneous murine lineages with altered immunologic responsiveness, the availability of reagents with which to evaluate regulation of expression of genes of the MHC, and greater understanding of the importance of cytokines have suggested that genetic and developmental mechanisms are responsible for successful human pregnancy (Beer and Billingham, 1976; Croy et al, 1993; Guilbert et al, 1993; Hunziker and Wegmann, 1986; Mellor and Munn, 2000; Tangri et al, 1994; Wegmann et al, 1991). Although not precisely understood, these mechanisms involve at a minimum antigen-specific T-cell tolerance, immune deviation (a propensity to develop Th2 responses), and the control of immunogenicity at the maternal-fetal interface as discussed above.

Abnormalities of maternal-fetal immunologic interaction can lead to spontaneous abortion or to morbidity or mortality for the fetus or newborn, as seen in pregnancies complicated by rhesus (Rh) isoimmunization. Approximately 75% of Rh-negative women with Rh-incompatible fetuses give birth to unaffected or mildly affected infants (Baskett et al, 1986; Berlin et al, 1985; Eklund and Nevanlinna, 1986; Mills and Napier, 1988). The regulation of the maternal immunologic response suggested by this heterogeneity is complex. Raum and colleagues (1984) studied the genetic immunoregulation of this response. These investigators demonstrated that a specific complement type of genetically determined allotypic variants of the second and fourth complement proteins of the classical complement pathway and factor B of the alternative complement pathway, all of which are encoded by genes within the MHC on the short arm of human chromosome 6, is tightly linked to a single extended haplotype, which is associated with fetal or neonatal morbidity and mortality. This observation suggests that genes that are closely linked to the MHC regulate maternal immunologic responsiveness to the Rh antigen. Preconceptual or antenatal determination of the complement type of Rh-negative women might supplement utilization of measurement of maternal anti-Rh titer to assess fetal risk. Genetic and developmental regulation of maternal immunologic response to polysaccharide antigens also plays a role in determining the risk of individual infants for systemic bacterial infection with polysaccharide-encapsulated organisms. Similar genetic markers may soon be available from studies of women in whose sequential infants group B streptococcal infection has developed within the first 3 months of life (Christensen and Christensen, 1988).

### **Immunologically Mediated Fetal Loss Syndromes**

Considerable experimental evidence derived from certain breeding combinations of mice shows that maternal immune responses can result in spontaneous fetal loss. The most extensively studied is the CBA/J  $\times$  DBA/2 breeding combination, which results in a 20% to 30% rate of spontaneous fetal resorption (Bobe and Kiger, 1989; Bobe et al, 1986). This resorption rate is increased two- to three-fold when pregnant mice are treated with substances that induce IFN- $\gamma$ , such as double-stranded RNA (dsRNA) and polyinosinic polycytidylic acid, a double stranded polymer, commonly used to mimic viral exposure (de Fougerolles and Baines, 1987; Kinsky et al, 1990). The IFN- $\gamma$  effect can be partially reversed by antiserum that blocks NK cell activation. Immunohistochemical analysis of resorption sites showed infiltration with NK cells and macrophages and excessive production of nitric oxide and TNF- $\alpha$  (Duclos et al, 1994; Haddad et al, 1995, 1997). Pre-immunizing females with macrophages, pharmacologic inhibition of nitric oxide production, blocking of TNF- $\alpha$ , and administration of IL-10 all were found to reduce fetal loss (Gendron et al, 1990; Haddad et al, 1995). Collectively, these data argue that the inflammatory conditions at the maternal-fetal interface play a critical role in successful pregnancy.

Another series of murine investigations points to a clear-cut role for maternal T-cell alloresponses in mediating spontaneous fetal loss. When monocytes are induced to differentiate into macrophages *in vitro* using macrophage colony-stimulating factor, they become inhibitors of T-cell proliferation rather than activators. This inhibition was shown to be the result of selective degradation of tryptophan by the inducible enzyme indoleamine 2,3-dioxygenase (IDO). Serum tryptophan levels fall during pregnancy, possibly in response to IDO expression by syncytiotrophoblast cells, which make the enzyme as early as 7.5 days after coitus. Given the localization of IDO to the maternal-fetal interface and the immunosuppressive effects of tryptophan depletion, it seemed plausible to investigators that this pathway played a role in survival of the fetal allograft. This hypothesis was confirmed using either normal or recombinase-activating gene (RAG) knockout mice (which lack T and B cells) together with the IDO inhibitor 1-methyl-tryptophan. Normal mice carrying allogenic fetuses lost all their conceptuses by 11.5 days after coitus when they were treated with the inhibitor. In contrast, RAG-deficient mice treated with 1-methyl-tryptophan deliver healthy litters of normal size, demonstrating an immunologic basis for the observation (Munn et al, 1998, 1999). The fact that tryptophan levels fall during human pregnancy suggests that these data will have relevance to human fetal loss syndromes.

Other factors that may contribute to fetal loss syndromes are Th1 and Th2 cytokines. Data from mice demonstrate that Th2 cytokines such as IL-4 and IL-10 inhibit Th1-mediated graft rejection. These and other data have led to the hypothesis that Th2 cytokines produced at the maternal-fetal interface promote maternal tolerance. This broad concept is beyond the scope of this chapter. Several experiments, however, may elucidate mechanisms related to unexplained recurrent abortions. In murine models, leukemia inhibitory (LIF) factor is required for embryo implantation (Stewart, 1992). LIF-deficient mice are fertile, but their blastocysts fail to implant. LIF deficiency in women with unexplained recurrent abortions has been documented, and LIF production by maternal T cells from healthy pregnancies is positively associated with IL-4 production and inversely associated with IFN- $\gamma$  (Piccinni et al, 1998). These data suggest that the balance of Th1 and Th2 cytokines is important in both establishing and maintaining pregnancy and that LIF is a critical early regulator.

## DEVELOPMENTAL FETAL-NEONATAL IMMUNOLOGY

### Humoral Immunity

#### Complement

The complement system consists of approximately 40 plasma and cell surface proteins (Table 35–1) that interact dynamically to regulate multiple functions of this immunologic effector system (Frank, 2000). These functions include cytolysis of bacteria, nonspecific opsonization, release of anaphylotoxins, solubilization of immune complexes, and induction of B-cell proliferation and dif-

ferentiation. Activation of the complement cascade can occur via the classical or alternative pathway. The activation steps in these pathways have been reviewed (Frank, 2000). Several characteristics of this cascade are important for the fetal-neonatal immunologic response. First, although the specificity of classical pathway activation results from interaction of antigens with antibodies of several isotypes, activation of the alternative pathway is antibody independent and may be initiated by structures such as endotoxin and polysaccharides that are frequently encountered among pathogenic organisms. For the fetus or infant who lacks type-specific IgG for immunologic recognition, the alternative pathway may be critical for triggering the effector functions of the complement cascade (Cole, 1987; Cole and Colten, 1984; Edwards, 1986; Stossel et al, 1973). Second, the enzymatic activation of the complement cascade permits prompt amplification of its functions: Deposition of a single immunoglobulin molecule or C3b fragment can generate enzymatic cleavage of thousands of later-acting components and, thus, multiple complement activities (Pangburn and Muller-Eberhard, 1984). In addition, the alternative pathway may be amplified via a positive feedback activation mechanism, because C3b, an activation product of the alternative pathway C3 convertase, is a component of this convertase (Volanakis, 1989). Because of the importance of antibody-independent recognition for the immunologic responsiveness of the fetus and infant, the positive amplification loop of the alternative pathway is critical for rapid generation of complement effector functions without specific immunologic recognition.

Complement activation via either pathway occurs in two distinct phases, proteolysis and assembly. First, early-acting components of the classical pathway (C1, C4, and C2) or alternative (factor B, factor D, and C3) pathway are activated by highly specific, limited proteolysis. Proteolytically activated components form specific enzymatic complexes composed of components of the classical (C2a and C4b) or alternative (C3bBb) pathway, which activate the third component of complement (C3). These two endopeptidases have identical substrate specificities: Each cleaves the single peptide bond Arginine<sub>77</sub>-Serine<sub>78</sub> of the  $\alpha$  chain of C3 (Volanakis, 1989). The rates of formation and dissociation of both C3 convertases are regulated by multiple soluble proteins (e.g., factor H, factor I, C4b-binding protein) and membrane-associated proteins (e.g., membrane cofactor protein, decay-accelerating factor [DAF]) (Schieren and Hansch, 1993). During activation of the early-acting classical components, small (8 to 10 kilodaltons [kd]) peptides are released by proteolytic cleavage from the second, third, and fourth components of complement. These fragments and an activation fragment of the fifth component of complement, C5a, have anaphylatoxin activities and modulate vascular permeability, smooth muscle reactivity, and chemotaxis of polymorphonuclear leukocytes and monocytes.

Upon activation of C3 by either convertase, the second phase of complement activation is initiated—assembly of the membrane attack complex by protein-protein interaction of terminal (C5 to C9) complement proteins (Muller-Eberhard, 1986). This complex alters membrane integrity

**TABLE 35-1****Summary of Recommendations for Immunization During Pregnancy**

<b>Immunization</b>	<b>Recommendation</b>
<b>Live Virus Vaccines</b>	
Measles	Contraindicated
Mumps	Contraindicated
Poliomyelitis	Not routine; increased risk exposure; should be avoided
Rubella	Contraindicated
Yellow fever	Travel to high-risk areas only
Varicella	Contraindicated
<b>Inactivated Viral Vaccines</b>	
Influenza	Serious underlying diseases; >14 weeks of gestation
Rabies	Same as for nonpregnant woman
Hepatitis A	Safety not determined during pregnancy; individualized risk assessment
Hepatitis B	Pre- and post-exposure for at-risk women
<b>Inactivated Bacterial Vaccines</b>	
Cholera	To meet international travel requirements; individualized to reflect actual need
Meningococcus	Same as for nonpregnant woman
Plague	Selective vaccination of exposed persons
Typhoid	Travel to endemic areas; no data available for pregnant women
Pneumococcus	Same as for nonpregnant woman; safety during first trimester not evaluate
Bacille Calmette-Guérin (BCG)	Contraindicated
<b>Toxoids</b>	
Tetanus-diphtheria	Same as for nonpregnant woman
<b>Hyperimmune Globulin</b>	
Hepatitis B	Postexposure prophylaxis given along with hepatitis B vaccine initially, then vaccine alone at 1 and 6 months
Rabies	Postexposure prophylaxis
Tetanus	Postexposure prophylaxis
Varicella	Same as for nonpregnant woman
<b>Pooled Immune Serum Globulins</b>	
Hepatitis A	Postexposure prophylaxis
Measles	Postexposure prophylaxis

Data from American College of Obstetricians and Gynecologists: Immunization During Pregnancy (Technical Bulletin No. 160). Washington, DC, ACOG, October 1991; and from Guidelines for vaccinating pregnant women, 1998. Available on line at [www.cdc.gov/nip/publications/preg\\_guide.pdf](http://www.cdc.gov/nip/publications/preg_guide.pdf).

via a transmembrane channel and thereby causes cytolysis of bacteria or cells.

Studies of fetal-neonatal complement have focused on quantification of serum concentrations of individual components, determining hepatic and extrahepatic synthesis rates, examining maternal-fetal transport of these proteins, and assessing specific effector functions of the classical and alternative pathways. In the human, Gitlin and Biasucci (1969) reported detectable concentrations of C3 (1% of adult levels) and C1 inhibitor (20% of adult levels) by immunochemical methods as early as 5 to 6 weeks of gestation. By 26 to 28 weeks of gestation, both C3 and C1 inhibitor concentration increased to 66% of adult levels (Gitlin and Biasucci, 1969). Since these studies, many investigators have demonstrated that functionally and immunochemically measured complement protein concentrations in cord blood increase with advancing gestational age and that they are only 50% to 75% of adult concentrations at full-term gestation (Davis et al, 1979,

1980; Fietta et al, 1987; Frank, 2000; Miyano et al, 1987; Shapiro et al, 1983; Sonntag et al, 1998; Strunk et al, 1979). The important roles of complement regulatory proteins, decay-accelerating factor, membrane cofactor protein (MCP), and CD59 prompted later examination of the ontogeny of these proteins in the human fetus (Simpson et al, 1993).

To examine the possible mechanisms of this developmental increase in serum concentrations of complement proteins, investigators have studied the hepatic synthesis rates of individual complement proteins in the human liver obtained at different gestational ages (Adinolfi and Colten, 1972; Gardner, 1967; Gitlin and Biasucci, 1969). They have shown that C2, C3, C4, C5, factor H, and C1 inhibitor are synthesized by the human fetal liver; C3 and C1 inhibitor synthesis can be demonstrated as early as 4 to 5 weeks of gestation. A marked increase in C4 synthesis by the fetal liver occurs at approximately 15 weeks of gestation, coincident with an increase in serum concentration.

The hepatic synthesis mechanisms that regulate this increase, either a change in the amount of C4 produced by individual hepatocytes or a change in the number of hepatocytes that produce C4, are not yet determined. Extrahepatic fetal synthesis of complement has been shown in the large and small intestines at 19 weeks of gestation (Colten et al, 1968) and in fetal monocytes obtained from cord blood (Sutton et al, 1986). An additional source of developmentally regulated complement proteins is the tissue fibroblast. Strunk and colleagues (1994) have demonstrated that regulation of endotoxin-induced synthesis of the third component of complement (C3) and factor B is pretranslationally regulated in the fetus, translationally regulated in the newborn, and transcriptionally regulated in the adult.

On the basis of studies of genetically determined, structurally distinct complement variants in maternal and cord serum, no transplacental passage from mother to fetus of C3, C4, factor B, or C6 has been observed (Colten et al, 1981; Propp and Alper, 1968). The presence of detectable amounts of C2 and C1 inhibitor in cord blood but not in the sera of mothers with genetic deficiencies of these proteins suggests that fetal-maternal transport of these components does not occur.

Regulation of complement effector functions in the fetus and newborn infant has not been as extensively examined. Opsonization of invading microorganisms without specific immunoglobulin recognition requires activation of the alternative pathway. For infants born prematurely or without organism-specific maternal IgG, alternative pathway activation provides a critical mechanism for triggering complement effector functions (Baker et al, 1986; Cole, 1987; Correa et al, 1994; Edwards, 1986). For example, Stossel and colleagues (1973) demonstrated opsonic deficiency in 6 of 40 cord sera specimens examined because of decreased factor B concentrations, despite normal C3 and IgG levels. The functional contribution of the classical pathway to neonatal effector functions has been assessed through the use of cord blood-mediated opsonophagocytosis by adult polymorphonuclear leukocytes of group B streptococci type Ia (Edwards et al, 1983). This serotype may be opsonized by classical pathway components in the absence of specific antibodies and thus permits evaluation of the function of classical pathway activation. In 8 of 20 neonatal sera examined, decreased bactericidal activity was detected and correlated with significantly lower functional activity of C1q and C4. These studies did not determine whether this decrease was mediated by an inhibitor of function or by an intrinsic change in functional activity of these components in neonatal sera. The importance of the terminal complement component C9 for cytolysis of multiple isolates of *Escherichia coli* was suggested by in vitro experiments in which killing of *E. coli* by neonatal serum samples was limited by C9 but not by other classical pathway components (Lassiter et al, 1992, 1994).

Even though lower serum concentrations of classical and alternative complement pathway proteins may contribute to enhanced susceptibility of infants to systemic infection, other complement functions important for fetal-neonatal well-being but not related to antimicrobial response may require decreased activation of the classical

and alternative pathways. For example, reduced serum concentration of C4b-binding protein (8% to 35% of levels found in pooled adult plasma), a critical regulator of classical pathway C3 convertase activity, has been noted in fetal and neonatal sera (Fernandez et al, 1989; Malm et al, 1988; Melissari et al, 1988; Moalic et al, 1988). Lower C4b-binding protein concentration increases the functional anticoagulant activity of protein S with which it complexes and thereby contributes to reduced coagulation function of the fetus and newborn. Consideration of functions besides immunologic effector functions may be important to our understanding of the developmental regulation of complement component production.

Because of the low plasma concentrations of individual complement proteins, administration of purified, recombinant complement proteins has been considered as an adjunct to immunoglobulin replacement therapy and polymorphonuclear leukocyte transfusion in the treatment of neonatal systemic bacterial infection (Cairo et al, 1987; Hill et al, 1986; Kalli et al, 1994; Krause et al, 1989). Although a provocative idea, this approach must be studied thoroughly to ensure that effector functions of complement activation in resting and uninfected tissues are not triggered in an unregulated fashion. Peripheral administration of one or more complement proteins might result in the unregulated activation of complement at tissue sites that would compromise rather than enhance neonatal survival. Consequences of such unregulated activation have been suggested by the detection of the complement anaphylatoxin C5a in pulmonary effluent of infants with chronic pulmonary inflammation in whom bronchopulmonary dysplasia develops (Groneck et al, 1993, 1994). Concern has also been raised that unregulated complement activation may occur in some infants who undergo extracorporeal membrane oxygenation (Johnson, 1994).

Complement activation is the regulator of multiple effector functions of the host immunologic response. Further studies of the fetus and newborn infant will be aimed at understanding the developmental and genetic regulation of immunologic and nonimmunologic functions of this important group of plasma and cell surface proteins.

## Immunoglobulins

*Immunoglobulins* are a heterogeneous group of proteins detectable in plasma and body fluids and on the surface of B lymphocytes. Although these proteins have multiple, diverse functions, they are classified as a family of proteins because of their capacity to act as antibodies—that is, to recognize and bind specifically to antigens. The rapid advances in our understanding of molecular structure and regulation, genetic diversity, and differences in function of immunoglobulins have been reviewed (Colten and Gitlin, 1995). The functions of immunoglobulins relevant to fetal-neonatal immunity are summarized in Table 35–2.

The five known classes of immunoglobulins are IgG, IgM, IgA, IgE, and IgD. The prototype immunoglobulin molecule consists of a pair of identical heavy chains that

determine the immunoglobulin class in combination with a pair of identical light chains. Disulfide bonds and electrostatic forces link the chains. Each immunoglobulin molecule contains two identical domains with antigen-

binding activity (Fab) and a third fragment (Fc) devoid of antibody activity. The antigen-binding activity involves sites on both the heavy and light chains, whereas sequences in the Fc region of the heavy chain are involved

in mediating immunoglobulin effector functions. Functions of individual immunoglobulin classes are different but overlapping.

### **Immunoglobulin G**

IgG is the most abundant immunoglobulin class in human serum, accounting for more than 75% of all antibody activity in this compartment. Its monomeric form circulates in plasma and has a molecular mass of approximately 155 kD; in adults, approximately 45% of total body IgG is in the extravascular compartment. The human conceptus is able to produce IgG by 11 weeks of gestation (Gitlin and Biasucci, 1969; Fudenberg, 1965). The importance of the contributions of IgG to immunologic function is illustrated by the clinical problems encountered in individuals who are genetically deficient in its production: These patients have recurrent infections if not treated with immunoglobulin replacement therapy (Sorensen and Polmar, 1987). The observations by several investigators that infants in whom group B streptococcal sepsis develops have low concentrations of type-specific IgG prompted attempts at acute or prophylactic treatment with immunoglobulin replacement therapy (Stiehm et al, 1987). Although successful in some trials, replacement therapy has not proved as efficacious in newborns as it has in individuals with genetically determined hypogammaglobulinemia (Noya and Baker, 1989). This difference may be due in part to the fact that fetal-neonatal IgG synthesis is regulated by both developmental and genetic mechanisms (Cates et al, 1988).

The kinetics of IgG placental transport suggest both passive and active transport mechanisms. Because IgG transport begins at approximately 20 weeks of gestation, preterm infants are born with lower IgG concentrations than term infants or their mothers. The full-term infant has a complete repertoire of maternal IgG antibodies. Thus, provided that relevant maternal IgG has been transported to the fetus, newborns are not susceptible to most viral and bacterial infections (e.g., measles, rubella, varicella, group B streptococci, and *E. coli*) until transplacentally acquired antibody titers decrease to biologically nonprotective concentrations at 3 to 6 months of age. The regulation of IgG production in preterm infants has been a topic of study for five decades (Ballou et al, 1986; Dancis et al, 1953). Although adults with antibody deficiency syndromes have a higher rate of infections when IgG concentrations fall below 300 mg/dL, the serum IgG concentrations of many preterm infants decrease to less than 100 mg/dL apparently without consequences. These observations suggest that preterm infants have additional immunologic protective mechanisms or that regulation of IgG function is not accurately assessed by serum IgG concentrations alone in preterm infants. Studies also suggest that low serum concentrations of IgG in the newborn may result from reduced ability of neonatal B cells to undergo immunoglobulin isotype switching because of decreased or ineffective expression of the ligand for the B cell surface protein CD40 on activated cord blood T cells (Brugnoni et al, 1994; Fuleihan et al, 1994).

IgG functions in host defenses in several ways. It can neutralize a variety of toxins in plasma by direct binding.

After antigen binding, IgG can activate the complement cascade via interaction with the early-acting complement components. The Fc portion of IgG can interact with cell surface receptors on mononuclear phagocytes and polymorphonuclear leukocytes and thereby promote clearance of immune complexes and phagocytosis of particles or microorganisms. Finally, the presence of IgG on specific target cell antigens (e.g., tumors or allogeneic transplant tissues) can mediate antibody-dependent cellular cytotoxicity, a mechanism through which lymphocyte subpopulations recognize nonself antigens.

### **Immunoglobulin M**

IgM represents approximately 15% of normal adult immunoglobulin. IgM circulates in serum as a pentamer of disulfide-linked immunoglobulin molecules joined by a single cross-linking peptide. The size of IgM (molecular mass >900 kD) restricts its distribution to the vascular compartment. Although the antibody-binding affinity of monomeric IgM is low, the multivalent structure of the molecule provides high pentameric antibody avidity. IgM synthesis has been detected in the human conceptus at 10½ weeks of gestation (Rosen and Janeway, 1964). Because maternal-fetal transport of IgM does not occur, elevated concentrations of IgM in the fetus or newborn (>20 mg/dL) are suggestive of intrauterine infection or immunologic stimulation (Alford et al, 1969; Stiehm et al, 1966). However, because it is technically difficult to distinguish IgM molecules with specificity for individual organisms, diagnosis of infections through analysis for specific IgM antibody remains of limited usefulness.

IgM is important to fetal-neonatal host defenses for several reasons. First, the IgM molecule is the most efficient of any immunoglobulin isotype in activation of the classical complement pathway. It thus can trigger multiple effector functions of this cascade. Second, its pentameric structure provides conformational flexibility to accommodate multivalent ligand binding. Third, because of its localization in the vascular compartment and its high efficiency in complement activation, IgM plays a prominent role clearance of invading microorganisms from serum.

### **Immunoglobulin A**

Although IgA accounts for approximately 10% of serum immunoglobulins, it is detectable in abundance in all external secretions. In serum, IgA is present as a monomer (molecular weight, 160 kD), whereas in secretions, it exists as a dimer (molecular weight, 500 kD) attached to a J chain identical to that found in IgM. Besides the structural difference between serum and mucosal IgA, IgA found in secretions is attached to an additional protein called the secretory component (SC). This protein is a proteolytic cleavage fragment of the receptor involved in the secretion of polymeric IgA onto mucosal surfaces and into bile. Secretory IgA produced locally on mucosal surfaces by plasma cells is thus readily distinguishable from serum IgA. Although not rigorously quantified, the amount of IgA produced daily is estimated to exceed immunoglobulin production of all isotypes combined. Despite its

relative abundance, and unlike IgM and IgG, IgA cannot activate the classical pathway of complement nor effectively opsonize particles or microorganisms for phagocytosis.

Although IgA is detectable on the surface of human fetal B cells at 12 weeks of gestation, adult concentrations of serum IgA and secretory IgA are not achieved until approximately 10 years of age. Because serum IgA is not transplacentally transferred in significant amounts, IgA is almost undetectable in cord blood. Colostrum-derived secretory IgA may provide a source of IgA found in both the gastrointestinal tract and other secretions of the newborn infant. Unlike other immunoglobulin isotypes, amino acid sequences of the hinge region of the IgA-2 subclass confer partial resistance to bacterial proteases. IgA is thus more resistant than other immunoglobulin isotypes to proteolytic effects of gastric acidity. Although considerable investigation suggests that passive immunization with IgA does occur with breastfeeding in humans, the overall importance of IgA in host defenses is currently not well characterized.

### ***Immunoglobulin E***

The concentration of IgE in serum is undetectable by standard immunochemical techniques and accounts for approximately 1/10,000 of the immunoglobulin in adult serum. IgE circulates in the monomeric form (molecular weight, 190 kd). Structurally, IgE lacks a hinge region. It is produced by most lymphoid tissues in the body but in greatest amounts in the lung and gastrointestinal tract. It is not secreted, and the appearance of IgE in body fluids generally occurs only with induction of inflammation. IgE cannot activate complement nor act as an effective opsonin. Its primary function identified to date is to mediate immediate hypersensitivity reactions. Specifically, antigen-specific IgE triggers mast cell degranulation with resultant bronchoconstriction, tissue edema, and urticaria via interactions with IgE receptors on the mast cell surface. Because of the presence of IgE in lung secretions and its potential importance in mediating allergic pulmonary and gastrointestinal reactions, considerable interest has been focused on use of serum IgE concentrations to identify premature infants at risk for development of reactive airways disease or in the diagnosis of gastrointestinal hypersensitivity reactions (Bazara et al, 1971; Jarrett, 1984).

### ***Immunoglobulin D***

Although IgD is found in trace quantities in adult human serum and has neither complement-activating activity nor the capacity to opsonize particles or microorganisms, approximately 50% of cord blood lymphocytes exhibit IgD on their cell surface (Colten and Gitlin, 1995). These pre-B lymphocytes express surface IgM and IgD simultaneously. Because of its wide distribution on B cells, IgD may play an important role in primary antigen recognition for the fetus and newborn infant.

### **Immunoglobulin Replacement Therapy**

Klesius and coworkers (1973) suggested that lack of antibody to group B streptococci occurs in infants at risk for systemic infection with this organism. The maternal con-

tribution to type-specific IgG was subsequently supported by the work of Hemming and associates (1976) and Baker and Kasper (1976). Animal and human studies have suggested that type-specific IgG can reduce mortality from systemic group B streptococcal infections. However, opsonization is not the sole mechanism of this protective effect (Fischer, 1988). Strain- and species-specific differences in protective effects of IgG have been noted. In addition, timing of administration and dosage of IgG can affect outcome. Prenatal administration has been attempted in only a small number of cases (Morell et al, 1986), but postnatal administration has been studied extensively. Although no major short-term adverse effects were noted, studies in the 1980s to test the efficacy of immunoglobulin replacement therapy to prevent or treat bacterial infection were generally inconclusive (Noya and Baker, 1989). Over the past 10 years, investigators have focused on assessment of intravenous immunoglobulin replacement to prevent nosocomial infections in preterm infants and to treat infection in infants.

Because of low serum immunoglobulin concentrations and a concurrent greater susceptibility to infection in preterm infants, several investigators have proposed prophylactic administration of immunoglobulin to prevent antibody deficiency and nosocomial infection in such patients (Baker et al, 1992; Clapp et al, 1989; Fanaroff et al, 1994; Kinney et al, 1991; Magny et al, 1991; Weisman et al, 1994). With one exception (Baker et al, 1992), these well-designed, placebo-controlled studies have failed to show consistent benefit of this strategy using different preparations of immunoglobulin, different treatment groups, and different dosage regimens.

In septic infants, the results of immunoglobulin replacement have been difficult to interpret because of the complexities in study design associated with enrolling acutely ill infants and the small numbers of enrolled infants. Sidiropoulos and colleagues (1986) and Haque and coworkers (1988) compared antibiotics alone with antibiotics plus intravenous immunoglobulin. Each study suggested therapeutic benefit, although neither was blinded nor placebo-controlled. A small, placebo-controlled pilot study of 22 patients reported by Christensen and associates (1991) demonstrated no difference between placebo-treated and immunoglobulin-treated groups with respect to survival but did show a marked rise in numbers of immature polymorphonuclear leukocytes in the immunoglobulin-treated group. In a study of prophylactic immunoglobulin therapy in infants who weighed 500 to 2000 g, Weisman and coworkers (1993a) randomly assigned 31 infants to receive either placebo or immunoglobulin treatment. Five of 17 placebo-treated infants died during the first 7 days after birth, but none of the 14 who received immunoglobulin died. Long-term survival rates were not significantly different in the two groups (Weisman et al, 1993a). Because group B streptococci are common causal organisms in neonatal bacterial sepsis, and because there are varying amounts of antibody against this organism in standard immunoglobulin preparations, Weisman and coworkers (1993a) have developed hyperimmune immunoglobulin for use in treatment of infected infants by immunizing plasma donors. Administration of this

## Cellular Immunity

immunoglobulin preparation to 20 newborns significantly increased serum group B streptococci type-specific opsonic activity. Human monoclonal antibodies against group B streptococci, *E. coli* K1, and *Neisseria meningitidis* have also been reported, but no large clinical trials have been reported as exploring the efficacy of these preparations (Hill, 1993a; Weisman et al, 1993b).

Cairo and colleagues (1992), comparing neutrophil transfusions with immunoglobulin replacement therapy in 35 newborns with sepsis, observed better survival in the neutrophil-treated group. Whitley (1994) has suggested the potential benefit of immunoglobulin therapy and concomitant administration of antiviral therapy for infants with herpes simplex encephalitis or disseminated infection. These studies suggest that intravenous immunoglobulin is more appropriate as a therapeutic agent for infants with established infection than as a preventive strategy, but further studies are required to document efficacy (Hill, 1993b; Weisman et al, 1993b).

Besides prophylactic or acute treatment of systemic infection, immunoglobulin replacement therapy has been used in other clinical situations. Oral immunoglobulin administration with a preparation that contains IgG and IgA has been proposed for prevention of necrotizing enterocolitis (Eibl et al, 1988). Necrotizing enterocolitis did not develop in any of 88 preterm infants who received 600 mg of an oral IgA-IgG preparation daily for 28 days, whereas the disorder did develop in 6 of 91 control infants studied concurrently. Confirmation was achieved with radiography (pneumatosis, pneumoperitoneum, or hepatic portal vein gas) or histopathologic examination of specimens obtained during surgery or autopsy. Similar results have been reported in an Italian study of 132 Italian infants with birth weight less than 1500 g (Rubaltelli et al, 1991). However, a multicenter, placebo-controlled trial of oral IgG to prevent necrotizing enterocolitis failed to demonstrate efficacy (Lawrence et al, 2001). Intravenous immunoglobulin has also been used with some success in small numbers of infants with neonatal isoimmune thrombocytopenia (Massey et al, 1987). Although immunoglobulin replacement therapy may be a promising intervention in selected clinical circumstances, its role in the newborn as acute treatment of or prophylaxis for systemic infections, prevention of necrotizing enterocolitis, or treatment of isoimmune thrombocytopenia warrants further study (Noya and Baker, 1989).

The newborn infant, especially the preterm infant, is at increased risk for development of infection by a considerable spectrum of opportunistic organisms, including *Candida* species, herpes simplex virus, and cytomegalovirus. Developmental and genetic differences between adults and infants in cell-mediated immunologic responsiveness account for this enhanced susceptibility. Considerable investigative interest has focused on the molecular, cellular, and functional definitions of these differences (Bellanti et al, 1994; Hogg et al, 1993; Krensky and Clayberger, 1994; Leung, 1994). This discussion focuses on those developmental aspects of cell-mediated immunity known to be important for fetal or neonatal responsiveness to opportunistic infections.

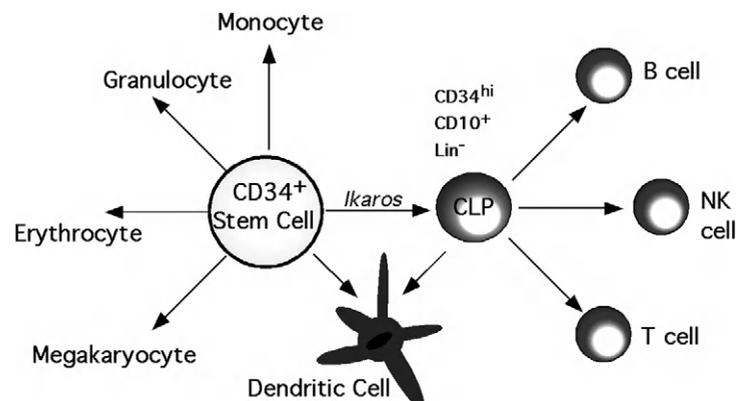

Lymphocytes play multiple critical roles in the cell-mediated immunologic response. The following three lymphocytic lineages have been identified from their cell surface and functional criteria: T, or thymus-dependent, lymphocytes; B, or bursa-derived, lymphocytes; and NK, or natural killer, lymphocytes (Abo et al, 1983; Baley and Schacter, 1985). All three types develop from CD34<sup>+</sup> CD38<sup>dim</sup> hematopoietic stem cells found in the fetal liver (Fig. 35-1). CD34 is also expressed on early committed progenitors, which differentially express other markers useful in lineage determination. Studies of a small subset of children with SCID have suggested, although not conclusively demonstrated, that defective development of all three cells occurs, implying the presence of a common lymphoid stem cell (Thompson et al, 1984).

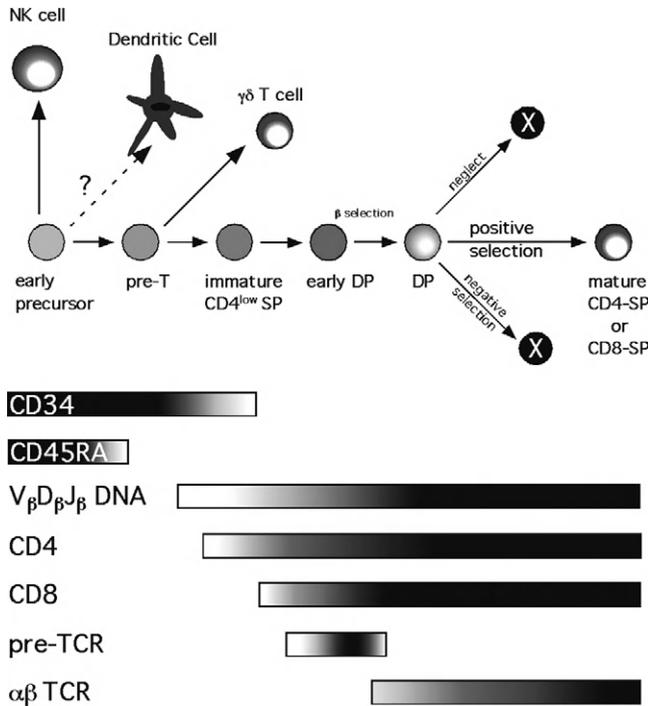

### Lymphocytes

#### T Lymphocytes

T lymphocytes, or T cells, develop in the thymus (Fig. 35-2), which is formed from the third brachial cleft and the third or fourth brachial pouch. Thymic lobes are generated when tissue from these sites moves caudally to fuse in the midline. Each lobe can be divided into the following three regions on the basis of structure and function: the cortex, the corticomedullary junction, and the medulla. The thymic cortex is composed of specialized epithelial cells that express MHC class I and class II molecules and mediate the early stages of T-cell maturation.

**FIGURE 35-1.** CD34<sup>+</sup> stem cells give rise to all cells in the hematopoietic lineage. This section focuses on the development of T, B, natural killer (NK), and dendritic cells, which develop from a common lymphoid precursor (CLP). Ikaros is a DNA binding protein involved in chromatin remodeling and is an essential regulator of lymphocyte development. Lin<sup>-</sup>, lineage marker depleted. (Data from Georgopoulos, 2002).

**FIGURE 35-2.** The stages of T-cell development that occur within the thymus. *Horizontal bar graphs* indicate the expression of lineage markers, important T-cell receptors/co-receptors, and complete *TCR-β* gene rearrangement. The gray scale approximates the level and timing of expression, with *black* indicating a higher level. DP, double positive ( $CD4^+ CD8^+$ ); VDJ, variable, diversity and joining segment recombination. (Data from Benoist and Mathis, 1999; Spits et al, 1998) (Adapted from Williams CB: *Development of the immune system*. In Rudolph C, Rudolph AM, Hostetter MK, et al [eds]: *Rudolph's Pediatrics*, 21st ed. New York, McGraw-Hill, 2002.)

This complex developmental process begins when multipotent  $CD1a^-$ ,  $CD5^-$ ,  $CD34^+$ ,  $CD38^{low}$  stem cells enter the thymus at the corticomedullary junction and migrate into the outer cortex (Res et al, 1996). Maturation continues as cells migrate back through the cortex toward the corticomedullary junction. The first committed T cells express low levels of CD4 and show DNA rearrangement at the T-cell receptor (TCR)  $\delta$  gene locus. These events are followed by low levels of CD8 expression and by rearrangement at the TCR  $\beta$  locus, which generates a pre-TCR on the cell surface (Spits et al, 1998). The pre-TCR is composed of several polypeptides, including a TCR  $\beta$  chain and the invariant pre-T $\alpha$  chain. Expression of the pre-TCR serves as an important developmental checkpoint ( $\beta$ selection) (von Boehmer and Fehling, 1997). Cells that do not successfully rearrange their TCR  $\beta$  chain cannot express the pre-TCR and die by apoptosis (Falk et al, 2001). The remaining cells generate antigen-specific receptors when the TCR  $\alpha$  chain replaces pre-T $\alpha$ . These intermediate to late-stage progenitors also express both the CD4 and CD8 co-receptors and are called “double positives.” The minor population of  $\delta\gamma$ T cells follows a similar developmental pattern.

Small double-positive cells ( $CD4^+$ ,  $CD8^+$ ,  $TCR^{low}$ ) constitute about three fourths of all thymocytes, reflecting the critical and rate-limiting developmental stage that fol-

lows. Further maturation requires that the unique TCR on each thymocyte interact with self-peptide–MHC complexes expressed on the surface of thymic epithelial cells. Several factors control the outcome of this interaction, including the strength and timing of the signal generated and the nature of the antigen-presenting cell (Bevan, 1997; Yun and Bevan, 2001). “Appropriate” interactions between thymocytes and thymic cortical epithelial cells stimulate sustained activation of the mitogen-activated signaling cascade (MAPK), resulting in continued development (positive selection). “Weak” interactions fail to generate a positive signal and result in T cell death by neglect. “Strong” interactions between T cells and bone marrow–derived antigen-presenting cells cause transient activation of the MAPK pathway, which leads to activation-induced cell death (negative selection) (Gong et al, 2001). Negative selection in the thymus is the primary mechanism by which self-reactive T cells are eliminated. The precise mechanisms involved in positive and negative selection are not known.

Thymocytes in the medulla are mature, in that they express either CD4 or CD8 and a single TCR heterodimer.  $CD4^+$  T cells recognize foreign antigenic peptide bound to HLA class II proteins, whereas those expressing CD8 are restricted to HLA class I molecules. In the human embryo, the first naïve, mature T cells appear at around 11 to 12 weeks of embryonic development. Thymopoiesis continues for many years thereafter. Naïve T cells express the adhesion molecule L-selectin ( $CD62L$ ), which allows them to home to peripheral lymphoid organs. This process requires the interaction between L-selectin ( $CD62L$ ) and GlyCAM-1,  $CD34$  expressed on high endothelial venules, or both to promote adhesion. The first T-cell proliferative responses that occur are to mitogens and can be measured at about 12 weeks of gestational age. By 15 to 20 weeks, antigen-specific responses can be detected (Adkins, 1999; Garcia et al, 2001). Maturation of immune responses continues throughout the first year of life, a fact that affects vaccination schedules (Gans et al, 1998). Kennedy and associates (2001) have shown that thymopoiesis continues at some level into adulthood.

The final component of T-cell development is independent of the thymus and involves peripheral (lymph nodes, spleen, and gut-associated lymphoid tissue) homeostatic mechanisms. These poorly understood events control the expansion of clones and the development of T-cell memory. Peripheral repertoire selection begins with activation of mature, naïve T cells. T-cell activation requires a complex molecular cascade that results in reorganization of signaling molecules in the membrane into the “immunologic synapse” and in signal transduction (Bromley et al, 2001). Many of the important biochemical events in this process have been described. TCR engagement by an appropriate MHC-peptide ligand results in phosphorylation of components of the CD3 complex. The CD3 complex is composed of the  $\alpha\beta$ TCR and  $\gamma$ ,  $\delta$ ,  $\epsilon$  and  $\zeta$  chains. These later molecules all contain specific amino acid sequences called immune receptor tyrosine-based activation motifs (ITAMs), which serve as molecular targets for the tyrosine kinases *fyn* and *lck*. The  $\zeta$  chain is thought to be the most critical component and is found as a homodimer. Each  $\zeta$  chain contains three ITAMs, which will bind the tyrosine kinase Zap-70 when sequentially phosphorylated.

Appropriate phosphorylation of  $\zeta$  results in a downstream cascade involving the tyrosine phosphorylation of multiple cellular substrates, including phospholipase C $\gamma$ 1, the guanine nucleotide exchange factor Vav, and the adaptor protein Shc. Ultimately the genetic program of the cells is altered, leading to the transcription of genes for cytokines, cytokine receptors, and transcription factors (Cantrell, 2002).

Initially after activation, all naïve T cells secrete IL-2. CD4<sup>+</sup> T cells will then differentiate into either Th1 or Th2 effectors. The mechanisms driving this differentiation continue to be the subject of considerable investigation. Th1 cells secrete IL-2, IFN- $\gamma$ , lymphotoxin (LT), and TNF- $\beta$ , and Th1 responses are generally pro-inflammatory. Th1 cytokines act synergistically to lyse virally infected cells, activate antigen-presenting cells as well as granulocytes. IFN- $\gamma$  also promotes the development of the Th1 phenotype and inhibits the development of Th2 cells. Th2 cells secrete IL-4, IL-5, IL-10, and IL-13. IL-4 induces immunoglobulin heavy chain class switching to the IgE isotype and promotes the development of the Th2 phenotype. IL-5 is an eosinophil growth factor. Thus Th2 cells are thought to promote antibody production and the allergic response via multiple mechanisms (Ouyang et al, 2001).

Activation of naïve T cells requires a second signal, and the most potent co-stimulatory molecule is CD28. The ligands for CD28 are B7-1 and B7-2, which are present on the surface of antigen-presenting cells. Cytotoxic T-lymphocyte antigen (CTLA-4), a molecule expressed only on activated T cells, also binds B7-1 and B7-2 and functions as a negative regulator of T-cell activation. Experiments with knockout mice demonstrate that CD28 is the major co-stimulatory receptor and that signaling through CTLA-4 attenuates CD28-dependent responses (Alegre and Thompson, 2001; Wood et al, 2001).

Control of the clonal proliferation seen in a primary immune response involves Fas/FasL-mediated cell death. This mechanism resets the peripheral immune system, thereby maintaining adequate clonal diversity. A small number of activated T cells do survive, and they differentiate into memory cells. Memory cells are defined functionally (more rapid response) and by the expression of certain cell surface markers. Early memory T cells are L-selectin<sup>low</sup>, CD45R0<sup>high</sup>, and CD44<sup>high</sup>. Late memory cells may become L-selectin<sup>high</sup>, which is a surface marker seen in naïve T cells. The ultimate number of memory cells has been shown in mice to reflect the initial antigenic load and clonal burst size. Memory T cells allow the secondary response to be both more rapid and more potent, characteristics that form the basis for vaccinations. The memory phenotype is not seen early in life, but grows with age. The precise mechanisms that generate and maintain memory T cells have not been determined, although it is known that the persistence of CD8<sup>+</sup> memory T cells in mice does not depend on the persistence of specific antigen (Sprent, 2002; Williams and Brady, 2001).

Immunocompetent T cells capable of responding to foreign lymphocytes in the mixed lymphocyte reaction are found in the fetal liver at 5 weeks of gestation. Before 8 weeks of gestation, lymphocytes are not detectable in the fetal thymus. After 8 weeks, lymphoid follicles, T lymphocytes, and Hassall corpuscles can be identified. By 12 to

14 weeks, T lymphocytes can be found in the fetal spleen (Timens et al, 1987). By 15 to 20 weeks, the fetus has readily detectable numbers of peripheral T lymphocytes.

### Natural Killer Cells

NK cells are a component of the innate immune response and represent about 10% to 15% of all peripheral blood lymphocytes. NK cells are present in the spleen, lungs, and liver but rarely in lymph nodes and thoracic duct lymph (Cerwenka and Lanier, 2001). Interestingly, NK cells are the major type of lymphocyte found in the maternal decidual tissue, where they represent up to 95% of all lymphocytes (King et al, 1996b). NK cells are distinguished from other lymphocytes by their morphology, function, and expression of distinct surface molecules. Expression of the cell surface markers CD16 (Fc $\gamma$ RIII) and CD56 (nerve cell adhesion molecule-1 [NCAM-1]) can be used to identify the NK population by analytical flow cytometry. Mature NK cells appear larger and more granular than T or B cells (Cooper et al, 2001). They are also distinguished by the presence of both activating and inhibitory receptors that are used to identify and kill selectively virally infected cells and tumors (Bianconi et al, 2001). NK receptors recognize MHC class I molecules on target cells, resulting in signals that suppress NK cell function. Target cells that are deficient or lacking in MHC class I activate NK cell function, leading to the release of lysosomal granules. These granules contain serine proteases, perforin, and TGF- $\beta$ , which disrupt the target cell membrane and induce an inflammatory response. Studies show significant lower NK cell activity in the fetus and neonate compared to the adult (Georgeson et al, 2001; Kadawaki et al, 2001).

NK cells are derived from hematopoietic precursors, probably from a common T/NK progenitor, and first make their appearance in fetal liver as early as 6 weeks of gestation. Committed CD34<sup>+</sup>, CD56<sup>-</sup> NK progenitors have been identified in the fetal thymus, bone marrow, and liver, although the thymus is probably not essential for NK cell development (Spits et al, 1998). Gene targeting experiments show that the transcription factors *Ets 1*, *IRF 1*, and *IRF 2* are required for NK cell development (Barton et al, 1998; Lohoff et al, 2000; Ogasawara et al, 1998). *Ets 1* is a 56-kd protein that contains a winged helix-loop-helix DNA-binding domain, capable of recognizing a purine-rich sequence containing the core consensus GGAA/T. Upon activation, *Ets 1* is phosphorylated, resulting in inhibition of DNA binding and rapid protein turnover. *Ets 1*-deficient mice lack both NK cells and NK cell activity (Barton et al, 1998). *IRF 1* appears to induce IL-15 expression, which promotes NK differentiation (Ogasawara et al, 1998). Initial studies also suggested the zinc finger transcription factor *Ikaros* was also essential. However, this interpretation was based on a knockout mouse that produced a dominant-negative form of *Ikaros* rather than a null allele (Guest et al, 1997). These later experiments do demonstrate that *Ikaros*-related proteins yet to be identified are essential for NK cell development. A lack of cell surface markers for NK precursors complicates these studies. In the human neonate, the NK population is immature:

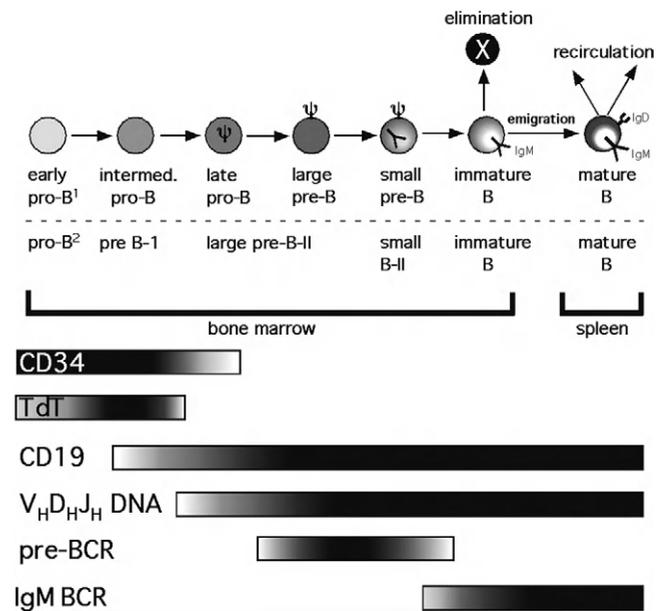

Only half of all NK cells express CD56, and the NK cytolytic activity is lower (Dominguez et al, 1993). This functional reduction in NK activity has been proposed as a factor contributing to the severity of neonatal herpes simplex virus infections.

NK cell receptors are fundamentally different from the TCR and B-cell receptor. NK receptor gene expression does not require gene segment rearrangement, and the receptors are not clonally distributed. Instead, NK cells use an array of stimulatory and inhibitory receptors to regulate their cytolytic functions. A cluster of 10 or more genes encoding NK receptors, termed killer immunoglobulin-like receptors (KIRs), has been located on human chromosome 19q13.4 (Biassoni et al, 2001; Lanier, 1998). Each of these type I glycoproteins recognizes a different allelic group of HLA-A-, HLA-B-, HLA-C-, or HLA-G-encoded proteins, and each KIR is expressed by only a subset of NK cells. Another family of Ig-like receptor genes termed ILT is present near the KIR locus at 19q13.3. These receptors are not as restricted as the KIRs and bind multiple HLA class I molecules. A third inhibitory receptor gene locus has been identified on chromosome 12p12 to p13. These genes encode a C-type lectin inhibitory heterodimeric receptor called CD94/ NKG2 that binds HLA-E. Importantly, those KIRs, ILT receptors, and CD94/NGK2s that have a long cytoplasmic tail with two immunoreceptor tyrosine-based inhibitory motifs (ITIMs) function as inhibitory receptors. Upon phosphorylation, the two ITIMs recruit and activate the Src homology domain 2 (SH2)-containing tyrosine phosphatases, which turn off the kinase-driven activation cascade (Ravetch and Lanier, 2000). The KIR family member KIR2DL4 is distinct from other KIRs in structure and distribution. KIR2DL4 binds HLA-G and has a single ITIM in its cytoplasmic tail and a lysine in the transmembrane region, which allow association with adaptor proteins. This inhibitory receptor was found on all NK cells in the placenta at term but not on circulating maternal NK cells, suggesting that expression of KIR2DL4 may be induced during pregnancy (Rajagopalan and Long, 1999). The colocalization of HLA-G on fetal trophoblasts and KIR2DL4-bearing NK cells certainly warrants further evaluation.

Other KIR or members of the C-type lectin superfamily serve as activating receptors (Moretta et al, 2001). These receptors lack the long cytoplasmic tail of the inhibitory receptors and therefore do not contain ITIMs. Instead, they have a charged amino acid in the transmembrane region that allows the receptor to associate with the adaptor molecule DAP12 (Lanier et al, 1998). This adaptor contains an immunoreceptor tyrosine-based activation motif (ITAM) that allows these receptors to activate NK cells. The physiologic role of these HLA class I-specific activating receptors remains unknown. Another group of NK cell-activating receptors has been identified, termed natural cytotoxicity receptors (NCRs) (Moretta et al, 2001). These proteins (NKp46, NKp30, NKp44) are Ig superfamily members with little similarity to one another or to other NK receptors. They are highly specific for NK cells, and they appear to interact with non-HLA molecules, although the precise ligands have yet to be identified.

## B Lymphocytes

B cells are lymphocytes that upon activation give rise to terminally differentiated, immunoglobulin-secreting plasma cells. Immunoglobulins form the humoral arm of the immune system and provide the main form of protection against many pathogens. B-cell development can be divided into embryonic and adult phases (Fig. 35-3). The embryonic phase begins in the fetal liver at the same gestational age as T-cell development, follows a similar time course, and utilizes similar developmental strategies. The adult phase occurs in the bone marrow and continues throughout life. In both phases, B-cell progenitors are selected at key developmental checkpoints for the presence of a functional BCR rearrangement and for the absence of BCR self-reactivity. The progenitors with self-reactive receptors either are eliminated or generate new antigen receptors by means of continued gene segment rearrangements that are not self-reactive. Both B-cell development and peripheral B-cell homeostasis require signal transduction through the BCR. Although the B-cell compartment is well formed before birth, diversification of the antibody repertoire and several important antibody responses are not developed until long after the neonatal period (Hardy and Hayakawa, 2001; Rohrer et al, 2000; Rolink et al, 2001; Yankee and Clark, 2000).

**FIGURE 35-3.** The stages of B-cell development in the bone marrow and spleen. Expression of the intracellular enzyme terminal deoxynucleotidyl transferase (TdT), the cell surface marker CD19, the pre-B cell receptor (pre-BCR) with the surrogate light chain ( $\psi$ ), and complete heavy-chain gene segment rearrangement is shown. The gray scale estimates the timing and level of expression, with *black* indicating a higher level. VDJ, variable, diversity and joining segment recombination; IgM, immunoglobulin M. (Kincade et al, 2000; Lassoued et al, 1883; Data from Melchers and Rolink, 1999; Rolink et al, 2001.) (Adapted from Williams CB: *Development of the immune system*. In Rudolph C, Rudolph AM, Hostetter MK, et al [eds]: *Rudolph's Pediatrics*, 21st ed. New York, McGraw-Hill, 2002.)

B-cell development begins before 7 weeks of gestational age in the fetal liver, and by 8 weeks, pre-B cells in various stages of maturation are seen. By 8 to 10 weeks, CD34<sup>+</sup> hematopoietic stem cells are also found in the bone marrow, and B-cell development begins there as well. The early phase of B-cell development, as in T-cell development, is antigen independent. The first committed progenitors (pro/pre-B-I) express CD34, terminal deoxynucleotidyl transferase (TdT), recombinase-activating genes (RAGs), and CD19 (Li et al, 1993). They lack immunoglobulin gene rearrangement (Allman et al, 1999). The next lineage is marked by heavy chain (H) diversity to joining (D<sub>H</sub> to J<sub>H</sub>) gene segment rearrangements, followed by variable to diversity/joining segment rearrangement. TdT is utilized during this process to insert nucleotides between the segments, creating additional diversity at a region that encodes the V<sub>H</sub> portion of antibody-binding sites. Late cells in this stage express an invariant surrogate light chain (SLC) (Kitamura et al, 1992). The normal light chain genes remain in germline configuration.

The first developmental checkpoint in B-cell development requires expression of SLC together with Ig $\alpha$  and Ig $\beta$  on the cell surface as the pre-BCR, marking the transition to the pre-B II stage. Expression of the pre-BCR is essential for positive selection of cells that have a functional  $\mu$ H chain rearrangement and for expansion of the pre-B cell lineage (Gong and Nussenzweig, 1996). Cells with a nonfunctional H chain rearrangement or with H chains that assemble poorly with SLC are unable to progress. V<sub>L</sub>-to-J<sub>L</sub> rearrangement takes place next, and the newly expressed polymorphic L chain protein replaces the surrogate light chain. The completed BCR is antigen-specific and contains the mIgM molecule. A second selection developmental checkpoint occurs here, and those B cells with self-reactive receptors are eliminated or edited (Hartley et al, 1991). Only 10% to 20% of the immature B cells survive this negative selection and migrate to the spleen, which they enter through the terminal branches of the central arterioles. Once in the spleen, they rapidly differentiate into membrane IgM<sup>+</sup>, membrane IgD<sup>+</sup>, B220<sup>+</sup> mature B cells, which enter the recirculating pool of B lymphocytes (Hardy and Hayakawa, 2001).

When mature B cells contact antigen through the BCR, a signal is transduced that promotes further growth and differentiation into surface Ig<sup>+</sup> memory cells and plasma cells (Calame, 2001). BCR signaling involves activation of the tyrosine kinases Syk and Btk, which are also involved in pre-BCR signal transduction. Certain mutations in Btk result in a failure of pre-BCR signaling, leading to X-linked agammaglobulinemia. Many B cell responses utilize the ability of B cells to capture antigen at vanishingly low concentrations, process the antigen into small peptide fragments, then present the antigen to Th cells in the context of MHC class II molecules. Antigen-specific T cells then form conjugates with antigen-presenting B cells. The T-cell membrane protein gp39 interacts with CD40 on B cells, triggering B clonal expansion, cytokine responsiveness, and isotype switching.

B lymphocytes with surface IgM are first found in the fetal liver at 9 weeks of gestation and in the fetal spleen at 11 weeks (Owen et al, 1977; Timens et al, 1987). Antigen-specific antibody production can be detected in the human

fetus by 20 weeks of gestation. Fetal spleen cells can synthesize IgM and IgG *in vitro* by 11 and 13 weeks of gestation, respectively.

### **Functional Differences Between Fetal and Adult Lymphocytes**

Multiple studies have documented differences in the proportions of fetal-neonatal T-lymphocyte subpopulations and B cells at different gestational ages and in a variety of perinatal disease states (Baker et al, 1987; Lilja et al, 1984; Pittard et al, 1985). In addition, functional differences between cord blood and adult T cells and B cells have been identified (Andersson et al, 1983; Bussel et al, 1988; Hauser et al, 1985; Hayward and Mori, 1984; Hicks et al, 1983; Jacoby and Oldstone, 1983; Nelson et al, 1986; Olding and Oldstone, 1974; Oldstone et al, 1977; Papadogiannakis and Johnsen, 1988; Pittard et al, 1984, 1989). Because of the potential importance of both of these areas to future immunologic treatment of newborns, each is reviewed here.

Although multiple functional and cell surface characteristics have been used to identify and study T lymphocytes, less mitogen-induced proliferation, weaker ability to induce immunoglobulin synthesis by B cells, presence of different proportions of helper and regulatory cell surface markers, and smaller capacity to produce lymphokines have all been shown to differentiate fetal-neonatal T cells from adult T cells. Even though the *in vivo* significance of these differences has not been defined, the fetus and newborn infant can mount a cell-mediated immunologic response against certain antigens comparable to that of adults. Differences in the regulation of this responsiveness in the fetus and newborn are most likely the result of the necessity of preserving the fetus's immunologic role as a graft.

Availability of monoclonal antibodies directed at epitopes found on functionally distinct T-cell subsets has permitted identification of differences in T-cell regulation in certain common perinatal medical and infectious conditions (Ryhanen et al, 1984; Wilson et al, 1985). From a therapeutic perspective, the decreased production of lymphokines has considerable potential for clinical utilization. Specifically, it has been shown that neonatal T cells produce less IFN- $\gamma$  than adult T cells (Frenkel and Bryson, 1987; Wakasugi and Virelizier, 1985; Wilson et al, 1986; Winter et al, 1983). Other investigators have elucidated the molecular details of IFN- $\gamma$  regulation in newborn T cells as follows: Methylation status of a specific nucleotide motif in the 5' regulatory region of the IFN- $\gamma$  gene correlates with transcription of the gene (Penix et al, 1993; Young et al, 1994).

These findings suggest that induction by IFN- $\gamma$  may play a major role in developmental regulation of immunologic responsiveness and may thereby provide an important reagent with which to enhance the capacity of infected infants to respond to invading microbes. Systemic administration of IFN- $\gamma$  to infants, as has been done in adults with chronic granulomatous disease, leprosy, and acquired immunodeficiency syndrome (AIDS) remains a possibility for further exploration. However, an alternative therapy in

the neonatal period could be in vitro activation of autologous lymphocytes, which has been used in adults with malignancies. Such an approach might avoid the unanticipated developmental regulatory problems of the systemic administration of a substance, such as IFN- $\gamma$ , that has multiple, potentially deleterious effects. Similar approaches may be considered in specific infections with individual cytokines—for example, TNF- $\alpha$  and GM-CSF (Cairo et al, 1991; Wilson et al, 1993).

Considerable investigation has focused on the ontogeny of B lymphocytes (Bofill et al, 1985; Gathings et al, 1977; Pedersen et al, 1983; Pereira et al, 1982; Tedder et al, 1985a, 1985b). In the fetus, these cells are detectable during the first trimester, but their expression of immunoglobulins differs from that observed in adults. B-cell precursors (pre-B cells) are detectable in human fetal liver at 8 weeks of gestation and in the bone marrow at 12 weeks. By the 15th week of gestation, the proportions of fetal B cells that express different immunoglobulin heavy-chain isotypes are equivalent to those in adults. These cells exhibit intracytoplasmic heavy chains. They lack stable surface immunoglobulin molecules characteristic of mature B cells but are the precursors of IgM<sup>+</sup> B lymphocytes. The generation of immunoglobulin isotype diversity within the B-cell lineage occurs in the fetus without apparent stimulation by multiple foreign antigens. However, a fetal-neonatal characteristic of B lymphocytes is their concurrent expression of two or three immunoglobulin isotypes. The molecular events that regulate isotype switching and diversity are being investigated (Colten and Gitlin, 1995).

Although B cells of full-term and preterm infants can synthesize IgM, IgG, and IgA, the response of human infants to certain foreign antigens is qualitatively distinct from that of adults. For example, as noted in early studies of antibody responses to *Salmonella* organisms, infants can respond vigorously to protein H antigen but are incapable of responding to polysaccharide antigenic determinants (the O antigens of the cell wall). These differences appear to be due to both intrinsic differences in B-cell responsiveness and greater suppressor T-cell activity in the fetus and newborn. Further understanding of the mechanisms that regulate B-cell function may permit individualized immunologic manipulation of antibody responsiveness specific for the developmental stages of preterm and full-term infants. For example, systemic administration of pharmacologic agents, such as recombinant human cytokines, may permit enhanced B-cell or T-cell responsiveness to specific infectious agents. Alternatively, in vitro exposure of autologous T or B cells to these cytokines may also permit administration of focused immunoenhancing therapy.

### Polymorphonuclear Neutrophils

As observed for T and B lymphocytes, neonatal polymorphonuclear neutrophils (PMNs) are present at early stages of gestation, but their functional capacities are different from those of adult PMNs. Progenitor cells that are committed to maturation along granulocyte or macrophage cell lineages (granulocyte-macrophage colony-forming units

[CFU-GM]) are detectable in the human fetal liver between 6 and 12 weeks of gestation in proportions comparable to those observed in adult bone marrow (Christensen, 1989). Human fetal blood has detectable CFU-GM from the 12th week of gestation to term (Christensen, 1989; Liang et al, 1988;). Although these progenitor cells are detectable in the fetus and newborn infant, developmental differences between adult and neonatal mature PMNs have been demonstrated—in signal transduction, cell surface protein expression, cytoskeletal rigidity, microfilament contraction, oxygen metabolism, and intracellular antioxidant mechanisms (Hill, 1987; Ricevuti and Mazzone, 1987).

Besides intrinsic differences in PMN function, induction of specific functions as well as maturation of these cells are developmentally regulated by the availability in the microenvironment of specific inflammatory mediators and growth factors (Christensen, 1989; Vercellotti et al, 1987). For example, an activation product of the fifth component of complement, C5a, is a chemoattractant at sites of inflammation. Low concentrations of C5 in neonatal sera may not permit establishment of chemoattractant gradients at sites of inflammation in newborns comparable to those in adults. Differences between adult and fetal-neonatal PMN functions may thus reflect intrinsic cellular differences required for fetal well-being as well as differences in the availability or activity of substances that regulate PMN function.

The recognition that systemic bacterial infection in newborns is commonly accompanied by profound neutropenia prompted investigation of neutrophil kinetics in infected infants (Christensen et al, 1980, 1982; Santos et al, 1980). These studies have suggested diverse, developmentally specific regulatory mechanisms required for mobilization of the neutrophil response to infection. Lack of neutrophil precursors in bone marrow aspirates of infected infants and systemic neutropenia motivated several investigators to give neutrophil replacement therapy to neutropenic, infected infants (Christensen et al, 1980). Although this approach has been successful in some cases, the results have not been uniformly beneficial (Cairo, 1984, 1987; Menitove and Abrams, 1987; Stegagno et al, 1985;). Immunoglobulin replacement therapy treatment with recombinant cytokines has also been observed to have beneficial effects on mobilization of neutrophils during bacterial sepsis (Christensen et al, 1991). This heterogeneity emphasizes the importance of individualizing immunologic interventions for the developmental stage of the infant and the invading microorganism being treated. In vitro treatment of neutrophil precursors in peripheral neonatal blood with recombinant cytokines as well as adjunctive therapy with immunoregulatory proteins may provide future options for this therapy (Cairo, 1991; Gillan et al, 1994; Hill, 1993b; Hill et al, 1991).

### Monocytes and Macrophages

Cells committed to phagocyte maturation (granulocyte or monocyte-macrophage) are detectable in the human fetal liver by the 6th week of gestation and in peripheral fetal blood by the 15th week. Unlike granulocytes, whose tissue half-life is hours to days, macrophages migrate into tissues

and reside for weeks to months. In a tissue-specific fashion, these cells regulate availability of multiple factors, including proteases, antiproteases, prostaglandins, growth factors, reactive oxygen intermediates, and a considerable repertoire of monokines.

The importance of macrophages in the neonatal response to infectious agents has been documented in multiple studies. For example, increased antibody response and protection from lethal doses of *Listeria monocytogenes* were induced in newborn mice by administration of adult macrophages (Lu et al, 1979). Functional differences in chemotaxis and phagocytosis between adult and neonatal cells have been observed and most likely result from both intrinsic fetal-neonatal monocyte-macrophage characteristics and nonmacrophage factors (e.g., decreased production of the lymphokine IFN- $\gamma$ ) (English et al, 1988; Stiehm et al, 1984; van Tol et al, 1984). Inducible expression of individual complement proteins by lipopolysaccharide (LPS), a constituent of gram-negative cell walls, has also been shown to differ in adult and neonatal monocyte-macrophages (Sutton et al, 1986, 1994). This difference suggests that even though signal transduction mediated by LPS, LPS-induced transcription, and accumulation of messenger RNAs (mRNAs), which direct the synthesis of the third component of complement and factor B, are comparable in adult and neonatal cells, a translational regulatory mechanism does not permit these important inflammatory proteins to be synthesized by LPS-induced neonatal cells. This observation emphasizes the fact that fetal-neonatal monocyte-macrophages may have functions developmentally distinct from those of adult cells. For example, in utero production of growth factors and removal of senescent cells during tissue remodeling may be critical to fetal development (Kannourakis et al, 1988). Concurrent induction of these functions and immunologic effector functions in fetal monocyte-macrophages would potentially elicit nonspecific inflammation in actively remodeling tissues.

Besides antibacterial functions, neonatal monocyte-macrophages contribute to tissue-specific regulation of the microenvironment in individual organs. For example, considerable attention has focused on the contributions of these cells to antioxidant defenses and to regulation of protease-antiprotease balance. Because of the importance of these functions in tissue injury and repair, tissue- and injury-specific treatment by appropriately targeted and primed monocyte-macrophages may provide therapeutic options for treatment of a spectrum of problems, from oxygen toxicity in the lung to hemorrhage in the brain.

### Specific Immunologic Deficiencies

The most common reason, besides prematurity, for the greater immunologic susceptibility to infection in neonates is administration of corticosteroids for treatment or prevention of bronchopulmonary dysplasia. Although pulmonary and neurodevelopmental benefits have been attributed to this therapy (Abman and Groothuis, 1994; Cummings et al, 1989), caution has developed about the possible adverse effects of steroid administration (Bancalari, 2001; Barrington, 2002; Committee on the Fetus and

Newborn, 2002). Even though the mechanisms that lead to steroid-induced amelioration of pulmonary disease have not been completely elucidated, pulmonary inflammatory response, as measured by concentrations of the anaphylatoxin C5a, leukotriene B<sub>4</sub>, IL-1, elastase- $\alpha$ -proteinase inhibitor, and a number of neutrophils, has been shown to be attenuated in steroid-treated infants (Groneck et al, 1993). Whereas shorter courses of steroids may reduce side effects, including immunosusceptibility, the availability of nebulized steroids may provide effective anti-inflammatory therapy with minimum toxicity (Cole et al, 1999).

Well over 100 primary immunodeficiency diseases are now recognized. The physician should attempt to differentiate infants with specific genetically regulated immunologic deficiencies from those with developmentally regulated, environmentally induced, or infection-related susceptibility to microbial invasion (Rosen, 1986; Rosen et al, 1984).

A careful family history during an antenatal visit may be helpful in identifying relatives removed by as many as two to four generations who have histories suggestive of genetic immunodeficiency. Because of the availability of antenatal diagnostic techniques for several of these diseases, initiation of treatment immediately after or possibly before birth can be considered (Flake et al, 1996; Harland et al, 1988; Holzgreve et al, 1984; Perignon et al, 1987; Puck et al, 1997).

### Severe Combined Immunodeficiency

SCID is a rare category of diseases affecting both B and T cells. The estimated frequency is 1 in 70,000 to 100,000 live births (Buckley et al, 1997; Stephan et al, 1993;). Before the identification of the genes involved in producing the SCID phenotype, investigators classified patients with the disorder by analyzing the number, cell surface proteins, and function of circulating lymphocytes. The most common subgroups are T<sup>-</sup>B<sup>-</sup> SCID, T<sup>-</sup>B<sup>+</sup> SCID, and adenosine deaminase deficiency.

T<sup>-</sup>B<sup>+</sup> SCID accounts for more than half of all cases of SCID, and both X-linked and autosomal recessive forms exist (Fischer, 2000). About 80% of patients with T<sup>-</sup>B<sup>+</sup> SCID are males with the X-linked form, which is the result of deleterious mutations in the "common" gamma chain ( $\gamma_c$ ) shared by the IL-2, IL-4, IL-7, IL-9 and IL-15 cytokine receptors (Noguchi et al, 1993). Defects in the  $\gamma_c$  protein abrogate development of T cells and NK cells and lead to B-cell dysfunction despite normal B-cell numbers. IL-7 receptor signaling is essential for T-cell development within the thymus, and the deficiency of this cytokine accounts for the absence of T cells (Cao et al, 1995; DiSanto et al, 1995; Peschon et al, 1994). IL-15 is implicated in NK-cell development, and reductions in IL-4 receptor signaling are thought to contribute to the poor B-cell function seen in  $\gamma_c$ -deficient patients (Mrozek et al, 1996). Nevertheless, the precise mechanisms involved in the NK-cell developmental defect and the B-cell functional defect are largely unknown.

The less common, autosomal recessive form of T<sup>-</sup>B<sup>+</sup> SCID is primarily due to mutations in the Janus-associated tyrosine kinase JAK3 (Macchi et al, 1995; Russell et al,

1995). This kinase is expressed in cells of hematopoietic lineage and associates with  $\gamma_c$  as part of the cytokine receptor–signaling cascade. The T<sup>-</sup>B<sup>+</sup>NK<sup>-</sup> immunophenotype of affected patients is identical to that seen in  $\gamma_c$  deficiency. Rarely, patients with autosomal recessive T<sup>-</sup>B<sup>+</sup> SCID have NK cells. In two such patients, a defect was found in the IL-7R $\alpha$  chain (Puel et al, 1998). This finding was predicted by the phenotype of the IL7R knockout mouse, and the data imply that the IL-7 receptor is not essential for NK-cell development.

Clinically, the X-linked and autosomal recessive forms of T<sup>-</sup>B<sup>+</sup> SCID are indistinguishable. Affected infants often appear normal at birth. In the neonatal period, a morbilliform rash, probably the result of attenuated graft-versus-host disease from transplacental passage of maternal lymphocytes, may be the only symptom of SCID (Rosen, 1986). Over the first several months of life, as the acquired maternal antibody levels drop, failure to thrive and undue susceptibility to infection become universal features. Intractable diarrhea, pneumonia, and persistent thrush, especially oral thrush, are the triad of findings most commonly seen in infants with this disease (Stephan et al, 1993).

Mutations in the gene encoding adenosine deaminase (ADA), an enzyme in the purine salvage pathway, account for about 20% of all cases of SCID. Mutations in another enzyme in the purine salvage pathway, purine nucleoside phosphorylase (PNP), are found in about 4% of patients with SCID (Fischer, 2000; Fischer et al, 1997). The ADA-deficient phenotype is variable, and neonatal onset, delayed onset, and partial forms have been described (Santisteban et al, 1993). In neonatal-onset ADA deficiency, patients have a profound T, B, and NK cell lymphopenia, with a clinical presentation similar to that of T<sup>-</sup>B<sup>+</sup> SCID (Hirschhorn, 1990). Even though ADA is normally present in all mammalian cells, life-threatening disease in ADA deficiency is limited to the immune system. Less severe manifestations include flaring of the costochondral junction as seen on the lateral chest radiograph (“rachitic rosary”) and pelvic dysplasia. Other findings associated with ADA deficiency are hepatic and renal dysfunction, deafness, and cognitive problems (Fischer, 2000; Rogers et al, 2001). Patients who lack ADA accumulate deoxy-adenosine triphosphate (dATP) in red blood cells and lymphocytes, and the concentration correlates with disease severity. The ADA substrates, adenosine and deoxyadenosine, are found at increased levels in the serum and urine. Studies in ADA-deficient mice suggest that developing thymocytes are particularly sensitive to these metabolic derangements and that the few T cells that do mature have signaling defects (Blackburn et al, 2001). The precise mechanism by which the accumulation of ADA substrates results in the immunologic disease seen in humans remains unclear (Yamashita et al, 1998).

The remaining 20% of patients with SCID lack mature T and B cells but have functional NK cells (T<sup>-</sup>B<sup>-</sup>NK<sup>+</sup>). These patients exhibit an autosomal recessive pattern of inheritance and have defects in the V(D)J recombination machinery (Schwarz et al, 1996). Somatic recombination of variable, diversity, and joining DNA segments is a critical step in development of B and T cells. A rearranged IgM heavy chain and TCR  $\beta$  chain form components of

the pre-B and pre-T receptors, which provide essential survival signals for developing lymphocytes. In the absence of recombination, these lymphocyte precursors do not receive a survival signal and so die, producing the T<sup>-</sup>B<sup>-</sup> SCID phenotype. NK cells do not require somatic cell recombination and survive. In the recombination process, DNA cleavage is mediated by RAG1 and RAG2, the recombination-activating proteins, which recognize specific sequences flanking V, D, and J segments. The two proteins act in concert to introduce a double-stranded DNA break and leave hairpin-sealed coding ends. Recruitment of a DNA-dependent protein kinase, and other components of the general DNA repair machinery, completes the process.

Mutations in the genes encoding both RAG1 and RAG2 have been identified in patients with T<sup>-</sup>B<sup>-</sup>NK<sup>+</sup> SCID (Corneo et al, 2000). In some cases, the same RAG mutations have been found in patients with Omenn syndrome (Corneo et al, 2001). Omenn syndrome is clinically characterized by failure to thrive, diarrhea, erythroderma, alopecia, hepatosplenomegaly, and lymphadenopathy. This finding implies that factors other than RAG mutations also contribute to the Omenn phenotype. Finally, a small subset of patients with T<sup>-</sup>B<sup>-</sup>NK<sup>+</sup> SCID also have increased sensitivity to ionizing radiation, suggesting mutations affecting the DNA repair mechanism (Fischer, 2000). This supposition is strengthened by murine and equine SCID, in which specific defects in the DNA-dependent protein kinase involved in V(D)J recombination and DNA repair have been identified.

The diagnosis of SCID is often suggested by an opportunistic or unusually severe infection in the setting of profound lymphopenia (<1000 lymphocytes/mm<sup>3</sup>) (Gennery and Cant, 2001). Only 10% of patients with SCID have lymphocyte counts in the normal range. T cells detectable in peripheral blood of affected infants shortly after birth may be either maternal T cells or circulating thymocytes. The thymus gland is not seen on chest radiographs. Histologically, the gland is composed of islands of endodermal cells that have not become lymphoid and contain no identifiable Hassall corpuscles. Lymphocyte subpopulation analysis using monoclonal antibodies to cell surface markers and analytical flow cytometry (FACS) is the most important confirmatory test. As noted previously, each phenotypic pattern suggests a specific diagnosis and molecular defect. Other useful tests are measurements of ADA and PNP activity in red blood cells and of isohemagglutinins as a marker of specific IgM production. Quantitative immunoglobulin levels are not particularly helpful in the diagnosis of neonatal SCID, because most IgG is maternal in origin and IgA and IgM levels are often low in the neonatal period. Once the immunophenotype has been established, a precise molecular diagnosis should be obtained, and genetic counseling provided. Females carrying deleterious mutations in the *IL2RG* gene (X-linked SCID) can be identified by nonrandom inactivation of the X chromosome in lymphocytes. Prenatal diagnosis is available through gene identification from a chorionic villous biopsy.

When a fetus at risk for a genetic form of SCID is identified, treatment should begin in the delivery room and should be coordinated with antenatal diagnostic interventions.

Specifically, cord blood samples should be obtained for white blood cell count and differential, lymphocyte subset determinations, karyotype (if not performed antenatally), mitogen stimulation studies, and immunoglobulin measurements. Because the majority of children with genetic SCID do not become ill within the first week of life, care in an incubator should be provided, and staff should observe strict hand-washing technique.

SCID is a pediatric emergency and, if untreated, is invariably fatal. Most untreated patients die in the first year of life. Treatment of SCID begins with aggressive antibiotic and antiviral therapy for infections, intravenous immunoglobulin replacement, and prophylaxis for *Pneumocystis carinii* infection. Besides greater susceptibility to opportunistic infections, these infants are susceptible to development of graft-versus-host disease, either before birth, as a result of engraftment of maternal T lymphocytes, or after birth, as a result of the engraftment of T lymphocytes present in transfused blood products (Pollack et al, 1982; Thompson et al, 1984). Thus, infants in whom SCID is suspected should receive only irradiated blood products and should not be given live viral vaccines.

In 1968, Good and colleagues performed the first successful bone marrow transplantation (BMT) in a patient with SCID (Gatti et al, 1968). Allogeneic BMT, preferably from an HLA-matched sibling, is now the standard treatment for most types of SCID (Buckley, 2000). In these procedures, conditioning regimens are not required for engraftment. Recipients usually become chimeric, with T and NK cells only of donor origin. B-cell function is frequently deficient, and many patients continue to require monthly therapy with intravenous immune globulin. Survival rates for this type of BMT exceed 90%. When no HLA-identical donor is available, haploidentical transplants have been used successfully, although overall survival is lower with such transplants (Fischer, 2000). The rates of engraftment after haploidentical transplantation of patients with T<sup>-</sup>B<sup>-</sup>NK<sup>+</sup> SCID are low. This is likely due to host NK-cell function, and some form of preconditioning may be indicated in this subset of patients. In addition to BMT, ADA deficiency can be treated with enzyme replacement. This involves weekly injections of ADA coupled to polyethylene glycol. Response, consisting of decreasing deoxy-adenosine triphosphate levels and increasing T cell numbers, is seen in most patients within weeks. Finally, gene therapy of patients with ADA deficiency and  $\gamma$ c SCID has been attempted. These protocols involve gene transfer into peripheral T cells or CD34<sup>+</sup> stem cells, which are then transfused into the patient. Results of some experiments have been encouraging (Kohn, 2001).

### Wiskott-Aldrich Syndrome

Wiskott-Aldrich syndrome (WAS), another form of immunodeficiency, is characterized by severe eczema, thrombocytopenia, higher risk of malignancy, and susceptibility to opportunistic infection. Other manifestations, which may be present in the newborn period, are petechiae and bruises, bloody diarrhea, and hemorrhage after procedures. WAS is inherited as a sex-linked recessive trait (Rosen, 1986). In untreated cases, children survive longer

than infants with SCID (median survival, 5.7 years). T lymphocytes in affected patients are decreased in number and diminished in function. Reductions in platelet size and thrombopoiesis are also noted. Affected children can be treated with BMT, and the 5-year survival after HLA-identical sibling BMT is about 90% (Filipovich et al, 2001). Even though transplantation corrects the T-cell defects, thrombocytopenia persists. As for children with SCID, all blood products given to children with WAS should be irradiated before administration to avoid T-cell engraftment and graft-versus-host disease.

The gene responsible for the Wiskott-Aldrich syndrome was cloned in 1994 (Derry et al, 1994). It is composed of 12 exons and encodes a 502-aminoacid cytoplasmic protein (WASP) expressed in all hematopoietic cells. Other mammalian WASP family members include a more widely expressed N-WASP and three WAVE/Scar isoforms. These proteins have multiple domains and are important regulators of actin polymerization (Symons et al, 1996). They have a common carboxy-terminal region, through which they activate Arp2/3, an actin-nucleating complex involved in actin assembly and cytoskeletal structure. Their amino termini are distinct, allowing the proteins to couple Arp2/3 activation to a wide variety of different intracellular signals. More than 340 mutations in WASP have been described, which have profound effects on cell motility, signaling, and apoptosis (Rengan and Ochs, 2000).

### DiGeorge Syndrome

The embryologic anlage of the thymus gland and the parathyroid gland is the endodermal epithelium of the third and fourth pharyngeal pouches. When normal development of these structures is disturbed, thymic and parathyroid hypoplasia can occur (Rosen, 1986). Infants with this disorder, DiGeorge syndrome, may exhibit abnormalities of calcium homeostasis during the neonatal period (hypocalcemia and tetany) and variable T-cell deficits, which appear to depend on the presence and number of small, normal-looking ectopic thymic lobes. In addition, these infants have congenital conotruncal cardiac defects, low-set ears, midline facial clefts, hyomandibular abnormalities, and hypertelorism.

The availability of methodology for performing gene dosage studies and more refined cytogenetic techniques (fluorescence in situ hybridization [FISH]) has permitted description of a contiguous gene syndrome that includes DiGeorge phenotype (Hall, 1993). The DiGeorge syndrome is now known to result from various-sized deletions on chromosome 22q11 in more than 90% of patients (Markert et al, 1998). This deletion has been linked to several other diagnostic labels, including velocardiofacial (Shprintzen) syndrome, Cayler syndrome, and Opitz G/BBB syndrome. Collectively, these are now referred to as the *22q11 deletion syndromes*. The cardiac anomalies associated with the 22q11 deletion syndrome are variable but usually involve the outflow tract and the derivatives of the branchial arch arteries. These defects include interrupted aortic arch type B, truncus arteriosus, and tetralogy of Fallot.

Children with the 22q11 deletion syndrome also exhibit a higher incidence of receptive-expressive language difficulties,

cognitive impairment, and behavioral problems including psychotic illness (Scambler, 2000). The cardiovascular defects have been shown to be the result of haploinsufficiency of TBX1 (Merscher et al, 2001). In the nursery, identification of infants with congenital conotruncal abnormalities should prompt consideration of this syndrome. Fetal thymic implants can correct the immunologic deficits (Reinherz et al, 1981).

## IMMUNIZATION

### Maternal Immunization

Immunization before pregnancy has been effective in preventing several specific neonatal infections, including diphtheria, pertussis, tetanus, hepatitis B, and rabies (American College of Obstetrician and Gynecologists, 1991; Hackley, 1999; Hepatitis B virus, 1991; Stevenson, 1999; Faix, 2002). For example, in developing countries, immunization during pregnancy with tetanus toxoid is a cost-effective method of preventing neonatal tetanus and of providing up to 10 years of protection for infants (Gill, Karasic et al, 1991; Schofield, 1986). The benefits for both mother and infant, from induction during pregnancy of maternal IgG antibody that can be transferred to the fetus and protect both the fetus and mother against postpartum morbidity and mortality, are substantial (Faix, 2002; Insel et al, 1994; Linder and Ohel 1994). However, immunization during pregnancy is biologically distinct from immunization of nonpregnant individuals. Vaccine epitopes may be shared with vital fetal or placental tissues; therefore, vaccination may lead to unanticipated maternal or fetal morbidity (Faix, 2002). Maternal immunization may induce an antibody response in the fetus, as has been demonstrated with tetanus toxoid (Gill et al, 1983), and thereby have potentially undesirable immunologic side effects (e.g., immunologic unresponsiveness or tolerance) in the infant.

Nevertheless, the increase in availability of potentially protective transplacentally transferred IgG through active maternal vaccination prompted the Institute of Medicine to recommend establishment of a program of active immunization to control early-onset and late-onset group B streptococcal disease in both infants and mothers (Institute of Medicine and National Academy of Sciences, 1985). Efforts to develop safe, effective vaccines for protection from group B streptococcal infections have encountered the same difficulties with immunogenicity and safety observed in the development of other vaccines that induce protection from polysaccharide-encapsulated organisms (Baker et al, 1988; Noya and Baker, 1992). The availability of conjugate vaccines, which include group B streptococcal polysaccharide antigens covalently linked either to tetanus toxoid or to a protein in the membrane of group B streptococci (beta C protein) (Madoff et al, 1994; Wessels et al, 1993) have shown considerable promise.

The indications for active vaccination during pregnancy rest on assessment of maternal risk of exposure, the maternal-fetal-neonatal risk of disease, and the risk from the immunizing agents (American College of Obstetricians and Gynecologists, 1991; Faix, 2002; Hackley, 1999; Stevenson, 1999). In general, immunization with live viral vaccines during pregnancy is not recommended. Preferably, immu-

nizations with live viral vaccines are performed before pregnancy occurs. However, rare instances may occur in which live viral vaccine administration is indicated. For example, if a pregnant woman travels to an area of high risk for yellow fever, administration of that vaccine might be indicated because of the susceptibility of the mother and the fetus, the probability of exposure, and the risk to the mother and fetus from the disease. More common examples in the United States are influenza and polio virus vaccination. If a chronic maternal medical condition would be adversely affected by influenza, active immunization may be indicated during pregnancy. Similarly, if imminent exposure to live polio virus in an unprotected woman is anticipated, live oral polio virus vaccine may be used during pregnancy. If immunization can be completed before anticipated exposure, inactivated polio virus vaccine can be given. A summary of recommendations for immunizations during pregnancy is given in Table 35-3 and can be found at [www.cdc.gov/nip/publications/preg\\_guide.pdf](http://www.cdc.gov/nip/publications/preg_guide.pdf).

For the pediatrician, maternal immunization represents an important preventive intervention. Breast-feeding does not adversely affect immunization, and inactivated or killed vaccines pose no special risk for breast-feeding mothers or their infants (Atkinson et al, 2002; Recommended childhood immunization schedule, 2002b). Maternal immunizations with vaccines against polysaccharide-encapsulated organisms (e.g., *Haemophilus influenzae* type b and group B

TABLE 35-3

#### Recommended Schedule of Hepatitis B Immunoprophylaxis to Prevent Perinatal Transmission

Vaccine Dose* and HBIG†	Age
<b>Infant Born to Mother Known to be HBsAg-Positive</b>	
First	Birth (within 12 hr)
HBIG	Birth (within 12 hr)
Second	1-2 mo
Third	6 mo
<b>Infant Born to Mother Not Screened for HBsAg</b>	
First‡	Birth (within 12 hr)
HBIG	If mother is found to be HBsAg-positive, give 0.5 mL as soon as possible, i.e., not later than 1 wk after birth
Second	1-2 mo
Third§	6-18 mo

HBIG, hepatitis B immune globulin; HBsAg, hepatitis B surface antigen.

\*Refer to [www.cdc.gov/nip/recs/child-schedule.pdf](http://www.cdc.gov/nip/recs/child-schedule.pdf) for appropriate vaccine dose.

†HBIG (0.5 mL) given intramuscularly at a site different from that used for vaccine.

‡First dose is same as that for infant of HBsAg-positive mother. Subsequent doses and schedules are determined by maternal HBsAg status.

§Infants of HBsAg-positive mothers should be vaccinated at 6 mo.

Data from Peter G (ed): 1997 Red Book: Report of the Committee on Infectious Diseases, 24th ed. Elk Grove Village, IL, American Academy of Pediatrics, 1997, p 258.

streptococci) may decrease morbidity and mortality from these diseases during the first 3 to 6 months of the infant's life (Amstey et al, 1985; Baker et al, 1988; Faix, 2002; Walsh and Hutchins, 1989). The possibility of reducing the risks of development of hepatocellular carcinoma, cirrhosis, and chronic active hepatitis from perinatal transmission of hepatitis B through prenatal screening and active and passive immunization of the infant is substantial (Hepatitis B vaccination, 2002; Kao and Chen, 2002). The implications of maternal vaccination during pregnancy for preterm infants have not been studied.

The anthrax attacks of September 2001 have raised the possibility of the need for pre-exposure or post-exposure immunization programs that may include pregnant women. Currently available data suggest that the anthrax vaccine licensed since 1970 in the United States has no effect on pregnancy and does not increase adverse birth outcomes (Inglesby et al, 2002; Wiesen and Littell, 2002). A second infectious agent that might be used in a bioterrorist attack is variola virus (smallpox). Although eradicated in 1977, this virus remains a concern owing to its lethality, especially in pregnancy (Enserink, 2002; Suarez and Hankins, 2002). Pregnancy is a contraindication to smallpox immunization (Suarez and Hankins, 2002). However, if an intentional release of smallpox virus should occur, pregnant women should be immunized because of their high risk of mortality if unprotected (Suarez and Hankins, 2002).

### Infant Immunization

Advances in understanding of the developmental regulation of immunity have suggested that immunization during the neonatal period offers important advantages (Lawton, 1994). The recommendations of the American Academy of Pediatrics for immunization of infants are given in Table 35-3 (Committee on Infectious Diseases et al, 2002; Recommended childhood immunization schedule, 2002). Immunization against *H. influenzae* type b and pneumococci should be considered for infants who are discharged from intensive care nurseries at or after 2 months of age. For the preterm infant, although different clinical approaches are used by practitioners, including reducing the dosage of immunogen, postponing the first immunization until a corrected age of 2 months, and waiting for the infant to achieve an arbitrary body weight (e.g., 10 pounds), the American Academy of Pediatrics recommends administering full-dose diphtheria, tetanus, and pertussis (DTP) immunization beginning at 2 months of age (Atkinson et al, 2002). These recommendations, that no correction needs to be made for prematurity when routine immunization is initiated in preterm infants, have been supported by longitudinal evaluations of serum antibody response in preterm infants (Bernbaum et al, 1989; Conway et al, 1993; D'Angio, 1999; Siegrist, 2001).

The Committee on Infectious Diseases of the American Academy of Pediatrics and the Advisory Committee on Immunization Practices of the U.S. Public Health Service have recommended universal immunization of infants to reduce hepatitis B-associated morbidities (e.g., chronic hepatitis, hepatocellular carcinoma, cirrhosis) (Atkinson et al, 2002; Committee on Infectious Diseases et al, 2002).

All infants born to women who test negative for hepatitis B surface antigen (HBsAg) should begin a hepatitis immunization schedule in the newborn period or within the first 2 months of life (Committee on Infectious Diseases et al, 2002). In 1999, the U.S. Agency for Toxic Substances and Disease Registry raised concern about the possibility that administration of thimerosal-containing vaccines, including the hepatitis B vaccines, might lead to mercury exposure that exceeded federal guidelines (Clark et al, 2001). This concern prompted the American Academy of Pediatrics and the U.S. Public Health Service to recommend jointly that hepatitis B immunization be postponed until 2 months of age in low-risk infants. By late 1999, the availability of thimerosal-free hepatitis vaccine was sufficient for the resumption of the immunization of all newborn infants in the United States.

All infants, regardless of gestational age at the time of birth, whose mothers test positive for HBsAg should receive passive immunization within 12 hours of birth and active immunization within 7 days of birth and then at 1 and 6 months of age. Special efforts should be made to complete the hepatitis B vaccination schedule within 6 to 9 months in populations of infants with high rates of childhood hepatitis B infection (Peter, 1994). For premature infants who weigh less than 2000 g at birth and are born to HBsAg-negative women, vaccination may be delayed until just before discharge or until 2 months of age, when other immunizations are given. These infants do not need routine serologic testing for anti-HBsAg after the third dose of vaccine. The infant whose mother tests negative for HBsAg but has received active or passive immunization during pregnancy because of exposure to hepatitis B should receive no treatment as long as the mother was HBsAg-negative at the time of birth.

Yeast-derived recombinant hepatitis B vaccines have excellent safety records, induce minimum adverse reactions, and are highly immunogenic (Greenberg, 1993). The recommended dose of hepatitis B vaccine for infants varies by manufacturer and the HBsAg status of the mother: For infants of HBsAg-negative mothers, 5.0 µg of Recombivax HB or 10.0 µg of Engerix-B are recommended; for infants of HBsAg-positive mothers, 5.0 µg of Recombivax HB or 10.0 µg of Engerix-B are recommended. The need for more than two booster doses and the feasibility of combining antigens in multivalent vaccines are currently under study. These guidelines for hepatitis immunization of infants have been developed for implementation for term and preterm infants. However, the extremely preterm infant whose mother is HBsAg-positive, a population seen with growing frequency owing to the coincidence of intravenous drug abuse and carriage of HBsAg, has not been studied.

Short-term and long-term neonatal immunologic protection after fetal exposure to maternally administered vaccines against anthrax or smallpox, the mass use of which might be prompted by a bioterrorist attack, has not been studied. Similarly, guidelines for neonatal immunization against these agents are not currently available. Before the eradication of smallpox, smallpox vaccine was routinely administered to older infants and children (Centers for Disease Control and Prevention, 2001). No data or experience are available on immunization of newborn infants

with anthrax vaccine (Advisory Committee on Immunization Practices, 2000). For post-exposure prophylaxis in newborn infants, both chemotherapy (amoxicillin, ciprofloxacin, or doxycycline) and immunization should be considered (Atkinson et al, 2002). Clinicians faced with decisions concerning immunization strategies for newborn infants after a bioterrorist attack should consult the web site for the Centers of Disease Control and Prevention ([www.cdc.gov](http://www.cdc.gov)).

# Identification, Evaluation, and Care of the Human Immunodeficiency Virus–Exposed Neonate

Karen P. Beckerman

## EARLY HISTORY OF THE AIDS PANDEMIC

In the last months of 1980, previously healthy young men began to present for care with complaints of chronic illness without apparent etiology. Their complaints included fever, malaise, weight loss, lymphadenopathy, candidiasis, abdominal pain, headaches, and new-onset seizures. By late 1981, reports of an unprecedented clinical syndrome appeared in the U.S. Public Health Service's *Morbidity and Mortality Weekly Report* and several prominent medical journals. Two of these focused on nine young men who had been admitted to tertiary referral centers with *Pneumocystis carinii* pneumonia. At the time of publication, five of the nine men had died and the other four were severely and chronically ill. It quickly became clear that the fatality rate for this mysterious syndrome would approach 100%.

During these very early years of the epidemic, it appeared as if the syndrome could be defined by the groups who first presented for medical attention. Thus, "Gay Cancer" and "GRID" (gay-related immunodeficiency) were the names the world initially heard in connection with the human immunodeficiency (HIV). All too soon, however, the syndrome was identified in others, including intravenous drug users, transfusion recipients, and hemophiliacs. Inexplicably, Haitian immigrants started to present with identical symptoms and findings yet had no behavioral risks in common with other groups. Even so, the concepts of being either "at risk" or "not at risk" for the syndrome of opportunistic infections and immunodeficiency were universally adopted.

Dr. Peter Piot, Director of UNAIDS, has noted, "Denial has been a characteristic of this epidemic at all levels." In 1982, the first reports of infants with noncongenital (i.e., *acquired*) immunodeficiency were rejected, first by national meetings and then by prominent journals, with comments that these children certainly did not have "the homosexuals' disease" (Shilts, 2000). In 1983, Dr. Piot led a team cosponsored by the Centers for Disease Control and Prevention (CDC) and the National Institutes of Health (NIH) that studied an illness that was filling hospitals in Kinshasa, Zaire (now Congo), with equal numbers of previously healthy young men and women who were

emaciated and dying. The team identified 36 cases of acquired immunodeficiency syndrome (AIDS). The report of their findings—that an identical immunodeficiency syndrome was heterosexually spread in Africa, and therefore that *everyone in the world* was at risk (Gellman, 2000)—was rejected for publication 12 times.

From our perspective two decades later, it is difficult to grasp the fear that accompanied the first scientific recognition of the spread of HIV type 1 (HIV-1) infection. In the United States and Europe, identification of at-risk groups helped investigators define transmission patterns, identify and isolate the etiologic agent, and develop diagnostic assays within several years of the first reports. However, the concept of "risk" also served to foster worldwide ignorance of what we now know to be a virtually universal risk of infection.

Recognition of this history is important precisely because most of society's attitudes and values that fostered the global spread of HIV/AIDS in the 1980s and 1990s persist today. Infected women are still routinely asked, by otherwise well-meaning caregivers, "Are you an intravenous drug user, a prostitute or both?" Questionnaires given to women entering prenatal care continue to inquire about HIV risk factors, even when we know that any pregnant woman has had unprotected exposure to semen and is at risk of infection. To this day, treatment, transmission prevention, and research among those "not at risk" (a euphemism for individuals who are not gay, do not have multiple sexual partners, are not hemophiliac, and do not use injection drugs) have been neglected. In parts of the developed world, where vertical (mother-to-child) transmission rates among treated pregnant women are less than 1% to 2%, infected infants continue to be born to "low-risk" mothers who were never tested during pregnancy. In the United States, hundreds of new cases of pediatric HIV/AIDS are reported annually. Tragically, many infected infants are often diagnosed only when they present with advanced AIDS. Even though some states mandate HIV screening for all infants before discharge from the newborn nursery, many do not. Determination of all infants' HIV exposure status will remain a major challenge in every newborn nursery for a long time to come. Excellent standard references on the management of pediatric HIV-1 infection are readily available, including comprehensive reviews (Khoury and Kovacs, 2001) and U.S. Public Health Service Guidelines, which are frequently updated and readily available on the Internet (Centers for Disease Control and Prevention [CDC], 2003).

## PATHOGENESIS OF HIV DISEASE

### Transmission of the Virus

Transmission of HIV requires the exchange of bodily fluids. Numerous studies have demonstrated that casual household or community contacts are not associated with transmission or acquisition of HIV/AIDS. The three general mechanisms by which the virus can be passed from one individual to another are sexual, parenteral, and perinatal.

Different types of exposure to infection are associated with different risks of infection (Royce et al, 1997). One sexual transmission occurs for every 100 to 1000 exposures.

Male-to-female transmission risk is about ten times greater than female-to-male transmission risk. Needlestick injury from an infected source carries a transmission risk between 0.5% and 1%, with the risk from needle sharing significantly greater. The risk of transmission through blood transfusion is greater than 90%. Without antiretroviral prophylaxis or maternal treatment, risk of mother-to-child transmission is about 25%.

### Sexual Transmission

Sexual transmission is the dominant mode of transmission of HIV worldwide. Increased rates of sexual transmission are associated with other sexually transmitted diseases, particularly those producing genital ulcers, such as genital herpes and syphilis. Inflammatory conditions of the male or female genital tract result in both higher HIV viral loads in genital secretions and decreased integrity of genital mucosal defenses. Chronic immune activation due to other infectious diseases, such as tuberculosis and intestinal parasitic diseases, may enhance susceptibility to infection by the virus and are also associated with greater HIV disease activity in persons already living with the virus.

Nonhuman primate studies of the closely related simian immunodeficiency virus (SIV) have revealed a dynamic picture of early events in HIV transmission. Spira and colleagues (1998) reported that vaginal inoculation of adult rhesus macaques was followed by infection of dendritic cells in the lamina propria of the cervicovaginal mucosa. Within 2 days, virus could be identified in draining internal iliac lymph nodes. By day 5, virus could be detected in the blood.

### Parenteral Transmission

Parenteral transmission is the dominant route of transmission in many regions. Eastern Europe and Central Asia have the world's fastest-growing epidemic, and 90% of 1.2 million infections have been officially attributed to injection drug use. The immediate site of viral replication after intravenous exposure is not well established, but it would stand to reason that after injection, the virus would have immediate access to tissues of the central immune compartment.

Transmission by injection drug use also fuels transmission by sexual and mother-to-child routes, because the virus spreads through populations of men and women of reproductive age.

### Mother-to-Child Transmission

Mother-to-child-transmission is incompletely understood. Transfer of virus from maternal to fetal or neonatal tissues is thought to occur during one of three discrete periods—antepartum (before the onset of labor), peripartum (during labor and delivery), and breast-feeding. Studies of early viral dynamics in infected neonates suggest that the peripartum period is the time of highest risk (Mofenson, 1997).

We do not know how the virus travels from mother to baby before delivery. Many investigators postulate that virus from maternal genital secretions access the fetus via mucosal routes. Others have studied transplacental routes

of transmission. Regardless, no route of transmission except for blood transfusion is as successful as perinatal transmission (Royce et al, 1997).

After delivery, transmission through breast milk is responsible for up to 16% of transmissions to babies who were not perinatally infected (Nduati et al, 2000a). Neonatal primates that were inoculated orally required doses 10 times higher than those in vaginal and rectal inoculations to establish infection but, once infected, had demonstrable circulating virus within 1 week. Interestingly, breast milk from infected mothers contains HIV-specific cytolytic CD8<sup>+</sup> T cells, which may partially protect nursing infants from transmission of HIV through breast milk (Sabbaj et al, 2002).

## HIV and Immune Destruction

### Life Cycle

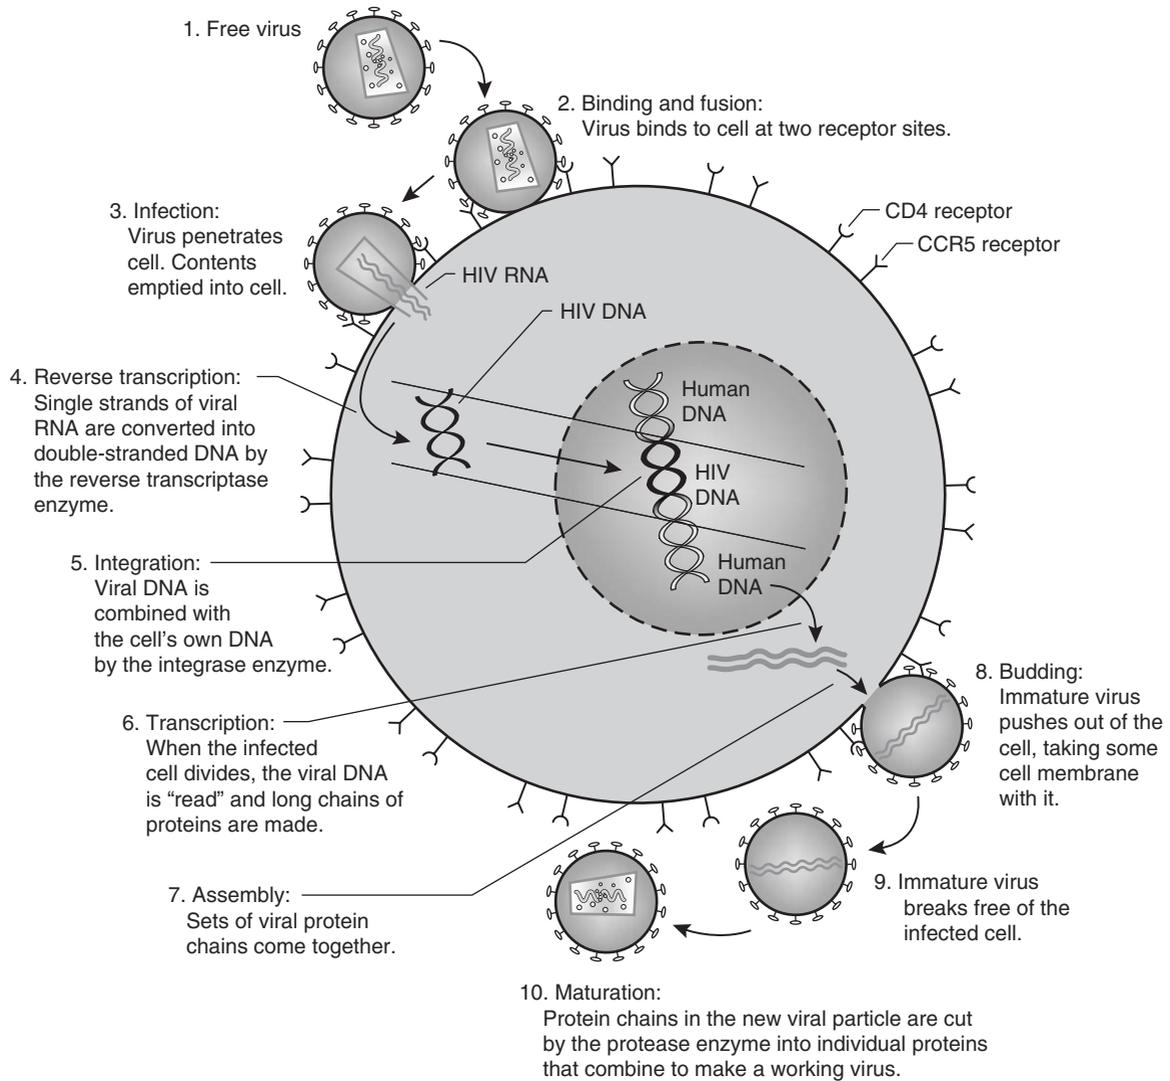

The life cycle of HIV-1 is summarized in Figure 36–1; details are also available on line in an animated format (HIV Life Cycle, 2002). Like these cartoons, most models of HIV-1 infection are based on experimental data derived from the infection of cell culture or animals with high titer free virus. We do not know whether transmission of HIV-1 can occur in vivo without critical cell-to-cell interactions. Regardless, whether cell-associated or free, HIV-1 depends on host cell surface receptor expression for cell entry. Once in a cell, the virus requires host cytoplasmic pathways for its journey to and from the host nucleus, where it utilizes the infected cell's transcriptional capacity for production of viral proteins. Immature viral particles bud out from the host cell, and the creation of infectious virions finally depends on the action of viral protease.

### Pathogenesis of Immune Destruction

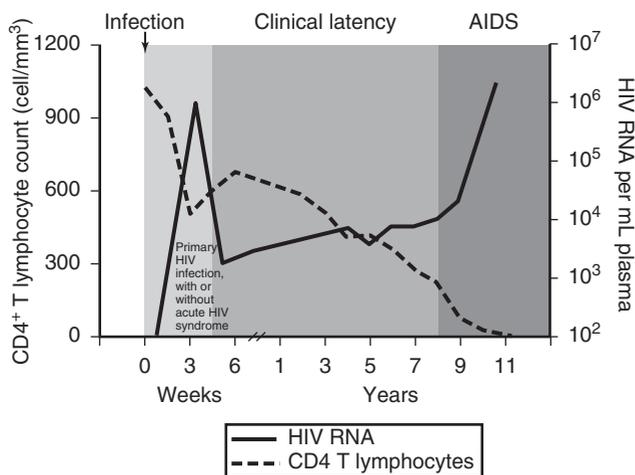

HIV-1 infection appears to have three phases (Fig. 36–2). *Primary infection* is characterized by acute symptoms of viral illness and extremely high plasma viremia. With the onset of an antiviral immune response, signaled by the appearance of anti-HIV antibodies and cytotoxic T cells, plasma viremia falls by 2 or more logs, and a so-called *latent phase* begins; levels of virus and infected cells are detected in the peripheral circulation at an individual set point (Pantaleo et al, 1993b). Without antiretroviral therapy, plasma viremia slowly increases, and the latent phase ends after about 10 years with a rapid increase in circulating HIV-1 and a collapse of immune function (fully-expressed AIDS).

Our understanding of HIV disease was revolutionized in the early 1990s, when potent antiretrovirals, quantitative assays of viral replication based on the polymerase chain reaction (PCR), and in situ PCR techniques became available for study of HIV-1 cellular kinetics and viral dynamics in lymphoid tissues (Embretson et al, 1993; Pantaleo et al, 1993a). These techniques have demonstrated that HIV-1 infection is characterized by massive HIV-1 production and immune cell turnover during all phases of the disease, long before immunodeficiency sets in.

Many mechanisms of HIV-1-induced immunodeficiency have been described. Broadly speaking, they include

**FIGURE 36-1.** Life cycle of the human immunodeficiency virus.

**FIGURE 36-2.** Three phases of HIV disease: Primary infection characterized by high viral load and normal but falling CD4 count. Clinical latency with stable viral load at an individual's set point and gradually falling CD4 count. AIDS or symptomatic HIV disease, with high viral load, low CD4 count and immunodeficiency.

direct killing of infected cells by the virus or the host, induction of programmed cell death (*apoptosis*), induction of abnormal cytokine production by infected cells, disruption of the architecture of lymphoid tissues, disruption of hematopoiesis and lymphoid differentiation, and evolution or diversification of the virus during infection to variants with greater virulence (Coffin, 1995). Unifying all such theories is the observation that deterioration of immune function is driven by constantly repeated cycles of massive viral replication (more than 10<sup>10</sup> virions/day) (Perelson et al, 1996) and immune cell turnover of more than 10<sup>9</sup> cells/day.

### Immune Activation

Immune activation plays a key role in the pathogenesis of HIV-1 disease (Lawn et al, 2001). Commonly, immune activation due to co-infection (mycobacterial, parasitic, viral, or bacterial) renders infected individuals more infectious and may make the uninfected more susceptible to transmission. Although interactions between activation of the immune system and progression of HIV disease are

complex, the inflammatory response clearly promotes cell-to-cell transmission of HIV-1. In fact, at least one clinical study has suggested that chorioamnionitis may be associated with higher rates of vertical transmission (Mofensen et al, 1999).

China and India are experiencing serious localized epidemics affecting 5 million people. At current rates of spread, 45 million more people (in addition to the 42 million infected today) will have acquired the virus by 2010 (AIDS Epidemic Update, 2002).

**MATERNAL-CHILD HEALTH AND HIV/AIDS**

**The Global Pandemic**

The HIV/AIDS pandemic has affected the health of women and children unlike any previous infectious scourge. Soon it will bypass the Black Death as the greatest cause of mortality in history. Typically, people are infected in their youth, during their prime productive and reproductive years. After acute infection, time to death ranges from 9 to 11 years (see Fig. 36–2). Those who die represent an irreplaceable loss to their families, communities, and society. They leave in their wake unfarmed land, untaught students, hospitals without doctors and nurses, depleted armies, civil services, and police forces, and, of course, orphans. The scope of the problem is difficult to grasp. Within the next few years, however, if the pandemic continues unchecked, 25% of children younger than 15 years in the most devastated regions will be orphans, numbering 44 million by the year 2010. By 2020, teenagers will outnumber adults in Sub-Saharan Africa.

The infection has been reported in all parts of the world (Fig. 36–3). Seventy percent of those living with HIV/AIDS occupy Sub-Saharan Africa. Eighty-one percent of infected women are African. More than 95% of infected children are African. No other region has reported the high seroprevalence seen in Africa; however, rapid and even explosive growth of the pandemic has been reported in Eastern Europe, the Baltic States, the Russian Federation, and several Central Asian Republics.

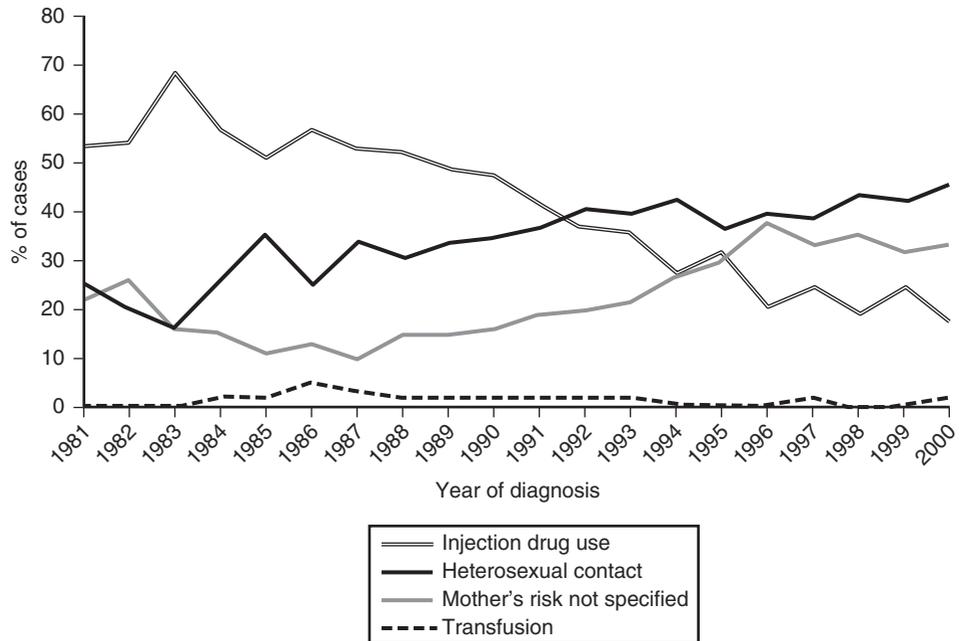

**Women**

HIV/AIDS spares no one, but it has become increasingly apparent that women are at special risk of infection. In 2002, 58% of people living with HIV in Southern Africa were women. Among residents of this region 15 to 19 years old, HIV seroprevalence is twice as high in young women as in young men. Women are likely to become infected at a significantly earlier age than men, for both biologic and demographic reasons—they become sexually active and marry at younger ages, and because of their position in many societies, they are more often unable to negotiate safer sex with their sexual partners. On a per exposure basis, women are ten times more likely than men to become infected (AIDS Epidemic Update, 2002).

**Children**

HIV/AIDS threatens the health of children from multiple perspectives (see Fig. 36–3). The devastation of the epidemic undermines the health and safety of all members of a society, especially the most vulnerable. Older children are at great risk of becoming sexually infected. Indeed, given current trends, 50% of all Sub-Saharan 15-year-olds will someday themselves become infected with HIV. All babies of HIV-infected mothers face a 20% risk of dying before their second birthday, whether they themselves are infected or not (Nduati et al, 2000a). Less than half of the babies who are infected will survive to age 3 years.

**FIGURE 36-3.** Centers for Disease Control and Prevention analysis of mother’s exposure category, by year of diagnosis for perinatally acquired AIDS, 1981 to 2000, United States. Note that most women with “risk not specified” probably acquired HIV by heterosexual contact, raising that category to about 70% of total in 2000.

## Mothers

Our understanding of the impact of infectious disease on maternal health is incomplete. Before the introduction of antibiotics, pneumonia, tuberculosis, and influenza were associated with markedly higher mortality during pregnancy. Indeed, before the 1950s, active tuberculosis was considered a justifiable reason for abortion. Today, effective antibiotic therapies and supportive treatment have obscured any effects that these infections may have on maternal health as well as any effect that pregnancy and lactation may have on the course of infection.

A similar situation exists in our understanding of HIV disease and maternal health. Several comprehensive studies conducted both before and after the availability of effective antiretroviral therapies have shown that pregnancy does not alter the course of HIV disease in resource-rich settings. The same may not be true for resource-poor regions. Women in these latter areas lack access to not only effective antiretroviral treatment but also to prophylaxis and treatments for opportunistic infections and endemic scourges such as tuberculosis, parasitic disease diseases, and malaria, not to mention adequate sewage and clean water.

Two studies have appeared suggesting that in resource-poor settings, HIV-infected women are at markedly higher risk of death after the birth of a child. A multivariate analysis of 4000 pregnant Malawi women found that 3% of pregnant women infected with HIV died before their babies' first birthdays, vs. 0.3% of uninfected pregnant women (McDermott et al, 1996). Nduati and colleagues (2000b), at Kenyatta Hospital in Nairobi, noted that breast-feeding by HIV-infected breast-feeding women had an 11% risk of death by 2 years after delivery. Both studies noted markedly higher death rates among the infants of mothers who died, regardless of transmission status.

## HIV/AIDS in High-Income Countries

Only 1.6 million people, or 4% of the total global population infected with HIV, are living in high-income countries (AIDS Epidemic Update, 2002). In these resource-rich regions, routes of transmission were first identified among homosexuals and injection drug users. Rates of heterosexual transmission have risen every year (see Fig. 36–3), and the virus has spread disproportionately among marginalized populations over the last decade. In the United States, African-Americans and Latinos account for 62% of new infections yet make up only 20% of the population. This trend is even more marked among U.S. women: In 2001, 63% of newly diagnosed women were black, and 13% were Hispanic (CDC, 2001a). Forty percent of new AIDS diagnoses during 1999 occurred among residents of the poorest U.S. counties, with the Southeast disproportionately represented (Karon et al, 2001).

## Impact of Antiretroviral Agents

The introduction of potent antiretroviral therapies in the mid-1990s markedly reduced deaths due to AIDS in most regions of the developed world. Still, 23,000 HIV-related deaths were reported in these countries in 2002. In the

United States, HIV/AIDS remains the leading cause of death for African-American men between the ages of 25 and 44 years and the third most common cause of death among Hispanic men of the same age.

Potent antiretroviral therapies not only have reversed AIDS mortality trends in the developed world (Fig. 36–4A); they have also completely altered patterns of transmission of HIV from mothers to children (Fig. 36–4B). Almost 10 years ago, the astonishing results of the Pediatric AIDS Clinical Trial Group (PACTG) Study 076 protocol were announced (Connor et al, 1994). This prospective, placebo-controlled, randomized trial demonstrated that zidovudine prophylaxis during pregnancy, delivery, and early infancy reduced the rate of vertical HIV transmission from 25% to 8%. It became evident that the efficacy of the strategy was even greater in the field, where experience in New York State and other areas soon showed that zidovudine prophylaxis was consistently associated with transmission risk of 5%. Less than 2 years later, additional antiretroviral agents became available for actual treatment of HIV, disease and it became possible to measure HIV disease activity via plasma HIV-1 RNA assays. Soon thereafter, clinicians observed that women who could achieve control of their disease did not transmit the virus to their offspring and that potent therapeutic combinations were associated with low transmission risk even when maternal HIV replication was not completely suppressed.

In contrast, antiretrovirals have not yet had a demonstrable effect on the incidence or mortality of HIV and AIDS in resource-poor regions. Sub-Saharan Africa, home to 29.4 million people living with HIV, lost 2.4 million citizens to death from HIV in the last year and will experience 3.5 million new infections in the coming year (AIDS Epidemic Update, 2003).

## Treatment of Maternal HIV-1 Infection

Nowhere in the epidemic has the impact of combination antiretroviral therapy and opportunistic infection prophylaxis been more far-reaching than in maternal-child health in resource-rich regions. Control of maternal HIV disease both improved maternal health and survival and virtually eliminated the problem of AIDS orphans in the West. Moreover, aggressive antiretroviral therapy during pregnancy appears to offer almost complete protection from perinatal HIV-1 infection to the fetus and neonate.

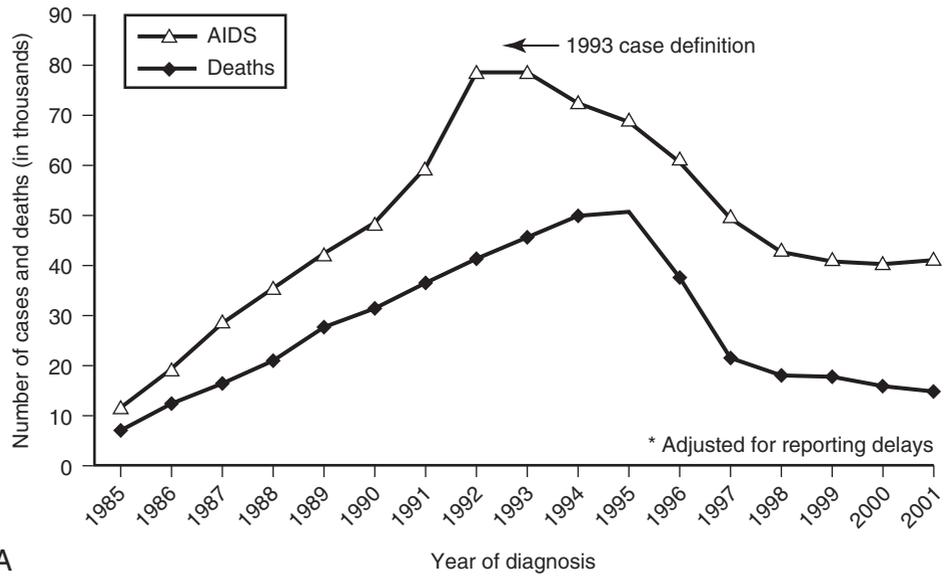

U.S. Public Health Service Guidelines for the management of HIV disease during pregnancy, antiretroviral therapy for adults and adolescents, and for opportunistic infection prophylaxis have been updated and are an excellent resource that all practitioners should consult. They are easily accessed as living documents on the CDC Web site ([www.AIDSinfo.nih.gov/guidelines/](http://www.AIDSinfo.nih.gov/guidelines/)).

## General Principles

General principles of HIV care during pregnancy have been articulated elsewhere and are summarized in Table 36–1.

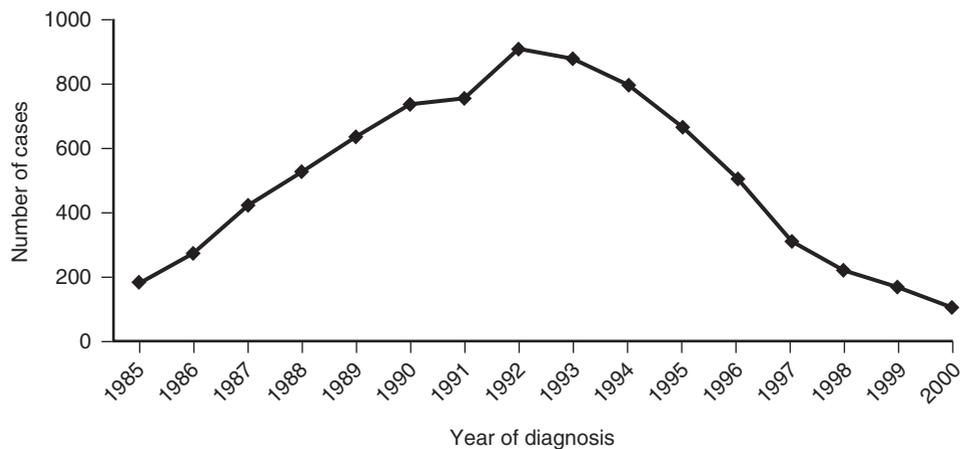

Women diagnosed with HIV infection during pregnancy often present in crisis. As with any patient, the basics of safety, shelter, and nutrition must be attended to

ESTIMATED INCIDENCE OF AIDS AND DEATHS OF ADULTS AND ADOLESCENTS WITH AIDS\*, 1985–2001, UNITED STATES

- Self-determination of reproductive choice and HIV therapy
- Nondirective, supportive education and counseling
- Intensive monitoring of HIV disease activity, particularly as term approaches
- Prophylaxis for opportunistic infections
- Aggressive use of antiretrovirals to suppress maternal HIV replication
- Protection of mothers from mono- and dual-drug therapies likely to induce antiretroviral resistance
- Informed maternal choice regarding timing and route of delivery

first. First assessment of a newly diagnosed woman must include definitive assessment of other family members, especially her other children. For those older than 12 to 18 months, HIV antibody testing may be enough. For those younger than 1 year, more involved virologic testing may be required (Table 36-2). The first few clinic visits should be directed at education and counseling, with clinical focus on assessment of the stage of maternal disease and, most important, prophylaxis or detection and treatment of opportunistic infection.

**Prophylaxis Against Opportunistic Infection**

Opportunistic infection prophylaxis during pregnancy follows general adult guidelines. Individuals with CD4 T-cell

**TABLE 36-2**

**Diagnostic Testing Schedule for Infants Exposed to Human Immunodeficiency Virus Type 1**

Laboratory Assay	Tube or Other Media Needed	Laboratory Instructions	Birth (1st 48 hrs of life)	Age 2 wks	Age 1 mo (4-6 wks)	Age 3 mos (12-14 wks)	Age 6 mos (24-28 wks)	Age 1 yr (50-54 wks)	Age 1 1/2 yrs (76-80 wks)	Until Sero-reversion
HIV-1 DNA PCR	Yellow-top (= acid citrate dextrose)	Room temperature	✓	✓ May be considered for very-high-risk infants	✓	✓	✓	✓	✓	✓
HIV-1 RNA PCR	Lavender-top (= EDTA)	Send when repeating test because of positive DNA PCR result or when DNA PCR is not available See text and Table 36-1

Ab, antibody; ALT, alanine transferase; AST, aspartate transaminase; CBC, complete blood count; EDTA, ethylenediaminetetraacetic acid; HCV, hepatitis C virus; HIV, human immunodeficiency virus; HIV-1, HIV type 1; PCR, polymerase chain reaction.  
From Bay Area Perinatal AIDS Center, Departments of Obstetrics, Gynecology and Reproductive Sciences and Pediatrics, July 1, 2001.

counts lower than 200 cells/mm<sup>3</sup> should be started on *P. carinii* prophylaxis regardless of reproductive status. Trimethoprim-sulfamethoxazole (TMP-SMX) is the agent of choice. Theoretically, there is a risk of neonatal anemia when this agent is administered close to term, but the maternal benefits of prophylaxis far outweigh any theoretical fetal risk. Women with CD4 T-cell counts lower than 50 cells/mm<sup>3</sup> should receive *Mycobacterium avium* pneumonia prophylaxis with azithromycin; TMP-SMX also offers toxoplasmosis prophylaxis in this setting. Women who have had an opportunistic infection should receive appropriate prophylaxis regardless of CD4 count.

Many authorities now recommend that patients whose CD4 T-cell counts have been restored to more than 350 cells/mm<sup>3</sup> may be offered a trial of stopping opportunistic infection prophylaxis. Although some pregnant women with established HIV infection may be interested in this strategy, I have advised against stopping prophylaxis during pregnancy. There is ample time after pregnancy to consider such options.

### Antiretroviral Therapy

Recommendations regarding the initiation of antiretroviral therapy for adults have changed significantly in the past few years (Guidelines, 2002). From earlier recommendations to “hit early, hit hard” in order to avoid immunodeficiency and other complications of HIV disease, guidelines have moved to stress the advantages of delaying therapy as long as possible in order to avoid, or at least postpone, the complications of antiretroviral therapy. These complications are summarized in Table 36–3. Of greatest concern are metabolic complications and the induction of antiretroviral resistance.

All individuals with symptomatic HIV infection should be counseled about the lifesaving nature of combination antiretroviral therapy. Therapy should be initiated when patients believe they are ready. Guidelines are less uniform for individuals with asymptomatic HIV infection. Generally, therapy should be started for anyone with a CD4 T-cell count less than 350 cells/mm<sup>3</sup> or a viral load

**TABLE 36–3**

#### Antiretrovirals: Mechanisms of Action with Selected Toxic Effects and Complications

Agents	Mechanism of Action	Selected Toxic Effects/Complications
Nucleoside RT inhibitors (NRTIs): Zidovudine Lamivudine Stavudine Abacavir Tenofovir	Phosphorylated intracellularly to the 5'-triphosphate metabolite that inhibits viral RT by competing with thymidine triphosphate for incorporation into viral DNA, then prematurely terminating DNA synthesis by preventing further 5' to 3' phosphodiester linkages	Bone marrow toxicity resulting in maternal and neonatal anemia Most pronounced with zidovudine Lactic acidosis and hepatomegaly/steatosis are most strongly associated with stavudine and stavudine/didanosine Severe hypersensitivity in 3% of patients
Non-nucleoside RT inhibitors (NNRTIs): Nevirapine Delavirdine Efavirenz	Specific noncompetitive inhibitors of viral RT Bind directly to a hydrophobic cavity near the active site of RT and cause a conformational change in the enzyme	Cross-class drug resistance emerges rapidly and uniformly when administered as single agent Rash is common and more frequent in women Hepatotoxicity, hepatitis; may be severe or fatal, especially with nevirapine Neural tube defects in non-human primates found in preclinical studies of efavirenz (see text) CNS or psychiatric symptoms with efavirenz.
Protease inhibitors (PI): Indinavir Ritonavir Nelfinavir Lopinavir	Competitive inhibitors of HIV protease, an enzyme required for the formation of infectious virus PIs block virus maturation and cause the formation of immature, noninfectious virions, limiting further infectious spread Certain PIs given in combination with ritonavir exhibit markedly enhanced pharmacokinetics	Hyperbilirubinemia Lipid abnormalities with increased triglycerides and LDL Glucose intolerance, type 2 diabetes Increase in gestational diabetes not reported Body fat composition and distribution abnormalities <sup>†</sup>
Fusion inhibitors: Enfuvirtide	Block HIV from entering human cells by blocking virus–cell membrane fusion	Requires subcutaneous injection <sup>†</sup> Bacterial pneumonia, severe allergic reaction, injection site reaction, and infection

CNS, central nervous system; HIV, human immunodeficiency virus; LDL, low-density lipoprotein; RT, reverse transcriptase (also known as viral RNA-dependent DNA polymerase)

<sup>†</sup>Also reported with non-PI regimens.

greater than 55,000 copies/mL. Considerable evidence exists to supporting a lower viral load cutoff for women, 35,000 copies/mL (Considerations, 2002).

International experience to date has consistently shown that the most powerful predictor of transmission risk is maternal viral load (Dorenbaum et al, 2002; Garcia et al, 1999) and that treatment with triple-antiretroviral combinations during pregnancy is associated with transmission risk of 1% to 2% or less (Ioannidis et al, 2000). HIV-infected pregnant women should be offered a combination of three or more antiretroviral agents regardless of the stage of their infection. For those with symptomatic infection or CD4 T cell counts less than 350 cells/mm<sup>3</sup>, treatment should be initiated or continued as it would for anyone not pregnant, with the primary aim of achieving a durable suppression of maternal viral replication in order to preserve or restore maternal health. For women with asymptomatic infection, and CD4 T cell counts greater than 350 cells/mm<sup>3</sup>, and viral loads less than 35,000 copies/mL, antiretrovirals are still indicated for the prevention of transmission of HIV to the fetus; therapy can safely be stopped after pregnancy is over as long as mother's health continues to be monitored.

### Antiretroviral Agents

#### Currently Available HIV Therapies

Four classes of antiretroviral agents are now available for treating HIV infection (see Table 36–3). First-line combinations are made up of two nucleoside transcriptase inhibitors (NRTIs) and either a protease inhibitor (PI) or a non-nucleoside reverse transcriptase inhibitor (NNRTI). The fusion inhibitor enfurvidine is generally reserved for patients who have received numerous antiretrovirals and have experienced virologic breakthrough using multiple different potent combinations.

All classes of antiretrovirals have serious side effects, advantages, and disadvantages. Determination of optimal combinations must factor in patient preference, other medications, stage of HIV disease, ease of administration, and reproductive plans. Protease inhibitors can now be taken either twice daily alone (as with nelfinavir) or along with small doses of ritonavir (as with indinavir and lopinavir), which markedly enhances pharmacokinetics. Efavirenz is a highly potent, once-daily NNRTI that has become very popular. Unfortunately, preclinical evaluation of efavirenz in nonhuman primates demonstrated serious neural tube defects in 2 of 20 exposed fetuses. A prospective registry of the use of antiretroviral agents in pregnancy has received no reports of neural tube defects in 84 cases reported with first-trimester efavirenz exposure. Still, the use of efavirenz during the first trimester remains of great concern.

#### Teratogenicity

Teratogenicity of antiretrovirals has been of great concern since they first became available. Teratogenicity of these agents is being closely monitored by industry and the U.S. Food and Drug Administration (FDA). The Antiretroviral

Pregnancy Registry has collected more than 4000 voluntary, prospective reports of antiretroviral exposure during pregnancy (Committee APRS, 2003). Overall, the prevalence of birth defects has been 2.5 per 100 live births. Among these exposures, 1242 occurred during the first trimester, and the prevalence of birth defects was 2.8 per 100 live births. These proportions compare favorably with the CDC's population-based birth defects surveillance system, in which total prevalence of birth defects identified among births from 1991 through 1995 was 3.1 per 100 live births (Table 36–4).

The registry now has sufficient enrollment to detect at least a twofold increase in risk of overall birth defects and of defects of cardiovascular and genitourinary systems for the commonly used antiretrovirals listed in Table 36–4. Retrospective reports are also collected by the Registry. No pattern of defects, isolated or syndromic, has been found in the evaluation of these reports.

**Efavirenz.** One NNRTI, efavirenz, has been of special concern ever since results of a developmental toxicity study of cynomolgus monkeys were released. Pregnant monkeys received efavirenz and achieved plasma levels equivalent to therapeutic human dosages. Three of 20 efavirenz-treated fetuses had birth defects (one with anencephaly and unilateral anophthalmia, another with microphthalmia, and a third with cleft palate). There were no birth defects in the 20 controls. The Registry has insufficient numbers of reports of infants exposed to efavirenz during organogenesis (i.e., before 12 weeks of gestation) to allow draw conclusions to be drawn regarding human teratogenicity of this agent. Of 118 first-trimester exposures, 4 infants (3.4%) had birth defects (polydactyly, hydronephrosis, bilateral hip dislocation, and urinary obstruction), but no prospective reports of neural tube defects have been received by the registry. Women anticipating pregnancy should be advised not to take efavirenz. When first-trimester exposure inadvertently occurs, women should be offered early ultrasonography and maternal serum screening for neural tube and other defects.

**TABLE 36–4**

#### Summary of Birth Defect Rates Following First-Trimester Exposure to Frequently Used Antiretrovirals from the Antiretroviral Pregnancy Registry

Regimen	Rate (No. Defects/ No. Live Births)	Prevalence (95% Confidence Limits)
Lamivudine	28/940	3.0% (2.0, 4.3)
Stavudine	7/323	2.2% (0.9, 4.4)
Zidovudine	25/886	2.8% (1.8, 4.1)
Nelfinavir	10/343	2.9% (1.4, 5.3)
Nevirapine	5/248	2.0% (0.7, 4.7)
		3.1% (3.1, 3.2)
Committee APRS, 2003		

### ***Antiretrovirals and Neonatal Mitochondrial Dysfunction***

A study from France has described mitochondrial dysfunction in 8 (out of 1754) HIV-exposed, uninfected infants who were exposed to zidovudine or zidovudine-lamivudine in utero (Blanche et al, 1999). Two infants experienced progressive mitochondrial dysfunction and death; 6 others had various degrees of nonfatal illness, as diagnosed by screening for symptoms of mitochondrial dysfunction, such as seizures and other neurologic abnormalities, or laboratory evidence of mitochondrial dysfunction, such as persistent lactic acidosis, abnormal liver enzyme values, or abnormal nuclear magnetic resonance (NMR) findings.

Immediately after this report, U.S. investigators pooled all available data from the CDC and NIH. Of 23,000 children exposed in utero to zidovudine, lamivudine, or both, the investigators could identify no children with mitochondrial disease (MacIntosh, 1999).

### ***Antiretrovirals and Prematurity***

In 1998, data appeared from three Swiss cohorts reporting preterm delivery in 10 of 30 infants exposed to protease inhibitors in utero (Lorenzi et al, 1998). Multiple reports from the United States do not show a link between the use of protease inhibitors and prematurity. In fact, many caregivers have the impression that optimization of maternal health using protease inhibitor-based and non-protease inhibitor-based regimens enhances pregnancy outcome and birth weight.

### ***Virologic Breakthrough During Pregnancy***

Virologic breakthrough during pregnancy can occur both in antiretroviral-experienced women and in women who have just been diagnosed and started on therapy. Because plasma HIV-1 RNA levels are highly correlated with transmission risk, we measure viral loads at least monthly in most pregnant women. Transiently detectable viremia (or “blips”) in those whose virus has been consistently undetectable is probably of limited consequence for both maternal and fetal health.

By far, the most common reasons for virologic breakthrough are difficulties with tolerance of and adherence to medication regimens. Patients should be counseled in detail, and practical, supportive advice should be given to improve adherence. Pill boxes and other aids are extremely helpful. Up to half of HIV-infected pregnant women have not disclosed their infection to their sexual partner. Some women are marginally housed. Support in connection with such issues of daily living may significantly help adherence.

Therapeutic recommendations in the setting of virologic breakthrough vary significantly. While caregivers are addressing adherence, they can obtain resistance testing and carefully consider switching a patient's medications. If a woman is experiencing virologic breakthrough near term with very high ( $>10^4$  to  $10^5$  copies/mL) viral loads, there may not be time to await resistance testing results, and it

may be prudent to empirically (but thoughtfully) add or replace agents in order to achieve the maximum control possible around the time of delivery. Significantly, simply adding a single dose of the NNRTI nevirapine during labor to ongoing antiretroviral therapy did not decrease transmission rates and did induce NNRTI resistance among mothers with incomplete virologic control (Dorenbaum et al, 2002).

We do not know how virologic breakthrough in women receiving therapy may influence transmission rates. PACTG Study 367 has reported transmission rates of 1% among women on 3 or more medications at the time of delivery (Shapiro et al, 2000). The study has not yet included analysis of maternal plasma HIV-1 RNA among women on therapy. It may be that combination therapy is effective at preventing vertical transmission even when virologic control is not perfect. Generally, considerations of maternal health are the best guide to treatment decisions in this setting.

### ***Antiretroviral Resistance and Maternal-Child Health***

**Viral Dynamics and the Development of Resistance.** From our earliest laboratory and clinical work with antiretroviral agents, it has been clear that HIV-1 is capable of rapidly evolving drug resistance to medications designed to block its replication. Two general phenomena contribute to the virus's extraordinary success at overcoming barriers to its production, high rates of viral replication and high rates of genomic mutation (Coffin, 1995). Several billion  $CD4^+$  T cells are productively infected at any given time. More than a billion die and are replaced every day. Infected individuals produce on the order of  $10^{10}$  particles of HIV-1 per day. Mutation rates are high, because (1) insertion and deletion mutations are common with two RNA copies per virion and (2) RNA strand breaks can force template switching. Furthermore, the two polymerases involved in HIV-1 production, HIV-1 reverse transcriptase and cellular RNA polymerase, both lack proofreading activity.

Early clinical success of antiretroviral therapy was significantly hindered by the lack of long-term effectiveness of single antiretroviral agents. The recognition in the mid-1990s that combination therapy could be given not only to enhance potency of single-drug therapy but also to forestall the development of antiretroviral resistance (both by creating multiple blocks to viral replication and decreasing mutation rates by suppressing replication rates) led to the ongoing success of HIV treatment and reversal of AIDS mortality trends in many parts of the developed world (see Fig. 36-4A).

Despite the dramatic reduction of HIV-related morbidity and mortality in the developed world, antiretroviral resistance has been a widespread problem that has limited the efficacy of treatment (Yerly et al, 1999). Little and associates (2002) have documented transmission of resistant HIV-1 variants among recently infected, antiretrovirally naïve, predominantly male groups, the rate of which has risen dramatically to as high as 23%. These investigators also found the rate of multiple-

drug resistance to be more than 10%. Today, resistance poses a major threat to the management of antiretroviral therapy.

**Antiretroviral Resistance in Pregnant Women and Perinatally Infected Infants.** Data describing the prevalence of antiretroviral resistance among HIV-infected women of child-bearing age are limited, but it is reasonable to assume that women harbor resistant virus at rates similar to those for men.

Mother-to-child transmission of HIV-1 with high-level resistance to zidovudine was first reported in 1993 (Masquelier et al, 1993). Only low-level genotypic resistance was detected in samples from participants in the AIDS Clinical Trials Group Protocol 076 (ACTG 076) (all of whom had CD4 counts  $>200$  cells/mm<sup>3</sup>) and was not associated with transmission risk (Eastman et al, 1998). However, the Women and Infants Transmission Study Group found that 25% of maternal isolates had at least one zidovudine-associated resistance mutation and that the presence of resistance was independently associated with a fivefold greater risk of transmission (Welles et al, 2000). The high-level lamivudine resistance mutation, M184 V, has been reported in 4 of 5 pregnant women receiving zidovudine and lamivudine (Clarke et al, 1999).

We do not know how the rising rates of antiretroviral resistance will affect mother-to-child transmission rates. Virologic breakthrough—that is, increasing viral load in a woman receiving therapy—is commonly associated with development of antiretroviral resistance. Although high viral loads also are associated with increased rates of vertical transmission (Garcia et al, 1999), we do not know whether resistant virus can be transmitted to the fetus–neonate as efficiently as wild-type virus. Mathematical modeling using data from retrospective surveys of clinical data has suggested that sexual transmission of resistant HIV from patients receiving antiretroviral therapy is only 20% that of wild-type virus (Brown et al, 2003). The same could be true of perinatal transmission.

Regardless, optimal initial treatment for any infected individual provides the best chance of therapeutic success for the long term. Thus, prevention of the transmission of antiretroviral-resistant HIV to neonates requires potent therapy to suppress maternal replication of both wild-type and resistant viruses. Resistance testing for HIV-infected women can optimize initial treatment, prevent development of resistance, and lower fetal exposure to resistant as well as wild-type HIV-1 (Yerly et al, 1999).

## IDENTIFICATION OF THE HIV-EXPOSED NEONATE

### Prevalence of Perinatal HIV-1 Exposure and Infection

Even though many pediatricians and neonatologists are unlikely to encounter HIV-1 infection in their patients, the stark reality remains that all babies born today are at some risk, however large or small, of AIDS. Prevalence of HIV infection varies by a factor of more than 1000 in different parts of the world. Neonatal exposure and infection

rates also vary greatly. In some areas of Sub-Saharan Africa, 30% of infants of the more than 30% of pregnant women who are HIV-infected, that is, 1 in 10 babies, are HIV-infected. In the developed world, fewer than 1 in 3000 newborns are exposed to HIV, and fewer than 2% of these (one in 150,000) are HIV-infected.

Perinatal HIV-1 exposure is diagnosed by demonstrating anti-HIV-1 antibodies in maternal, cord blood, or neonatal serum. Although anti-HIV-1 serologic results from these sources is diagnostic of maternal infection status, it does not reflect any infant's actual infection status, only the exposure status (Table 36–5).

## Prevention of Pediatric AIDS

Potent antiretroviral therapies and current highly sensitive and effective techniques of screening the blood supply have rendered pediatric AIDS a preventable disease. Pediatric AIDS can be prevented at two points. First, and by far the most effective, is the prevention of pediatric infection by ensuring a safe blood supply and by treating maternal HIV infection during pregnancy. Second, even if an infant does become infected, early recognition and treatment with potent combinations of antiretrovirals can forestall both destruction of the pediatric immune system and the development of AIDS (Krogstad et al, 1999; Luzariaga et al, 1997). It is therefore doubly critical that no infant leave the newborn nursery before his or her HIV-1 exposure is known. Transmission rates in the developed world should approach zero, and no HIV-1–infected infant should be allowed to progress to AIDS. Diagnosis of pediatric AIDS at the time of presentation with an opportunistic infection happens only when we have missed both the opportunity to prevent transmission *and* the opportunity to prevent immune deficiency after infection.

## Clinical Presentations

Perinatal HIV-1 exposure alone has no clinical manifestations. The only way to determine any infant's exposure status is to determine maternal infection status, usually through antibody screening of maternal or neonatal blood or secretions. Similarly, until immunodeficiency sets in, neonatal HIV-1 infection is diagnosed only by demonstration of viral genome in the infant (Tables 36–5 and 36–6).

Pediatric AIDS can have general, infectious, or organ-specific manifestations, which have been thoroughly reviewed elsewhere (Khouri and Kovacs, 2001). Failure to thrive, said to be universal among HIV-infected children (Pollack et al, 1997), is caused by multiple complications of HIV disease. Malignancy may be the presenting clinical problem, but recurrent and especially chronic bacterial or viral infections are often the first sign of HIV disease. Infections can be either minor (otitis, sinusitis, skin and soft tissue infections) or serious (bacteremia, pneumonia, bone and joint infections) and may be seen in the context of pronounced hepatosplenomegaly and lymphadenopathy. Dermatologic complications of HIV infection are common. They range from allergic reactions

TABLE 36-5

**A Neonatologist's Guide to Laboratory Evaluation of the HIV-exposed Infant\***

	Test			
	HIV-1 Antibody Test	HIV-1 Culture	HIV-1 DNA PCR	Plasma HIV-1 RNA
Common term used for test	"HIV test"	"Culture"	"PCR"	"Viral load" or "viral burden"
What it does	Detects the presence of antibody Reflects infant's exposure status and maternal infection status but not infant infection status	Detects replicating HIV in infant PBMCs co-cultured with donor lymphocytes	Detects the presence of integrated, proviral DNA in the genome of infant's PBMCs by PCR	Also a PCR-based technique Measures the amount of viral RNA in plasma of infant
What result means	Sero-reversion to negative at 12-18 months confirms negative PCR test finding that infant is uninfected Remains the "gold standard," final determination of infant infection status	If result is positive, infant is infected	If result is positive, infant is infected If negative at least twice, including once after 2 months of age, suggests strongly that infant is not infected	Quantitative result reflects HIV-1 disease activity If unknown infection status, >3000 copies/mL, infant is likely infected. If below limits of detection at least twice, infant may be uninfected Potential for false-positive results at <3000 copies/mL
Results reported	Qualitative: "positive" or "negative"	Qualitative: "positive" or "negative"	Qualitative: "positive" or "negative"	Quantitative: number of copies of HIV-1 RNA per mL plasma
Time required for results	1-2 days	30-40 days	7-14 days	3-10 days
Advantages	Sero-reversion (loss of detectable maternal HIV-1 antibody by 12-18 months of age) remains the gold standard for proof that an infant is uninfected	Very low false-positive rate False-negative results reported	Low false-positive rate False-negative results reported	Wider availability Faster turnover
When indicated	If PCR results have all been negative, should be performed at 1 year of age and then every 6 months until result is negative	For diagnosis of infection when antibody status is not informative	For diagnosis of infection when antibody status is not informative	To assess HIV-1 disease activity in individuals known to be infected with HIV-1
When performed?	Starting at 12 months of age, then every 6 months until result is negative	Has largely been replaced by PCR-based systems of HIV detection	First 48 hrs of life, then at 4-6 wks, 3 mos, and 6 mos of age	Used to quantify viral replication and disease activity in individuals known to be infected May be used with caution during suspected primary HIV infection or in exposed infants
Disadvantages	May cause confusion regarding infant exposure and infection status when performed prior to 12 mo Result will be negative during primary acute maternal HIV infection; see text	Long turnaround time	Send-out laboratory assay False-positive results reported	Because of the possibility of false-positive reading of low copy numbers, not currently recommended for diagnosis of HIV-1 infection; this situation may change

\*Expert consultation is always recommended.

ELISA, enzyme linked immunosorbent assay; HIV-1, human immunodeficiency virus type 1; PBMC, peripheral blood mononuclear cell; PCR, polymerase chain reaction.

TABLE 36–6

**Commonly Used Terms Describing HIV Infection Status and Their Interpretation in Non-Breast-feeding Infants**

Common-Usage Term	Usual meaning	Technical Meaning	Meaning in Infants Younger than 1 Yr	Source of Confusion
HIV-positive	Infected with HIV	Individual has anti-HIV antibodies in blood or other body fluids	Infant has been exposed to HIV during gestation and may or may not be infected with HIV	All infants of HI-infected mothers test “positive” for HIV antibodies until 12-18 months of age, regardless of whether they are infected or uninfected
HIV-negative	(1) not infected with HIV or (2) in acutely infected individual, seroconversion has not yet occurred	Individual does not have detectable HIV antibody	Infant is not infected with HIV: either was not exposed to HIV during gestation or was exposed to HIV and has already cleared maternal antibody	Even though viral tests give earlier, reliable assessment of infant’s infection status, absence or loss of HIV antibody remains the “gold standard” for proof of uninfected status of perinatally exposed infants
HIV-DNA PCR–negative	Individual or infant older than 1 month is not infected with HIV	On highly sensitive testing for intracellular viral genome, no HIV DNA can be detected	If infant is older than 1 month, result suggests infant is not infected A negative result at birth suggests that an exposed infant was not infected early, i.e., before the peripartum period.	Two thirds of infected infants are infected during the peripartum period and test DNA-PCR negative at birth Follow-up testing is required.
HIV-DNA PCR–positive	Individual is infected with HIV	HIV-DNA that has been integrated into the host’s cellular DNA is detected	Detection before infant is 48 hours old suggests early transmission, before the peripartum period. With detection after this age, timing of transmission is indeterminate*	
HIV-RNA PCR undetectable	HIV viral replication is not detectable Not usually used for diagnostic testing, but rather to monitor efficacy of treatment			

\*Identification of “late” i.e., breast milk, transmission of HIV, requires negative HIV-DNA PCR testing after 1 month of age followed by positive HIV DNA PCR result, or documentation of HIV antibody negativity followed by seroconversion.

to medications and noninfectious dermatoses to bacterial, viral, or fungal infections.

*P. carinii* pneumonia (PCP) is the most common AIDS-defining illness in children. It manifests in more than a third of infected infants, usually between 3 and 6 months of age (Simonds et al, 1993). It may be associated with other generalized signs of immunosuppression, such

as failure to thrive and candidiasis. Short of demonstration of parasites in tissue or bronchiolar lavage specimens, PCP is difficult to diagnose. Tachypnea, hypoxia, and low-grade fever are common, but chest radiographs are often nondiagnostic, especially early in the illness (Simonds et al, 1993). Once infants require intubation, mortality approaches 90%, although it is considerably reduced with

the use of antibiotics and corticosteroids (McGlaughlin et al, 1995). Even so, without antiretroviral therapy, median survival for infants who survive is only 19 months.

*Candida* esophagitis and oral candidiasis are common in pediatric AIDS. Other fungal infections are associated with profound immunodeficiency. Many AIDS-defining opportunistic infectious seen in adults are less common in children, although asymptomatic shedding of cytomegalovirus has been described (Kovacs et al, 1999).

Disorders of hematopoiesis are found in almost all pediatric AIDS patients. As disease progresses, the CD4<sup>+</sup> T-cell population decreases, followed by depletion of CD8<sup>+</sup> lymphocytes. Anemia, neutropenia, and thrombocytopenia occur regularly and result from both HIV and antiretroviral-induced bone marrow failure. Peripheral destruction of platelets may also contribute to thrombocytopenia.

Neurologic and developmental manifestations of pediatric AIDS are commonly seen by 2 years of age and are encountered in one of five perinatally infected children (Cooper et al, 1998). Progression of neurologic disease may be indolent or rapid and is generally thought to be secondary to viral replication and abnormal production of central nervous system cytokines rather than opportunistic infection.

Cardiac and pulmonary complications of HIV infection have been described. Cardiomyopathy with decreased cardiac output may be the result of myocardial infection by HIV or other organisms or the result of HIV-associated immune dysregulation (Shearer et al, 2000). Cardiac dysfunction caused by in utero antiretroviral exposure has not been demonstrated. Lymphoid interstitial pneumonitis affects young children, is associated with slow disease progression, and may result in chronic oxygen dependency.

Gastrointestinal, renal and malignant complications of HIV disease have been well described. Gastrointestinal illness can be due to enteric infections or to malabsorption syndromes. Hepatitis due to infection or medications is common and also contributes to growth failure (Khoury and Kovacs, 2001). In the pre-antiretroviral era, renal disease was found in 10% of infected children but was generally asymptomatic (Strauss et al, 1989). Cancer has become a very unusual presentation of pediatric HIV disease. By the late 1990s, national surveys reported less than 2% of infected children with AIDS-associated malignancy. Kaposi sarcoma, commonly seen in men with advanced HIV disease, has been reported only rarely in children (Granovsky et al, 1998).

### **HIV Testing Beyond the Neonatal Period**

Many caregivers are reluctant to consider AIDS in the differential diagnosis of ill children who are believed to be at low risk for HIV-1 infection. In the setting of recurrent pneumonia, nonspecific pulmonary problems, hepatosplenomegaly, or lymphadenopathy, to mention only a few manifestations of HIV disease in the neonatal period, AIDS must be ruled out. If the mother was screened during pregnancy, the possibility exists that she could have become infected after the test. Primary maternal infection

is associated with negative serologic results during the so-called window period—placing the infant in double jeopardy: He or she will test negative on standard HIV-1 antibody screens and will be exposed to extremely high viral titers without the benefit of protection from antiretroviral drugs. In such cases, which have already been reported (Van Tine et al, 1999), diagnosis cannot be made without the assistance of PCR testing for viral genome (see Table 36–5).

## **PREVENTION OF MOTHER-TO-CHILD TRANSMISSION**

### **Counseling and Care of HIV-Affected Families**

HIV care services for women of reproductive age often neglect reproductive health. Reproductive choice and reproductive counseling must be nondirective, educational, and supportive. HIV-infected women must have access to the full range of reproductive health services, including family planning, contraception, abortion, and pregnancy care. Caregivers must inquire about a patient's long-term and short-term reproductive plans, provide access to reliable contraceptive and safer sex methods, and tailor antiretroviral therapy appropriately. For example, women who report that they might like to become pregnant should not be started on efavirenz, despite its convenience as a once-daily pill.

### **Preconceptional and Prenatal Counseling by Pediatricians**

Given the important implications for general family health, pediatricians may be asked to provide counseling to women or couples who are anticipating pregnancy or are already pregnant. Although there is no set formula for such counseling, it must be based on several fundamental issues. First, the right to found a family is a fundamental human right that has been articulated in international law. Second, with treatment, prospective HIV-infected parents in the developed world are likely to live out their natural lives and can expect to raise their children to adulthood. Third, with treatment, HIV-infected women are highly unlikely to transmit the virus to their babies. The odds that their baby will be born uninfected are greater than 98%.

By the same token, prospective parents need to know what they and their infants will experience because of their exposure to HIV. During pregnancy, women will be closely monitored and they will be offered aggressive treatment aimed at maximizing control of viral replication around the time of delivery. Concerns about the teratogenicity of antiretrovirals should be addressed (see earlier discussion). Parents should be aware that their perinatally exposed infant will receive antiretroviral prophylaxis as well as multiple venipuncture for blood sampling for the assessment of transmission status during the first year of life (see Table 36–2). They must also understand that the virus can be transmitted to the infant by breast milk and that formula feeding is therefore highly recommended. Finally, infected individuals must understand that although

available therapies are effective, lifesaving, and improving, there is still no cure for the infection.

## Planning for Delivery and the Neonatal Period

### Maternal Adherence to Therapy

Maternal HIV plasma viremia is the most important predictor of perinatal transmission of HIV-1. Late pregnancy care is focused on maintaining control of maternal viremia or achieving the best control possible. Most data from the current era of highly active antiretroviral therapy suggest that use of antiretrovirals, and not necessarily route of delivery, is the most important determinant of HIV-1 perinatal transmission rates.

### Route of Delivery

Many factors determine the route of delivery in the setting of maternal HIV-1 infection. The first and most important is informed maternal choice. Women should be aware that elective cesarean section before rupture of membranes and before onset of labor has been shown in two retrospective (Mandelbrot et al, 1998; The mode of delivery, 1999) and one prospective study (Elective caesarean-section, 1999) to be associated with lower risk of transmission when mothers received either no antiretrovirals at all or zidovudine prophylaxis alone. Both CDC practice guidelines (CDC, 2003) and the American College of Obstetricians and Gynecologists state that scheduled cesarean section at 38 weeks of gestation should be recommended or offered to all HIV-infected women. Both groups acknowledge that data are insufficient to demonstrate benefit of elective abdominal delivery when maternal viral loads are lower than 1000 copies/mL or when rupture of membranes or labor has already occurred. These recommendations are based on studies performed before the current era of potent antiretroviral therapy; all participants of those studies received either no antiretrovirals or zidovudine alone during pregnancy.

In fact, lower transmission rates with elective cesarean section have not been demonstrated when mothers are taking potent combination antiretroviral therapy, regardless of maternal viral load. PACTG Study 316 reported on 1248 mother-baby pairs (Dorenbaum et al, 2002). Seventy-seven percent of them received combinations of two or more antiretrovirals, and 41% received protease inhibitor–based triple combinations; viral load at delivery was available for 95% of mothers. Only 34% delivered by elective cesarean section. The overall HIV transmission rate was 1.5%. Univariate analysis found that the risk for transmission was significantly higher for women with low CD4 T-cell counts and higher viral loads but did not differ significantly with route of delivery. Multivariate analysis revealed that the only significant predictor of transmission was maternal viral load at delivery. Significantly, 56% of the 18 infected infants had positive HIV DNA PCR results at birth, suggesting that the majority of transmissions occurred before the peripartum period and could not have been prevented by interventions at delivery such as elective cesarean section.

Several studies have shown a small but significant risk of respiratory complications among infants delivered electively by cesarean at term (Krantz et al, 1986), and any woman is at increased risk of bleeding and infection when delivered abdominally.

Our understanding of the mechanisms of the vertical transmission of HIV is incomplete. Elective abdominal delivery, performed according to a woman's choice, remains a reasonable alternative in the setting of HIV disease. An infected woman should be counseled, however, that if she is taking combination therapy, vaginal delivery may be as safe as cesarean section for her baby, particularly if her viral load is less than 10,000 copies/mL (Dorenbaum et al, 2002). Even at higher viral loads, the highest risk of transmission in PACTG Study 316 was 7%. Furthermore, elective cesarean delivery will not decrease the risk of transmission for babies infected before the peripartum period or if membranes rupture or labor occurs before the scheduled delivery date. Women must understand that combination therapy offers highly significant protection to the fetus throughout pregnancy, whenever and however it is born.

### Intrapartum Prophylaxis

Intrapartum prophylaxis, which has been standard for almost 10 years, is summarized in Table 36–7. Zidovudine should not be administered during labor if the patient is allergic to the medication. If a woman is doing well on a stavudine-based regimen, either she should not be given intravenous zidovudine or the stavudine should be stopped before the zidovudine infusion is initiated. Stavudine and zidovudine should not be administered together because they are mutually antagonistic (Havir et al, 2000). In the setting of documented laboratory and clinical signs of high-level maternal resistance to zidovudine, many workers in the field find it pointless to initiate a maternal zidovudine infusion before delivery. Others believe that the infusion should still be given because the benefits of zidovudine are not completely understood. Expert consultation and patient education and choice, along with a plan clearly formulated before delivery, are extremely important.

### The Postpartum-Neonatal Period

Neonatal caregivers are in a key position to teach and reinforce the principle that in order to take care of their babies, women must also take care of themselves. The postpartum period is a time of challenges to adherence to therapy. Daily schedules are disrupted by irregular infant feeding and sleeping patterns. Many women shift their focus from their own therapy and health to their baby's health needs for general care, HIV prophylaxis, and testing. Attention to their own health, and especially to their own therapy, is likely to decrease substantially. These challenges can be met by prenatal planning for adequate support systems for both baby and mother. Coordination of infant prophylaxis and maternal dosing schedules by pediatric and maternal health care teams greatly facilitates adherence to both interventions and

**TABLE 36-7****Public Health Service Guidelines for Intrapartum, Neonatal Antiretroviral and Opportunistic Infection Prophylaxis for Perinatally HIV-1 Exposed Infants\***

Age	Dosage	Adjustment(s)
Intrapartum, given to mother (see text)	Zidovudine, 2 mg/kg intravenous loading dose, followed by zidovudine, 1 mg/kg continuous infusion	Discontinue when cord is clamped
0-6 weeks, gestational age 35 weeks or greater at birth	Zidovudine, 2 mg/kg PO or IV q6 h	Per infant weight gain
0-2 weeks, gestational age 30-35 weeks at birth	Zidovudine, 1.5 mg/kg IV q12 h or 2.0 mg/kg PO q12 h	Decrease dosing interval to q8 h at 2 weeks of age
0-4 weeks, gestational age less than 30 weeks at birth	Zidovudine, 1.5 mg/kg IV q12 h or 2.0 mg/kg PO q12 h	Decrease dosing interval to q8 h at 2 weeks of age
6 weeks to 1 year or until HIV infection is fully excluded	Trimethoprim-sulfamethoxazole, 150-750 mg/m <sup>2</sup> /day in 2 divided doses	Per infant's growth

\*Data from the Centers for Disease Control and Prevention (2003), and Khoury and Kovacs (2001).

should always be a part of obstetric-neonatal discharge planning.

### Neonatal Antiretroviral Prophylaxis

Antiretroviral and opportunistic infection prophylaxis guidelines for HIV-exposed neonates have been in place since 1994 (Connor et al, 1994), are summarized in Table 36-7, and are available as a living document on the Internet (CDC, 2003).

No guidelines exist for prophylaxis of infants in the setting of documented high-level clinical and laboratory maternal resistance to zidovudine, particularly that involving codon 215. Practice in this area is inconsistent and controversial. Planning for neonatal prophylaxis must begin during pregnancy and should be coordinated with those who will be caring for the baby. Consultation with pediatric virologists with experience in the use of non-zidovudine-containing regimens in infants is highly recommended. Parents must be counseled about the risks and benefits of alternative prophylaxis strategies for their infants and must be included in the decision-making process.

### Neonatal Prophylaxis Against Opportunistic Infection

Before the current era of antiretroviral prophylaxis, when 25% of HIV-exposed newborns were themselves infected, PCP was a common opportunistic infection

during the first year of life and carried exceptionally high mortality (see earlier discussion). Even though perinatal HIV transmission has decreased markedly, recommendations for opportunistic infection prophylaxis in infants of indeterminate infection status remain in place (CDC, 2001b, 2003). Many parents question the necessity of opportunistic infection prophylaxis after they have been told their infants are not infected with HIV, and some authorities have suggested that prophylaxis may be terminated once HIV infection is fully excluded (CDC, 2003).

### Infant Feeding and HIV Transmission

Transmission of HIV-1 in breast milk has been well documented and occurs in 14% to 16% of exposed infants who were not infected perinatally. In resource-rich regions, feeding with breast milk substitutes has been a straightforward and acceptable method of eliminating such transmission. In the developing world, the risks and benefits of this intervention are very complex. In Thailand and certain sections of Nairobi, Kenya, where sanitary water supplies are available, breast milk substitutes have proved both safe and beneficial for mother and baby (Nduati et al, 2000a, 2000b). Results of other studies have been less straightforward. Variables such as the extent of mixed feeding as well as availability of both clean water supplies and supplies of breast milk substitutes profoundly affect the risks and benefits of bottle-feeding HIV-exposed infants in the developing world.

Interestingly, viral load in breast milk is generally low (Sabbaj et al, 2002), and Aldrovandi (2003) reported viral load to be undetectable in the milk of five women who were taking potent combination therapy. The impact of combination therapy on breast milk transmission in the developing world is completely unknown. As with all other issues, planning for infant feeding and suppression of lactation are best dealt with long before the baby is born.

### Site-of-Care Issues for Mother and Baby

Every community has its own resources and limitations. Care can be provided for HIV-affected families in many different ways and by several different specialties and health care teams from different backgrounds. However, it is clear that pregnant women and women with children can attend only so many visits to so many clinics in the space of a week. It is also clear that women, even those with life-threatening illnesses, will neglect their own health in order to care for their children. For this reason, multidisciplinary clinics have been very successful in a variety of settings. A woman is far more likely to attend her own medical appointments when they occur in conjunction with care of her children. In some areas, the challenges to such “one-stop” family-centered programs may be insurmountable; in others, such programs can be put in place simply by manipulating caregivers’ schedules.

The Bay Area Perinatal AIDS Center at San Francisco General Hospital has provided family-centered HIV care since 1989. Currently, care at the center is coordinated by a family nurse practitioner. This professional and an obstetrical/infectious disease specialist give prenatal and HIV care in consultation with primary HIV caregivers and neonatologists. Antepartum admission orders, postpartum orders, and nursery admission orders are all discussed and prepared in advance of the delivery admission. Neonatal, postpartum, and ongoing family care are given by the family nurse practitioner and family medicine faculty with a strong interest in HIV care.

### EVALUATION OF TRANSMISSION STATUS OF HIV-1-EXPOSED INFANTS

Careful follow-up and months of testing are required to evaluate the transmission of infants exposed to HIV (see Table 36–6). We generally accept that negative results of two viral tests, at least one of which has been performed after 1 month of age, are highly suggestive that an infant is not infected. Even so, authorities stress the importance of ongoing evaluation and care of exposed infants so that sero-reversion to “HIV-negative” status can be documented between 1 and 2 years of age. Parents should be counseled about the availability of national and international studies of children who have been HIV and referred to appropriate centers for participation.

Table 36–5 summarizes available HIV diagnostic tests and their meaning in the setting of perinatal exposure to HIV-1. Of greatest importance here is that HIV antibody status before a baby is 1 year old reflects the mother’s

infection status and the baby’s own exposure status, but does not reflect the baby’s infection status.

### CONCLUSION

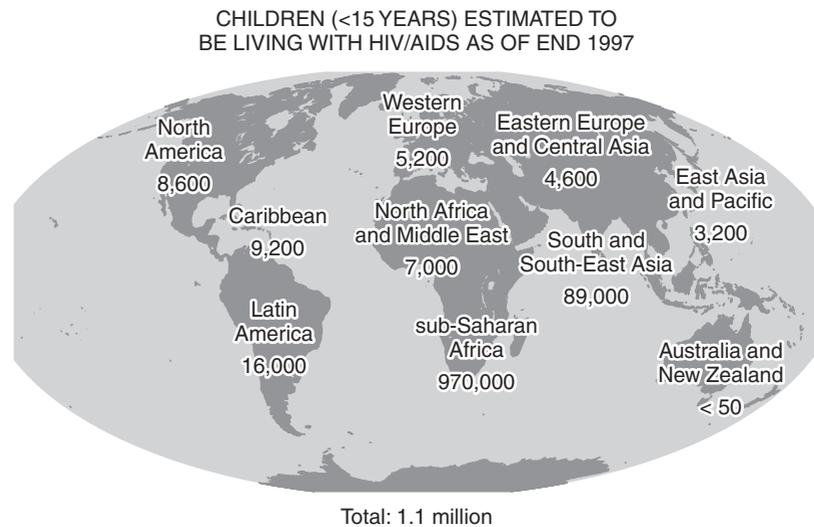

Pediatric HIV infection has become a disease of the developing world, where more than 90% of HIV-exposed and more than 98% of HIV-infected children live (Fig. 36–5). Without therapy, morbidity and mortality are high for all infected individuals and are worse for children. Even exposed uninfected children face the virtual certainty of becoming orphans by their tenth birthdays and a 50% chance of some day becoming infected themselves. By 2010, the epidemic will have produced 44 million orphans.

Solutions to this crisis exist. HIV transmission, whether sexual, vertical, or parenteral, is virtually 100% preventable. Progression to AIDS and death is also preventable. The United States and rest of the developed world have not always been immune to devastation, and in the early 1990s, both a pediatric HIV epidemic and an AIDS orphan crisis loomed very large in a number of wealthy countries. Although the potential to arrest all HIV transmission remains a goal unfulfilled, potent antiretroviral combination therapy has not only reversed AIDS mortality trends (see Fig. 36–4A) but has virtually eliminated mother-to-child transmission of the virus in the United States (see Fig. 36–4B). The current challenge in this country is to miss no opportunity to treat disease and prevent transmission. Already, our tolerance for vertical transmission events has come close to zero.

Our attitudes must be no different regarding the epidemic in the developing world. Given global resources today, the death of a mother from AIDS is just as much a preventable tragedy in any other country as it is in our own. Similarly, the infection of a single baby represents our global failure to protect the world’s children, whether that child was born in affluence to a U.S. woman who never suspected her own HIV infection or to a mother in the developing world with no access to testing or therapy.

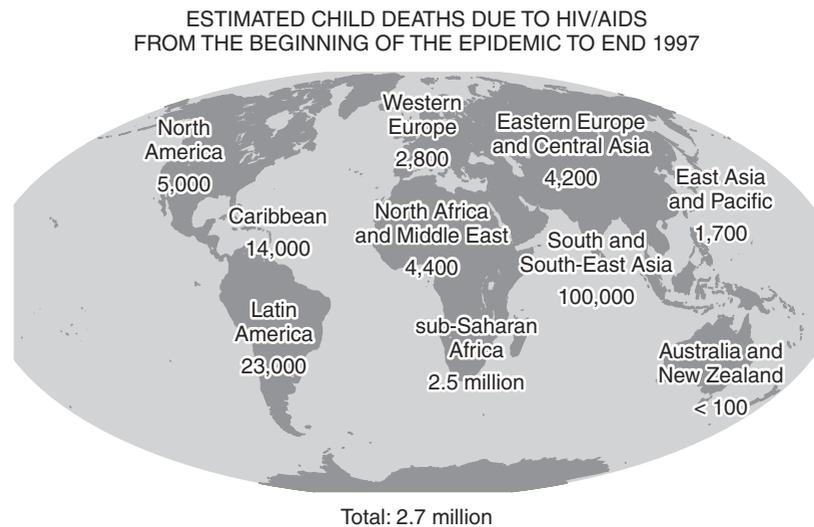

Prevention of pediatric HIV infection is not easy but it is entirely possible. It requires universal screening, aggressive approaches to the management of maternal infection, and careful coordination of disparate services with a clear goal of family-centered care. With adequate newborn screening and follow-up, even the rarely infected neonate should never be allowed to progress to full blown AIDS.

Advocacy for those whose lives have been most devastated by the HIV/AIDS pandemic is not just a fundamental part of good global citizenship and humanitarian compassion. It is also a critical element of preserving the health of our own families and societies. We are now at the beginning of the third decade of HIV/AIDS, and we have long understood that the infection knows no social, economic, or geographic barriers. If global transmission remains unchecked and the global standard of treatment continues to consist of either no therapy or suboptimal therapy, the ensuing crisis in transmission and loss of antiretroviral efficacy will not stop at our collective door.

## Viral Infections of the Fetus and Newborn

Erica S. Pan, F. Sessions Cole,  
and Peggy Sue Weintrub

Many viral infections are acquired in utero, or congenitally. Alternatively, numerous infections may also occur perinatally or postnatally, although it is often difficult to ascertain the time of acquisition. The clinical manifestations and long-term effects differ according to when the infection was acquired.

*Congenital infection* is defined here as infection transmitted any time during gestation excluding the last 5 to 7 days. The most common infections acquired in utero are those due to cytomegalovirus (CMV), rubella virus, *Toxoplasma gondii*, *Treponema pallidum*, human immunodeficiency virus (HIV), and human parvovirus B19 (Kinney and Kumar, 1988; Stamos and Rowley, 1994). The somewhat misnamed TORCH group, an acronym first used in 1971, signifies toxoplasmosis, rubella, cytomegalovirus, and herpes simplex virus, with the O standing for “other infections” (Nahmias et al, 1971). The confusion generated by this acronym arises because “H,” or herpes simplex, rarely belongs to the group and because syphilis and many other significant infections are omitted from it (Stamos and Rowley, 1994). For many years, numerous hospitals offered a panel of serologic tests for these four organisms, a practice that led to uncertainty about the significance of each test and an oversimplification of the approach to diagnosis. These congenital infections have clinical features in common, but they are distinguishable, and the differential diagnosis of congenital infection should not be limited to these four organisms alone (Cullen et al, 1998; Kinney and Kumar, 1988). HIV is covered in Chapter 36.

Clinical findings for congenital viral infections are listed in Table 37–1. The most common manifestations are hepatomegaly, splenomegaly, pneumonia, bone lesions, and cytopenias. The most significant congenital viral infections (excluding HIV) are CMV, rubella, parvovirus B19, and, less commonly, herpes simplex virus (HSV) and varicella.

Some viruses may rarely cause intrauterine infection but are more commonly transmitted just before or during delivery; this pattern is characteristic of herpes simplex virus, varicella, hepatitis B and C viruses, and others. Viruses such as enterovirus and hepatitis A can also be acquired in the perinatal period. Other viruses of importance that are more commonly transmitted postnatally, and sometimes nosocomially, are respiratory viruses, rotavirus, and, occasionally, hepatitis A. Figure 37–1 summarizes significant

viruses and the relative distribution of intrauterine, perinatal, and postnatal infections.

### DIAGNOSTIC APPROACH

The incidence of congenital infection in the fetus and newborn infant is high (0.5% to 2.5%) (Alpert and Plotkin, 1986), and a significant number of congenitally infected infants are asymptomatic. Evaluation begins with a complete family and maternal history, including information on birth weights and medical problems of siblings, maternal illness during pregnancy, drug use, sexual orientation and medical history of sexual partners, and information about the mother’s travels, country of origin, and blood transfusions.

Common clinical features associated with specific congenital infections in the neonate are listed in Table 37–2. Whether children born with a single finding—for example, birth weight less than the third percentile for gestational age without other signs—should be evaluated is unclear. Studies from Sweden and Canada suggest that isolated growth retardation is not associated with congenital infection (Andreasson et al, 1981; Primhak and Simpson, 1982). However, growth retardation has been described as the only manifestation of congenital infection with CMV, rubella, and toxoplasmosis (Alpert and Plotkin, 1986).

### CYTOMEGALOVIRUS

Cytomegalovirus (CMV) is a member of the herpes virus family and has the largest DNA genome of any known virus (Adler, 1986b). CMV infection at any age is usually asymptomatic. After a period of active replication, the virus usually becomes latent but retains the capability of reactivation under special circumstances. Such reactivation occurs commonly during pregnancy. A primary infection or reactivation during pregnancy can lead to congenital infection of the fetus. CMV is now the most common congenital viral infection in developed countries, overtaking rubella since the introduction of rubella immunizations (Demmler, 1991). Perinatal or postnatal infection is also common but rarely results in symptomatic infection.

#### Incidence

In developed countries, CMV seroprevalence rates range widely from 50% to 90% among adult women (Mustakangas et al, 2000; Wong et al, 2000). Older age, lower socioeconomic and educational status, and non-white ethnicity are all associated with higher rates of detectable CMV antibody (Demmler, 1991; Mustakangas et al, 2000; Nelson and Demmler, 1997). The incidence of viral excretion in the cervix or urine appears to rise during pregnancy from approximately 3% in the first trimester to as much as 25% to 50% at term (Montgomery et al, 1972). Estimated seroconversion rates during pregnancy range from 0.7% to 4.1% (Stagno et al, 1984).

Approximately 40,000 infants are born with congenital CMV infection annually in the United States (Griffiths, 1993; Stagno and Whitley, 1985a). This infection rate

**TABLE 37-1**

**Clinical Features Commonly Associated with Congenital Viral Infections in Neonates**

- Growth restriction
- Hepatosplenomegaly
- Jaundice (>20% direct-reacting bilirubin)
- Hemolytic anemia
- Petechiae and ecchymoses
- Microcephaly and hydrocephaly
- Intracranial calcification
- Pneumonitis
- Myocarditis
- Cardiac abnormalities (especially peripheral pulmonic stenosis [rubella])
- Chorioretinitis
- Keratoconjunctivitis
- Cataracts
- Glaucoma
- Nonimmune hydrops

(approximately 1%) is greater than rates observed in England, Denmark, and Sweden (approximately 0.3%) and comparable with the rate in Africa (1.4%) (Peckham, 1991; Starr et al, 1970). Similarly, worldwide estimates range from 0.4% to 2.3% of all live births (Stagno et al, 1982a). It has been estimated that approximately 40% of primary maternal infections transmit CMV to the fetus compared with only 1% to 2% of reactivated infections (Demmler, 1991). Most evidence has shown that a primary maternal CMV infection is more likely than a recurrent infection to cause congenital infection (Stagno et al, 1982b), but later data

**TABLE 37-2**

**Clinical Findings in Congenitally Infected Infants that Suggest a Specific Diagnosis**

Congenital Infection	Findings
Rubella	Eye: cataracts, cloudy cornea, pigmented retina Skin: "blueberry muffin" syndrome Bone: vertical striation Heart: malformation (ductus, pulmonary artery stenosis)
Cytomegalovirus	Microcephaly with periventricular calcifications Petechiae with thrombocytopenia Jaundice Hearing loss Inguinal hernias in boys
Toxoplasmosis	Hydrocephalus with generalized calcifications Chorioretinitis
Syphilis	Osteochondritis and periostitis Eczematoid rash Mucocutaneous lesions (snuffles)
Herpes	Skin vesicles Keratoconjunctivitis Acute central nervous system findings
Varicella	Limb hypoplasia Dermatomal scarring Gastrointestinal tract atresia
Lymphocytic choriomeningitis virus	Hydrocephaly Chorioretinitis Intracranial calcifications

suggest that symptomatic congenital infection in children of women with non-primary CMV infection may occur more often than previously appreciated (Boppana et al, 1999). Estimated rates of CMV susceptibility and transmission in pregnancy are given in Figure 37-2.

The incidence of *perinatal* (up to 1 month after birth) infection and *postnatal* (up to 12 months after birth) infection is still higher than that of intrauterine infection. Typically, the infant is exposed to virus shed from the cervix, excreted in breast milk, or, less commonly, shed from other infants infected with the virus. Approximately 50% of babies born to mothers excreting virus at term acquire infection in the first weeks of life (Reynolds et al, 1973). Many of these babies are infected through breast milk (Hayes et al, 1972). All infants, regardless of the route of infection, excrete virus for a prolonged period, usually for at least 1 year (Emanuel and Kenny, 1966). Although the incidence of perinatal and postnatal CMV infections is higher, these infants typically have asymptomatic or self-limited disease but do not have the neurologic sequelae seen in some congenitally infected infants (Demmler, 1991).

Nosocomial infant-to-infant transmission of CMV has been reported, but it occurs infrequently (Adler, 1986b; Spector, 1983; Yeager et al, 1972). Transfusion-related

**FIGURE 37-2.** Characteristics of cytomegalovirus infection in pregnancy. (From Stagno S, Whitley RT: *Herpesvirus infections of pregnancy. Part I: Cytomegalovirus and Epstein-Barr virus infections.* *N Engl J Med* 313:1270-1274, 1985.)

infections were first reported in 1969, when infants in newborn intensive care units demonstrated a syndrome consisting of respiratory distress, hepatosplenomegaly, lymphocytosis, and a “septic appearance” (King-Lewis and Gardner, 1969; McCracken et al, 1969). In 1971, noting the connection between seropositive blood used for exchange transfusion and the acquisition of CMV by CMV-seronegative recipients, Luthardt and colleagues suggested that such infections could be prevented by selection of CMV-seronegative donors. Subsequent investigators observed that exclusive use of CMV-seronegative blood eliminated CMV infection in hospitalized seronegative infants (Adler, 1986a; Yeager et al, 1981). Between 3 and 12 CMV infections occur per 100 units of transfused blood, and in premature infants, seroconversion occurs in 10% of 30% of those transfused with CMV antibody-positive blood (Lamberson et al, 1988). Although the frequency of postnatal transfusion-acquired CMV has decreased with the use of leukodepletion and of CMV-seronegative donors, a high index of suspicion must be maintained when symptoms consistent with CMV infection occur in infants who have received multiple transfusions.

The prevalence of acquired CMV infection may be significantly increased in different populations by differences in prevalence of breast-feeding and child-rearing practices. In the United States, this effect may be greatest among infants born to women of higher socioeconomic status who send their children to daycare centers or are daycare center workers themselves (Stagno and Cloud, 1994). For CMV-seronegative women in the reproductive age range exposed to increasing numbers of CMV-seropositive children, the risk of primary infection rises.

### Maternal Exposures and History

Child care providers (including daycare workers, special education teachers, and therapists) appear to have a higher risk of occupational exposure to CMV from infants and young children, compared with other women of child-bearing age working with similar populations (CDC, 1985).

Health care workers using routine infection control practices are not at increased risk of CMV acquisition. Like most

healthy individuals, more than 90% of pregnant women with primary CMV infections remain asymptomatic. When symptoms do occur, they are nonspecific and vague, often described as a “flu-like syndrome.” Potential manifestations include fever, fatigue, headache, myalgia, lymphadenitis, and pharyngitis. Prenatal ultrasonography findings that would also raise concern for intrauterine CMV infection are oligohydramnios or polyhydramnios, nonimmune hydrops, fetal ascites, intrauterine growth restriction, microcephaly, cerebral ventriculomegaly or hydrocephalus, intracranial calcifications, pleural or pericardial effusion, hepatosplenomegaly, intrahepatic calcifications, echogenic bowel, and pseudomeconium ileus (Nelson and Demmler, 1997).

### Etiology and Pathogenesis

The fetus can be infected by either a primary maternal infection (Davis et al, 1971) or a reactivated maternal infection (Stagno et al, 1982b). A newborn infant without congenital infection can be infected perinatally by his or her mother at the time of delivery or postnatally through breast milk, by acquisition from the nursery or home environment, or by transfusion of blood from a donor.

CMV infection can occur throughout gestation, but there is a higher incidence of adverse fetal sequelae if primary maternal infection occurs during the first trimester. The virus is transmitted first to the placenta via infected leukocytes, then replicates within placental fibroblasts, syncytiotrophoblasts, and cytotrophoblast cells. From there the virus infects the fetus hematogenously via the umbilical cord (Trincado and Rawlinson, 2001). Once the fetus is infected, viral replication occurs primarily in the tubular epithelium of the kidneys (Scott et al, 1997). The virus is then excreted in fetal urine and subsequently in amniotic fluid. It is assumed that once infected amniotic fluid is ingested, the virus replicates further in the oropharynx, enters the fetal circulation, and hematogenously spreads to target organs (Lazzarotto et al, 1999b). The mechanism of hearing loss secondary to congenital CMV infection is not known.

Little is known about the effect of virulence factors in congenital CMV infections. Although all strains are

serologically related, there appear to be some variations in antigenicity, and evidence is emerging that certain envelope glycoprotein B genotypes are predominant in congenital or perinatal infections (Bale et al, 2000; Lukacs et al, 2001; Trincado et al, 2000). Newer evidence supports the theory that some women with pre-existing immunity who give birth to infants with symptomatic CMV infection may have a newly acquired strain rather than reactivated latent infection (Boppa et al, 2001).

### Clinical Spectrum

Prospective studies report that up to 90% of infants with congenital CMV infections are asymptomatic at birth and that milder manifestations of infections are more common than the classic syndrome.

In the classic form of congenital CMV infection, cytomegalic inclusion disease, newborn infants have acute progressive disseminated disease. They show petechiae and ecchymoses, and they are jaundiced at birth or jaundice appears within a few hours and becomes intense. The liver and spleen are enlarged and firm and may increase in size for a number of days. Fever, respiratory distress, or pallor may appear. Puncture wounds bleed for many minutes, and hemorrhage from internal organs may cause death. Infants infected with the virus are often born prematurely. Table 37-3 is a summary of the frequency of various clinical and laboratory findings in 285 infants in the National Congenital CMV Disease Registry (Istas et al, 1995). Petechiae, hepatosplenomegaly, and jaundice are the

most common signs during the neonatal period. Although microcephaly was seen in only one third of the infants in the Registry at birth, a number of additional children may become microcephalic as they grow older. Nine percent (25 of 285) of infants in the Registry died of the CMV disease. Most fatalities occur before 3 months of age, primarily because of severe neurologic impairment.

Visual deficits, when present, are most commonly secondary to cortical visual impairment or sequelae of chorioretinitis such as optic atrophy or macular scars. One small prospective study of CMV-infected infants reported that approximately 20% of symptomatic patients had moderate to severe visual impairment, and approximately 30% had strabismus (Coats et al, 2000). Many other isolated defects have been reported in conjunction with congenital CMV infection, but because approximately 1% of all infants are infected, CMV may not always be the cause of abnormality.

A presumptive diagnosis may sometimes be made after the infant is several months of age if a virus is found and the clinical syndrome is classic. Other causes of congenital infection must be ruled out, because there is extensive overlap in the symptoms of several types of infections.

### Laboratory Evaluation

There is no universal standard regarding prenatal screening for CMV, and an optimal approach has not yet been delineated. Some countries administer routine prenatal screening for CMV, and various investigators are researching

**TABLE 37-3**

**Characteristics of the 285 Infants Enrolled in the National Congenital Cytomegalovirus Disease Registry (January 1, 1990, through December 31, 1993)**

Characteristic	No. of Infants Affected	% of Infants Affected
Non-neurologic abnormalities:		
Petechiae or purpura	154	54
Small for gestational age	135	47
Hepatosplenomegaly	114	40
Jaundice at birth	108	38
Pneumonia	24	8
Neurologic abnormalities:		
One or more of the following abnormalities	194	68
Intracranial calcifications	106	37
Microcephaly	104	36
Unexplained abnormality	78	27
Hearing impairment	70	25
Chorioretinitis	30	11
Seizures	30	11
Neonatal death*	25	9
Laboratory findings:		
Platelet count $\leq 75000/\text{mm}^3$	136	48
Direct bilirubin level $\geq 3 \text{ mg/dL}$	102	36
Alanine aminotransferase level $>100 \text{ U/L}$	66	23
Hemolytic anemia	32	11

\*Data not systematically collected.

Data from Istas AS, Demmler GH, Dobbins JG, Stewart JA: Surveillance for congenital cytomegalovirus disease: A report from the National Congenital Cytomegalovirus Disease Registry. *Clin Infect Dis* 20:665-670, 1995.

optimal protocols for testing and correlation with clinical outcomes. The use of immunoglobulin (Ig) M antibody testing in mothers and infants has been difficult to interpret, for several reasons. First, mothers with reactivation as well as primary infection may have positive CMV IgM. Second, IgM testing itself has wide variability in accuracy and reproducibility, although it has improved with enzyme immunoassay and immunoblot techniques (Trincado and Rawlinson, 2001). Third, it is estimated that only 10% of pregnant women in whom IgM is detected will transmit infection to their fetuses.

Some centers use the combination of anti-CMV IgM and IgG avidity results to screen pregnant women. Use of CMV-specific IgG avidity testing has proved to be helpful in discriminating between primary infection and recurrent infection. Typically, IgG avidity is greater than 80% in women with recurrent CMV infection, but low IgG avidity is demonstrated for 18 to 20 weeks after a primary infection (Grangeot-Keros et al, 1997; Lazzarotto et al, 1999a). These tests are not routinely available for clinical use. Some investigators have examined the potential correlation between maternal CMV antigenemia or viremia and neonatal outcomes, but study results are inconclusive (Lazzarotto et al, 1999b).

Prenatal diagnosis of congenital CMV can be established by isolation of the virus from amniotic fluid obtained by amniocentesis (Grose et al, 1992) or from fetal blood (Enders et al, 2001). A specific nucleic acid test (NAT) for CMV in amniotic fluid or chorionic villus sampling via polymerase chain reaction (PCR) has been studied, but these tests have not conclusively shown correlation with clinical symptoms (Dong et al, 1994; Jones et al, 2000; Liesnard et al, 2000; Revello et al, 1999). In Italy and the United States, researchers have found quantitative PCR in the amniotic fluid of women to be helpful in predicting symptomatic CMV infection of their fetus or newborn (Guerra et al, 2000; Lazzarotto et al, 2000; Lehman et al, 2001).

The laboratory diagnosis of congenital CMV infection in the infant can be made with certainty only through detection of the virus in organs or culture specimens at birth or within the first 2 to 3 weeks of life. The most sensitive detection system is growth of the virus from urine in tissue culture, and most neonatal culture results are positive within 3 to 7 days (Stagno and Whitley, 1985a; Kinney and Kumar, 1988). A more rapid method of viral isolation, called the shell vial assay, is available in many clinical viral laboratories. In this method centrifugation is performed to enhance viral attachment to cells; then, 16 to 72 hours after inoculation, the culture vials can be stained with fluorescein-conjugated monoclonal antibody to CMV antigen. This technique usually produces results within 24 hours (Rabella and Drew, 1990). It is impossible to determine whether CMV infection was acquired congenitally, perinatally, or postnatally in infants more than about 3 weeks old, because infection acquired during all three periods would result in positive culture results in such infants. Both symptomatic and asymptomatic congenitally infected infants shed virus in their urine for an average of 4 years and for as long as 10 years (Noyola et al, 2000).

Results of serologic testing of an infant at the time of delivery have often been difficult to interpret, because 50% to 75% of women have anti-CMV IgG, which is trans-

placentally transmitted to the infant, and serial antibody titers cannot absolutely differentiate between congenital infection and perinatally acquired infection. It is estimated that only 50% of congenitally infected infants produce IgM antibody (Nelson and Demmler, 1997).

The principal types of abnormalities found on other laboratory tests in infants with symptomatic CMV infection at birth are listed in Table 37-3. Elevations in liver transaminases and thrombocytopenia are common. Other cytopenias, such as anemia (usually hemolytic) and neutropenia, have also frequently been reported. The urine usually contains bile but no urobilin. Albumin is commonly present, as are some red and white blood cells. Sediment that has been dried, fixed, and stained with hematoxylin and eosin often demonstrates the characteristic inclusion bodies within desquamated renal epithelial cells, so-called owl's-eye cells.

Abnormal head computed tomography (CT) findings are noted in 70% to 80% of symptomatic infants, and 90% of those with abnormal CT findings demonstrate neurologic sequelae (Boppana et al, 1997; Noyola et al, 2001). Neuro-radiographic findings include periventricular intracranial calcifications (which may also be seen on plain skull films), ventriculomegaly, cerebellar hypoplasia, and, less commonly, myelination delay consistent with migrational disorders such as lissencephaly, schizencephaly, and pachygyria (Barkovich and Lindan, 1994; Hayward et al, 1991).

Pathologic examination of aborted fetuses or autopsy of infants with symptomatic CMV infection shows characteristic multinuclear giant cells with both cytoplasmic and intranuclear inclusion bodies in many organs, including liver, lungs, brain, pancreas, and kidneys. Mononuclear cell infiltration and diffuse fibrosis may be intense. The brain contains areas of necrosis, often subependymal and periventricular, and glial overgrowth, containing heavy deposits of calcium. Petechiae and larger hemorrhages involve the skin and serous surfaces (Kasprzak et al, 2000; Ko et al, 2000).

### Treatment

The CMV virus differs from herpes simplex and varicella viruses in that it lacks the enzyme thymidine kinase. This feature renders it resistant to antiviral agents that depend on the enzyme for their action, such as acyclovir. Attempts to treat CMV infection with idoxuridine, cytosine arabinoside, adenine arabinoside, interferon inducers, interferon alpha, corticosteroids, cytotoxic agents, and CMV IgG have all failed. Transient reduction in the titer of virus excretion in the urine may be seen with such approaches, but no clinical benefit has been detected.

Anecdotal accounts and case series on the use of ganciclovir have reported variable results (Nigro et al, 1994). A phase II multicenter trial to test the safety and pharmacokinetics of using intravenous ganciclovir for 6 weeks in 47 severely symptomatic infants showed a transient decrease in viral urine titers, and at 2 years of follow-up, 24% of infants were developing normally. Side effects included neutropenia and thrombocytopenia, and 19% of subjects discontinued the drug due to toxicity (Whitley et al, 1997). This transient reduction in viral shedding is difficult to interpret, because other evidence suggests that duration of viral shedding does not correlate with clinical outcome

(Noyola et al, 2000). A phase III randomized, controlled study of 42 infants showed a higher proportion (68%) of infants in the placebo group with worsening of hearing based on BSER test results compared with 21% of infants treated with intravenous ganciclovir for 6 weeks. A significant proportion (63%) of treated infants also developed severe neutropenia during treatment compared with controls (21%) (Kimberlin et al, 2003). Thus, the risk to benefit ratio of administering this intravenous drug for 6 weeks with the frequent side effect of neutropenia makes its use controversial.

### Prognosis

The fate of the congenitally infected infant who is normal at birth is still not clear. Two early series indicated variable risks of deafness and reduction of IQ scores (Hanshaw et al, 1976; Reynolds et al, 1974). In both instances, however, the case finding method was measurement of cord IgM level; an increase in this value might be found only in more severely affected infants (possibly reflecting primary infection in the mother). In another follow-up study, the children were found to be normal at 4 years, but audiometric screening was not performed (Kumar et al, 1973). A Swedish study monitored CMV-infected infants who remained asymptomatic (including no hearing loss) at 12 months of age, and no differences were noted in development or intelligence at 21 months and 7 years of age in these subjects compared with uninfected matched controls (Ivarsson et al, 1997). Thus, most early evidence suggested that infected infants who are asymptomatic at birth will have minimal to no sequelae other than potential hearing loss.

However, congenital CMV infection is currently the leading cause of sensorineural hearing loss in childhood in developed countries. It is now estimated that 7% to 15% of asymptomatic congenitally infected infants have sensorineural hearing loss (Fowler et al, 1997; Williamson et al, 1992). Severity of hearing loss ranges from mild to profound, and of those with hearing loss, approximately half have bilateral deficits, and half have progressive hearing loss. In one fifth of the infants with hearing loss, onset is delayed to 2 to 5 years of age (Fowler et al, 1997). Visual impairment in asymptomatic infants is rare (Coats et al, 2000).

For congenitally infected infants who are symptomatic at birth, mortality rates range from 4% to 30%, and at least 90% of symptomatic neonates have late complications (Griffiths, 1993; Stagno and Whitley, 1985a). Of those who survive, 60% to 75% have intellectual or developmental impairment (Berenberg and Nankervis, 1970), about one third have hearing loss, one third have neuromuscular disorders (spasticity or seizures), and a smaller proportion experience visual impairment due to reactivation or late-onset chorioretinitis. Of all the CMV-infected infants who eventually develop hearing loss, only one third are identifiable with newborn hearing screening at birth (Fowler et al, 1999); thus, these infants should have close audiologic follow-up for the first several years of life.

Neurologic outcomes in congenitally infected infants vary, but microcephaly (when adjusted for weight and gestational age) is the most specific predictor, and head CT

scan abnormality the most sensitive prognostic factor, for poor cognitive outcome and motor disability (Noyola et al, 2001). Duration of viral shedding has no correlation with long-term outcomes (Noyola et al, 2000). Up to one third of infected infants are normal late in childhood, and those who demonstrated minimal abnormalities at birth have the greatest chance of being normal at long-term follow-up. Strabismus and amblyopia may develop, so these infants should have close ophthalmologic follow-up throughout their lives (Coats et al, 2000).

### Prevention

There is currently no convincing evidence supporting the benefits of antiviral therapy for CMV infection during pregnancy. Preliminary research efforts to develop a vaccine are in progress. The most important means of prevention are basic hygiene and hand-washing for pregnant women, especially after contact with urine, diapers, oral secretions, and other body fluids.

## HERPES SIMPLEX VIRUS INFECTIONS

Herpes simplex viruses are classified into two types. HSV-1 causes approximately 98% of oral infections (gingivostomatitis and pharyngitis), 7% to 50% of primary genital herpes, and almost 100% of encephalitis after the newborn period. HSV-2 causes 90% of primary genital herpes, 99% of recurrent genital infections, and most cases of aseptic meningitis (Nahmias and Roizman, 1973; Freij and Sever, 1988). It is likely that most infections are acquired from the mother shortly before or at the time of delivery, though some are acquired from other sources. Considering the high frequency of oro-labial herpes in the adult population, however, acquisition of herpes simplex from such lesions must be extremely rare.

### Incidence

Seroprevalence of HSV-2 ranges from 20% to 45% and varies with gender and ethnicity (Fleming et al, 1997). The incidence of genital herpes infections has risen steadily since the 1970s (Whitley, 1994), and the frequency of neonatal disease has concomitantly increased (Prober et al, 1988). Approximately 70% to 85% of neonatal herpes simplex infections are caused by HSV-2 (Kimberlin et al, 2001). Frequency of neonatal disease differs among populations according to socioeconomic status as well as incompletely understood immunologic factors (Nahmias and Roizman, 1973; Nahmias et al, 1971; Whitley, 1993). Estimated incidence of neonatal HSV infection is one in 3500-10,000 deliveries (Whitley, 1993). Primary genital herpes infection in a pregnant mother results in an attack rate of 33% to 50% for her infant, whereas recurrent maternal infection results in a 1% to 3% attack rate (Arvin, 1991; Brown et al, 1997; Prober et al, 1987).

### Etiology and Pathogenesis

Some infants with HSV have been described with a syndrome more closely resembling congenital viral infection; they were probably infected in utero during the first or second trimester (Florman et al, 1973; Freij and Sever,

1988; South et al, 1969). These cases compose approximately 5% of neonatal HSV infections (Kimberlin, 2001). Primary genital HSV infections that occur during the first half of pregnancy are associated with a higher frequency of spontaneous abortions and stillbirths (Freij and Sever, 1988; Stagno and Whitley, 1985b).

Most HSV-infected infants (approximately 85%) acquire HSV from the maternal genital tract at the time of delivery, although only 15% to 30% of mothers who give birth to infants with neonatal HSV infection have a known history of genital HSV (Whitley, 1988). HSV lesions have been reported to develop at the site of intrapartum monitoring electrodes on the infant's scalp. A smaller number of infants are infected several days before delivery and are born with clinically evident disease. Cases proved to have been acquired from individuals other than the mother, or even from the mother at any time other than during delivery, are rare (Linnemann et al, 1978; Yeager et al, 1983). Postnatal infections are estimated to contribute approximately 10% of neonatal HSV infections. There are also anecdotal case reports of postnatally acquired HSV infection after procedures such as instrumentation during ophthalmologic examinations for premature infants and ritual circumcisions performed by Orthodox Jewish *mohelim* (Hutchinson et al, 2000; Rubin and Lanzkowsky, 2000).

The pathogenic mechanisms responsible for the newborn infant's susceptibility to herpes infection do not depend on a single key difference between adult and infant but are the results of a spectrum of immunologic deficiencies (Arvin, 1991; Burchett et al, 1992; Jenkins and Kohl, 1992). Among the currently identified cellular deficits are the inability of the neonatal macrophage and unstimulated neonatal lymphocyte to mediate early viral containment, and a profound defect in natural killer cell cytotoxicity (Kohl, 1985). The contribution of transplacentally acquired antibody is unresolved, but type-specific antibody is probably partially protective (Arvin, 1991; Arvin and Prober, 1993; Kohl, 1991). Antibody-dependent effector mechanisms, including antibody-dependent cellular cytotoxicity, which may rely on lymphocytes, macrophages, and polymorphonuclear leukocytes, may be responsible in different infants for the conflicting data concerning anti-HSV antibody titers and protection from infection. The genetic and developmental regulatory mechanisms of these varied immunologic defects suggest different immunoregulatory interventions that are individualized for specific infants.

Disseminated disease may infect and infiltrate several different organs. Macroscopic examination shows that many viscera, but chiefly the liver, lungs, and adrenal glands, are riddled with pale yellow, firm, necrotic nodules, measuring 1 to 6 mm in diameter. Under the microscope, massive coagulation necrosis can be seen to involve the parenchyma, stroma, and vessels in these areas. Necrotizing, calcifying lesions of the brain may also be found. Intracellular eosinophilic inclusions as well as multinucleated giant cells, which represent the individual cell's response to viral infection, may be observed (Singer, 1981).

### Clinical Spectrum

Although most neonatal HSV infections occur perinatally, there are several case reports of infants born with congenital

malformations more suggestive of in utero HSV infection. Clinical manifestations involve multiple systems, primarily the skin, central nervous system (CNS), and eyes. Reported findings include extensive dermatologic scarring or bullae, microencephaly or hydranencephaly, encephalitis, microphthalmia or chorioretinitis, and sometimes hepatosplenomegaly (Baldwin and Whitley, 1989; Hutto et al, 1987).

Most infants with perinatal or postnatal HSV infection are normal at birth, illness developing after 3 days of age. Approximately 40% to 50% of affected infants are less than 36 weeks in gestational age (Whitley, 1988). Overt herpetic disease in the maternal genital tract is evident in only about one third of patients (Overall, 1994). In the remaining two thirds, the virus likely originates from an asymptomatic maternal genital infection.

The clinical manifestations of disease have been classified into the following three groups: (1) localized skin, eye, and mouth (SEM) disease, (2) encephalitis or CNS disease, and (3) disseminated disease. SEM disease without overt CNS involvement represents approximately 20% of all cases of neonatal herpes. Localized CNS disease with or without skin, eye, or oral cavity involvement is seen in approximately 33% of infants with neonatal herpes. Approximately 50% of all cases of neonatal herpes manifest as disseminated disease (Whitley, 1993).

Less than half of infants with any form of HSV infection have fever; only 30% to 40% of patients have the classic vesicular skin lesions at presentation, and only two thirds of patients have skin lesions at any time during infection. On the neonatal skin, HSV produces the characteristic grouped vesicles seen in later life, although individual lesions may be large and even bullous, and late lesions are typically eroded, flat, irregular ulcers with an erythematous base.

Disseminated disease usually begins toward the end of the first week of life. Skin vesicles may be the first or a later sign, but they do not appear at all in almost half of patients. Systemic symptoms, although insidious in onset, progress rapidly. Poor feeding, lethargy, and fever may be accompanied by irritability or convulsions if the CNS is involved. These symptoms are followed rapidly by jaundice, hypotension, disseminated intravascular coagulation, apnea, and shock. This form of disease is indistinguishable at its onset from both neonatal enterovirus infection and bacterial sepsis. Thus, herpes infection should be considered in the differential diagnosis of infants who have fever during the first 2 weeks of life.

Localized disease may begin somewhat later, with most cases appearing in the second to third week of life. When the CNS is the primary site of infection, the skin or eyes may or may not be involved. The infants are lethargic, irritable, and tremulous, and seizures are common and difficult to control.

Other less common but potentially localized or disseminated findings are keratoconjunctivitis or chorioretinitis, which account for approximately 5% of HSV manifestations, and pneumonitis, which can begin as a focal infiltrate but may become generalized. Supraglottitis, intracranial hemorrhage, aseptic meningitis, and fulminant liver failure have also been described in association with neonatal HSV infection (Abzug and Johnson, 2000; Greenes et al, 1995; Kohl, 1994; Schlesinger and Storch, 1994).

### Laboratory Evaluation

Except when encephalitis is the only manifestation of disease, HSV is readily recovered from clinical samples. In the disseminated form, virus is present in blood, conjunctivae, respiratory secretions, urine, and, in approximately half of the patients, the central nervous system. In the localized form, the virus can usually be found at the site of disease. Definitive microbiologic diagnosis requires growth of the virus in tissue culture. Fortunately, HSV can be detected in culture because of its cytopathic effect in 24 to 48 hours in most instances. When herpes neonatorum is suspected, viral cultures of the throat, conjunctiva, blood, stool or rectum, and urine should all be obtained, as should scrapings of any suspicious skin lesions. Of these sites, skin and conjunctival HSV cultures have the highest yield (Kimberlin et al, 2001). The mother's genital tract should also be sampled if there is a high index of suspicion. Scrapings of skin vesicles may show giant, multinucleated cells when stained with Wright or Giemsa stain (the Tzanck smear), typical of either herpes or varicella virus infection, although this test has low sensitivity. Demonstration of viral antigens in cytologic smears by means of enzyme immunoassays is more sensitive than the Tzanck smear, and direct fluorescent antibody staining also provides rapid results (Alpert and Plotkin, 1986). Serologic assays are rarely helpful in neonatal infections.

CSF should be sent for cell count, protein, and glucose measurements, and HSV DNA PCR analysis. PCR of the CSF yields a much higher sensitivity for HSV than viral CSF culture. There is a wide variability of reliable PCR results, depending on individual laboratory expertise and experience. False-positive and false-negative results may occur early in the disease; thus, as with all tests, results should be interpreted cautiously and in conjunction with clinical evaluation. Usually if the CNS is involved, evaluation of the CSF reveals a lymphocytosis, often red blood cells, normal or high protein level, and low or normal glucose level. Some experts recommend obtaining a second CSF specimen for evaluation at the end of antiviral therapy, and it has been reported that persistence of HSV DNA may be a poor prognostic factor (Kimberlin et al, 1996b; Malm and Forsgren, 1999). Research is under way to investigate the utility of quantitative HSV PCR as well as PCR of serum and other respiratory, gastrointestinal, and urinary samples (Diamond et al, 1999; Revello et al, 1997).

In disseminated disease, liver transaminase elevations consistent with hepatocellular injury are usually found. Infants with CNS disease should also undergo neuroradiographic imaging with CT or magnetic resonance imaging (MRI). Imaging may demonstrate early, nonspecific lack of gray-white matter junction differentiation and general signs of encephalitis. Later findings include dilated ventricles, parenchymal echogenicity, cystic degeneration, and intracranial calcifications (O'Reilly et al, 1995). Newborn HSV encephalitis is not usually confined to the temporal lobes as is classically described in older patients. Electroencephalography (EEG) should also be performed in infants with CNS or disseminated disease to evaluate for seizure activity; EEG findings will be abnormal in approximately 80% of such patients (Kimberlin et al, 2001).

### Treatment

After the appropriate specimens are collected and sent for viral culture and PCR analysis, the infant should receive acyclovir, 60 mg/kg/day intravenously divided into 3 doses given every 8 hours, for 14 days in SEM disease and 21 days in disseminated or CNS disease (American Academy of Pediatrics [AAP], 2003). This treatment has been shown to be effective in all forms of the disease, reducing mortality and, to a lesser extent, long-term sequelae. Shorter intervals between initiation of treatment and onset of symptoms have been shown to decrease mortality and morbidity (Whitley, 1991). Herpetic keratoconjunctivitis should receive topical ophthalmic antiviral therapy along with parenteral treatment. No persuasive human data currently exist supporting the use or efficacy of intravenous immunoglobulin or cytokines to treat HSV. Monoclonal antibodies have proved helpful in animal models and will likely be studied in humans within the next few years (Kimberlin, 2001).

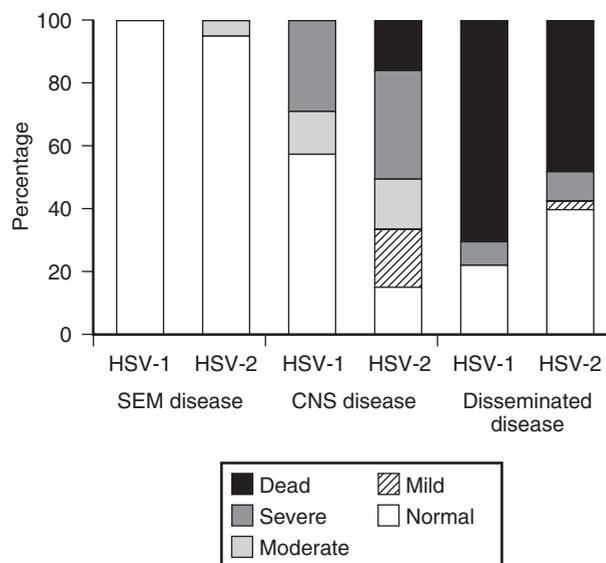

The Collaborative Antiviral Study Group is currently conducting randomized controlled studies to evaluate long-term oral suppressive acyclovir therapy after neonatal HSV in the prevention of recurrent skin lesions and neurologic sequelae. Phase I and II trials demonstrated fewer cutaneous recurrences in the treatment group but did not have enough subjects to analyze the impact on neurologic outcomes (Kimberlin et al, 1996a). Neutropenia has been reported in 20% to 50% of neonates receiving long-term acyclovir therapy. The emergence of acyclovir-resistant HSV strains is also a concern (Kimberlin et al, 1996a; Oram et al, 2000).

### Prognosis

Overall mortality for neonatal HSV infection with treatment is approximately 20%. Infants with localized SEM disease typically have minimal mortality and lower morbidity. Despite a lack of detectable CNS disease upon presentation, neurologic abnormalities develop later in approximately 5% of this group. The survival results reported by the Collaborative Antiviral Study Group trials for infants with CNS or disseminated disease treated between 1981 and 1997 are shown in Figure 37-3 (Kimberlin et al, 2001).

The mortality rates in infants with localized CNS disease range from 4% to 14% with antiviral therapy, and most survivors have long-term neurologic sequelae. Risk factors for increased morbidity and mortality from CNS infection include prematurity and seizures upon initiation of therapy (Kimberlin et al, 2001; Kohl, 1999). Infants with disseminated disease have an even higher mortality without antiviral therapy; 80% die, and survivors have serious neurologic sequelae (Whitley, 1988). With antiviral therapy, 20% to 60% die, and 40% to 55% of survivors suffer neurologic sequelae (Freij and Sever, 1988). High-dose acyclovir has improved mortality rates but has had less impact on morbidity. Lethargy at initiation of therapy has been noted to be associated with a higher mortality rate in neonates with disseminated HSV infection (Kimberlin et al, 2001).

Even with antiviral treatment, the prognosis for survivors of disseminated HSV infection is poor. Microcephaly, spasticity, paralysis, seizures, deafness, blindness, or a combination of these conditions develops in more than half of infants with disseminated disease. Infants with skin

involvement often have recurrent crops of skin vesicles for several years. More than three episodes of recurrent skin lesions within the first 6 months of life is a prognostic sign for poor neurologic outcome (Whitley, 1991).

### Prevention

If a mother has active genital herpes simplex infection at the time of delivery and if the membranes are either intact or have been ruptured for less than 4 hours, both the AAP and the American College of Obstetrics and Gynecology (ACOG) recommend delivery by cesarean section (AAP, 2003; ACOG practice bulletin, 2000). There is a 30% to 50% risk to the child inadvertently delivered vaginally during primary maternal infection; thus, most experts recommend surveillance HSV cultures of conjunctiva, oropharynx, and nares at 24 to 48 hours after birth. Some experts recommend empiric intravenous acyclovir treatment for 10 to 14 days of any infant born vaginally to a mother with known active primary HSV infection, whereas others advocate such a measure only if the infant is symptomatic or results of HSV cultures or other diagnostic tests are positive.

Because active recurrent maternal genital HSV infection at the time of delivery poses a less than 5% risk of infection to the infant, cesarean section is also strongly recommended in this situation, although the issue is more controversial. Many experts also recommend surveillance viral cultures of infants born to mothers with recurrent HSV infection. In all cases, infants should be observed closely for signs of infection, and parents should be educated about the signs and symptoms of neonatal HSV (AAP, 2003).

Infants in whom HSV infection is known or highly suspected should be put in isolation with contact precautions, and skin lesions should be covered. Any health care provider with active herpetic whitlow should not have

direct patient care responsibilities for neonates (AAP, 2003).

Several clinical phase I, II, and III trials are ongoing to investigate the utility of various HSV vaccines to prevent genital infections (Stanberry, 1998).

## VARICELLA

Varicella zoster is a DNA virus in the herpes virus family. Primary varicella infection, commonly known as *chickenpox*, usually results in a fever and a characteristic vesicular exanthem beginning on the face or trunk. It is often accompanied by other systemic symptoms, such as headache and malaise. Secondary infection or reactivation, usually referred to as zoster or shingles, is characterized by a painful vesicular rash in a dermatomal distribution. Primary varicella infection during pregnancy can result in congenital malformations.

There is some confusion about the term *congenital varicella* that would probably be best resolved if the term were reserved for the rare cases transmitted to the fetus in the first or second trimester of pregnancy (Laforet and Lynch, 1947; Sraubstein et al, 1974). Also often called “congenital varicella” but probably more appropriately termed *neonatal varicella* are those cases of perinatal varicella acquired late in the third trimester, which become apparent in the newborn on or before the tenth day of life.

### Incidence

Before the advent of routine varicella immunization in childhood in the United States, seroprevalence surveys estimated that approximately 95% of women were immune (Gershon, 1975). Primary varicella-zoster virus (VZV) infections occurred during pregnancy with a frequency of 5 to 7 per 10,000 pregnancies in the United States (Balducci et al, 1992; Brunell, 1992). For pregnant women with primary varicella infection, the transmission rate to the fetus is estimated to be approximately 25%. Only 4% to 8% of infected fetuses have symptomatic disease, so congenital varicella syndrome (CVS) is rare (Enders et al, 1994; Liesnard et al, 1994).

At least 96 cases of CVS have been reported in the literature (Sauerbrei and Wutzler, 2000). The risk of symptomatic intrauterine VZV infection after maternal varicella during the first 20 weeks is approximately 1% to 2% (Enders et al, 1994; Paryani and Arvin, 1986; Pastuszak et al, 1994; Siegel, 1973). Unlike first-trimester mumps and rubella infection, first-trimester varicella infection does not commonly result in a detectable increase in fetal wastage (Brunell, 1992; Siegel and Fuerst, 1966). Paryani and Arvin (1986) reported that 1 of 11 infants born to women with varicella during the second trimester demonstrated herpes zoster during infancy; among 16 infants born to women with varicella during the third trimester, 2 had varicella at birth. Two thirds of symptomatic infected infants reported are female (Sauerbrei and Wutzler, 2000).

Neonatal varicella is much more common than congenital varicella. For infants whose mothers contract varicella 5 days or less before delivery or up to 2 days after delivery, the infant attack rate is 17% to 31% (Brunell, 1992; Feldman, 1986; Meyers, 1974). Neonatal varicella may

develop despite the administration of varicella zoster immune globulin (VZIG) to the infant at birth.

Although primary maternal varicella infection has been associated with congenital infection and potential sequelae, transmission secondary to maternal reactivation with clinical zoster during pregnancy has not been reported. A prospective study of infants born to 366 mothers with a clinical history of zoster during pregnancy found no infants with congenital malformations consistent with intrauterine VZV infection (Enders et al, 1994). Of the few case reports of infants with malformations born to mothers with clinical zoster during pregnancy, none has had findings classically associated with CVS or laboratory evidence of intrauterine infection with VZV (Sauerbrei and Wutzler, 2000). See Figure 37-4 for an overview of perinatal varicella infection.

### Etiology and Pathogenesis

CVS is acquired from a maternal primary varicella infection that occurs during the first or second trimester. The virus is thought to be transmitted transplacentally during the viremia that precedes or accompanies the rash. Ascending infection from cervical infection has also been proposed as a potential mechanism of transmission (Sauerbrei and Wutzler, 2000). It has been suggested that some of the congenital malformations associated with maternal varicella infection may actually be the consequence of zoster reactivation of the fetus in utero rather than direct effects of the primary viral infection. This explanation is supported by the common clinical finding of a dermatomal distribution of skin lesions in the newborn. Immature fetal cell-mediated immune response may explain the short latency period as well as the inadequate protection from the consequences of reactivation infection (Higa et al, 1987; Kustermann et al, 1996). Pathology reports have noted destruction of neural tissue with residual dystrophic calcifications, chronic active inflammation in non-

neural tissues surrounding viral inclusions, and chronic villitis of the placenta (Bruder et al, 2000; Petignat et al, 2001; Qureshi and Jacques, 1996).

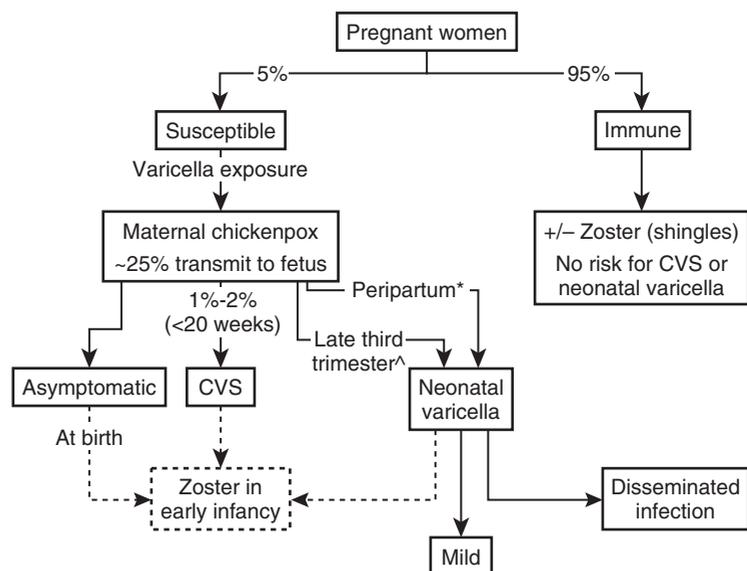

Neonatal varicella is probably transplacentally acquired in most cases. Because the incubation period for varicella is between 10 and 21 days, cases beginning in the first 10 days of life are considered to have been acquired in utero. The prognosis, however, differs markedly between those cases in which maternal illness began 5 or more days before delivery and those in which maternal illness occurred from 5 days before to 2 days after delivery. In the first group, neonatal disease usually begins with the first 4 days of life, and the prognosis is good. Early case series reported survival in 27 of 27 infants (Gershon, 1975). Presumably, maternal immunity has appeared before delivery and has been transferred to the baby before birth. In the second group, neonatal disease begins between 5 and 10 days after delivery. Of 23 cases described, 7 infants (30%) died of overwhelming varicella, and 2 barely survived after severe disease (Brunell, 1966). Serious postnatal infection acquired from maternal varicella via breast-feeding has not been reported.

### Clinical Spectrum

As with many other congenital viral infections, there is likely a wide clinical range of VZV disease. In the only large prospective study, involving more than 1300 pregnant women with varicella infection, 7% to 12% of the infants had serologic evidence of disease postnatally but remained asymptomatic. At least 1% to 2% of congenitally infected infants may be asymptomatic at birth and demonstrate zoster in early infancy (Enders et al, 1994).

The rare cases of CVS are characterized by the presence of unusual cicatrices, often in a dermatomal distribution, asymmetric muscular atrophy with limb hypoplasia, low birth weight, neurologic abnormalities (cortical or spinal

**FIGURE 37-4.** Overview of varicella infection during pregnancy. *Peripartum* is defined as between 5 days before and 2 days after delivery; *Late third trimester* is defined as between 2 weeks and 5 days before delivery. *Dotted lines* denote potential outcome. CVS, congenital varicella syndrome.

CVS = Congenital varicella syndrome

cord atrophy, seizures, microcephaly, encephalitis, Horner syndrome), and ophthalmologic abnormalities (chorioretinitis, microphthalmia, atrophy, and cataracts) (Brunell, 1992; Feldman, 1986; Sauerbrei and Wutzler, 2000). Gastrointestinal abnormalities are reported in 15% to 23% of cases; findings include duodenal stenosis, dilated jejunum, small left colon, intestinal atresia or bands, and hepatic calcifications (Alkalay et al, 1987; Jones et al, 1994). Table 37-4 summarizes the frequencies of clinical findings in 96 infant cases of CVS (Sauerbrei and Wutzler, 2000).

Neonatal varicella follows typical maternal varicella and thus can usually be anticipated. Disease that is evident at birth or that appears in the first 4 days of life is usually mild, with a few cutaneous lesions, presumably due to modification of the illness by maternal immunity. When the disease appears in the infant during the riskiest period (between 5 and 10 days of age), it closely resembles varicella in the immunodeficient or immunosuppressed host. Recurrent crops of skin vesicles develop over a prolonged period, reflecting the newborn infant's inability to control the infection. Typical presenting signs are fever, hemorrhagic rash, and visceral dissemination with involvement of the liver, lung, and brain. Secondary bacterial infection may occur.

#### Laboratory Evaluation

Prenatal diagnosis, by means of quantification of varicella-specific IgM on fetal blood obtained by cordocentesis or through PCR analysis of chorionic villi, fetal blood, and

amniotic fluid, has been attempted (Cuthbertson et al, 1987; Kustermann et al, 1996; Mouly et al, 1997). Although the yield of PCR on amniotic fluid or fetal blood is higher than that of serologic analysis of fetal IgM or viral cultures, large prospective studies of correlation of such findings with clinical outcomes have not been performed. Prenatal ultrasonographic findings include polyhydramnios, hydrops, progressive intrauterine growth restriction, microcephaly, limb hypoplasia, and liver hyperechogenicities (Pretorius et al, 1992). Abnormal ultrasonographic findings may not develop in a fetus for at least 5 weeks after maternal infection (Kerkering, 2001).

Serologic studies can be performed postnatally on infants (Paryani and Arvin, 1986). Suspected congenital infection with varicella may be confirmed by the finding of persistent VZV IgG beyond the presumed duration of passive transfer of maternal antibodies (at least 6 to 7 months). Detection of fetal IgM may also confirm infection, but it is less useful because only about one fourth of infants reported with classic CVS have positive VZV IgM titer values (Enders et al, 1994; Sauerbrei and Wutzler, 2000). Scrapings of skin lesions, as with herpes simplex infections, may show large multinucleated cells when stained with Wright or Giemsa stain (Tzanck smears), but this procedure is not commonly performed. The virus can be grown in tissue culture or detected by direct fluorescent antibody (DFA) staining of cells from skin and visceral lesions, but viral tests in infants with congenital infection are often extremely low yield compared with those infants with acquired varicella infections. Neuroradiographic

**TABLE 37-4**

**Main Symptoms of Infants with Congenital Varicella Syndrome Cited in the Literature (N = 96)\***

Symptom	No. of Infants Affected	% of Infants Affected
Skin lesions: cicatricial scars, skin loss	70	76
Neurologic defects or diseases: cortical atrophy, spinal cord atrophy, limb paresis, seizures, microcephaly, Horner syndrome, encephalitis, dysphagia	55	60
Eye diseases: microphthalmia, exophthalmia, chorioretinitis, cataracts, nystagmus, anisocoria, optic atrophy	47	51
Limb hypoplasia and other skeletal anomalies	45	49
Intrauterine growth retardation	20	22
Muscle hypoplasia	19	21
Gastrointestinal abnormalities	14	15
Developmental delay	11	12
Genitourinary abnormalities	11	12
Defects of the cardiovascular system	7	8
Defects of other organs	6	7

demonstration of intracranial calcifications has been reported but is not common (Kerkering, 2001).

### Treatment

No controlled studies examining the effect of antiviral therapy to prevent or treat congenital varicella syndrome have been conducted. Treatment of the infected pregnant woman with acyclovir is unlikely to be effective in preventing fetal infection, because viremia with VZV typically takes place 1 to 2 days before the characteristic rash, and antiviral therapy shortens the duration of infection by only about 1 day. Anecdotal observations have noted a potential effect of acyclovir on the progression of eye disease in CVS (Sauerbrei and Wutzler, 2000). No recommendations can be made to use acyclovir for treatment or prevention of CVS.

If symptoms of neonatal varicella are severe, treatment with intravenous acyclovir, 60 mg/kg/day divided into doses every 8 hours, should be given.

### Prognosis

Prospective studies of the long-term outcomes of congenitally infected infants with VZV have not been performed, and there is probably a wide continuum of disease. Among the 96 congenitally infected infants reviewed by Sauerbrei and Wutzler (2000), 14 (15%) had clinical signs of zoster during early infancy. Some experts consider early zoster infection as one criterion for diagnosis of infection with VZV in utero. Mortality rates for CVS are estimated at 30%. Deaths generally occur within the first few months of life, usually secondary to severe pulmonary disease (Pastuszak et al, 1994; Sauerbrei and Wutzler, 2000). Before the use of VZIG and acyclovir, mortality rates for neonatal varicella were also approximately 30% (Isaacs, 2000).

### Prevention

If a susceptible pregnant woman has a significant exposure to varicella, administration of high-titered VZIG should be seriously considered. Infants of mothers in whom varicella develops from 5 days before to 2 days after delivery should receive VZIG as soon as possible (125 units) (AAP, 2003). Such preparations have been shown to prevent chickenpox in exposed older children (Brunell et al, 1969) but do not always prevent infection (Reynolds et al, 1999). Approximately 50% of exposed infants treated with VZIG may still have varicella infection, but the disease is often attenuated, and only approximately 10% have severe disease (Hanngren et al, 1985).

Follow-up of infants exposed to VZV and treated with VZIG may include consideration of serologic testing (enzyme immunoassay, latex agglutination, or indirect fluorescent antibody staining for IgG) to determine whether asymptomatic infection has elicited immune protection. Repeat exposure of infants in whom varicella did not develop more than 3 weeks after administration of VZIG should prompt administration of another dose of VZIG (AAP, 2003). If special globulin preparations are not available, standard intravenous immune globulin (IVIG) may be given. The infant should also be put in respiratory isolation for 28 days or until discharge, because administration of VZIG may prolong the incubation period.

In the event of a significant varicella exposure in a nursery situation, infants whose mothers have no history of

chickenpox and who have undetectable anti-varicella antibody titers should be considered candidates for VZIG. All exposed infants less than 28 weeks of gestational age, regardless of maternal history, should receive VZIG (AAP, 2003). The recommended dosage is 125 units/10 kg. Little experience is available to guide treatment of extremely premature infants, but fractional doses are not recommended; currently, all infants should receive 125 units.

The best means of prevention is to follow current recommendations for universal varicella immunization of all children at 12 to 15 months of age as well as susceptible adolescents and adults at high risk of exposure to varicella. None of the 362 women followed in a pregnancy registry for inadvertent exposure to varicella vaccine during or within 3 months of pregnancy has given birth to an infant with congenital varicella syndrome (Shields et al, 2001). Nonetheless, it is recommended that adolescents and women of child-bearing age should avoid pregnancy for at least 1 month after immunization.

## HUMAN PARVOVIRUS B19

Parvovirus B19, a single-stranded, small DNA virus, is the only member of the parvovirus family that causes disease in humans. Infection with parvovirus B19 is more commonly known as *fifth disease* or *erythema infectiosum*; it is classically described as a childhood exanthem with a “slapped cheek” rash. Considerable interest in the role of human parvovirus B19 infection in neonatal hydrops fetalis (nonimmune) and fetal aplastic crisis has developed since cases of fetal deaths in humans associated with maternal parvovirus B19 infection were reported in the 1980s (Brown et al, 1984; Kinney et al, 1988).

### Incidence

Approximately 50% to 80% of adults in the United States are seropositive for human parvovirus B19 (Anderson, 1987). A significant proportion of child-bearing women is thus presumably susceptible to human parvovirus B19 infection. Although large studies are not available, the overall risk of maternal exposure or infection to the fetus appears low (Berry et al, 1992; Sheikh et al, 1992). It is estimated that one quarter to one third of maternal parvovirus infections are transmitted to the fetus (Alger, 1997; Gratacos et al, 1995). It is difficult to estimate risk of sequelae, but approximately 1% to 12% of pregnancies in which infection occurs before 20 weeks of gestational age have resulted in fetal loss, and up to 1% of those infected after 20 weeks may lead to fetal hydrops or death (Markenson and Yancey, 1998; Yaegashi et al, 1998). The risk of adverse sequelae appears to be highest during the second trimester. Thus, at most, the fetus of a pregnant woman with a significant exposure to parvovirus B19 has a 1% to 3% risk of hydrops or death.

Various estimates suggest that human parvovirus B19 infection contributes from 10% to 27% of cases of nonimmune hydrops fetalis (Essary et al, 1998; Markenson and Yancey, 1998; Yaegashi et al, 1994). Although there are case reports of neurologic and ophthalmologic anomalies associated with maternal parvovirus B19 infections, no prospective studies or characteristic anomalies have conclusively identified the virus as a human teratogen. Two

studies undertaken to examine the association between human parvovirus B19 infection and congenital anomalies have failed to reveal any connection (Kinney et al, 1988; Mortimer et al, 1985). There have been at least three case reports of fetal encephalopathy associated with in utero infection with parvovirus B19 (Alger, 1997).

### Etiology and Pathogenesis

The most common route of transmission of parvovirus B19 is via respiratory droplets. Typically, once the virus establishes infection, viremia occurs along with systemic symptoms such as fever and malaise. It is important to note that viremia lasts only 1 to 3 days, and the characteristic immune-mediated rash develops 1 to 2 weeks later, when the host is no longer infectious.

Potential pathogenic mechanisms involve the recognized affinity of parvovirus B19 for progenitor erythroid cells of bone marrow. The blood group P antigen is a main cellular receptor for parvovirus B19, and it is found on red blood cells and on placental trophoblast cells (Jordan et al, 2001). Fetal infection most likely occurs hematogenously via the placenta during maternal viremia. Parvovirus B19 infection then causes a pronormoblast arrest, which leads to fetal anemia, nonimmune hydrops, and, sometimes, progressive congestive heart failure (Kinney et al, 1988). The fetus is especially susceptible to adverse consequences of red blood cell infection secondary to short erythrocyte life span and rapidly expanding blood volume, especially during the second trimester. It has been well established that antibody-mediated immune response is crucial to protection from acquired parvovirus B19 infection. Data also suggest that cell-mediated immune responses may contribute to the pathogenesis of congenital infection (Jordan et al, 2001).

Pathologic studies of human fetuses infected with parvovirus B19 have suggested that myocardial inflammation and subendocardial fibroelastosis may also contribute to fetal hydrops (Morey et al, 1992). It has also been postulated that parvovirus B19 infection leads to cytotoxicity and subsequent anemia by inducing apoptosis of infected red blood cells (Yaegashi et al, 1999). Neuropathologic findings in the infected hydropic fetus include perivascular calcifications, primarily in the cerebral white matter, as well as multinucleated giant cells. Viral DNA has been demonstrated in the brain and liver (Isumi et al, 1999).

### Clinical Spectrum

Parvovirus B19 infection causes erythema infectiosum, or fifth disease, in normal hosts, aplastic crisis in patients with hemolytic disorders, and chronic anemia in immunocompromised hosts. A substantial proportion of infected adult women may also have arthropathy in association with parvovirus B19 infection. Maternal symptoms have been present in up to two thirds of documented cases of nonimmune hydrops fetalis associated with parvovirus B19 infection (Yaegashi et al, 1998).

Little data are available regarding clinical outcomes of infected infant survivors, but two prospective studies in the United Kingdom of more than 300 congenitally exposed infants found the risk of major congenital or developmental abnormality to be less than 1% (Miller et al, 1998; Prospective study, 1990).

### Laboratory Evaluation

The diagnosis of human parvovirus B19 infection is most commonly made clinically. Serologic confirmation is necessary in high-risk situations, such as after a significant exposure of a pregnant woman. Both radioimmunoassays and enzyme-linked immunosorbent assays (ELISAs) are available for detection of human parvovirus B19-specific IgG and IgM (Kinney and Kumar, 1988). Presence of anti-parvovirus B19 IgM in fetal blood or amniotic fluid may confirm fetal infection but may be detected in only one fifth of infected fetuses (Torok et al, 1992). False-positive results of anti-parvovirus B19 IgM testing have also been reported, including cross-reactions with anti-rubella IgM (Dieck et al, 1999).

In the context of a human parvovirus B19 infection in a symptomatic, pregnant woman, elevated or rising weekly measurements of maternal serum alpha-fetoprotein may indicate that the fetus is infected. Elevated maternal alpha-fetoprotein concentration may also be a marker for an adverse outcome (Carrington et al, 1987). Serial fetal ultrasonographic evaluations of infected pregnant women are recommended to evaluate and follow for fetal hydrops or demise.

Other techniques to diagnose fetal parvovirus B19 infection have been studied and utilized, but most are not commonly available. Virus can be cultured from tissue in suspension cultures of bone marrow cells from persons with hemolytic anemias but it is difficult to isolate, so this is not a routinely feasible method of prenatal or postnatal diagnosis. Electron microscopy and histology have permitted visualization of parvovirus in fetal blood, ascitic fluid, tissue, and amniotic fluid, but the utility and sensitivity of these evaluations have not been well studied (Markenson and Yancey, 1998). Finally, molecular probes with DNA PCR can detect human parvovirus B19 DNA in tissues, maternal and fetal serum, amniotic fluid, and urine and may become the most useful and sensitive means of diagnosis once they are more widely available (Dieck et al, 1999; Kinney and Kumar, 1988).

### Treatment

Spontaneous resolution of fetal hydrops with normal neonatal outcome has been reported in approximately one third of cases (Humphrey et al, 1991; Rodis et al, 1998a; Sheikh et al, 1992). Because two thirds of fetuses do not recover without intervention, fetal transfusion is usually recommended to attempt to improve pregnancy outcome (Boley and Popek, 1993; Brown et al, 1994). The earlier fetal transfusion is attempted, the more likely it is to be successful. After appropriate serologic or molecular diagnosis, the clinician should care for each case individually because there are insufficient data to predict outcome with certainty. Treatment of the pregnant woman or the neonate with intravenous immune globulin (IVIG) has not been shown to improve fetal outcomes and so is not routinely recommended.

### Prognosis

Mortality rates for fetal hydrops due to all nonimmune causes have ranged from 50% to 98%, even in the 1990s with more aggressive therapies (Wy et al, 1999). Prognosis and survival do seem to vary with etiology, and hydrops secondary to parvovirus B19 seems to have a better outcome than that from other causes (Ismail et al, 2001). Although

few long-term prospective studies of infants born to mothers with documented primary parvovirus B19 infection have been conducted, most reported infants appear to have normal development. One small case-control study, involving approximately 200 mother-infant pairs in each group, found no differences in frequency of developmental delay between infants born to women with confirmed primary parvovirus B19 infection during pregnancy and infants born to mothers with evidence of preconceptional immunity (Rodis et al, 1998b). Data on long-term neurodevelopmental outcomes for infants who received transfusions in utero because of hydrops secondary to parvovirus B19 infection are still insufficient, but most transfused hydropic fetuses with hemolytic disease appear to do well (Ismail et al, 2001).

### Prevention

If a pregnant woman has a significant exposure to an infectious case of parvovirus B19, she should be counseled regarding the potential risk of infection. Anti-parvovirus IgM and IgG serologic analyses should be performed, and if they show evidence of primary infection, serial fetal ultrasonographic evaluations should be performed. Postexposure passive immunization with immunoglobulin is not currently recommended, because the period of maternal viremia has passed by the time diagnosis with parvovirus B19 infection is made (Boley and Popek, 1993). Efforts are under way to research and develop vaccines to prevent parvovirus B19 infections (Franssila et al, 2001).

Pregnant health care providers should be counseled about the potential risks to the fetus from parvovirus B19 infections and should, at a minimum, wear masks when caring for immunocompromised patients with chronic parvovirus B19 infection or patients with parvovirus B19-induced aplastic crises. Some hospitals exclude pregnant health care providers from caring for these high-risk patients, but this issue remains controversial. Standard droplet precautions should be practiced for patients with transient aplastic crises during hospitalization to avoid transmission to health care providers (AAP, 2003).

## RUBELLA

Rubella virus is a single-stranded RNA virus belonging to the *Togaviridae* family. Humans are the only known natural hosts. Rubella infection, commonly known as *German measles*, usually results in a mild illness in adults and children but can have serious consequences when a fetus is infected. Physicians became aware of the teratogenicity of the rubella virus in 1941, when Gregg made the association of maternal rubella with cataracts in infants. Not until the global pandemic of 1964 to 1965, however, were the multiple manifestations of the congenital rubella syndrome (CRS) fully appreciated and the later consequences well delineated. The capacity to grow the virus in tissue culture led rapidly to the development of vaccines and a reduction in the incidence of congenital disease, at least in the United States and other developed countries. The United States has established the goal of elimination of indigenous rubella infections by the year 2010 (U.S. Department of Health and Human Services, 2000).

### Incidence

Since the availability of rubella vaccine in 1969, the incidence of rubella in the United States has significantly decreased. The annual incidence of rubella cases has dropped 99%, from 58 per 100,000 population in 1969 to less than 0.5 per 100,000 population in 1997 to 1999 (Danovaro-Holliday et al, 2001). Although the majority of cases in the past occurred in school-aged children, the proportion of cases has shifted since the mid- to late 1990s, with more than 80% occurring in adults. Three fourths of reported rubella infections since 1997 have been in Hispanic persons, and 80% of outbreak-related cases were in foreign-born persons (CDC, 2000).

The number of CRS cases in the United States has dramatically declined, and rubella in people emigrating from Latin America has now contributed a large portion of the cases (Control and prevention of rubella, 2001). From 1997 to 2000, 30 cases of CRS were reported, 23 of which (77%) were infants of mothers born in Latin America or the Caribbean (Danovaro-Holliday et al, 2001). In other parts of the world, where routine rubella immunization has not or has only lately been implemented, CRS continues to contribute significantly to pediatric morbidity and mortality. It is still the most common vaccine-preventable cause of birth anomalies in the world, as more than 100,000 cases of CRS are estimated to occur annually in developing countries (World Health Organization, 2000).

Maternal rubella infection that occurs in the period of time from 1 month before conception through the second trimester may be associated with disease in the infant. The classic findings of congenital rubella predominate with onset of maternal infection during the first 8 weeks of gestation (Miller et al, 1982). Both the risk and severity of fetal infection decline after the first trimester, and the risk of any congenital defects from infection is low after 17 weeks of gestation (Lee and Bowden, 2000). The incidence of congenital rubella defects after maternal rubella infection varies widely among reported series. A study of 1016 women with serologically confirmed rubella infection at different stages of pregnancy who were followed prospectively provides the most useful estimate of the risks of congenital rubella infection (Miller et al, 1982). The frequency of congenital infection after maternal rubella with a rash is 70% to 80% during the first 12 weeks of pregnancy, 30% to 54% at 13 to 14 weeks of gestation, and 10% to 25% at the end of the second trimester (Miller et al, 1982; South and Sever, 1985).

### Etiology and Pathogenesis

Rubella virus is transmitted from person to person via respiratory droplets. Once the oral or nasopharyngeal mucosa are infected, viral replication occurs in both the upper respiratory tract and nasopharyngeal lymphoid tissue. The virus then spreads contiguously to regional lymph nodes and hematogenously to distant sites. Fetal infection is presumed to occur during maternal viremia. The exact mechanism of teratogenesis is unknown, but theories include a virus-induced apoptosis of cells leading to a cytopathic effect and a virus-induced inhibition of cell division. Fetuses infected with rubella demonstrate cellular damage in multiple sites and a non-inflammatory necrosis in target organs, including eyes, heart, brain, and ears (Lee and Bowden, 2000).

Although positive rubella IgG titers should incur immunity, rare cases of documented maternal re-infection (typically subclinical) with rubella have been reported, and the estimated risk is approximately 8% (Morgan-Capner et al, 1991). Approximately 20 cases of CRS after maternal reinfection have been reported in the literature, and none has caused symptomatic CRS when the known re-infection occurred after 12 weeks of gestation (Bullens et al, 2000).

### Clinical Spectrum

Typical illness in adults and children with acquired rubella infection consists of an acute generalized maculopapular rash, fever, and arthralgias, arthritis, or lymphadenopathy. Conjunctivitis is also common. Often a mild prodrome of mild systemic symptoms precedes the rash by 1 to 5 days. The rash classically begins on the face and spreads caudally to the trunk and extremities. Symptoms generally last up to 3 days, and the incubation period ranges from 14 to 21 days.

Infants with congenital rubella are usually born at term but often are of low birth weight. The most common isolated sequela is hearing loss. The next most common findings are heart defects, cataracts, low birth weight, hepatosplenomegaly, and microcephaly. Table 37-5 summarizes the clinical findings for congenital rubella reported to the National Congenital Rubella Syndrome Registry (NCRSR). The triad of deafness, cataracts, and congenital heart disease constitutes the classic syndrome. Approximately one third of the infants in the NCRSR has only one or two defects,

but more than 60% show at least three manifestations of the disease. In addition, systemic illness, characterized by purpura, hepatosplenomegaly, jaundice, pneumonia, and meningoencephalitis, can occur. A comparison of the frequency of clinical findings in prospective studies with those in past case series reports reveals a slightly different proportion of outcomes than previously noted. For instance, 45% to 70% of infants have cardiac lesions, including patent ductus arteriosus, peripheral pulmonic stenosis, and valve abnormalities (Reef et al, 2000; Schluter et al, 1998). A variety of other signs may be present. Additional ocular findings are pigmentary retinopathy, microphthalmia, and strabismus. The skin lesions have been described as resembling a "blueberry muffin," and represent extramedullary hematopoiesis within the skin (Brough et al, 1967).

Deafness, the most common manifestation, occurs, along with retinopathy as a consequence of both first and second trimester maternal infections (Miller et al, 1982; Ueda et al, 1979). In a prospective study following pregnant women with confirmed rubella infection by trimester, rubella-associated defects (primarily congenital heart disease and deafness) were observed in nine infants infected before the 11th week. Thirty-five percent of infants (9 of 26) infected between 13 and 16 weeks had deafness alone (Miller et al, 1982). Cataracts occur with maternal rubella before the 60th day after the 1st day of the last menstrual period; heart disease is found almost exclusively when maternal infection is before the 80th day (i.e., first trimester). Among the manifestations that may occur after the newborn period (late-onset disease) are a generalized rash with seborrheic features that may persist for weeks, interstitial pneumonia (either acute or chronic), abnormal hearing from involvement of the organ of Corti, central auditory imperception, and progressive rubella panencephalitis (Franklin and Kelley, 2001; Phelan and Campbell, 1969; Reef et al, 2000; Sever et al, 1985).

A higher than expected incidence of autoimmune diseases, such as thyroid disorders and diabetes mellitus, have also been reported years after the diagnosis of congenital rubella (McEvoy et al, 1988; Reef et al, 2000). Infants with late-onset disease sometimes have immunologic abnormalities, including dysgammaglobulinemia or hypogammaglobulinemia (Hancock et al, 1968; Hayes et al, 1967; Soothill et al, 1966). Others have also observed cellular immunity dysfunction (Fuccillo et al, 1974; South et al, 1975). The principal immunologic problem in late-onset disease may be defective cytotoxic effector cell function, which leads to defective elimination of virus and immune complex disease (Verder et al, 1986), but immunodeficiencies and autoimmune diseases in patients with congenital rubella are poorly understood.

### Laboratory Evaluation

All pregnant women who are exposed to rubella should be screened for evidence of previous immunity, and if none is found, they should be tested for rubella IgG and IgM antibodies. A positive IgM titer or a rise in paired IgG titers is indicative of recent infection. Women with such findings should also be evaluated to try to determine the likely gestational age at time of infection in order to assess the potential risk to the fetus (CDC, 2001).

**TABLE 37-5**

**Clinical Characteristics of Congenital Rubella Syndrome in Cases Reported to the National Congenital Rubella Syndrome Registry, United States, 1985 to 1996**

Clinical Characteristics	No. of Cases	% of Cases
Heart disease (any congenital)	86	70.5
Patent ductus arteriosus	62	50.8
Pulmonary stenosis	22	18.0
Other congenital heart conditions	36	29.5
Hearing loss	73	59.8
Low birth weight	70	57.4
Very low birth weight (<1500 g)	15	12.3
Low birth weight (1500-2500 g)	55	45.1
Cataracts	52	42.6
Purpura	45	36.9
Hepatomegaly	43	35.2
Splenomegaly	42	34.4
Thrombocytopenia	41	33.6
Microcephaly	28	23.0
Radiolucent bone disease	24	19.7
Jaundice	18	14.8
Mental retardation	15	12.3
Pigmentary retinopathy	10	8.2
Meningoencephalitis	9	7.4
Glaucoma	4	3.3

Data from Schluter WW, Reef SE, Redd SC, Dykewicz CA: Changing epidemiology of congenital rubella syndrome in the United States. *J Infect Dis* 178:636-641, 1998.

The laboratory diagnosis of congenital rubella can only be made definitively during the first year of life, unless the virus can be recovered later from an affected site, such as the lens. Diagnosis can be made with any one of the following four criteria: (1) positive anti-rubella IgM titer, preferably determined with enzyme immunoassays, but indirect assays are acceptable, (2) a significant rise in rubella IgG titer between acute and convalescent measurements 2 to 3 weeks apart, or persistence of high titers longer than expected from passive maternal antibody transfer; (3) isolation of rubella virus cultured from nasal, blood, throat, urine, or CSF specimens (throat swabs have the best yield), and (4) detection of virus by reverse transcriptase-PCR in specimens from throat swabs, CSF, or cataracts obtained from surgery (CDC, 2001).

The infected infant may excrete the virus for many months after birth despite the presence of neutralizing antibody and, thus, may pose a hazard to susceptible individuals in the environment. Only rarely can the virus be recovered after 1 year of age. An exception to this rule is the cataract, in which the virus may remain for as long as 3 years. In late-onset disease, the virus may also be found in affected skin and lung.

Other laboratory findings are thrombocytopenia, hyperbilirubinemia, and leukopenia. Radiographic findings include large anterior fontanelle, linear areas of radiolucency in the long bones ("celery stalking"), increased densities in the metaphyses, and irregular provisional zones of calcification. The radiographic changes seen in rubella are not pathognomonic of the disease but resemble those seen in other congenital infections, such as cytomegalic inclusion disease.

### Treatment

There is no specific therapy for congenital rubella. Initially, the infant may need general supportive care, such as administration of blood transfusion for anemia or active bleeding, seizure control, and phototherapy for hyperbilirubinemia. Long-term care requires a multidisciplinary approach consisting of occupational and physical therapy, close neurologic and audiologic monitoring, and surgical interventions as needed for cardiac malformations and cataracts.

### Prognosis

The consequences of fetal rubella infection may not be evident at birth. Infection in the first or second trimester may lead to deafness or persistent growth restriction (Miller et al, 1982). Although infection in the third trimester may also lead to intrauterine growth retardation, this growth problem does not persist, suggesting that the mechanism of growth restriction among infants infected in the first or second trimester may be different (Miller et al, 1982). In one study of 123 infants with documented congenital rubella, 85% were not diagnosed until after discharge from the nursery (Hardy, 1973). Communication disorders, hearing defects, some mental or motor retardation, and microcephaly by 1 to 3 years of age were among the major problems that were discovered after the newborn period. A predisposition to inguinal hernias was also noted.

Longitudinal studies of somatic growth show that most infants with congenital rubella remain smaller than average throughout infancy but grow at a normal rate. Stunting of growth was more common after rubella infection in the

first 8 weeks of pregnancy than after later infection. Even in the absence of mental retardation, neuromuscular development is commonly abnormal. A study that followed up 29 children without mental retardation found that 25 had other abnormalities; hearing loss, difficulties with balance and gait, learning deficits, and behavioral disturbances were found in more than half of the affected children (Desmond et al, 1978).

### Prevention

There is no effective antiviral therapy against congenital rubella infection, so the most useful practice is to ensure that women who are considering pregnancy are immune to rubella. The Advisory Committee on Immunization Practices recommends screening of all pregnant women for rubella immunity and postpartum vaccination of those who are susceptible (CDC, 1998). Live attenuated rubella virus vaccine is safe and effective (Lepow et al, 1968), although the duration of immunity is uncertain. The vaccine is recommended for children at 12 to 15 months of age and at 4 to 5 years of age. It is also recommended for women of child-bearing age in whom results of both a hemagglutination inhibition antibody test and a pregnancy test are negative. Although no cases of symptomatic congenital rubella infection have been reported as a consequence of vaccination during pregnancy of the more than 500 cases monitored, vaccination is not recommended during pregnancy because of the theoretical hazard to the fetus (Control and prevention of rubella, 2001; Josefson, 2001; Tooke, 2001). A mild rubella-like illness is sometimes seen after immunization, with arthralgia occurring 10 days to 3 weeks after injection. Immunization in the postpartum period has infrequently led to polyarticular arthritis, neurologic symptoms, and chronic rubella viremia (Tingle et al, 1985).

The problem of management of the pregnant woman who is exposed to or who contracts the disease should be resolved after the known risks are weighed. If, at the time of exposure, serum antibody is detectable, the fetus is probably protected. Administration of immunoglobulin will not prevent rubella viremia or infection in the mother. Immunoglobulin may reduce the likelihood of fetal infection but will not eliminate the risk; thus, the CDC does not routinely recommend the use of immunoglobulin to a pregnant woman for postexposure prophylaxis unless she does not wish to terminate the pregnancy under any circumstances (CDC, 2001).

Decisions about the termination of pregnancy should be made only after maternal infection has been proven and should also take into account the risk of rubella-associated damage to the fetus, which is highest when maternal infection occurs during the first 8 weeks of pregnancy.

## LYMPHOCYTIC CHORIOMENINGITIS VIRUS

Lymphocytic choriomeningitis virus (LCMV) is a member of the *Arenaviridae* family, and rodents are the primary reservoir, primarily mice and hamsters. These rodents are infected asymptotically in utero, can harbor chronic infection, and can excrete virus in urine, feces, saliva, nasal secretions, milk, and semen for life. Typically, mice remain asymptomatic but hamsters may demonstrate viremia and viruria with variable symptoms (Jahrling and Peters,

1992). Sequelae of human exposure to LCMV ranges from asymptomatic infection to nonspecific, flulike symptoms, and a proportion of infections have neurologic manifestations. LCMV was described as an etiology for congenital infection first in England in 1955, in a 12-day-old infant who died (Komrower et al, 1955) and later in the United States (Barton et al, 1993; Larsen et al, 1993). Because LCMV has only lately been recognized as a source of congenital infection, it is likely underdiagnosed.

### Incidence

Human seroprevalence ranges between less than 1% and 10% worldwide and varies extensively with geographic region (Ambrosio et al, 1994; Childs et al, 1991; Marrie and Saron, 1998; Stephensen et al, 1992). At least one small surveillance study noted a higher prevalence in women (Marrie and Saron, 1998). Lower socioeconomic status and older age are associated with higher seroprevalence. Studies conducted in the 1940s through the 1970s found that approximately 8% to 11% of cases of aseptic meningitis and encephalitis were associated with LCMV virus infection (Meyer et al, 1960; Park et al, 1997b). In temperate climates, human exposure may occur more often during the fall and winter seasons, when rodents move indoors. Several outbreaks have been reported in laboratory personnel working with hamsters and mice (Dykewicz et al, 1992; Hinman et al, 1975; Vanzee et al, 1975). Multiple outbreaks associated with pet hamsters have also been reported in the United States (Biggar et al, 1975; Maetz et al, 1976) and Europe (Brouqui et al, 1995; Deibel et al, 1975).

Congenital infection, however, is rarely reported. A total of 55 cases have been diagnosed worldwide since the first case in 1955, and 27 of those occurred in the United States (Barton and Mets, 2001; Greenhow and Weintrub, 2003). The true frequency of congenital LCMV infection, however, is unknown, because there are no surveillance studies of the disorder. As with other congenital infections, there may be a wide spectrum of disease, including asymptomatic and subclinical or nonspecific infections.

### Etiology and Pathogenesis

Humans acquire LCMV infection from aerosolized particles, bites, or fomite contact with virus excreted from rodents (Jahrling and Peters, 1992). Human-to-human horizontal transmission has not been documented. The pathogenesis of LCMV infection is poorly understood, although it likely involves both cell-mediated and antibody-mediated immunity. Like other arenaviruses, LCMV is not cytopathic. Both animal and *in vitro* models strongly suggest that disease is an immunopathologic process mediated by the host CD8<sup>+</sup> T-cell response (Craighead, 2000). It is also postulated that the high rate of spontaneous mutations allows both variability in pathogenicity and a mechanism of escape from humoral response during the initial phase of infection (Ciurea et al, 2001).

Like other arenaviruses, LCMV replicates either at the site of infection or in corresponding lymph nodes, and then produces a viremia. It is thought that during the viremic stage, the virus travels to parenchymal organs and potentially the CNS. Pathologic findings include lymphocytic infiltration and extramedullary hematopoiesis. In the two congenitally infected infants for whom neu-

ropathology results were available, cerebromalacia, glial proliferation, and perivascular edema were reported (Barton et al, 1993). In adult mice inoculated intracranially with LCMV, subsequent viral proliferation in the ependyma, meninges, or both have been described (Peters, 1997). This viral infiltration, along with the host inflammatory response, may lead to aqueductal stenosis and subsequent hydrocephalus.

### Clinical Spectrum

It is estimated that asymptomatic or mild LCMV infections occur in approximately one third of patients infected. However, the classic presentation of LCMV infection is a nonspecific, “flulike” or “mononucleosis-like” illness that is often biphasic. Symptoms are fever, malaise, nausea, vomiting, myalgias, headache, photophobia, pharyngitis, cough, and adenopathy. After defervescence and resolution of these constitutional symptoms, a second phase of CNS disease may develop. Neurologic manifestations occur in approximately one fourth of infectious episodes and vary from aseptic meningitis to meningoencephalitis. Transverse myelitis, Guillain-Barré syndrome, and deafness have also been reported. Other manifestations are pneumonitis, arthritis, myocarditis, parotitis, and dermatitis. Recovery may take months but does usually occur without sequelae (Craighead, 2000; Peters, 1997).

When LCMV infection occurs during pregnancy, maternal symptoms, when present, typically appear during the first and second trimesters, but only 50% to 60% of mothers of infants diagnosed with LCMV congenital infection recall having symptoms (Wright et al, 1997). Known maternal exposure to rodents is reported in only about one fourth to one half of cases (Barton and Mets, 2001). Typically, exposed women are from rural settings or have substandard housing conditions.

The complete spectrum of disease secondary to congenital LCMV infection is still uncertain, because no prospective surveillance studies of outcome after infection have been performed. Of the cases reported, chorioretinitis is the most common manifestation, present in more than 90% of cases. Other ocular findings are chorioretinal scars, optic atrophy (usually bilateral), nystagmus, esotropia, exotropia, leukocoria, cataracts, and microphthalmia (Barton and Mets, 2001; Brezin et al, 2000; Enders et al, 1999). Some ophthalmologic findings resemble those seen in the lacunar retinopathy of Aicardi syndrome (Wright et al, 1997).

Most infants are born at term, and birth weights are generally appropriate or large for gestational age. Thirty-five percent to 40% of infants reported with congenital LCMV have had microcephaly or macrocephaly at birth (Barton and Mets, 2001). Systemic symptoms are rare, although hepatosplenomegaly and jaundice have been noted. Other individual case report findings are pes valgus, dermatologic findings consistent with staphylococcal scalded-skin syndrome (Wright et al, 1997), spontaneous abortion (Biggar et al, 1975), and intrauterine demise secondary to hydrops fetalis (Enders et al, 1999). It is important to note that because systemic symptoms are typically minimal at birth, diagnosis of LCMV infection often is not made until an affected infant is a few months of age, when microcephaly, macrocephaly, visual loss, or developmental delay may be noted.

### Laboratory Evaluation

Serology is the most reliable and feasible method to diagnose LCMV. In most reports, the diagnosis was established by testing of infant's serum, CSF, or both; in some, maternal serum testing was the key. Testing all three fluids provides the most information. Because of the low baseline population seroprevalence, positive titers for LCMV are much more useful for diagnosis than detection of antibodies to microbes such as CMV and toxoplasmosis. There is a commercially available immunofluorescent antibody (IFA) test that detects both IgM and IgG for LCMV. It has better sensitivity than the complement fixation and neutralizing antibody tests that also have been used (Lehmann-Grube et al, 1979; Lewis et al, 1975). Complement fixation titers generally do not rise until more than 10 days after onset of infection, but IFA results may be positive within the first few days of illness (Deibel et al, 1975). The CDC also has an enzyme-linked immunosorbent assay test for IgM and IgG; it may be more useful for diagnosis in an older child because it can detect increased IgG later than and persistent IgG for longer than the IFA test. Some studies have found antibody as late as 30 years after suspected exposure. Virus can be cultured in Vero cell lines or inoculated into newborn mice, but use of these methods is uncommon. Reverse transcriptase-PCR has been used in serum and CSF to diagnosis LCMV and as a surveillance tool; it may become more available in the future (Enders et al, 1999; Park et al, 1997a).

Information about routine laboratory data in patients diagnosed with congenital LCMV infection is minimal, but thrombocytopenia and hyperbilirubinemia have been reported. CSF findings are variable. Up to one half of cases demonstrate a mild increase in white blood cell count (up to 64 cells/ $\mu$ L in one case series of 18 infants), the serum protein concentration may be normal or mildly elevated, and the serum glucose concentration may be normal or mildly decreased (Wright et al, 1997). Among infants reported in whom neuroradiographic imaging was performed, 89% (17 of 19) had hydrocephalus or intracranial periventricular calcifications. "Flattened gyri" or lissencephaly, schizencephaly, and other findings consistent with a migrational disorder have also been reported (Barton and Mets, 2001).

### Treatment

Therapy for LCMV infection has never been attempted, but ribavirin has been used for management of other arenavirus infections and inhibits LCMV growth in vitro (Géssner and Lother, 1989). No current recommendations can be made regarding the use of antivirals in congenital LCMV infection.

### Prognosis

Because congenital LCMV infections have been recognized relatively recently and the existing data come from case reports, there may be a wider spectrum of disease than is currently appreciated. The proportion of asymptomatic infected infants is unknown. For the 25 infant cases reported, estimated mortality rates are 16% to 35% between birth and 21 months of age (Barton and Mets, 2001; Wright et al, 1997). Among infants who survived, 84% (32 of 38) have neurologic sequelae, including spastic quadriplegia, mental retardation, developmental delay, seizures, and visual loss (Barton and Mets, 2001). Sensorineural

hearing loss is less common, and has only been reported in 2 infants (Barton and Mets, 2001; Wright et al, 1997).

Some ophthalmologists suggest that among patients with developmental delay and visual loss consistent with chorioretinitis, LCMV congenital infection may be underdiagnosed. A study in Chicago of prospectively diagnosed patients with chorioretinitis and patients in a home for severely mentally retarded children with chorioretinal scars found six children with elevated LCMV titers and normal toxoplasmosis, CMV, rubella, and HSV titers (Mets et al, 2000). Two children with chorioretinal scars and elevated LCMV titers have been reported in France (Brezin et al, 2000).

### Prevention

Public health officials and clinicians should be aware that (1) wild, laboratory, and pet rodent exposure can lead to intrauterine infection with LCMV virus and (2) congenital infection has been associated with potentially devastating ophthalmologic and neurologic sequelae. Pregnant women need to be educated about the potential risks of exposure to infected rodent excreta and instructed to avoid rodents and rodent droppings whenever possible.

## ENTEROVIRUSES

Enteroviruses are single-stranded RNA viruses belonging to the Picornaviridae family. The enteroviruses of humans include polioviruses 1, 2, and 3, coxsackieviruses A and B, and the echoviruses. Poliovirus infection of newborn infants has become extremely rare. According to early accounts, however, severe, often fatal diseases developed in infants infected in the perinatal period, with a high incidence of paralysis occurring in the survivors (Bates, 1955; Cherry, 1990). This review is limited to consideration of the neonatal diseases associated with coxsackieviruses and echoviruses most commonly seen today.

### Incidence

Enterovirus infections are seasonal, occurring most commonly during the summer and autumn in temperate climates. The incidence varies from year to year, with outbreaks sometimes caused by a single coxsackievirus or echovirus serotype, and sometimes by several (Sawyer et al, 1994). Disease in newborn infants is uncommon but reflects the frequency of infections in the population at large (Krajden and Middleton, 1983). Low socioeconomic status and bottle-feeding have been associated with increased risk of enteroviral infections in newborns (Jenista et al, 1984). Nursery outbreaks of both coxsackievirus B (Brightman et al, 1966; Rantakallio et al, 1970) and echovirus infections (Jankovic et al, 1999; Nagington et al, 1978) have been reported and associated with severe, and sometimes fatal, illnesses.

Enteroviral infections account for at least one third of neonatal febrile admissions for suspected sepsis overall, and for between half and two thirds of admissions during peak enteroviral season (Byington et al, 1999; Dagan, 1996). Neonatal aseptic meningitis is also frequently caused by enteroviral infections. In a review of neonatal meningitis seen over a 15-year period in Galveston, Texas, enterovirus was the most common cause of meningitis in newborn infants older than 7 days and accounted for 33% of all

cases of neonatal (<28 days of age) meningitis (Shattuck and Chonmaitree, 1992). Enteroviruses, along with other viruses, have also been implicated as a potential cause of sudden infant death syndrome, possibly from myocarditis or pulmonary infection, but their role is still poorly delineated (Grangeot-Keros et al, 1996; Shimizu et al, 1995).

### Etiology and Pathogenesis

Infection may take place either in utero, intrapartum, or postnatally. Intrauterine infections likely occur transplacentally secondary to maternal viremia. Regardless of whether the mother, a family member, or some other caretaker is the source of the infection, severe disease results more often when the baby lacks antibody to the infecting strain (Jenista et al, 1984). Other potential factors determining severity of disease are the virus strain or serotype and the quantity of the inoculum. It is not clear why the newborn infant is so highly susceptible to overwhelming illness, but growing evidence suggests that lack of type-specific antibody is a crucial factor.

It appears that any of the non-polio enteroviruses can cause disease in the newborn infant. A retrospective chart review of 24 newborn infant enteroviral infections in Toronto found that 10 infants died, 12 had aseptic meningitis, and 5 had myocarditis (Krajden and Middleton, 1983). Of the 24 isolates, 7 were echovirus, 15 were coxsackievirus B, one was coxsackievirus A, and one was nontypable. Types of coxsackievirus B are associated primarily with myocarditis or aseptic meningitis or combinations of the two (Kibrick and Benirschke, 1958). Echoviruses, however, are seen more often with severe nonspecific febrile illnesses with disseminated intravascular coagulation (Nagington et al, 1978), aseptic meningitis (Cramblett et al, 1973), or hepatitis (Modlin, 1980). With both groups of viruses, nonspecific febrile illnesses, with or without a rash, are commonly seen.

Enterovirus infections primarily target the heart, CNS, liver, and adrenal glands. In coxsackievirus B infections, myocardial necrosis and inflammation may be seen that are patchy or diffuse, with extensive infiltration by lymphocytes, mononuclear cells, histiocytes, and some polymorphonuclear leukocytes. Similar infiltrates are seen in the meninges in both coxsackievirus and echovirus infections. When liver or adrenal glands are involved, there is usually extensive hemorrhage as well as inflammation and necrosis.

### Clinical Spectrum

As with many other viruses, most infections with enterovirus are asymptomatic. Well-recognized clinical syndromes associated with enteroviral infections in children include hand-foot-mouth disease, herpangina, aseptic meningitis, and acute hemorrhagic conjunctivitis. Enterovirus infection is also likely to cause a large proportion of nonspecific febrile illness, especially in young infants.

When neonatal disease is acquired vertically from the mother, the infant is characteristically well at birth, although premature delivery is more common in this group. The mother, however, may be febrile at this time or may have a history of recent high fevers and gastrointestinal symptoms. Fever, anorexia, and vomiting develop in the baby after an incubation period of 1 to 5 days. The onset of illness occurs in the first week of life in more than 50% of

affected infants (Krajden and Middleton, 1983). At that point, the clinical evolution depends on the infecting virus and the extent of involvement.

In most instances, the disease is mild and self-limited. A rash may appear in some infants, and aseptic meningitis in others. A review of 29 infants with enteroviral infections younger than 2 weeks old reported that 5 of 29 infants had severe multisystem disease, and all survived (Abzug et al, 1993). In severe disseminated disease, disseminated intravascular coagulation (DIC), refractory hypotension, and death may follow quickly. If myocarditis is present, the liver rapidly enlarges, the heart dilates, and the heart sounds become muffled. However, in many infants, myocardial involvement is temporary, and recovery occurs over the course of several weeks.

The severity of CNS infection is also variable. Enteroviruses can produce overwhelming meningoencephalitis, sometimes with cranial nerve signs. It is more common, however, to see moderate or mild meningitis characterized by temporary irritability, lethargy, fever, and feeding difficulty.

Some infections, particularly those with echoviruses, are characterized by a rampant and overwhelming hepatitis (Modlin, 1980). Others exhibit primarily pulmonary disease or gastrointestinal involvement including diarrhea and necrotizing enterocolitis (Lake et al, 1976). Intracranial bleeding ranging from small, grade I to massive, severe hemorrhage has also been reported as a complication of neonatal enteroviral infection (Abzug, 2001; Abzug and Johnson, 2000; Swiatek, 1997). Other, rarely associated findings include disseminated vesicular rash, dermal hematoipoiesis, and hemophagocytic syndrome (Barre et al, 1998; Bowden et al, 1989; Sauerbrei et al, 2000).

Acquired postnatal enteroviral disease in infants is characterized primarily by high fever, irritability, lethargy, or poor feeding. One fourth of infected infants presents with diarrhea or vomiting with or without an erythematous maculopapular rash. Mild conjunctivitis has also been observed. Respiratory tract symptoms are less common (Dagan, 1996). Unfortunately, there is significant overlap between enteroviral and bacterial neonatal infections, and the two syndromes are difficult to distinguish. Duration of illness varies from less than 24 hours to longer than 7 days but generally lasts 3 to 4 days.

### Laboratory Evaluation

Viral culture from stool or rectal swab, nasopharyngeal swab, blood, buffy coat, urine, or CSF remains a reliable diagnostic test. Stool or rectal swab and respiratory tract cultures have the highest yield. Cultures usually become positive within a few days and most often within 1 week (Dagan, 1996). The wider availability of PCR analysis provides greater sensitivity and more rapid results, especially when performed on CSF. PCR may also be performed on serum or mononuclear cell suspension (Prather et al, 1984). Serologic tests for enteroviruses have been reported but are less useful than culture and PCR (Swanink et al, 1993).

Infants with meningitis typically have moderate CSF pleocytosis. Thrombocytopenia, elevated transaminase values, hyperbilirubinemia, hyperammonemia, hematologic abnormalities consistent with disseminated intravascular

coagulation, anemia, peripheral leukocytosis, and abnormal chest radiographs are among other potential laboratory findings. The echocardiogram and electrocardiogram may show diffuse myocardial inflammation. Liver biopsies have been performed in severe cases, and usually, viral cultures of the specimens are negative (Abzug, 2001).

### Treatment

The manifestations of myocarditis and heart failure must be treated with slow digitalization, diuretics, aggressive fluid management, and other supportive measures. Disseminated intravascular coagulation should be treated with vitamin K, fresh frozen plasma, platelets, and other supportive measures as indicated. Both plasma infusions (including maternal plasma transfusion) and exchange transfusions have been attempted in overwhelming enterovirus infections, with unclear beneficial effects (Jantusch et al, 1995). There is no evidence that steroids are of benefit.

IVIG has anecdotally been reported to treat neonatal enteroviral infections with various results (Kimura et al, 1999; Valduss et al, 1993). Only one randomized trial has systematically studied its use, in 16 neonates with severe enteroviral infection. Decreased viremia and viruria along with faster resolution of irritability, jaundice, and diarrhea was demonstrated in patients administered IVIG with high titers of neutralizing enteroviral-specific antibodies. However, there were no significant differences in other major clinical outcomes, such as duration of hospitalization, fever, and symptoms of acute illness between treatment and control groups (Abzug et al, 1995). Although further investigation with larger numbers of patients are needed, routine use of IVIG for neonatal enterovirus infections cannot be recommended at this time.

The antiviral drug pleconaril has been developed specifically to treat picornavirus infections (enteroviruses and rhinoviruses). Data in neonates are limited, but one center has reported that two of three treated infants with severe enteroviral hepatitis survived (Aradottir et al, 2001). The Pleconaril Treatment Registry Group reported that five of six neonates with severe enteroviral infection who were treated with pleconaril survived, with minimal or no sequelae (Rotbart and Webster, 2001). A multicenter study of pleconaril treatment for neonatal enteroviral meningitis sponsored by the National Institutes of Health showed disappointing results (Abzug et al, 2003). The drug is not currently licensed or used for the treatment of enteroviral infections.

### Prognosis

Prognostic factors for severe neonatal disease include peripartum maternal illness, earlier age of onset of neonatal disease, absence of serotype-specific antibody, and absence of fever and irritability (Abzug et al, 1993). All of these risk factors are most consistent with vertical intrauterine enteroviral infection rather than acquired infection.

By the time disseminated intravascular coagulation has developed, the prognosis is grave. Prothrombin time longer than 30 seconds was a risk factor for death in one retrospective case review (Abzug, 2001). Highest mortality rates are associated with the combination of severe hepatitis, coagulopathy, and myocarditis. Severe hepatitis due to enteroviral infection is associated with mortality rates ranging from 30% to 80% (Abzug, 2001; Modlin, 1986).

Few long-term follow-up studies have been published, but the available information suggests that infants who survive severe enteroviral neonatal disease have a complete recovery in most instances. Outcomes of 6 of 11 survivors with follow-up ranging from 9 to 48 months reported normal growth and no residual medical problems or liver dysfunction (Abzug, 2001).

The prognosis after CNS involvement is also unclear. Most patients do well. A number of early studies of infants younger than 3 months with aseptic meningitis suggested that there may be some impairment of intellectual development in comparison with carefully selected control groups (Farmer et al, 1975; Sells et al, 1975). However, in a series of nine children with enteroviral meningitis and nine matched controls evaluated for sequelae at approximately 4 years of age, no differences in mean IQ level, head circumference, detectable sensorineural hearing loss, or intellectual functioning were detected. Receptive language functioning of the meningitis group was significantly less than that in control subjects (Wilfert et al, 1981). A similar case-control follow-up study of 33 subjects, who were compared with siblings used as controls, reported no neurodevelopmental sequelae (Bergman et al, 1987).

### Prevention

Anecdotal reports of the use of IVIG in nursery outbreaks to prevent further horizontal transmission of enteroviral infection produce conflicting results (Carolane et al, 1985; Kinney et al, 1986; Nagington et al, 1983). Because there are multiple non-polio enteroviral serotypes that cause clinical disease, development of anti-enteroviral immunization is difficult. Standard contact precautions should be used for the treatment of hospitalized infants with known or suspected enteroviral infections (AAP, 2003).

## VIRAL HEPATITIS

There are now six distinct viruses known to cause viral hepatitis—hepatitis A, B, C, D (delta), E, and G viruses—although only B and C are of major importance in the newborn. The main features of each virus type are listed in Table 37–6 (Krugman, 1992). Hepatitis A virus (HAV) is passed by fecal-oral transmission and is a rare cause of neonatal disease, although it has been nosocomially transmitted in the setting of a neonatal intensive care unit. Hepatitis E virus (HEV) is similar to hepatitis A in its mode of transmission and clinical manifestations, except for an increased mortality in hepatitis E–infected pregnant women. There are no data regarding perinatal transmission of hepatitis E. Hepatitis D virus (HDV) may cause only co-infection or super-infection with hepatitis B virus. Its only clinical significance is that hepatitis B infection may become more severe when hepatitis D virus is present. Perinatal transmission is uncommon (AAP, 2003).

Hepatitis G virus (HGV), also known as GB virus type C (GBV-C), has been associated with acute and chronic hepatitis and usually is noted as a co-infection with hepatitis B or C. Perinatal transmission can occur in 60% to 80% of infants born to HGV-viremic mothers, but of infants studied for up to 2 years, none has demonstrated clinical hepatitis attributed to the HGV infection (Ohto et al, 2000; Wejstal et al, 1999; Zanetti et al, 1998; Zuin et al, 1999). The clinical

TABLE 37-6

**Viral Hepatitis Types A, B, C, D, E, and G: Comparison of Clinical, Epidemiologic, and Immunologic Features**

Feature	Hepatitis A	Hepatitis B	Hepatitis C	Hepatitis D (delta)	Hepatitis E	Hepatitis G/GB Virus Type C
Virus	Hepatitis A virus (HAV)	Hepatitis B virus (HBV)	Hepatitis C virus (HCV)	Hepatitis D virus (HDV)	Hepatitis E virus (HEV)	Hepatitis G virus (HGC) (GB virus type C [GBV-C])
Family	Picornavirus	Hepadnavirus	Flavivirus	Satellite	Calicivirus	Flavivirus
Genome	RNA	DNA	RNA	RNA	RNA	RNA
Incubation period	15-40 days	50-180 days	1-5 mos	2-8 wks	2-9 wks	Unknown
Mode of transmission						
Oral (fecal)	Usual	No	No	No	Usual	No
Parenteral	Rare	Usual	Usual	Usual	No	Usual
Perinatal	Rare	Yes	Yes	Only with HBV	Unknown	Yes
Other	Food- or water-borne	Sexual contact	Sexual contact less common	Sexual contact less common	Water-borne transmission in developing countries	Sexual contact; probably less common
Sequelae						
Carrier state	No	Yes	Yes	Yes	No	Yes
Chronic disease	No cases reported	Yes	Yes	Yes	No cases reported	Yes; controversial

Data from Krugman S: Viral hepatitis: A, B, C, D, and E—prevention. *Pediatr Rev* 13:245-247, 1992.

significance and impact of HGV infection are still poorly understood. Hepatitis B and C viruses are both transmitted vertically and are the primary focus of this discussion.

## Hepatitis B

The issues that are most important to neonatologists are the frequency with which hepatitis B virus (HBV) is transmitted to infants at the time of birth, the short-term and long-term consequences of these infections, the importance of greater surveillance for maternal carriage of HBV, and the availability of effective HBV immunoprophylaxis (Krugman, 1988).

### Incidence

In certain parts of the world and among certain ethnic groups, as many as 7% to 10% of all infants acquire hepatitis B infections at the time of birth, and almost all of these infections become chronic. In the United States, approximately 20,000 infants are born annually to mothers who are chronic HBV carriers (Mast et al, 1998). The frequency of transmission depends primarily on the prevalence of the hepatitis B carrier state among women of child-bearing age. The relationship of these infections to chronic liver failure and hepatic carcinoma in adult life has been noted (Balistreri, 1988; Beasley and Hwang, 1984).

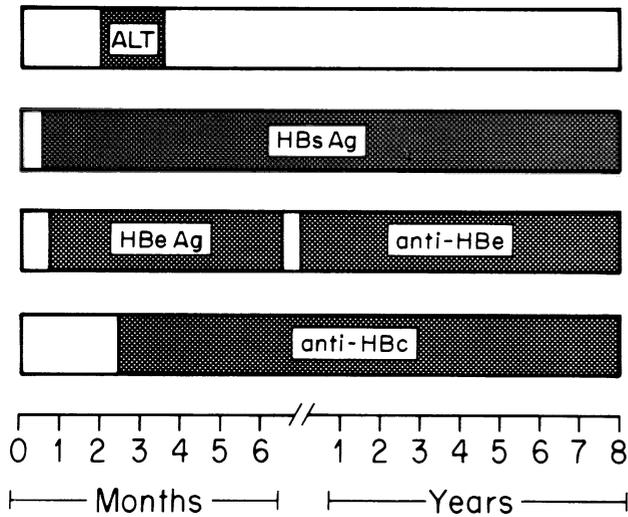

The incidence of neonatal hepatitis B infection depends on a number of factors. Women with acute hepatitis B infection during the first or second trimester rarely transmit the virus to their infants (Krugman, 1988; Stevens, 1994). The carriage rate for hepatitis B surface antigen (HBsAg) varies from 0.1% in the United States and

Europe to 15% in Taiwan and parts of Africa, with intermediate rates in Japan, South America, and Southeast Asia. Transmission rates among immigrant women in Western countries appear to parallel the rates in their countries of origin (Krugman, 1988).

Another factor is the potential of the infection to be transmitted from the mother at the time of delivery. The likelihood of transmission is great if symptomatic acute disease is present (60% to 70% transmission) (Gerety and Schweitzer, 1977). Infants of hepatitis B e antigen (HBeAg)-positive mothers have an 80% to 90% chance of becoming HBsAg carriers (Okada et al, 1976). Chronic neonatal infection occurs in less than 10% of infants of HBeAg antigen-negative mothers (Krugman, 1988). The serologic and biochemical courses of subclinical infection are outlined in Figure 37-5. Although HBsAg has been found in breast milk, breast-feeding does not appear to have any influence, either positive or negative, on the rate of transmission (Beasley et al, 1975).

### Etiology and Pathogenesis

HBV is a DNA virus that localizes primarily in hepatic parenchymal cells but circulates in the bloodstream, along with several subviral antigens, for periods ranging from a few days to many years. Transplacental leakage of HBeAg-positive maternal blood is a potential source of intrauterine infection (Lin et al, 1987). During either acute or persistent viremia in the mother, the virus itself or viral antigens may rarely cross the placenta and cause intrauterine infection, or more commonly, infection may occur perinatally during labor or delivery (Chisari and Ferrari, 1995; Xu et al, 2001). Most infants born to mothers

**FIGURE 37-5.** Serologic and biochemical courses of subclinical hepatitis B infection progressing to asymptomatic chronic carrier state. ALT, alanine aminotransaminase; anti-HBc, antibody to hepatitis B core antigen; anti-HBe, antibody to hepatitis B e antigen; HBeAg, hepatitis B e antigen; HBsAg, hepatitis B surface antigen. (From Krugman S: *Hepatitis B virus and the neonate*. *Ann N Y Acad Sci* 549:129, 1988.)

infected with HBV test negative for HBsAg at birth and, in the absence of prophylaxis, become HBsAg-positive during the first 3 months of life, suggesting that transmission is primarily peripartum (Krugman, 1988, 1992; Mulligan and Stiehm, 1994; Shapiro, 1993).

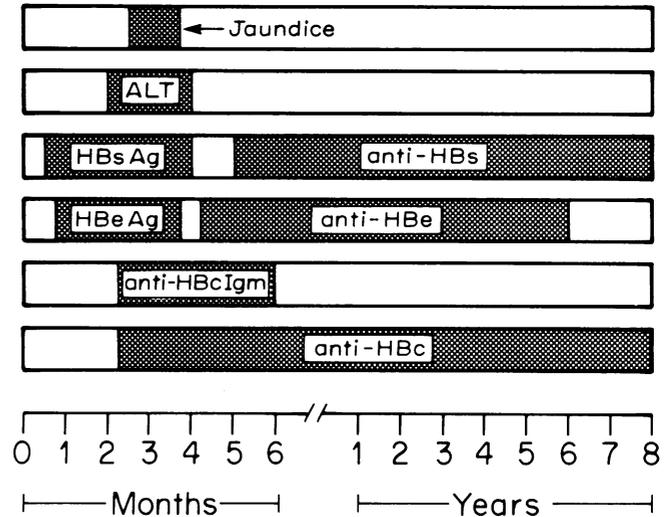

#### Clinical Spectrum and Laboratory Evaluation

Infants with hepatitis B infection do not show clinical or chemical signs of disease at birth. Without immunoprophylaxis, the usual pattern is the development of chronic antigenemia with mild and often persistent enzyme elevations, beginning at 2 to 6 months of age (Mulligan and Stiehm, 1994). Less commonly, the infection becomes clinically manifest, with jaundice, fever, hepatomegaly, and anorexia, followed by either recovery or chronic active hepatitis. Rarely, fulminant hepatitis is seen and can be fatal (Delaplane et al, 1983).

Laboratory tests are essential in the diagnosis of hepatitis B infection. Evaluations of serum enzymes and of bilirubin reflect the extent of liver damage. Several helpful serologic tests identify the virus involved (Krugman, 1988) (Fig. 37-6 and Table 37-7). HBsAg appears early, usually before liver disease is found; it persists in those who become chronic carriers or disappears in the 5% of infants who resolve the infection. HBeAg and antibody against HBeAg (anti-HBe) testing can be employed to assess infectivity but are rarely used clinically.

#### Prevention

For immunoprophylaxis to be successful, maternal screening is important (Cruz et al, 1987; Summers et al, 1987). The U.S. Public Health Service's Advisory Committee on Immunization Practices (ACIP) and the ACOG have recommended routine screening of all pregnant women (CDC, 1991; Guidelines for hepatitis B screening, 1993).

**FIGURE 37-6.** Chemical, serologic, and biochemical courses of acute hepatitis B infection followed by recovery. ALT, alanine aminotransaminase; anti-HBc, antibody to hepatitis B core antigen; anti-HBcIgm, immunoglobulin M antibody to hepatitis B core antigen; anti-HBe, antibody to hepatitis B e antigen; anti-HBs, antibody to hepatitis B surface antigen; HBeAg, hepatitis B e antigen; HBsAg, hepatitis B surface antigen. (From Krugman S: *Hepatitis B virus and the neonate*. *Ann N Y Acad Sci* 549:129, 1988.)

In developing countries, such a strategy is neither feasible nor affordable. In areas where hepatitis B virus infection is hyperendemic, all newborn infants should be routinely immunized (Hsu et al, 2001).

In 1991, the ACIP recommended that universal childhood vaccination against hepatitis B virus begin in the neonatal period, with the intention of eliminating transmission of HBV in the United States (CDC, 1991). Hepatitis B vaccination is recommended for all infants, whether their mothers test HBsAg negative or positive. For infants born to HBsAg-negative mothers, the three-dose vaccination schedule should be initiated in the neonatal period or by 2 months of age (Table 37-8). The second dose is given 1 to 2 months after the first dose, and the third dose at 6 to 18 months of age (AAP, 2003). Vaccination may be delayed until just before hospital discharge in preterm (birth weight less than 2000 g) infants born to HBsAg-negative mothers.

All infants born to HBsAg-positive women should receive both active and passive immunization within 12 hours of birth. The dosage amounts of the two hepatitis B vaccines currently licensed in the United States are given in Table 37-9. If maternal HBsAg status is unknown, it should be checked immediately, and the infant should receive the first dose of HBV vaccine immediately. Infants of women who test positive should be given hepatitis B immune globulin (HBIG) as soon as possible and within 1 week after birth (AAP, 2003). The highest immunization failure rate (3 of 21 infants, or 14%) has been observed in infants of HBeAg-positive women and those infected in utero (Farmer et al, 1987; Tang et al, 1998). It is recommended that infants born to HbsAg-positive mothers undergo postimmunization testing for anti-HBS and HbsAg 3 to 9 months after completion of the series,

TABLE 37-7

**Diagnostic Tests for Hepatitis B Virus (HBV) Antigens and Antibodies**

Factor to Be Tested	Hepatitis B Virus Antigen or Antibody	Use
HBsAg	Hepatitis B surface antigen	Detection of acutely or chronically infected persons Antigen used in hepatitis B vaccine
Anti-HBs	Antibody to HBsAg	Identification of persons who have resolved infection with HBV Determination of immunity after immunization
HBeAg	Hepatitis B e antigen	Identification of infected persons at increased risk for transmitting HBV
Anti-HBe	Antibody to HBeAg	Identification of infected persons with lower risk for transmitting HBV
Anti-HBc	Antibody to HBcAg*	Identification of persons with acute, resolved, or chronic HBV infection (not present after immunization)
Immunoglobulin M (IgM) anti-HBc	IgM antibody to HBcAg	Identification of acute or recent HBV infection (including those in HBsAg-negative persons during the “window” phase of infection)

\*No test is commercially available to measure hepatitis B core antigen (HBcAg).

Modified from and used with permission of the American Academy of Pediatrics: Hepatitis B. In Pickering JL, ed: *2003 Red Book: Report of the Committee on Infectious Diseases*. 26th ed. Elk Grove Village, IL: American Academy of Pediatrics, 2003, p 322.

for identification of breakthrough carriers and of infants who may benefit from revaccination (CDC, 1991).

### Treatment

There is no therapy for acute hepatitis B infection. Interferon (IFN- $\alpha$ ) and antiretroviral drugs such as lamivudine, an antiretroviral drug that blocks HBV polymerase, have been approved for treatment of chronic hepatitis B in children, but success is widely variable. Based on small studies, lamivudine treatment results in clearance of HBeAg in 23%-37.5% of HBV-infected children followed for 6-12 months, but relapse and drug resistance remain important concerns (Hagmann, 2003; Jonas, 2002). Studies investigating the use and efficacy of adefovir dipivoxil for HBV treatment in pediatrics are currently under way (Rosenthal, 2003).

### Prognosis

Most long-term follow-up studies have shown that children vaccinated at birth have high levels of protection until at least 5 years of age. Approximately 5% to 10% of infants born to HbeAg-positive mothers become chronic HBV carriers despite combined active and passive immunoprophylaxis with HBIG and HBV vaccine (Kato et al, 1999). Failure of immunoprophylaxis may be associated with the level of maternal viremia and specific HBV genetic variants (Ngu et al, 1998). Infants who become infected with HBV perinatally have a 90% risk of chronic infection, and 15% to 25% of those with chronic infection die of HBV-related liver disease (primarily hepatocellular carcinoma) as adults (CDC, 1991).

## Hepatitis C

In 1989, hepatitis C virus (HCV) was found to be the main cause of non-A, non-B, parenterally transmitted hepatitis; subsequently, HCV has been found to account for a significant portion of the cases of sporadic acute and chronic hepatitis (Weiss and Persing, 1995). Vertically transmitted hepatitis C infection in infants is associated with a higher rate of chronic hepatitis but less liver injury compared with adult HCV infections (Tovo et al, 2000).

### Incidence

The seroprevalence for anti-HCV antibody in pregnant women ranges from 0.7% to 4.4% worldwide (Conte et al, 2000). In the United States, seroprevalence in pregnant women and the general population is estimated to be 1% to 2% (AAP, 2003). Forty percent to 50% of women with HCV have no identified known risk factors for infection (Bortolotti et al, 1998). The vertical transmission rate of HCV is approximately 5% to 11% from HIV-negative mothers and ranges from 10% to 20% from mothers co-infected with HIV (Hillemanns et al, 2000; Palomba et al, 1996; Polywka et al, 1997; Tajiri et al, 2001). One study has shown, in a multivariate analysis, that higher risk of vertical transmission is related more to maternal use of injection drugs than to HIV infection itself, although the mechanism for this finding is still unclear (Resti et al, 2002). The risk of HCV infection from transfused blood after the advent of HCV screening is estimated to be less than 1 in 1 million units transfused (AAP, 2003).

TABLE 37-8

### Recommended Schedule of Hepatitis B Immunoprophylaxis to Prevent Perinatal Transmission

Vaccine Dose* and HBIG	Age
Infant born to mother known to be HBsAg-positive	
First dose HBIG <sup>†</sup>	Birth (within 12 hrs)
Second dose	Birth (within 12 hrs)
Third dose	1-2 mos
	6 mos
Infant born to mother not screened for HBsAg	
First dose <sup>‡</sup> HBIG <sup>‡</sup>	Birth (within 12 hrs) If mother is found to be HBsAg-positive, give 0.5 mL as soon as possible, not later than 1 wk after birth
Second dose	1-2 mos
Third dose	6-18 mos <sup>§</sup>

\*See Table 37-9 for appropriate vaccine dose.

<sup>†</sup>HBIG (0.5 mL) given intramuscularly at a site different from that used for vaccine.

<sup>‡</sup>First dose is same as that for infant of HBsAg-positive mother. Subsequent doses and schedules are determined by maternal HBsAg status.

<sup>§</sup>Infants of HBsAg positive mothers should be vaccinated at 6 mos.

HBIG, hepatitis B immune globulin; HBsAg, hepatitis B surface antigen.

### Etiology and Pathogenesis

HCV is less efficiently transmitted by sexual contact than HBV. Risk factors for HCV infection include transfusion, intravenous drug use, frequent occupational exposure to blood products, and household or sexual contact with an infected person (Weiss and Persing, 1995). Lots of IVIG contaminated with HCV were reported between April 1993 and February 1994, but since that time, routine screening for HCV with PCR and application of a viral inactivation process during manufacturing have been implemented to reduce the risk of transmission (AAP, 2003; Schiff, 1994).

Transmission of HCV from mother to child is thought to occur either in utero or at the time of delivery and rarely by breast-feeding. Viral genotypes and infection and replication in maternal peripheral blood monocytes may also affect the ability of the virus to infect the fetus or newborn (Azzari et al, 2000; Zuccotti et al, 1995). Data regarding the correlation of HCV RNA titer in the mother with the risk of vertical transmission are conflicting, although most studies have reported an association (Conte et al, 2000; Lynch-Salamon and Combs, 1992; Ohto et al, 1994; Resti et al, 1998; Tajiri et al, 2001). The effect of vaginal delivery versus cesarean section also remains controversial (Gibb et al, 2000; Paccagnini et al, 1995).

Transmission of HCV via breast milk has not been demonstrated conclusively, but HCV can be found in breast milk and colostrum (Gurakan et al, 1994; Zimmermann et al, 1995). Hepatitis C viral titers in the breast milk of infected women, when found, are typically much lower than in the serum, but variability of levels may correlate with maternal viremia (Kumar and Shahul, 1998; Lin et al, 1995). In a study following 65 HCV antibody-positive women and their exclusively breast-fed infants, 5 of the mothers became symptomatic with correlating higher HCV-RNA titers during or soon after delivery. The infants of all 5 of these women tested negative on HCV-RNA PCR at birth, but three became symptomatic and HCV-RNA positive by 3 months of age. The investigators of this study suggest that the higher viral load in the mothers may have raised the risk of transmission to the infants during breast-feeding (Kumar and Shahul, 1998). Other smaller studies have reported rare to no HCV transmission when infected mothers breast-feed their infants (Fischler et al, 1996; Polywka et al, 1999). Studies comparing breast-fed and bottle-fed infants born to HCV-infected mothers have not shown a statistically significant difference in vertical transmission, but both were small studies with sample sizes possibly insufficient for detection of a low level of transmission (Lin et al, 1995; Resti et al, 1998). No large, prospective studies have been performed to clarify whether breast-feeding is an independent mode of vertical transmission of HCV, so the topic remains controversial. Although HCV-RNA has also been described in saliva, cord blood, and amniotic fluid, the role of these fluids in vertical transmission is still uncertain (Delamare et al, 1999; Ogasawara et al, 1993).

### Clinical Spectrum and Laboratory Evaluation

Acquired HCV infection typically causes jaundice in one third of cases and significant increases in alanine aminotransferase (ALT) in almost all persons infected. Most neonates perinatally infected with HCV do not show clinical symptoms or at most have hepatomegaly. They may have elevated liver ALT either briefly or intermittently. The increases in ALT values, when tested, are most commonly noted between 3 and 6 months of age. HCV-RNA PCR results may be negative initially at birth or within the first few days of life but typically become positive by 1 to 2 weeks of age and remain so until at least 5 years of age. Highest sensitivity of PCR is reported to be after 1 month of age (Gibb et al, 2000; Thomas et al, 1997). Confirmatory serologic anti-HCV IgG antibody tests should be delayed until exposed infants are at least 15 to 18 months old, when at least 99% will have cleared maternal antibody (Dunn et al, 2001). Before 18 months of age, only a positive HCV PCR result can confirm diagnosis of neonatal infection; positive anti-HCV IgG results may still be due to passively acquired maternal antibody. IgM assays are not available or reliable for perinatal diagnosis of HCV. Liver ultrasonographic findings are usually normal or may consist of a mild diffuse increase in echogenicity. Liver biopsies, when performed, typically demonstrate mild to moderate chronic persistent hepatitis (Palomba et al, 1996; Tovo et al, 2000).

TABLE 37-9

## Recommended Dosages of Hepatitis Vaccines

	Vaccine and Dosage*	
	Recombivax HB, $\mu\text{g}$ (mL)†	Engerix-B, $\mu\text{g}$ (mL)‡
Infants of HBsAg-negative mothers, children and adolescents younger than 20 yrs	5 (0.5)	10 (0.5)
Infants of HBsAg-positive mothers (HBIG, 0.5 mL, also is recommended)	5 (0.5)	10 (0.5)
Adults (20 yrs or older)	10 (1.0)	20 (1.0)
Patients undergoing dialysis and other immunosuppressed adults	40 (1.0)§	40 (2.0)¶

\*Both vaccines are administered in a 3- or 4-dose schedule; 4 doses may be administered if a birth dose is given and a combination vaccine is used to complete the series. Only single-antigen hepatitis B vaccine can be used for the birth dose. Single-antigen or combination vaccine containing hepatitis B vaccine may be used to complete the series.

†Available from Merck & Co Inc, West Point, PA. A 2-dose schedule, administered at 0 mo and then 4 to 6 mo later, is available for adolescents 11 to 15 years of age using the adult dose of Recombivax HB (10  $\mu\text{g}$ ). In addition, a combination of hepatitis B (Recombivax, 5  $\mu\text{g}$ ) and *Haemophilus influenzae* type b (PRP-OMP) vaccine is licensed for use at 2, 4, and 12 to 15 months of age (Comvax).

‡Available from GlaxoSmithKline Biologicals, Rixensart, Belgium. The U.S. Food and Drug Administration has licensed this vaccine for use in an optional 4-dose schedule at 0, 1, 2, and 12 mo of age.

- In addition, a combination of hepatitis B (Engerix-B, 20  $\mu\text{g}$ ) and hepatitis A (Havrix, 720 ELU) vaccine (Twinrix) is licensed for use in people 18 years of age and older in a 3-dose schedule administered at 0, 1, and 6 or more months later.
- Also, a combination of diphtheria and tetanus toxoids and acellular pertussis (DTaP), inactivated poliovirus (IPV), and hepatitis B (Engerix-B, 10  $\mu\text{g}$ ) is licensed for use in people from 6 weeks through 6 years of age in a 3-dose schedule administered preferably at 2, 4, and 6 months of age (Pediarix [GlaxoSmithKline Biologicals, Rixensart, Belgium]). For additional information, see Pertussis (p 479).

§Special formulation for patients undergoing dialysis.

¶Two 1.0-mL doses given in 1 site in a 4-dose schedule at birth and ages 1, 2, and 6-12 mos.

HBIG, hepatitis B immune globulin; HBsAg, hepatitis B surface antigen.

## Treatment

Interferon and ribavirin are both approved by the U.S. Food and Drug Administration (FDA) to treat adults and children with chronic hepatitis C. Only 10% to 25% of adults treated with interferon have a sustained remission of disease (Bonkovsky and Woolley, 1999). Treatment with a combination of interferon and ribavirin achieves remission in closer to half of treated adults (Cornberg et al, 2002). Data on the use of these agents in infants and children are limited, and these therapies are not approved by the FDA for use in patients younger than 18 years. In Europe, Tovo and colleagues (2000) reported treating four pediatric patients with interferon for 1 year; viremia decreased to undetectable levels during treatment in all four patients, but two patients became viremic again once the treatment was stopped. Interferon therapy is still available only parenterally and is associated with significant side effects; thus, further research into its utility in pediatric HCV infection is needed.

Infants and children with persistent elevations in liver transaminases should be referred to a pediatric gastroenterologist for evaluation and management. The necessity for, as well as the frequency of, screening tests of liver function has not been established.

## Prognosis

In about one third of HCV-infected adults, chronic HCV infection leads to cirrhosis or liver failure within

20 years or hepatic cancer 20 to 30 years after infection (Iwarson et al, 1995). There are limited data regarding long-term follow-up in HCV-infected infants, but existing knowledge indicates that most children remain viremic until at least 5 to 6 years of age, and most develop chronic, persistent hepatitis. Studies monitoring infected children beyond 6 years of age have not been completed, but they are at risk for cirrhosis and, theoretically, hepatocellular carcinoma. Transient hepatitis C viremia with subsequent resolution has been reported (Padula et al, 1999; Ruiz-Extremera et al, 2000; Zanetti et al, 1995). All of the infants who have been followed up for an average of 3 to 4 years have been reported to have normal growth and development (Tovo et al, 2000). Concern has also emerged regarding the potential induction of autoimmune disorders by HCV.

## Prevention

There is currently no vaccine for hepatitis C, although research is under way. Like all other infants, infants with HCV should receive routine hepatitis B immunization. In addition, they should receive hepatitis A vaccination at 2 years of age. Parents should be advised to avoid unnecessary administration of medicines known to be hepatotoxic. Standard precautions are recommended for the hospitalized infant.

## RESPIRATORY VIRUSES

Any one of the large number of respiratory viruses can cause symptomatic respiratory disease in newborn infants. The association has been described for rhinoviruses, adenoviruses, parainfluenza viruses, influenza virus, and respiratory syncytial virus. Adenovirus, rhinovirus, and parainfluenza virus infections are generally characterized by mild rhinorrhea in neonates. All of these viruses, however, may at times cause clinical symptoms indistinguishable from those of bacterial infection, leading to increased diagnostic testing and unnecessary antibiotic treatment. Influenza virus infections are usually mild, but in the absence of maternally transmitted antibody, they can be life-threatening, with severe pneumonia, hypoxia, and a prolonged course.

The most extensive nursery outbreaks, however, have been caused by respiratory syncytial virus (RSV) (Hall et al, 1979; Wilson et al, 1989). Simultaneous outbreaks of RSV and parainfluenza virus type B have also been reported (Meissner et al, 1984).

### Respiratory Syncytial Virus

RSV is the major cause of viral pneumonia and bronchiolitis in infants and children. In temperate climates, it causes large annual epidemics during the cold months. Nosocomial infections are frequent during these times, and illness in the hospital staff is a major factor in its spread from infant to infant. Several nursery outbreaks have been described. In one of these outbreaks, cultures were obtained prospectively so that a full picture of the virus's pathogenicity and epidemiology could be drawn (Hall et al, 1979). Twenty-three of 66 infants hospitalized for 6 or more days were infected. Only 1 was asymptomatic. Clinical manifestations included pneumonia, upper respiratory infection, apneic spells, and nonspecific signs. Pneumonia and apnea were seen almost exclusively in infants older than 3 weeks, and nonspecific signs were most commonly observed in younger infants. Four (17%) infants died, 2 unexpectedly, during the course of infection. Infants in isolettes did not seem to be protected against acquisition of the infection. Eighteen of the 53 nursery personnel were infected during the outbreak; 83% of the infected nursery providers were symptomatic. RSV infection in preterm infants commonly appears to be associated with a new onset of apnea (Bruhn et al, 1977). After discharge from initial hospitalization, risk factors for infant rehospitalization secondary to RSV infection include premature gestational age, chronic lung disease, siblings in daycare or school, chronologic age of less than 3 months, and exposure to tobacco smoke (Carbonell-Estrany and Quero, 2001).

Diagnosis can be confirmed by direct fluorescent antibody (DFA) staining of nasopharyngeal or tracheal aspirate, nasopharyngeal swab, or other respiratory secretions. Culture of RSV may take 3 to 5 days and may be used if DFA staining is not available. The sensitivity of DFA staining for RSV varies from 80% to 90% (AAP, 2003).

Treatment and prevention of RSV infection in infants attracted considerable attention during the 1990s because of the clinical and economic impacts of these infections (Groothuis, 1994; Kinney et al, 1995; Levin, 1994; Meissner, 1994). Considerable debate has ensued concerning the effi-

cacy, safety, and potential effect on health care workers of ribavirin therapy, so its use remains controversial (AAP, 2003; Wald and Dashefsky, 1994). Treatment consists of nebulization of ribavirin by a small-particle aerosol generator supplied by the manufacturer into an oxygen hood, tent, or mask from a solution containing 20 mg of ribavirin per mL of water. The aerosol has been administered on various schedules for 3 to 5 days (e.g., 12 to 20 hours/day). Use of ribavirin in controlled trials has not demonstrated a significant effect on duration of mechanical ventilation, intensive care unit, or hospitalization (Meissner, 2001). Corticosteroids are not effective in the treatment of RSV.

Prevention efforts have focused on passive and active immunization. Standard immune globulin has not been shown to be efficacious for prevention of RSV infection in high-risk infants (Meissner et al, 1993). The efficacy of monthly prophylactic administration of RSV-specific immune globulin (RSV-IG) (750 mg/kg or 150 mg/kg) in 249 infants with cardiac disease or bronchopulmonary dysplasia was examined in a multicenter trial (Groothuis, 1994). In the high-dose (750 mg/kg) group, there were fewer lower respiratory tract infections, hospitalizations, days in hospital, and days in the intensive care unit as well as less use of ribavirin. This therapy requires the placement of an intravenous line and 4 to 6 hours of infusion.

Subsequently, a mouse monoclonal antibody, palivizumab, was developed, which provides similar protection against RSV (Palivizumab, 1998). Unlike anti-RSV immune globulin, which is a pooled human blood product, the monoclonal antibody does not confer the theoretical risk of acquiring blood-borne pathogens. Palivizumab is also substantially easier to administer because it is an intramuscular injection.

Recommendations by the American Academy of Pediatrics for the use of palivizumab and RSV-IGIV are as follows:

- Palivizumab or RSV-IGIV prophylaxis should be considered for infants and children younger than 2 years of age with chronic lung disease (CLD) who have required medical therapy (supplemental oxygen, bronchodilator, diuretic, or corticosteroid therapy) for CLD within 6 months before the start of the RSV season. Palivizumab is preferred for most high-risk children because of its ease of administration, safety, and effectiveness. Patients with more severe CLD may benefit from prophylaxis during a second RSV season if they continue to require medical therapy for respiratory or cardiac dysfunction.
- Recommendations for premature infants:
  - Infants born at 32 weeks of gestation or earlier may benefit from RSV prophylaxis, even if they do not have CLD. For these infants, major risk factors to consider include their gestational and chronologic ages at the start of the RSV season.
  - Infants born at 28 weeks of gestation or earlier may benefit from prophylaxis during their first RSV season, whenever that occurs during the first 12 months of life.
  - Infants born at 29 to 32 weeks of gestation may benefit most from prophylaxis up to 6 months of age.
- Most experts recommend that prophylaxis should be reserved for infants born between 32 and 35 weeks of

gestation who are younger than 6 months of age at the start of the RSV season AND two or more of the following risk factors:

- Child care attendance, school-aged siblings, exposure to environmental air pollutants, congenital abnormalities of the airways, or severe neuromuscular disease.
- Prophylaxis against RSV should be initiated just before onset of the RSV season and terminated at the end of the RSV season. In most seasons and in most regions of the Northern Hemisphere, the first dose of palivizumab should be administered at the beginning of November and the last dose should be administered at the beginning of March, which will provide protection into April.
  - To understand the epidemiology of RSV in their area, physicians should consult with local health departments or diagnostic virology laboratories or the Centers for Disease Control and Prevention if such information is not available locally. Decisions about the specific duration of prophylaxis should be individualized according to the duration of the RSV season. Pediatricians may wish to use RSV rehospitalization data from their own region to assist in the decision-making process.
- Children who are 24 months of age or younger with hemodynamically significant cyanotic and acyanotic congenital heart disease will benefit from 5 monthly intramuscular injections of palivizumab (15 mg/kg).
  - Decisions regarding prophylaxis with palivizumab in children with congenital heart disease should be made on the basis of the degree of physiologic cardiovascular compromise. Infants younger than 12 months of age with congenital heart disease who are most likely to benefit from immunoprophylaxis include:
    - Infants who are receiving medication to control congestive heart failure
    - Infants with moderate to severe pulmonary hypertension
    - Infants with cyanotic heart disease
  - Because a mean decrease in palivizumab serum concentration of 58% was observed after surgical procedures that use cardiopulmonary bypass, for children who still require prophylaxis, a postoperative dose of palivizumab (15 mg/kg) should be considered as soon as the patient is medically stable.
  - The following groups of infants are not at increased risk from RSV and generally should not receive immunoprophylaxis:
    - Infants and children with hemodynamically insignificant heart disease (e.g., secundum atrial septal defect, small ventricular septal defect, pulmonary stenosis, uncomplicated aortic stenosis, mild coarctation of the aorta, and patent ductus arteriosus)
    - Infants with lesions adequately corrected by surgery unless they continue to require medication for congestive heart failure
    - Infants with mild cardiomyopathy who are not receiving medical therapy
  - Dates for initiation and termination of prophylaxis should be based on the same considerations as for high-risk preterm infants. Unlike palivizumab, RSV-IGIV is contraindicated in children with cyanotic congenital heart disease (AAP, 2003; Committee on

Infectious Diseases and Committee on the Fetus and Newborn, 2003).

Additional preventive measures for high risk infants include eliminating or minimizing exposure to tobacco smoke, avoidance of crowds and situations in which exposure to infected individuals cannot be controlled, careful hand hygiene education of parents, vaccination against influenza beginning at 6 months of age, and restricted participation in child care during the RSV season whenever feasible.

The prospects for infant or maternal immunization with live attenuated and protein subunit vaccines are under active investigation and development (Piedra, 2000; Crowe, 2001).

Nosocomial spread of RSV and other respiratory viruses can be minimized by emphasis on hand washing by care providers between contacts with patients. Without additional special precautions, an attack rate of approximately 26% has been observed (Madge et al, 1992). Use of standard contact precautions, such as cohort nursing and the use of gowns and gloves for all contacts with RSV-infected children, can reduce the risk of nosocomial RSV infection to 9.5% (Madge et al, 1992).

## GASTROINTESTINAL VIRUSES

The best studied of the viruses that cause diarrhea are the rotaviruses. This important group of viruses, with at least four serotypes, is responsible for a large proportion of significant and sometimes severe diarrhea in infants 6 to 24 months of age (Cohen, 1991; Greenberg et al, 1994; Haffeejee, 1991; Taylor and Echeverria, 1993). Nursery-acquired infections are common in parts of the world where they have been sought; surprisingly, such infections appear to be benign in most infants. Two studies performed in nurseries in Sydney, Australia, and in London found that 30% to 50% of 5-day-old babies excreted the virus (Chrystie et al, 1978; Murphy et al, 1977). However, more than 90% of the infected infants were asymptomatic. The remaining symptomatic infants had loose stools and vomiting, but this figure was only slightly higher than the proportion of uninfected infants with the same symptoms.

# Toxoplasmosis, Syphilis, Malaria, and Tuberculosis

Pablo J. Sánchez and Amina Ahmed

## TOXOPLASMOSIS

*Toxoplasmosis* refers to the disease state that results from infection with the obligate protozoan parasite, *Toxoplasma gondii*. *Toxoplasma* is a coccidian that is ubiquitous in nature, and the cat is the definitive host. The organism exists in the following three forms: (1) an oocyst in which sporozoites are formed within the intestinal tract of the cat and that is shed in feces, (2) a tachyzoite or endozoite that is the proliferative form and was formerly referred to as a trophozoite, and (3) a tissue cyst that has an intracystic form termed *cystozoite* or *bradyzoite*. Nonfeline mammals and birds ingest infective oocysts from contaminated soil. Tissue cysts then accumulate in the organs and skeletal muscle of these animals. The possible routes of transmission from animal to human are direct contact with cat feces, ingestion of undercooked meat containing infective cysts, and ingestion of fruits or vegetables that have been in contaminated soil. Congenital infection results from placental infection and subsequent hematogenous spread to the fetus.

### Epidemiology

Toxoplasmosis is a worldwide medical problem. High prevalence of infection has been documented in Europe, Central America, and parts of Africa. However, seroprevalence rates differ considerably from one country to another, from one region of a country to another, and even from one ethnic group to another in the same region. These widely disparate seroprevalence rates among different adult populations throughout the world have been explained by differences in eating and sanitation practices that contribute to acquisition of infection. Eating undercooked or raw meat or unwashed raw fruits and vegetables, large cat populations, and even certain climactic conditions have been associated with higher risks of infection.

Among women of child-bearing age in the United States, the prevalence of antibody to *T. gondii* varies from approximately 3% to 30%, depending on the region of the country (Boyer and McAuley, 1994; Remington et al, 2001). The lowest seroprevalence rates have been found in the Mountain and Pacific states, and the highest rates have been seen in the Northeastern and Southeastern United States. Seroprevalence rates for pregnant women seem to be decreasing, although regional and ethnic differences persist.

The prevalence of congenital infection in Massachusetts and New Hampshire has been documented to be 0.08 per 1000 births through immunoglobulin (Ig) M screening

of newborn blood specimens collected on filter paper (Guerina et al, 1994). This finding compares with a rate of 3 to 10 per 1000 live births in Paris and Vienna, where maternal seroprevalence rates of about 70% and 40%, respectively, are observed. In Massachusetts, a case-control study involving 14 years of newborn screening for congenital toxoplasmosis found that the mother's birth outside the United States, particularly in Cambodia and Laos, as well as the mother's educational level and higher gravidity were strongly predictive of congenital infection (Jara et al, 2001).

### Natural History

Infection of the fetus occurs as a consequence of maternal primary infection during pregnancy or, rarely, just before conception (Villena et al, 1998b). Reactivation of latent *Toxoplasma* infection during pregnancy does not lead to fetal infection except among immunocompromised women such as those infected with the human immunodeficiency virus (HIV) (Dunn et al, 1997; Langer, 1983; Low incidence, 1996; Mitchell et al, 1990; O'Donohoe et al, 1991; Remington et al, 2001). Under these circumstances, however, the risk is low. In addition, maternal re-infection may result in congenital toxoplasmosis (Gavinet et al, 1997; Hennequin et al, 1997). Acute maternal infection which is usually acquired early in pregnancy may lead to fulminant fetal infection resulting in stillbirth, nonimmune fetal hydrops, preterm birth, and perinatal death (Wong and Remington, 1994). On the other hand, chronic *Toxoplasma* infection rarely has been associated with sporadic abortion (Remington et al, 1964).

Infection of the fetus occurs transplacentally during maternal parasitemia. Placental infection is an important intermediary step, and up to 16 weeks may elapse between placental infection and subsequent infection of the fetus. This time delay has been termed the *prenatal incubation period* (Remington et al, 2001). Congenital toxoplasmosis has occurred in twins and triplets (Couvreux et al, 1991; Sibalic et al, 1986; Wiswell et al, 1984). In monozygotic twins, the clinical manifestations are usually similar, whereas in dizygotic twins, discrepancies in clinical findings are common.

Approximately 40% of infants born to mothers who acquired toxoplasmosis during pregnancy are infected with *T. gondii*. The rate of vertical transmission varies according to the trimester in which the mother became infected, fetal infection rates increasing as pregnancy advances (Dunn et al, 1999; Remington et al, 2001; Wong and Remington, 1994). Specifically, when maternal infection occurs in the first trimester, 15% of infants are infected, whereas maternal infection in the second and third trimesters results in transmission rates of 30% and 60%, respectively. The severity of clinical manifestations is greatest, however, when maternal infection is acquired early in pregnancy. Maternal infection in the first trimester results in severe disease in as many as 40% of infected fetuses, and in stillbirth or perinatal death in an additional 35% of infants. Only about 15% of newborns have subclinical disease. However, maternal infection in the third trimester is rarely if ever associated with severe fetal disease or stillbirth, and about 90% of infants in such situations have subclinical infection.

Postnatally, transmission of *T. gondii* can occur from transfusion of blood or blood products or from transplantation of organ or bone marrow from a seropositive donor with latent infection. Although the organism has been detected in human milk, transmission by breast-feeding has not been documented.

The majority of newborns with congenital toxoplasmosis lack clinical signs of infection, although thorough evaluation may demonstrate eye or neurologic abnormalities in about 20% of cases. Clinically apparent disease is present in only about 10% to 25% of infected infants (Alford et al, 1969, 1974; Guerina et al, 1994). The clinical manifestations of toxoplasmosis are often indistinguishable from those seen with other congenital infections, such as cytomegalic inclusion disease and congenital syphilis. Approximately one third of infants has a generalized form of the disease that principally involves organs of the reticuloendothelial system. The abnormalities include temperature instability, hepatosplenomegaly, jaundice, pneumonitis, generalized lymphadenopathy, rash, chorioretinitis, anemia, thrombocytopenia, eosinophilia, and abnormal cerebrospinal fluid (CSF) indices (Table 38–1) (Boyer and McAuley, 1994;

Eichenwald, 1960). The other two thirds of infected infants principally manifest neurologic disease.

Central nervous system involvement is the hallmark of congenital *Toxoplasma* infection (Diebler et al, 1985; McAuley et al, 1994; Remington et al, 2001). Chorioretinitis, intracranial calcifications, and hydrocephalus are the most characteristic findings, occurring in approximately 86%, 37%, and 20% of symptomatic infants, respectively (see Table 38–1) (Boyer and McAuley, 1994; Eichenwald, 1960; Remington et al, 2001). This constellation of findings has been referred to as the “classic triad” of congenital toxoplasmosis; their presence should alert the clinician to the diagnosis. Intracranial calcifications may be single or multiple but typically are generalized and located in the caudate nucleus, choroid plexus, meninges, and subependyma (Müssbichler, 1968). They also may occur periventricularly as in cytomegalovirus infection. They are visualized best by computed tomography (CT) but are often detected on ultrasonography as well. Intracranial calcifications may resolve with appropriate antimicrobial therapy (McAuley et al, 1994). Hydrocephalus may be the only manifestation of disease. It results from the extensive periaqueductal and periventricular vasculitis with necrosis that causes obstruction of the ventricular system. Ventriculoperitoneal shunting is often required (Martinovic et al, 1982; McAuley et al, 1994). Abnormalities of the CSF are common; characteristically, they consist of lymphocytic pleocytosis and a markedly elevated protein content. Microcephaly, when present, indicates severe brain injury. Hypothermia as well as hyperthermia may occur secondary to hypothalamic involvement. *Toxoplasma* has been detected in the inner ear and mastoid, with the associated inflammation resulting in deafness. An ascending flaccid paralysis with myelitis has also been reported (Campbell et al, 2001).

Chorioretinitis secondary to congenital toxoplasmosis can manifest at any age. It usually manifests as strabismus in infants, and in older children, defects in visual acuity are more common. Typically, the eye lesion consists of a focal necrotizing retinitis that is often bilateral with involvement of the macula and even the optic nerve. Complications include blindness, iridocyclitis, and cataracts.

Other, less common manifestations of congenital toxoplasmosis are nonimmune hydrops fetalis, myocarditis, nephrotic syndrome, and immunoglobulin abnormalities with both hypergammaglobulinemia and hypogammaglobulinemia described. Bony abnormalities consisting of metaphyseal lucencies similar to those seen in congenital syphilis have also been reported (Milgram, 1974). A variety of endocrine abnormalities may occur, including hypothyroidism, diabetes insipidus (Oygur et al, 1998; Yamakawa et al, 1996), precocious puberty, and growth hormone deficiency.

### Diagnosis

Isolation of *T. gondii* from body fluids and tissues provides definitive evidence of infection. The organism can be isolated from placenta, amniotic fluid, fetal blood obtained by cordocentesis, umbilical cord blood, infant peripheral blood, and CSF by means of intraperitoneal and subcutaneous inoculation into laboratory mice (Foulon et al, 1999a; Remington et al, 2001; Wong and Remington, 1994). Mouse

†Infants with otherwise undiagnosed non-neurologic diseases during the first 2 months of life.

Adapted from Remington JS, McLeod R, Thulliez P, Desmonts G: Toxoplasmosis. In Remington JS Klein JO (eds): *Infectious Diseases of the Fetus and Newborn Infant*, 5th ed. Philadelphia, WB Saunders, 2001, p 246.

inoculation may require as long as 4 to 6 weeks for demonstration of the parasite. Although it is not a practical method, isolation of the organism should be attempted whenever possible. It is available at the *Toxoplasma* Serology Laboratory, Palo Alto Medical Foundation (860 Bryant St, Palo Alto, CA 94301; telephone: 415-326-8120). In addition, tissue culture has been used to isolate *T. gondii* from amniotic fluid.

Histopathologic examination of the placenta as well as tissues obtained at postmortem examination or by biopsy from stillborns or infants should be performed because the specimens may demonstrate the presence of tachyzoites. In addition, tachyzoites have been demonstrated in CSF, ventricular fluid, and aqueous humor by specialized staining techniques.

Polymerase chain reaction (PCR) analysis has been used successfully to detect *Toxoplasma* DNA in amniotic fluid, placenta, CSF, brain, urine, and fetal and infant blood (Foulon et al, 1999a; Fricker-Hidalgo et al, 1998; Grover et al, 1990; Guy et al, 1996; Hohlfield et al, 1994; Jenum et al, 1998; Romand et al, 2001). PCR performed on amniotic fluid obtained by amniocentesis has become the preferred method of confirming in utero infection. False-negative results have been reported, however, and interlaboratory variability in performance of PCR assays has been documented (Guy et al, 1996; Romand et al, 2001). PCR performed on neonatal CSF is recommended for the evaluation of possible central nervous system involvement.

Serologic assays for measurement of antibodies to *T. gondii* in serum and body fluids are the most widely used methods of diagnosing congenital toxoplasmosis (Boyer, 2001; Boyer and McAuley, 1994; Dannemann et al, 1990; Foudrinier et al, 1995; Guerina et al, 1994; Lappalainen et al, 1993; Naessens et al, 1999; Naot et al, 1991; Pinon et al, 2001; Remington et al, 1985; Robert-Gangneux, 2001; Robert-Gangneux et al, 1999a, 1999b; Villena et al, 1999; Wong and Remington, 1994). These tests are commercially available at the *Toxoplasma* Serology Laboratory. The more commonly used tests that detect *T. gondii*-specific IgG antibodies are the Sabin-Feldman dye test, which is considered the "gold standard" but requires live organisms, indirect immunofluorescent antibody (IFA) test, IgG enzyme-linked immunosorbent assay (ELISA), direct agglutination, and IgG avidity test.

In addition, a differential agglutination test has been developed as a confirmatory test to differentiate acute from chronic maternal infection. This test compares the IgG serologic titer obtained with the use of formalin-fixed tachyzoites (HS antigen) with those obtained with acetone- or methanol-fixed tachyzoites (AC antigen). The latter preparation contains stage-specific *Toxoplasma* antigens that are recognized by IgG antibodies only during early infection. An additional assay that may assist in ruling out maternal infection acquired in the first 3 months of pregnancy is the IgG avidity test performed by the ELISA technique. This test is based on the principle that although the antibody-binding avidity or affinity for an antigen is initially low after primary antigenic stimulation, IgG antibodies that are present from previous antigenic stimulation are usually of high avidity. Therefore, a high avidity result in the first trimester would exclude an infection acquired in the previous 12 weeks. Finally, an enzyme-linked immunofiltration assay (ELIFA) has been developed that allows discrimination between IgG anti-

bodies of maternal origin and IgGs synthesized by the fetus as well as identification of antibody subtypes in infected neonates (Zufferey et al, 1999).

Tests that detect *T. gondii*-specific IgM are (1) the double-sandwich IgM ELISA, which has a sensitivity of 75% to 80% and a specificity of 100% (Guerina et al, 1994), (2) the IgM immunosorbent agglutination assay (ISAGA), which is the most sensitive test but should not be performed on umbilical cord blood, because even small quantities of maternal IgM antibodies contaminating the specimen will yield a false-positive result (Boyer and McAuley, 1994); and (3) the IgM immunofluorescent antibody test. The last test is not recommended because it has both a much lower sensitivity than either the IgM ELISA or IgM immunosorbent agglutination assay and poor specificity secondary to rheumatoid factors and antinuclear antibodies, contributing to false-positive results. Other tests that are still being investigated include a *T. gondii*-specific IgA ELISA and IgA immunofiltration assay; a *T. gondii*-specific IgE immunofiltration assay; and IgG, IgM, and IgA immunoblotting tests.

Because the majority of adults with acquired *Toxoplasma* infection are asymptomatic, evaluation of the pregnant woman and fetus is usually prompted by either seroconversion or an elevated maternal *Toxoplasma* IgG titer (Couvreur et al, 1988; Daffos et al, 1988). The latter may reflect chronic or past infection, so the acuity of the maternal infection is determined serologically with the HS-AC differential agglutination test. If recent maternal infection is documented by an acute pattern on the HS-AC test, seroconversion, or rising IgG antibody titers, the fetus should be evaluated by ultrasonography, and amniotic fluid should be tested for specific *Toxoplasma* DNA with PCR. The latter has supplanted the need for cordocentesis, and a positive result confirms fetal infection (Hohlfield et al, 1994). Postnatally, serologic testing of paired maternal and infant sera should be performed at a reliable laboratory that will include assays for *Toxoplasma* IgG and IgM antibodies. Neonatal serum for *Toxoplasma* IgA determination by ELISA also should be considered because it may yield the only positive result in some infants.

Subinoculation of placental tissue, amniotic fluid, and umbilical cord blood into mice should be considered. If results of these tests suggest possible infection, the newborn should be evaluated fully with complete blood cell count and platelet determination, liver function tests, CSF evaluation (including tests for IgG and IgM antibodies and PCR) (Wallon et al, 1998), CT of the head, ophthalmologic examination, and hearing evaluation. The presence of neonatal IgM antibody in serum or CSF, or a positive PCR result for blood or CSF indicates congenital infection. In addition, at-risk infants should undergo serologic follow-up to detect rising serum IgG titers during the first year of life or persistence of IgG antibody beyond 12 to 15 months of age, when maternal IgG antibody has disappeared (Robert-Gangneux et al, 1999a, 1999b). Uninfected infants show a continuous decline in *Toxoplasma* IgG titer with no detectable IgM or IgA antibodies.

Low IgG titers and an HS-AC differential agglutination test that indicate remote maternal infection do not require further evaluation of the mother or infant unless the mother is infected with HIV. Because fetal infection has occurred during chronic *Toxoplasma* infection in HIV-

infected pregnant women, their infants should be evaluated serologically at birth for evidence of congenital infection. It has been suggested that HIV-infected pregnant women who have low CD4<sup>+</sup> T lymphocyte counts and who are seropositive for *Toxoplasma* antibody receive prophylaxis to prevent fetal infection (Beaman et al, 1992; Wong and Remington, 1994). However, insufficient data currently are available to recommend that such therapy be given routinely for this indication. Nevertheless, if such women previously have had toxoplasmic encephalitis, prophylaxis with pyrimethamine, sulfadiazine, and leucovorin (folinic acid) should be considered (Masur et al, 2002).

### Therapy

It is currently recommended that fetuses and infants younger than 1 year who are infected with *T. gondii* receive specific therapy effective against this congenital pathogen, even if they have no clinical signs of disease (Couvreur et al, 1988; Daffos et al, 1988; Foulon et al, 1999; Friedman

et al, 1999; Gilbert et al, 2001; Hohlfeld et al, 1989; Koppe et al, 1986; McAuley et al, 1994; McGee et al, 1992; Peyron and Wallon, 2001; Roizen et al, 1995; Vergani et al, 1998; Wallon et al, 1999; Wong and Remington, 1994). On the basis of comparison with untreated historic controls, outcome is improved substantially by maternal, fetal, and neonatal treatment. Spiramycin has been used in pregnant women with acute toxoplasmosis to reduce transplacental transmission of *T. gondii*. If fetal infection is confirmed after the 17th week of pregnancy, however, treatment with pyrimethamine, sulfadiazine, and folinic acid is recommended. Prenatal treatment of congenital toxoplasmosis reduces the clinical severity of infection in the newborn while shifting the disease to a more subclinical form. This effect in turn may ameliorate the long-term neurologic complications that are commonly seen among infants who have clinical manifestations in the neonatal period.

Neonatal treatment has also resulted in reductions in sensorineural hearing loss and neurodevelopmental and visual handicaps. Table 38–2 shows the recommended

**TABLE 38–2**

### Treatment Guidelines for Congenital Toxoplasmosis

	Therapy	Dosage (Oral Unless Specified)	Duration
In pregnant women with acute toxoplasmosis: For first 21 wks of gestation or until term if fetus not infected	Spiramycin*	1 g q 8 hr without food	Until fetal infection documented or excluded at 21 wks; if fetal infection documented, replaced with pyrimethamine, leucovorin, and sulfadiazine (see below)
If fetal infection confirmed after 18th week of gestation or if infection acquired in last few weeks of gestation	Pyrimethamine and	Loading dose: 100 mg/day in 2 divided doses for 2 days followed by 50 mg/day	Until delivery
	Sulfadiazine* and	Loading dose: 75 mg/kg/day in 2 divided doses (maximum, 4 g/d) for 2 days; then 100 mg/kg/day in 2 divided doses (maximum, 4 g/day)	Until delivery
Congenital <i>Toxoplasma</i> infection in infant	Leucovorin <sup>†</sup> Pyrimethamine and	10–20 mg qd Loading dose: 2 mg/kg/day for 2 days; then 1 mg/kg/day for 2 or 6 months; then 1 mg/kg/day on Mon, Wed, and Fri each week	Until delivery ≥1 yr
	Sulfadiazine* and	100 mg/kg/day in 2 daily divided doses	≥1 yr
	Leucovorin (folinic acid) <sup>†</sup>	10 mg 3 times weekly	≥1 yr
	Corticosteroids (prednisone) <sup>‡</sup>	1 mg/kg/daily in 2 daily divided doses	Until resolution of elevated (≥1 g/dL) CSF protein or active chorioretinitis that threatens vision

\*Available only on request from the U.S. Food and Drug Administration (301-827-2127; fax, 301-927-2475).

<sup>†</sup>Monitor blood and platelet counts weekly; adjust dosage for megaloblastic anemia, granulocytopenia, or thrombocytopenia.

<sup>‡</sup>When signs of inflammation or active chorioretinitis have subsided, dosage can be tapered and drug discontinued; use only in conjunction with pyrimethamine, sulfadiazine, and leucovorin.

Data from Boyer KM, McAuley B: Congenital toxoplasmosis. *Semin Pediatr Dis* 5:42, 1994; and Remington JS, McLeod R, Thulliez P, Desmonts G: Toxoplasmosis. In Remington JS, Klein JO (eds): *Infectious Diseases of the Fetus and Newborn Infant*. 5th ed. Philadelphia, WB Saunders, 2001, p 293.

guidelines for the treatment of congenital toxoplasmosis. In infants with congenital toxoplasmosis, the treatment consists of pyrimethamine, sulfadiazine, and folinic acids (Boyer and McAuley, 1994; McAuley et al, 1994; McLeod et al, 1992; Remington et al, 2001). The actual duration of therapy is not known, although prolonged courses, at least 1 year, are preferred. Currently, most experts recommend combined treatment until the patient is 1 year old (Remington et al, 2001; Villena et al, 1998a, 1998b).

Complete blood cell counts and platelet determination must be monitored closely while the patient is receiving therapy, because granulocytopenia, thrombocytopenia, and megaloblastic anemia may occur. These parameters usually improve once a higher dosage of folinic acid is administered or pyrimethamine and sulfadiazine are discontinued temporarily. The indications for adjunctive therapy with corticosteroids such as prednisone (0.5 mg/kg twice a day) are CSF protein concentration 1 g/dL or higher and chorioretinitis that threatens vision; corticosteroid treatment is continued until either condition resolves. Current therapies are not effective against encysted bradyzoites and therefore may not prevent reactivation of chorioretinitis and neurologic disease.

### Prognosis

Maternal toxoplasmosis acquired during the first and second trimesters has been associated with stillbirth and perinatal death secondary to severe fetal infection in approximately 35% and 7% of cases, respectively. Among infants born with congenital toxoplasmosis, the mortality rate has been reported to be as high as 12%. In addition, infants with congenital toxoplasmosis are at high risk for ophthalmologic, neurodevelopmental, and audiologic impairments, including mental retardation (87%), seizures (82%), spasticity and palsies (71%), and deafness (15%) (Eichenwald, 1960; Hohlfeld et al, 1989; Koppe et al, 1986; McAuley et al, 1994). Of neonates with subclinical infection, long-term follow-up reveals eye or neurologic disease in as many as 80% to 90% by the time they reach adulthood (Couvreur and Desmonts, 1962; Couvreur et al, 1984; McLeod et al, 2000; Saxon et al, 1973; Wilson et al, 1980). Data from the United States National Collaborative Treatment Trial show that treatment of neonates with congenital toxoplasmosis early and for 1 year resulted in more favorable outcomes than were reported for untreated infants or infants who were treated for only 1 month.

### Prevention

Pregnant women whose serologic status for *T. gondii* is negative or unknown, as well as women who are attempting to conceive, should be educated on the prevention of congenital toxoplasmosis through avoidance of at-risk behaviors that may expose them to cat feces or encysted bradyzoites in raw meat (Centers for Disease Control and Prevention [CDC], 2000; Eskild et al, 1996; Foulon et al, 2000; Jones et al, 2001; Wilson and Remington, 1980). Such women should be taught to wear gloves when changing cat litter boxes or gardening and to wash hands

well after such activities. Daily changing of cat litter will also decrease the chance of infection, because oocysts are not infective during the first 1 to 2 days after passage. In addition, feeding cats commercially prepared foods rather than undercooked meats or wild rodents reduces the likelihood of their becoming infected and capable of transmitting the infection to a pregnant woman. Oral ingestion of *T. gondii* can be prevented by either cooking meat to well done, smoking it, or curing it in brine, and by washing kitchen surfaces that come into contact with raw meat. Vegetables and fruits should be washed, and hands and kitchen surfaces should be cleaned after handling fruits, vegetables, and raw meat. Flies and cockroaches may serve as transport hosts for *T. gondii*, so their access to food must be prevented.

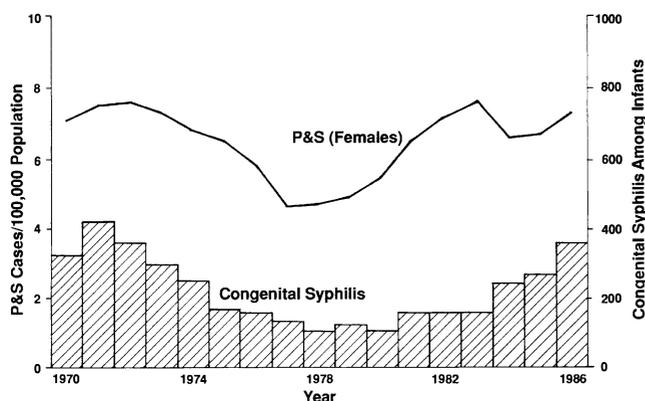

Routine serologic screening of women during pregnancy has been an effective means of prevention in such countries as France and Austria, where the incidence of congenital toxoplasmosis is high. No such screening is currently recommended in the United States. However, high-risk women, including those who are immunocompromised, should be screened early in pregnancy. Neonatal screening for IgM antibody has also been advocated so that asymptomatic infants can be detected and treated before neurologic symptoms develop (Peterson and Eaton, 1999). This strategy, however, has been hampered by the lack of readily available and reliable IgM test kits. Moreover, such screening will not detect the approximately 25% of infected infants who lack anti-*Toxoplasma* IgM antibody. Further studies involving cost analyses are needed to define the best preventive strategy for congenital toxoplasmosis in specific populations, regions, and countries.

## SYPHILIS

Before 1945, a chapter on congenital syphilis in a textbook devoted to diseases of the newborn would have been the most important one in the infectious disease section because of the great number of newborns affected and the broad variety of clinical syndromes produced. If this chapter had been omitted in the 1950s and 1960s, it would have been scarcely missed. In many parts of the United States, a young pediatrician might have completed 3 years of residency in a large urban hospital without ever having encountered one case. The situation has changed, however, and a new syphilis epidemic developed during the late 1980s and 1990s (Berry and Dajani, 1992).

### Incidence

During the 1930s and 1940s, in the congenital syphilis clinic of the Harriet Lane Home in Baltimore, Maryland, 60 to 80 infants and children attended each week for arsenic therapy. Many more were lost to follow-up before completing their 2- to 3-year course of treatment. It was unusual if fewer than three or four new examples were discovered in the general outpatient department in the course of 1 week. Then, for several decades, the frequency of the disease declined. The curve of incidence has been rising since the 1970s, however (Fig. 38-1).

**FIGURE 38-1.** Case rates of primary and secondary (P&S) syphilis among females and congenital syphilis among infants less than 1 year of age in the United States, 1970 to 1986 showing the beginning of the epidemic in the United States. (From Ingall D, Dobson SRM, Musher D: *Syphilis*. In Remington JS, Klein JO [eds]: *Infectious Diseases of the Fetus and Newborn Infant*. Philadelphia, WB Saunders, 1990, pp 367-394.)

From 1980 to 1986, the number of cases of congenital syphilis rose from 111 cases to 365 cases per year in the United States. More than 600 cases were reported in 1989. In 48% of cases, there was inadequate or no prenatal care, and treatment failed in 19% of total cases and in 35% of women who had prenatal care (Congenital syphilis, 1986). During the 1990s, the epidemic has not been restricted to a single region of the country: The South (178%), the Midwest (244%), and the West (777%) have all experienced dramatic increases in incidence of congenital syphilis (Dunn et al, 1993). By 2001, the spike in number of cases has all but disappeared ([www.cdc.gov/std/syphilis2001](http://www.cdc.gov/std/syphilis2001)).

### Etiology and Pathogenesis

The organism responsible for syphilis is *Treponema pallidum*. This delicate, corkscrew-shaped, flagellated, highly motile spirochete is almost identical in appearance to *Treponema pertenue*, which causes yaws. These two diseases, like smallpox and cowpox, produce a cross-immunity for each other. This fact was established by Alexander Schaffer, the first editor of this textbook, when, after having spent 2 years on yaws-infested Fiji without encountering one case of syphilis, he was transferred to yaws-free India, where syphilis became one of his major medical preoccupations.

Syphilis can be acquired by introduction of *Treponema* through an abrasion in the skin or mucous membrane or by transplacental transmission. Whereas adults and some children become infected percutaneously, young infants almost invariably receive the organism from their mothers via the placenta and the umbilical vein. Transplacental transmission may take place at any time during gestation but ordinarily occurs during the second half of pregnancy. Fetuses infected early may die in utero or are at high risk for significant neurodevelopmental morbidity. The impact of the current epidemic on potentially preventable fetal deaths has not been evaluated. The usual outcome of a third-trimester infection is the birth of an apparently

normal infant who becomes ill within the first few weeks of life. Whereas virtually all infants born to women with primary or secondary infection have congenital infection, only 50% are clinically symptomatic. Because of growing pressure from managed care organizations for early discharge of new mothers, which has occurred at the same time as the current epidemic, identification of congenitally infected, asymptomatic infants whose maternal infections occurred late in the third trimester and whose syphilis serologic test results are not yet positive at the time of delivery has presented an unusually difficult problem for tracking and treatment (Dorfman and Glaser, 1990). It is critical that all infants undergo serologic testing for syphilis at the time of delivery and have a source of primary health care capable of tracking both maternal and infant syphilis status (Chhabra et al, 1993; Zenker and Berman, 1991). Early latent infection results in a 40% infant infection rate, and late latent infection results in a 6% to 14% infant infection rate (Wendel, 1988).

### Pathology

Because *Treponema* enters the fetal bloodstream directly, the primary stage of infection is completely bypassed. There is no chancre and no local lymphadenopathy. Instead, the liver, the immediate target of the invasion, is flooded with organisms, which then penetrate all the other organs and tissues of the body to a lesser degree. Exactly where they take root and arouse local pathologic response, which in turn produces the presenting signs and symptoms, is unpredictable. Principal sites of predilection are the liver, skin, mucous membranes of the lips and anus, bones, and the central nervous system. If fetal invasion has taken place early, the lungs may be heavily involved in a characteristic *pneumonia alba*, but this condition is seldom compatible with life. *Treponema* may be found in almost any other organ or tissue of the body but seldom causes inflammatory and destructive changes in loci other than the ones named previously.

Under the microscope, the tissue alterations consist of nonspecific interstitial fibrosis with or without evidence of low-grade inflammatory response in the form of round cell inflammation. Necrosis follows regularly in bone but only rarely in other tissues. Localization and gumma formation are not common in the neonate. Noteworthy is extensive extramedullary hematopoiesis in the liver, spleen, kidneys, and other organs.

### Diagnosis

The most common signs and symptoms of congenital infection in the neonatal period are listed in Table 38-3. Additional diagnoses associated with congenital syphilis are nonimmune hydrops, nephrosis, and myocarditis (Wendel, 1988). The earliest sign of congenital syphilis may be snuffles, in which the nose becomes obstructed and begins to discharge clear fluid at first, then purulent or even sanguineous material later.

Cutaneous lesions appear at any time from the second week on. They are sparse or numerous and are copper-colored and may be round, oval, or iris-shaped and circinate or desquamative. Even more characteristic than their appearance is their distribution, which most frequently

### Clinical Features of Early Congenital Syphilis by Age

Feature	% of Patients with Finding	
	Age <4 Wks	Age >4 Wks
Hepatosplenomegaly	91	87
Joint swellings	3	34
Rash	31	55
Anemia	64	89
Jaundice	49	7
Snuffles	12	50
Metaphyseal dystrophy	95	91
Periostitis	37	80
Cerebrospinal fluid changes	44	37

Modified from Hira SK, Bhad GJ, Patel JB, et al: Early congenital syphilis: Clinicoradiographic features in 202 patients. *Sex Transm Dis* 12:177, 1985.

includes the perioral, perinasal, and diaper regions. Palms and soles are also involved, but the rash is soon replaced there by diffuse reddening, thickening, and wrinkling. In heavily infected infants, the rash may become generalized. Mucocutaneous junctions become involved in typical fashion. The lips become thickened and roughened and tend to weep. Radial cracks appear that traverse the vermilion zone up to and a bit beyond the mucocutaneous margins of the lips. These are the beginnings of the radiating scars that may persist for many years as rhagades. Similar mucocutaneous lesions involve the anus and vulva, but in these locations, the white, flat, moist, raised plaques known as “condylomata” are also encountered, although less frequently.

Radiographs of the bones show characteristic osteochondritis and periostitis in 80% to 90% of infants with symptomatic congenital syphilis. In most cases, the bone lesions are asymptomatic, but in a few, they are severe enough to lead to subepiphyseal fracture and epiphyseal dislocation, an extremely painful pseudoparalysis of one or more extremities, may supervene. About 20% asymptomatic, congenitally infected infants have metaphyseal changes consistent with

congenital syphilis. Radiographic alterations include an unusually dense band at the epiphyseal ends, below which is a band of translucency whose margins are at first sharp but that later become serrated, jagged, and irregular. The shafts become generally more opaque, but spotty areas of translucency throughout may give them a moth-eaten look. The periosteum of the long bones becomes more and more thickened. Epiphyses separate because the dense end plate breaks away from the shaft by fracture through the subepiphyseal zone of decalcification. This is exactly what happens in the pseudoparalysis of scurvy, although the reason for the weakening of the subepiphyseal bone is different. In syphilis, pseudoparalysis appears within the first 3 months of life; in scurvy, it seldom manifests before 5 months of life.

Signs of visceral involvement include hepatomegaly, splenomegaly, and general glandular enlargement. Palpable epitrochlear nodes are not pathognomonic but are highly suggestive of congenital syphilis. The liver may be greatly enlarged, firm, and nontender. Associated with this may be jaundice, which appears in the second or third week of life, is seldom intense, and does not persist for many days. Anemia, probably indicative of bone marrow infection and hematopoietic suppression, may become severe. Lesions in the gastrointestinal tract and pancreas may occur and may produce distention and delay in passage of meconium.

Clinical signs of central nervous system involvement seldom appear in the newborn infant, even though one third to one half of those infected suffer such involvement. The involvement is demonstrated by cerebrospinal fluid changes such as increased protein content, a mononuclear pleocytosis of up to 200 or 300 cells/mL, or by a positive result of the Venereal Disease Research Laboratories (VDRL) test (Table 38-4).

Diagnosis is confirmed by dark-field visualization of *Treponema* in scrapings from any lesion or from any body fluid, by visualization of characteristic bone changes on radiographs, and by positive serologic test results for syphilis. Serologic test results must be interpreted with caution, however. Because the IgG portion of reagin is transmitted across the placenta, its finding in the baby's serum means no more than that the mother has or has had syphilis. She may have been cured during pregnancy and yet still have quantities of reagin in her blood, or she may not have received treatment at all and still not have passed the disease on to her fetus. A

TABLE 38-4

### Severity of Disease and Cerebrospinal Fluid Findings in 108 Patients with High Risk for Congenital Syphilis

	Asymptomatic (normal)	Minimum Involvement	Intermediate Involvement	CNS Involvement
<b>% of infants affected:</b>				
Age 91-180 days (n = 47)	28	30	36	6
Age 181-365 days (n = 31)	45	32	20	3
Age 366-731 days (n = 30)	63	26	10	0
<b>Cerebrospinal fluid findings:</b>				
Cells/mL	0-5	5-30	0-100	10-200
Protein (mg/100 mL)	15-30	30-75	Moderate increase	50-200
VRDL titer result	Negative	Negative	Positive	Positive

Modified from Moore JF: *The Modern Treatment of Syphilis*, 2nd ed. Springfield, IL, Charles C Thomas, 1943; and Platou RV: *Adv Pediatr* 4:35, 1949.

higher titer in the infant's blood than in the mother's is not evidence of fetal infection, nor is an elevated concentration of total IgM in the cord serum.

The most helpful specific test result is a positive finding in the newborn's blood of IgM antibody against *T. pallidum* on IgM-FTA-ABS (fluorescent treponemal antibody absorption) (Lewis, 1992; Stoll et al, 1993). This is fluorescent *Treponema* antibody from which antibodies from treponemes other than *T. pallidum* have been removed by absorption. This finding is usually an indicator of congenital syphilis, although in the presence of rheumatoid factor, false-positive results of this test are occasionally seen. However, the result is not always positive at first, even when infection is present in the infant, possibly because if the infection is acquired late in pregnancy, specific antibodies have not had time to form.

Thus, when an infant's blood VDRL test result is positive at birth, the diagnosis of congenital syphilis is not justified unless pathognomonic signs are also present. If they are not, serial determinations of reagin titer must be performed. If antibodies are passively acquired, the titer decreases to zero within 4 to 12 weeks; it increases if the disease is actually present. If the IgM-FTA-ABS result is also positive at birth, treatment may be initiated. If this result is negative, however, the test should be repeated several times at 3- or 4-week intervals.

### Treatment

Treatment is recommended for all pregnant women with syphilis regardless of the stage of pregnancy (Table 38-5). Recommendations from the CDC (2002) for treatment of symptomatic or asymptomatic infants are listed in

Table 38-6. Long-term follow-up recommendations are outlined in Table 38-7.

Hardy and coworkers (1970) reported a rare case of a male infant who died of congenital syphilis. His mother had received penicillin G 10 days before delivery, and he was given massive doses for 17 days after birth. Even so, *T. pallidum* was recovered from the infant's eyes after his death.

## MALARIA

Malaria is a febrile disease caused by four species of *Plasmodium*—*P. falciparum*, *P. vivax*, *P. ovale*, and *P. malariae*. Humans acquire the infection from the bite of the female, nocturnally feeding *Anopheles* mosquito. Malaria remains the leading cause of death from parasitic infections in the world. An estimated 2 million deaths and 300 to 500 million cases of infection are attributed to malaria annually. Children have the highest mortality rate, followed by pregnant women (Alecrim et al, 2000). The greatest burden of disease and death is in Africa, where the rate of *P. falciparum* infection approaches 75% of the total population. In the United States, more than 1000 cases of malaria are reported annually to the CDC, and these occur almost exclusively in travelers and immigrants from endemic areas.

Congenital malaria, in contrast, remains rare, with only about 300 cases reported in the world literature (Balatbat et al, 1995). In the United States, an estimated 50 cases have been reported to the CDC in the last 50 years. A dramatic increase in the number of cases of congenital malaria that occurred in the United States from 1980 to 1981 was the result of a large influx of immigrants from endemic countries (Malviya and Shurin, 1984). With current

trends in immigration and foreign travel, congenital malaria not only will continue to be observed in the United States but also will probably increase in frequency in the years ahead. Because delay in diagnosis and treatment can result in significant morbidity and mortality, the differential diagnosis of fever in infants born to mothers who have lived or traveled in areas where malaria is endemic must include congenital malaria.

**Definition**

*Congenital malaria* is defined as malaria acquired by the fetus or newborn directly from the mother, either in utero or during delivery (Moran and Couper, 1999). Application of the definition has not been consistent. Some investigators have based diagnosis of congenital malaria on detection of parasites in the newborn within 24 hours of birth (Larkin and Thuma, 1991) whereas others have used detection of the parasites within the first 7 days of age (Moran and Couper, 1999). These age-specific criteria are most applicable in endemic regions where, in older infants, it is difficult to distinguish congenital malaria from malaria acquired through mosquito transmission.

Outside endemic areas, where postnatal transmission can be reasonably excluded, it is evident that clinical onset of disease in congenital malaria is usually delayed several weeks. These observations suggest that many cases of congenital malaria in endemic areas are likely misclassified as being postnatally acquired.

Congenital malaria also has been defined as umbilical cord blood parasitemia (Fischer, 1997), although the finding of parasites in cord blood is not uncommon in endemic areas and frequently clears without involving the peripheral circulation (Airede, 1991). Reinhardt (1978) found parasites in thick smears of cord blood in 22% of 198 infants born to women in the Ivory Coast, although the peripheral blood smears were negative for all of the infants. Similarly, 4% of 1009 infants born to Tanzanian women had parasites in umbilical cord blood, but in only 2 of 11 infants was evidence of parasitemia also detected on peripheral blood smear (McGregor, 1984). Parasitemia detected shortly after birth also may not evolve into clinically significant disease. In 10 of 35 congenitally infected newborns diagnosed at birth by Diallo (1983), parasites were no longer detectable in peripheral blood at 96 hours of age. In the remaining infants, blood smears for malaria

were negative within 30 days of age. Larkin and Thuma (1991) found peripheral parasitemia within 24 hours of age in 19 (65%) of 65 newborns, but only 7 had clinical signs of disease. Because all 19 newborns received antimalarial therapy, it is not known how many of them would have shown clinical manifestations of malaria if left untreated.

### Epidemiology

The existence of congenital malaria was questioned in the early part of the 20th century. In 1950, Covell tabulated all reports of congenital malaria, defined as detection of the parasite in infants in the first 7 days after birth. Rates of placental parasitemia ranged from 5% to 74% and of maternal parasitemia from 1% to 68%. The prevalence of congenital malaria was estimated to be 0.3% (16 of 5324 births). The low frequency of vertical transmission was attributed to the effective barrier served by the placenta to the passage of the parasite as well as to the protective effect of transplacentally acquired maternal antibody in the fetus and newborn.

Covell's findings confirmed the existence of congenital malaria and have been cited repeatedly as evidence of the rarity of the disease in endemic areas. Bruce-Chwatt (1952) found a placental infection rate of 20% among 228 pregnancies in Nigeria, but only 1 (0.4%) of the 235 neonates had parasitemia. Similarly, McGregor (1984) found no peripheral parasitemia in blood samples collected within 24 hours of age from 147 infants born to mothers with placental malaria. In 1958, Cannon found that 26% of placentas were infected and, in 1970, Williams and McFarlane found 37% of placentas infected. Parasitemia, however, was not detected in any of the umbilical cord blood samples in either series.

Later studies have reported incidence rates for congenital malaria ranging from 4% to 15% (Nyirjesy et al, 1993). In Zambia during a season of heavy malaria transmission, Larkin and Thuma (1991) identified peripheral parasitemia in 19 (29%) of 65 newborns born to 63 women, although only 7 (37%) of the 19 infants had clinical signs of disease at the time of diagnosis. Peripheral blood smears from 700 peripartum mothers at seven sites in Sub-Saharan Africa revealed a 15% prevalence of maternal parasitemia (Fischer, 1997). Congenital malaria, defined as umbilical cord blood parasitemia, was found in 7% of newborns and ranged from 0% to 23% at the various centers. These researchers concluded that congenital malaria should no longer be considered rare in endemic areas.

A summary of studies from Africa reported from 1950 to the late 1980s divides the incidence of maternal and congenital malaria into low-frequency and high-frequency groups (MacLeod, 1988). In six studies of 2103 infants, the prevalence of congenital malaria ranged from 0% to 0.2%, whereas in another six studies of 1821 infants, the prevalence ranged from 4% to 44%. However, there was no consistent difference between the two groups to account for the discrepant findings. Even in the report by Covell (1950), the frequency of congenital malaria at various study sites ranged from 0% to 10%.

It is apparent from these observations that the true incidence of congenital malaria in endemic areas is unknown but highly variable among different populations. Underreporting of disease in endemic areas is likely, in part because of suboptimal data collection but also sec-

ondary to the difficulty in distinguishing congenital malaria from malaria acquired postnatally in young infants by mosquito transmission. Other confounding factors are location of the study, definition of congenital malaria, and selection of study participants, which varied from unselected mothers in labor to women with placental or peripheral parasitemia.

In contrast to the rarity of congenital malaria in indigenous populations, Covell (1950) found that the prevalence of congenital malaria among nonimmune populations (i.e., Europeans residing in or visiting endemic areas) to be approximately 7%. It is postulated that congenital malaria is more common in infants born to these women because their levels of immunity are lower than those of the native population. Congenital malaria also is more common among infants of women who emigrate from areas in which malaria is endemic to areas that are free of malaria, presumably as a result of waning immunity from lack of continued exposure.

In the United States, the occurrence of congenital malaria is well documented because the country has been free of indigenous disease since the 1950s. From 1950 to 1991, 49 cases of congenital malaria were reported (Hulbert, 1992), and at least five additional cases have been described subsequently (Balatbat et al, 1995; D'Avanzo et al, 2002; Gereige and Cimino, 1995; Starr and Wheeler, 1998; Viraraghavan and Jantausch, 2000). As expected, almost all of the cases were imported. Up to 1979, an average of one case per year was reported to the CDC (Hulbert, 1992; Malviya and Shurin, 1984). From 1980 to 1981, 16 cases were reported (Quinn et al, 1982). This abrupt increase followed a rise in the total number of cases of malaria in the United States that occurred as a result of a large influx of refugees and immigrants from Southeast Asia (Mertz et al, 1981). Fifteen of the 16 infants were born to mothers from that region. In contrast, in the past 20 years, mothers of infants with congenital malaria have come from Mexico, Central America, and Africa, reflecting changes in immigration patterns.

### Natural History

Congenital infection occurs with all four species of *Plasmodium*. Among the 107 cases tabulated by Covell (1950), mostly all from Africa, 64% were caused by *P. falciparum*, 32% by *P. vivax*, and 2% by *P. malariae*. In Hulbert's (1992) review of 49 cases in the United States since 1950, 82% of infections were due to *P. vivax*, reflecting immigration patterns in the United States. *P. falciparum* and *P. malariae* accounted for 6% and 10% of infections, respectively. Infection with more than one species also is possible. In one report, concurrent infection with *P. malariae* and *P. vivax* was documented in a 6-week-old infant (MacLeod et al, 1982).

In endemic regions, both the prevalence and density of malarial parasitemia are increased in pregnant versus non-pregnant women (Fisher, 1997; McGregor, 1984). Prevalence rates are highest in primigravid women and decline with rising parity (McGregor, 1984). The propensity of pregnant women to have malaria is hypothesized to be due to diminished immunity associated with pregnancy, which allows for reactivation of symptomatic or asymptomatic parasitemia. In addition, parasitemia in the placental tissue

of women living in endemic areas is not an uncommon finding. In Africa, prevalence rates of placental malaria are 20% to 34%, although rates as high as 74% have been reported (McGregor, 1984).

Malaria in pregnancy may affect both the mother and fetus adversely. Several studies from areas where malaria is endemic have demonstrated an association between maternal peripheral or placental parasitemia and spontaneous abortion, premature delivery, and low birth weight (MacLeod, 1988; Nyirjesy et al, 1993; Subramanian et al, 1992). The best-documented sequela is low birth weight, secondary to either prematurity or intrauterine growth restriction. Bruce-Chwatt (1952) examined the placentas of 310 singleton deliveries in Lagos and found that 73 (24%) contained parasites. The average birth weight of infants born to mothers whose placentas were infected was 145 g less than that of those born with uninfected placentas. Similarly, Archibald (1956) and Jelliffe (1968) documented a decrease in birth weight of 170 g and 263 g, respectively, in infants born to mothers with placental parasitemia. With respect to peripheral parasitemia, Larkin and Thuma (1991) found a 469-g lower average birth weight without an increase in prematurity rate among 19 such infants compared with 46 infants without parasitemia. Additional supportive evidence of the effect of maternal malaria on birth weight is the rise in birth weight that is observed when pregnant women are given chemoprophylaxis (MacLeod, 1988; Nyirjesy et al, 1993).

The timing and mechanism of transmission of *Plasmodium sp.* from the mother to the fetus is not well understood. In utero transmission is supported by the finding of malarial parasites in fetal tissues at autopsy (Mertz et al, 1981), by umbilical cord blood parasitemia (McGregor, 1984), and by the onset of clinical signs of malaria within hours of birth (Brandenburg and Kenny, 1982; Covell, 1950; Gereige and Cimino, 1995). Alternatively, clinical findings in infants with congenital malaria may be delayed for several weeks after birth, suggesting infection at parturition (Hulbert, 1992). Transmission of malaria probably does not occur as a result of transplacental passage of the exoerythrocytic parasite. More likely, vertical transmission occurs by transfusion of parasitized maternal erythrocytes through a breach in the placental barrier that may occur either prematurely during pregnancy or during labor. Parasites in umbilical cord blood or fetal blood then may be cleared spontaneously, resulting in no disease manifestations, or may proliferate, with development of clinical signs of disease. Transmission of malaria by breast-feeding does not occur.

The clinical manifestations of congenital malaria, although occasionally seen within hours of birth (Brandenburg and Kenny, 1982; Gereige and Cimino, 1995), are typically delayed until an infant is several weeks of age. Among 49 infants with congenital malaria born in the United States, the mean age at onset of clinical signs was 5.5 weeks, with 96% of infants presenting between 2 and 8 weeks of age (Hulbert, 1992). The prolonged interval between birth and onset of clinical manifestations may be explained by transmission late in pregnancy or at delivery, so that multiple erythrocytic life cycles are required to produce clinically evident disease, or by the presence and amount of transplacentally acquired maternal antimalarial

antibodies. When such antibodies are present in sufficient concentrations, as in infants born to immune mothers, parasitic replication may be prevented or attenuated, and clinical signs may be mild, delayed, or even absent. On the other hand, among infants born to mothers with low or nonexistent immunity, parasitic replication is uninhibited, and clinical signs of malaria supervene. Preterm infants, who do not benefit from passive immunity, may manifest clinical signs earlier than full-term infants. In a review of premature neonates with congenital malaria, 4 of 5 infants were diagnosed in the first week of life (Ahmed et al, 1998), although the prompt medical evaluation afforded these infants may have facilitated earlier detection.

The clinical features of congenital malaria are nonspecific and often resemble those due to sepsis or other congenital infections. Fever is almost uniformly present, but without the characteristic paroxysmal pattern. In Hulbert's review of congenital malaria (1992), fever occurred in all 44 infants for whom clinical information was available. Other clinical signs are anorexia, vomiting, and irritability (Brandenburg and Kenny, 1982). On physical examination, hepatosplenomegaly, suggestive of a transplacentally acquired infection, is found in the majority of infants (Hulbert, 1992). Anemia, often hemolytic, thrombocytopenia, and hyperbilirubinemia are the most commonly reported laboratory abnormalities. Additional physical and laboratory findings among 49 infants with congenital malaria reviewed by Hulbert (1992) are provided in Tables 38–8 and 38–9. Most abnormalities resolve within several days of initiation of treatment.

### Diagnosis

The diagnosis of congenital malaria is based on microscopic demonstration of parasites on thick and thin blood smears. For detection of organisms, a thick blood film is preferred because it concentrates the red blood cells. Identification of the *Plasmodium* species, however, requires a thin blood film. Specimens for smears should be obtained from both the infant and the mother, and quantification of the parasitemia is helpful to assess the response to therapy. Often, the diagnosis of congenital malaria is made incidentally. In all 4 cases of congenital malaria reported by Quinn and associates (1982), the diagnosis was established by a hematology technician who noted malarial parasites on routine blood smears.

**TABLE 38–8**

#### Frequency of Physical Findings in 49 Infants with Congenital Malaria

Finding	Frequency*	%
Fever	44/44	100

The diagnosis of congenital malaria is often delayed because of its nonspecific features and the lack of clinical suspicion. In Hulbert's review (1992) of 49 infants with congenital malaria, the diagnosis was established within 2 weeks of onset of clinical manifestations in 81% of cases. For the remaining 19%, diagnosis was delayed to between 3 and 24 weeks. Maternal history of recent travel to or emigration from an endemic area may suggest the diagnosis but is often obscured by the lack of clinical or laboratory findings in the mother. Depending on her immune status as well as the infecting species of *Plasmodium*, the mother may be completely asymptomatic or severely ill. In the review by Hulbert (1992), only 24 (69%) of 35 mothers reported having fever at some time during their pregnancies, and in only 42% of the mothers of 49 infants with malaria did blood smears show malarial parasites.

Further confounding the early recognition of congenital malaria is that the lapse between malaria exposure in the mother and in utero infection of the infant may be prolonged. *P. vivax* and *P. ovale* can remain dormant in the liver, especially if the infected individual did not receive therapy for the exoerythrocytic forms, and can cause a delayed relapse of malaria. *P. malariae* may persist for 20 to 40 years before demonstrable parasitemia or clinical symptoms appear (D'Avanzo et al, 2002). In the review by Hulbert (1992), among 35 mothers of infants with congenital malaria, 3 had resided in the United States for 36, 60, and 84 months, respectively. Sixty-one percent of the mothers had been in the United States for less than 10 months, and 91% for less than 18 months, before delivery. Congenital malaria due to *P. malariae* has been reported in an infant whose mother lived in the United States for 5 years before delivery and did not have any clinical signs or symptoms of malaria for more than 20 years (Harvey et al, 1969). In North Carolina, congenital *P. malariae* infection was reported in a 10-week-old infant who was born to a mother who had emigrated

from the Democratic Republic of Congo 4 years before delivery (D'Avanzo et al, 2002).

### Therapy

The management of congenital malaria consists of supportive care and antimalarial therapy. Standard precautions are recommended. For all cases of congenital malaria, except those due to chloroquine-resistant *P. falciparum*, the recommended therapy is oral chloroquine sulfate (10 mg base/kg followed by 5 mg base/kg at 6, 24, and 48 hours later) (Quinn et al, 1982). Treatment with primaquine for *P. vivax* or *P. ovale* infection is not necessary because, as in transfusion-acquired malaria, congenital infection does not involve the transmission of exoerythrocytic parasites. If oral therapy is not possible, chloroquine may be administered by nasogastric tube (White et al, 1988). Parenteral administration of chloroquine has been associated with cardiovascular collapse and should be reserved for severe cases if oral administration is not possible (Quinn et al, 1982; White et al, 1988).

The treatment of congenital infection caused by chloroquine-resistant *P. falciparum* is not well defined. In older children, recommended regimens include quinine sulfate in combination with doxycycline or pyrimethamine-sulfadoxine and mefloquine (American Academy of Pediatrics [AAP], 2003a). The use of oral quinine sulfate (25 mg/kg/day divided in three doses for five days) and trimethoprim-sulfamethoxazole (8 mg/kg/day of trimethoprim in two divided doses for 5 days) is recommended by Quinn and associates (1982), who used this regimen to treat a 1-month-old infant. Ahmed and colleagues (1998) used a similar regimen for the treatment of an infant born at 28 weeks of gestation to a mother from Zaire. Other regimens used successfully in neonates are oral quinine sulfate and pyrimethamine-sulfadoxine (Gereige and Cimino, 1995) and intravenous quinine hydrochloride followed by oral quinine (Airede, 1991). Intravenous quinine hydrochloride is not available in the United States.

Parenterally administered quinidine gluconate may result in cardiac arrhythmias and should be reserved for severely ill infants, such as those with a higher than 5% parasitic load. These patients should be managed in the intensive care setting to allow for cardiac monitoring. Exchange transfusion may be considered when parasitemia exceeds 10% or if there is evidence of complications at lower parasite densities. With the rarity of *P. falciparum* congenital malaria in the United States, the growing pattern of resistance, and the potential toxicity associated with therapy, advice for the most current treatment recommendations should be sought from the CDC (telephone: 770-488-7788, www.cdc.gov).

The efficacy of antimalarial therapy should be monitored by means of sequential blood smears for percentage of parasitemia. Response to therapy with chloroquine for non-*P. falciparum* malaria is usually favorable (Brandenburg and Kenny, 1982; Dowell and Musher, 1991; Hindi and Azimi, 1980). The mother of an infant with congenital malaria should be screened for malaria. Even if the smear is negative, by definition she is harboring a *Plasmodium* infection and should be treated accordingly. Mothers may breast-feed while receiving antimalarial drugs. Only very

small concentrations of antimalarial drugs are detected in breast milk; the amount is neither harmful to the infant nor protective against malaria.

### Prognosis

The incidence of infant mortality secondary to maternal or congenital malaria in endemic areas is unknown. On the basis of its association with low birth weight, malaria in pregnancy is likely to be an underappreciated risk factor for increased infant mortality. In a review of studies between 1985 and 2000, Steketee and colleagues (2001) determined population-attributable risks for maternal malaria of 8% to 14% for low birth weight and of 3% to 8% for infant mortality. They estimated that 75,000 to 200,000 infant deaths annually are associated with malaria infection in pregnancy.

Among the cases of congenital malaria reported outside malarious areas, short-term outcome generally has been favorable. Most cases respond rapidly to therapy, and no neonatal deaths were reported among the 49 cases described by Hulbert (1992). Five premature neonates with congenital malaria have been reported, two of whom were born outside indigenous areas, but prematurity could not be attributed solely to maternal malaria for these infants. All five infants were treated successfully. It remains unclear whether the outcome of infants reported in the literature is due to an overall favorable prognosis for congenital malaria or to reporting bias.

### Prevention

The prevention of congenital malaria is based on avoidance of exposure and use of chemoprophylaxis. The use of mosquito netting, mesh screens on windows, insecticides, and mosquito repellents can decrease potential exposure to malarial parasites. For pregnant women traveling to areas where there is no chloroquine-resistant *P. falciparum* malaria, prophylaxis with chloroquine is recommended. The safety of chloroquine used for chemosuppression of malaria in pregnant women is well established (MacLeod 1988). The World Health Organization (WHO) advises pregnant women against traveling to areas where there is transmission of chloroquine-resistant *P. falciparum*. If such travel is unavoidable, consultation with an infectious diseases or malaria expert is advised.

Currently, mefloquine is the prophylactic drug of choice, including during the first trimester, for pregnant women who may be exposed to chloroquine-resistant *P. falciparum* (AAP, 2003). Although the product labeling of mefloquine does not recommend its use during pregnancy, it has not been associated with adverse fetal or pregnancy outcomes. Doxycycline and atovaquone-proguanil should not be used during pregnancy to prevent malaria. For those who cannot take the recommended antimalarial drug, the CDC should be contacted for advice on alternative drugs. There is no commercially available vaccine against malaria.

Because of the high prevalence of malaria in pregnancy, the WHO also advocates chemoprophylaxis for pregnant women living in malaria-endemic areas (Steketee et al, 2001). Antimalarial chemoprophylaxis during pregnancy may reduce the risk of malaria infection in

pregnant women and increase the birth weight of infants born to infected women. Nyirjesy and colleagues (1993) found that chloroquine prophylaxis, even in areas where chloroquine-resistant *P. falciparum* was endemic, protected against maternal and fetal malaria, low birth weight, and perinatal death. Other investigators have not found similar benefits, and the overall impact of prophylaxis on maternal and fetal outcome remains inconclusive. In practice, implementation of antenatal malaria prevention is limited by lack of access to medical care, poor compliance with therapy, and widespread presence of chloroquine-resistant organisms.

## TUBERCULOSIS

Tuberculosis remains the most extensive infectious epidemic in the world. Each year, an estimated 8 million new cases of tuberculosis occur worldwide, and approximately 3 million people die from the disease. Although 95% of cases occur in the developing world, there are approximately 18,000 new cases annually in the United States, and about 15 million people have latent tuberculosis. Given its impact on public health, the WHO has declared tuberculosis to be a global emergency.

Despite the prevalence of tuberculosis, congenital tuberculosis occurs rarely, with approximately 300 cases described in the world literature. Although the majority of cases was reported in the pre-chemotherapy era, a substantial number has been observed in the last few decades (Adhikari et al, 1997; Cantwell et al, 1994a; Mazade et al, 2001; Pejham et al, 2002). Given the propensity of tuberculosis to progress rapidly with immunodeficiency states, the current epidemic of HIV in countries with endemic tuberculosis is likely to result in active tuberculosis in many pregnant women with the potential for transmitting infection to their offspring (Adhikari et al, 1997). In addition, increased immigration from developing countries along with global mobility suggests that congenital tuberculosis will also be observed in developed nations. The clinician should maintain a high index of suspicion for tuberculosis in pregnant women and infants.

### Definition

Congenital tuberculosis is the result of in utero infection of the fetus with *Mycobacterium tuberculosis*. The fetus can acquire the infection transplacentally from a mother with hematogenous tuberculosis or by aspiration of amniotic fluid that has been infected from endometritis or the placenta. Infection of the newborn also can occur during delivery through aspiration of infected amniotic fluid or postnatally through contact with a tuberculous mother or ingestion of infected breast milk. Because of the difficulty in ascribing the precise mode of transmission, some researchers suggest that the term *perinatal tuberculosis* be used to describe the acquisition of tuberculosis before or shortly after birth (Lackmann, 1994). Historically, however, *congenital tuberculosis* has referred to tuberculous infection of infants that is acquired before birth, that is, either antenatally or intrapartum (Cantwell et al, 1994b).

In 1935, Beitzke proposed the following criteria to standardize the definition of congenital tuberculosis:

(1) tuberculosis must be established by isolation of *M. tuberculosis* from the infant, (2) a primary complex must be demonstrated in the liver as proof of dissemination of the tubercle bacilli from the umbilical vein, and (3) if the primary complex is not documented, either tuberculous lesions must be present in the neonate within a few days of age or postnatal infection must be excluded in the older infant with certainty—as for example, by immediate separation of the newborn from the infected mother. These criteria were developed before the introduction of chemotherapy, when infant mortality in congenital tuberculosis was high, thus allowing for demonstration of the primary liver complex at autopsy, and when prolonged separation of the mother and infant at birth was standard tuberculosis-control practice.

It is difficult and no longer practical to apply Bietzke's criteria for the diagnosis of congenital malaria. The higher survival rate makes the documentation of a primary complex impossible, and separation of the mother and infant at birth is unlikely because the disease in the mother is often unrecognized. Revised criteria were proposed that are more applicable to current practice and thus improve diagnostic sensitivity (Cantwell et al, 1994a). To meet these criteria, the infant must have proven tuberculous lesions and at least one of the following conditions must be present: (1) lesions in the infant in the first week of life, (2) a primary hepatic complex or caseating hepatic granulomas in the infant, the latter of which may be documented by percutaneous liver biopsy, (3) tuberculous infection of the placenta or maternal genital tract, and (4) exclusion of postnatal transmission by thorough investigation of contacts.

### Epidemiology

From 1953 through 1984, the incidence of tuberculosis in the United States declined an average of 5% per year, reaching a nadir of 9.4 cases per 100,000 population. From 1985 through 1992, there was a 20% increase in the total number of cases of tuberculosis in the United States. The resurgence of tuberculosis was attributed to (1) the co-epidemic of HIV infection, (2) the increase in immigration from countries with a high prevalence of tuberculosis, (3) increased tuberculosis transmission in congregate settings such as homeless shelters and prisons, and (4) a decline in public health funding for tuberculosis control. Since 1992, however, the number of cases in the United States has decreased each year, reaching a record low in 1998 with a case rate of 6.8 per 100,000. Despite the decrease in the total burden of disease, tuberculosis in the United States continues to disproportionately affect foreign-born individuals as well as the medically underserved—the urban poor and racial and ethnic minorities.

The current epidemiology of tuberculosis in pregnancy is not well delineated. With the resurgence of tuberculosis in the 1980s, the number of cases among women of child-bearing age rose by 40% (Cantwell et al, 1994a). In 1991, almost 40% of tuberculosis cases in minority women occurred in those between 15 and 35 years of age (Smith and Teele, 1995). In spite of the high incidence of tuberculosis in women of child-bearing age, congenital tuberculosis remains uncommon. Blackall (1969) reported only three cases among infants born to 100 mothers with tuberculosis,

and Ratner and colleagues (1951) identified no cases among infants born to 260 mothers with the disease. In a study of 1369 infants separated at birth from their tuberculous mothers and placed in foster care, only 12 children became tuberculin-positive during the 4 years of observation, and in all 12 cases, there was a source of infection in the postnatal environment (Smith and Teele, 1995).

The majority of the 300 sporadically reported cases of congenital tuberculosis were described in the pre-chemotherapy era. In 1980, Hageman and associates reviewed 24 cases of congenital tuberculosis reported in the English literature since the introduction of isoniazid (INH) in 1952 as well as 2 additional cases from their own experience. In the subsequent 25 years, more than 30 additional cases have been cited (Abughali et al, 1994; Cantwell et al, 1994a; Mazade et al, 2001; Pejham et al, 2002) in the United States. As would be expected, the majority of infants with congenital tuberculosis were born to foreign-born mothers. The low incidence of congenital tuberculosis is in part attributed to the high likelihood of infertility in women who have endometrial tuberculosis (Balasubramanian et al, 1999). However, underreporting may be a contributing factor and the true incidence of congenital tuberculosis as well as the rate of vertical transmission remain unknown.

### Natural History

The pathogenesis of tuberculosis in the pregnant woman is similar to that in nonpregnant adults. Tuberculous bacillemia can disseminate to the placenta, the endometrium, or the genital tract. Genital tuberculosis that occurred before pregnancy may be asymptomatic, although sterility in these cases frequently decreases the likelihood of congenital infection. Transmission to the fetus occurs by (1) hematogenous spread from the placenta via the umbilical vein, (2) aspiration in utero of infected amniotic fluid from either placental or endometrial infection, or (3) ingestion of infected amniotic fluid or secretions during delivery. The hematogenous route and in utero aspiration each probably account for approximately half of the cases of congenital tuberculosis. In addition, postnatal infection may occur from contact with a contagious mother or caregiver or ingestion of infected breast milk from a mother with tuberculous breast abscess. In the absence of a breast abscess, transmission of tuberculosis via breast milk has not been documented.

Tubercle bacilli have been demonstrated in the decidua, amnion, and chorionic villi of the placenta. It is unlikely that the fetus can be infected directly from the mother without the presence of a caseous lesion in the placenta, although even massive involvement of the placenta does not always result in congenital tuberculosis. When a tubercle ruptures into the fetal circulation, bacilli in the umbilical vein may infect the liver, forming a primary focus with involvement of periportal lymph nodes. The bacilli may also pass through the liver and right ventricle and into the lung, or may enter the left ventricle via the foramen ovale and pass into the systemic circulation. The organisms in the lung remain dormant until after birth, when oxygenation and circulation result in their multiplication and the subsequent development of

a primary pulmonary focus. Alternatively, if the caseous lesion in the placenta ruptures directly into the uterine cavity and infects the amniotic fluid, the fetus may inhale or ingest the bacilli, leading to primary foci in the lung, intestine, or middle ear.

Pathologic examination of tuberculosis in the fetus and newborn usually demonstrates disseminated disease, with the liver and lungs being principally involved. In Siegel's study (1934) of 38 postmortem cases, the lungs were involved in 97%, the liver in 82%, and the spleen in 76% of the infants. Other sites described are the gastrointestinal tract, kidneys, adrenal glands, and skin (Agrawal and Rehman, 1995; Hageman, 1980; Sood, 2000). Central nervous system involvement occurs in fewer than 50% of cases (Starke, 1997). It is not always possible to determine whether sites represent multiple primary foci or are secondary to primary lesions in the lung or liver. The only lesion in the neonate that is unquestionably associated with congenital infection is a primary complex in the liver; all others may be acquired congenitally or postnatally.

The clinical manifestations of congenital tuberculosis are nonspecific and resemble those of bacterial sepsis and other congenital infections. The affected infant is commonly born prematurely (Davis et al, 1960), but clinical signs typically do not appear until he or she is 2 to 4 weeks of age. In a review of 29 cases of congenital tuberculosis, the median age at presentation was 24 days of life, with a range of 1 to 84 days (Cantwell et al, 1994a).

On the basis of findings from infants with congenital tuberculosis that have been reported in the post-INH era, respiratory distress, hepatomegaly with or without splenomegaly, and fever are the most common presenting manifestations of disease (Abughali et al, 1994; Cantwell et al, 1994a; Hageman, 1980). Such features as failure to thrive, meningitis, and jaundice, which were more prevalent in the pre-INH era, are present in only a minority of infants today. Additional features are listed in Table 38–10. Otitis media with aural discharge has been described as the first sign of congenital tuberculosis (Gordon-Nesbitt and Rajan, 1973; Ng et al, 1995). Skin manifestations also are infrequently reported. In the two cases reported by Hageman and colleagues (1980), the lesions were initially papular and later pustular with surrounding erythema; skin biopsy confirmed granulomatous inflammation. It is important to emphasize, however, that many infected infants lack clinical signs of infection and are identified only after a parent or caregiver is diagnosed with tuberculosis.

### Diagnosis

Timely diagnosis of congenital tuberculosis requires a high index of suspicion. There are no typical clinical signs or radiographic findings. Diagnostic evaluation, consisting of a tuberculin skin test (TST), chest radiograph, lumbar puncture, and cultures of appropriate specimens (e.g., gastric aspirate, endotracheal aspirate, cerebrospinal fluid, and skin lesion), should be performed as soon as tuberculosis is suspected, and treatment should be initiated promptly.

Result of the Mantoux tuberculin skin test using 5 tuberculin units of purified protein derivative is usually “nonreactive” in neonates with tuberculosis. The lack of

response, or anergy, is likely secondary to the poor cell-mediated immunity in young infants. Alternatively, it may be due to overwhelming tuberculous disease or even to the fact that specific tuberculosis hypersensitivity may be delayed for up to 12 weeks after infection. Hageman and colleagues (1980) reported that among 14 infants with congenital tuberculosis who underwent skin testing, only 2 had positive test results at presentation. Seven infants subsequently demonstrated positive tuberculin skin tests, the earliest at 6 weeks of age, almost 4 weeks after presentation with clinical signs. Similarly, results of tuberculin skin tests performed in 9 of 29 patients described by Cantwell and associates (1994a) were all negative, although results of tests performed later in 2 of the 9 infants were reactive.

Radiographic findings vary according to the route of infection and the cause of illness. In most infants with congenital tuberculosis, chest roentgenographic findings are abnormal at presentation. Typically, a nonspecific parenchymal infiltrate, adenopathy, or a miliary pattern is noted. Sixteen (62%) of 26 patients reviewed by Hageman and colleagues (1980) had abnormal radiographic findings on presentation, 7 with a miliary pattern and 9 with nonspecific changes. Radiographic abnormalities developed in 4 other infants later. Among 29 cases reviewed by Cantwell and associates (1994a), 23 (79%) infants had chest radiograph abnormalities, which consisted of nonspecific infiltrates in 18 (78%) of infants. Cavitation secondary to progressive pulmonary involvement is an uncommon feature of congenital tuberculosis (Cunningham et al, 1982).

Microbiologic confirmation of disease should be sought from multiple sites. Smear and culture of gastric aspirate for *M. tuberculosis* are the most expedient and reliable

ways of establishing the diagnosis. Additional sources of culture are endotracheal aspirate, middle-ear discharge, and lymph node biopsy specimens. CSF should be evaluated and cultured, although the yield is low (Abughali et al, 1994; Cantwell et al, 1994a; Hageman et al, 1980). A biopsy of skin lesions is often helpful and definitive (Nemir and O'Hare, 1985). Hageman and colleagues (1980) found positive cultures of *M. tuberculosis* in 10 of 12 gastric aspirates, 3 of 3 liver biopsy specimens, 3 of 3 lymph node biopsy specimens, and 2 of 4 bone marrow biopsy specimens. In a later review by Cantwell and associates (1994a), biopsy and noninvasive procedures were useful for the diagnosis of 29 infants with congenital tuberculosis (Table 38-11).

Demonstration of a primary hepatic complex, which would require an open surgical procedure or autopsy, is not essential for diagnosis of congenital tuberculosis. In the appropriate clinical setting, a percutaneous liver biopsy specimen that demonstrates caseating granulomas is sufficient evidence for diagnosis (Cantwell et al, 1994a). PCR assays are available for testing of specimens such as gastric aspirates, respiratory secretions, and CSF, but they are not recommended for routine use because their sensitivity is similar to that of culture, and both false-positive and false-negative results occur.

The mother of a newborn in whom congenital tuberculosis is suspected should be evaluated for disease. Often, the mother is asymptomatic or has subclinical disease. Hageman and colleagues (1980) found that tuberculosis was diagnosed in only 10 (38%) of 26 mothers before the disease was discovered in their offspring. The majority of mothers (15, or 58%) were not diagnosed until after the disease became apparent in their infants. Similarly, Cantwell and associates (1994a) found that 50% of

mothers of infants with congenital tuberculosis were not diagnosed with tuberculosis at the time their infants demonstrated clinical signs. It is evident that the lack of a maternal history of tuberculosis should not deter the clinician from thoroughly investigating its possibility in the infant. Examination of the mother should include a tuberculin skin test and chest radiograph. Histologic examination of the placenta, if available, is strongly recommended, and an endometrial biopsy may also help in confirming disease (Balasubramanian et al, 1999; Cooper et al, 1985; Niles, 1982). The mother with tuberculosis should also undergo serologic testing for HIV antibody, and, if she is seropositive, the infant should be evaluated for perinatally acquired HIV infection.

### Therapy

The successful management of congenital tuberculosis depends on early recognition and treatment of the disease. Empiric therapy is provided often to neonates and should not be delayed while awaiting culture results, epidemiologic investigation, and follow-up tuberculin skin testing. The optimal treatment regimen for congenital tuberculosis has not been established because the rarity of the disease precludes evaluation in clinical trials. It is assumed that the regimens used for the treatment of tuberculosis in older children and adults are safe and efficacious for congenital tuberculosis. Until susceptibility test results are known, all infants with suspected or proven congenital tuberculosis should receive the following four antituberculous drugs: INH (10 to 15 mg/kg/day PO); rifampin (10 to 20 mg/kg/day PO); pyrazinamide (20 to 40 mg/kg/day PO); and either streptomycin (20 to 40 mg/kg/day IM), kanamycin (15 to 30 mg/kg/day IM), amikacin (15 to 22.5 mg/kg/day IV or IM), or ethambutol (15 to 25 mg/kg/day PO). The adjunctive

BCG, bacille Calmette-Guérin; CSF, cerebrospinal fluid; CT, computed tomography; INH, isoniazid; MRI, magnetic resonance imaging. (Adapted from American Academy of Pediatrics: Tuberculosis. In Pickering LK [ed]: 2003 Red Book: Report of the Committee on Infectious Diseases, 26th ed. Elk Grove Village, IL, American Academy of Pediatrics; 2003, p 642.)

use of corticosteroids such as prednisone (1 to 2 mg/kg/day) is recommended for the treatment of meningitis, because it decreases mortality and improves long-term neurologic outcome (Girgis, 1991). Corticosteroids also may be considered for pleural and pericardial effusions, endobronchial disease, and severe miliary tuberculosis.

Although INH is safe in the neonate, data on the safety and pharmacokinetics of the other agents are limited. Monitoring for clinical signs of hepatotoxicity is recommended. Routine determination of serum transaminase concentrations is indicated for infants with severe (e.g., meningeal or miliary) tuberculosis or with concurrent or recent liver disease as well as those receiving other hepatotoxic drugs. The risks of optic neuritis with ethambutol and of auditory and vestibular toxicities with streptomycin and kanamycin should be considered when these agents are used, and hearing or vision should be periodically monitored.

If the isolate is found to be susceptible, the regimen can be narrowed to three drugs (INH, rifampin, and pyrazinamide) for the first 2 months of therapy, followed by INH and rifampin to complete therapy. Directly observed therapy (DOT) is recommended for treatment of tuberculosis in children to ensure adherence and successful treatment. The duration of therapy is not established. Most experts would treat for 9 to 12 months because of the relatively compromised immune system of the young infant and the high likelihood of disseminated disease. For drug-resistant tuberculosis, longer duration of therapy with daily administration of medications is recommended. Pyridoxine should be given to breast-fed infants receiving INH. Although antituberculous drugs are secreted in human milk, their concentrations are low, and breast-feeding should be encouraged.

Infants with suspected or proven congenital tuberculosis require airborne precautions. Most children with tuberculosis are not contagious, and isolation of the hospitalized pediatric patient is directed at adult contacts who may be source cases and potentially contagious. Visitation of the hospitalized pediatric patient should be restricted to adults in whom contagious tuberculosis has been excluded. (AAP, 2003b).

The management of infants born to mothers who have latent tuberculosis infection or disease is outlined in Figure 38–2. Recommendations are based on the categorization of infection in the mother and the potential risk of transmission of tuberculosis to the infant (AAP, 2003b). Infants born to mothers with potentially contagious tuberculosis should be evaluated for congenital tuberculosis. The mother with latent tuberculosis infection is not contagious. However, to prevent reactivation disease in the mother and to prevent subsequent exposure of the infant, the mother should receive treatment with INH. Additionally, latent tuberculosis infection in the mother may be a marker for contagious tuberculosis within the household, and it is recommended that all household members and close contacts of the mother be evaluated for tuberculosis.

### Prognosis

The prognosis for congenital tuberculosis was dismal in the pre-chemotherapy era, the diagnosis often being only

made at autopsy. Although the survival rate has since improved, mortality remained about 50% secondary to delayed diagnosis. In the review by Hageman and colleagues (1980) of 26 cases of congenital tuberculosis reported between 1952 and 1980, 12 (46%) patients died, 9 of whom were untreated and were diagnosed at autopsy. In a subsequent review of 29 cases between 1980 and 1994, the mortality rate was 38% overall but decreased to 22% (5 of 23 infants) among infants who received antituberculous therapy (Cantwell et al, 1994a). Early diagnosis and initiation of antituberculous treatment are critical for a favorable outcome.

### Prevention

Prevention of congenital tuberculosis requires the control of the disease among women of child-bearing age. Collaboration between health care providers and the public health department is essential. Reporting of cases of tuberculosis to the local health department is mandatory for timely contact investigation, appropriate antituberculous therapy, and DOT services. In addition, tuberculin skin testing is recommended for pregnant women who are at increased risk of either acquiring tuberculosis or having latent infection. Risk factors include contact with a case of tuberculosis, recent family history of tuberculosis, positive TST result in a household member, immigration from or prolonged travel to countries with a high prevalence of tuberculosis, and frequent contact with people from such countries. Asymptomatic pregnant women with reactive TST results and normal chest radiographs should receive INH therapy along with pyridoxine after the first trimester of pregnancy.

Vaccination at birth with bacille Calmette-Guérin (BCG) vaccine, a live-virus vaccine prepared from attenuated strains of *M. bovis*, is recommended by the WHO for prevention of disseminated tuberculosis infection in infants and young children. Although the vaccine does not prevent infection with tuberculosis, it has a 50% to 80% protective efficacy against meningeal and miliary disease. In the United States, vaccination with BCG vaccines is not recommended except in rare circumstances in which continued exposure of the infant to individuals with untreated or ineffectively treated tuberculosis is completely unavoidable.

## Bacterial Sepsis and Meningitis

Richard A. Polin, Elvira Parravicini,  
Joan A. Regan\*, and H. William Taeusch

### NEONATAL BACTERIAL SEPSIS

The earliest description of infants with sepsis has been attributed to Ylppö, who first recognized sepsis as a cause of infant mortality in 1919 when he documented positive culture results from the heart in infants dying from a variety of pathologic conditions (Ylppö, 1919). It was his belief that the postmortem cultures were indicative of antemortem blood stream invasion. However, it was not until the 1930s that case reports began to appear in the pediatric literature in which the diagnosis of sepsis was confirmed before death occurred (Campbell, 1931). Subsequently, Dunham (1933) described 33 cases of neonatal sepsis at New Haven Hospital, most of which were diagnosed antemortem. In 60% of these cases, onset of sepsis was in the first week of life, but in only 10% were the infants symptomatic at birth. The most common pathogens responsible for neonatal sepsis during that time were hemolytic streptococci, staphylococci, and coliforms.

In her original report, Dunham (1928) noted the lack of specificity of the clinical manifestations of infections in the neonate and emphasized the difficulty in making the diagnosis. In 1949, Silverman and Homan described 25 infants with sepsis in whom blood stream infection appeared to be the major problem. Coliform organisms were responsible for the majority of cases of neonatal sepsis. In defining the syndrome, these researchers made the important observation that “the most rigorous definition of sepsis of the newborn confines itself to a group of infections which are presumably acquired at or shortly after birth.” Although that definition ignored the large number of nosocomial infections, it did indicate the importance of perinatal events in the pathogenesis of neonatal sepsis.

Early-onset bacterial sepsis remains a major cause of neonatal morbidity and mortality. However, data indicate that the sepsis-associated death rate (per 100,000 live births) declined by 21% between 1979 and 1994 (Fig. 39-1) (Stoll et al, 1998). In contrast, the number of preterm births during that same period increased significantly. This finding suggests that the decline in sepsis deaths is probably due to changes in obstetric care resulting in a smaller number of sepsis cases, (e.g., intrapartum antibiotic therapy), to improvements in neonatal intensive care, or to earlier identification of infected infants, all of which have resulted in

reduced case-fatality ratios. The basic treatment of infants with sepsis has not changed substantially over the last 50 years, (antibiotics with or without supportive care), so it is likely that further improvements in outcome will result from a greater understanding of the perinatal factors responsible for sepsis, interventions that address those factors, and better ways to identify the infected newborn.

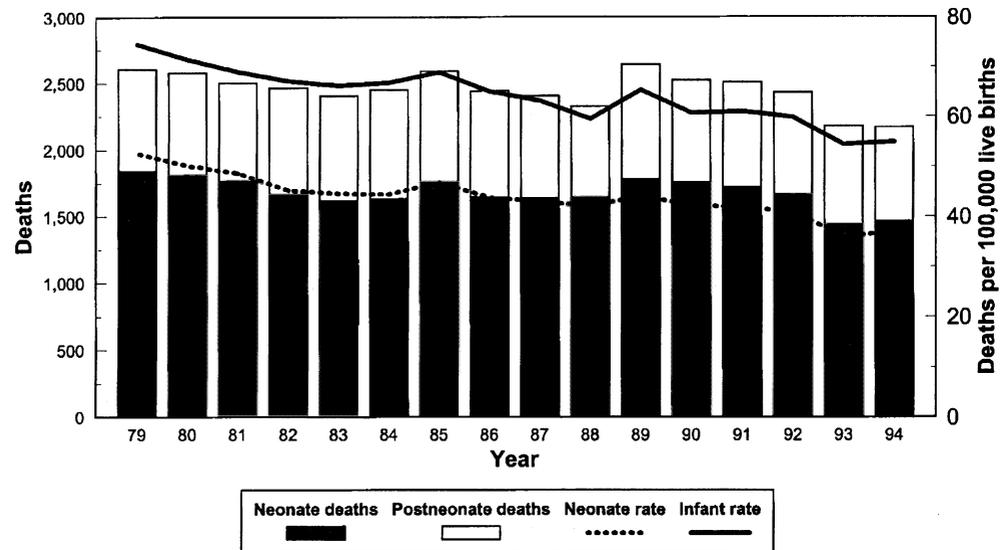

### Pathogenesis and Pathways of Early-Onset Bacterial Infections

Early-onset bacterial sepsis can manifest as a fulminant disease with immediate onset of respiratory distress after delivery (with or without cardiovascular instability) or on day 1 to 3 of postnatal life after an asymptomatic period. The sequence of events responsible for both presentations begins with colonization of the maternal genital tract (Fig. 39-2). The flora colonizing the lower genital tract in pregnant women contains large numbers of bacteria and fungi. As pregnancy progresses, there is a gradual increase in the frequency of colonization with *Lactobacillus* spp. and a decrease in the colonization rate with *Escherichia coli* and anaerobes (Goldenberg et al, 2000). Organisms that inhabit the cervix, vagina, or rectum can spread upward into the amniotic cavity through intact or ruptured membranes and cause amnionitis. Initially, they spread into the choriodecidual space (Fig. 39-3), and in some instances, they cross intact chorioamniotic membranes. Intra-amniotic infection is usually polymicrobial in etiology (Gibbs et al, 1980). The organisms most commonly recovered are *Bacteroides* spp., group B streptococci, other aerobic streptococci, aerobic gram-negative bacteria, and genital mycoplasmas (Oshiro et al, 1993). Factors affecting colonization with group B streptococci (GBS) are discussed later. Among a cohort of 11,989 women followed throughout pregnancy, the recovery of *Gardnerella vaginalis*, a heavy growth of *Bacteroides* spp., or isolation of *Mycoplasma hominis* was associated with a greater likelihood of intra-amniotic infection (Krohn et al, 1995). The role of *Chlamydia trachomatis* as an intrauterine pathogen is uncertain (Pankuch et al, 1984).

Intra-amniotic infection can be subclinical or clinical, but both types of infection may result in serious neonatal morbidity (Barton et al, 1999). Subclinical chorioamnionitis may be a common cause of preterm labor and preterm premature rupture of membranes (pPROM) (Hillier et al, 1988). In some cases, intrauterine infection occurs quite early in pregnancy and is not detected for months (Cassell et al, 1983). Vaginal organisms associated with spontaneous preterm labor and pPROM are listed in Table 39-1. Microbial pathogens can be recovered from the amniotic cavity in 10% to 15% of cases of spontaneous preterm labor and in 32% to 35% of women with pPROM (Kenyon et al, 2001a, 2001b). Risk factors for clinical intra-amniotic infection include low parity, long labor, prolonged rupture of membranes, multiple vaginal examinations during labor, internal fetal monitoring, prolonged duration of monitoring, and bacterial vaginosis (Newton et al, 1989; Soper et al, 1989). Other variables that affect the incidence of amnionitis are the antibacterial properties of the amniotic fluid, the size of the bacterial

\*Deceased.

**FIGURE 39-1.** Sepsis-associated death rate (per 100,000 live births) declined by 21% between 1979 and 1994. (Data from Stoll BJ, Holman RC, Schuchat A: Decline in sepsis-associated neonatal and infant deaths in the United States, 1979 through 1994. *Pediatrics* 102:18-24, 1998).

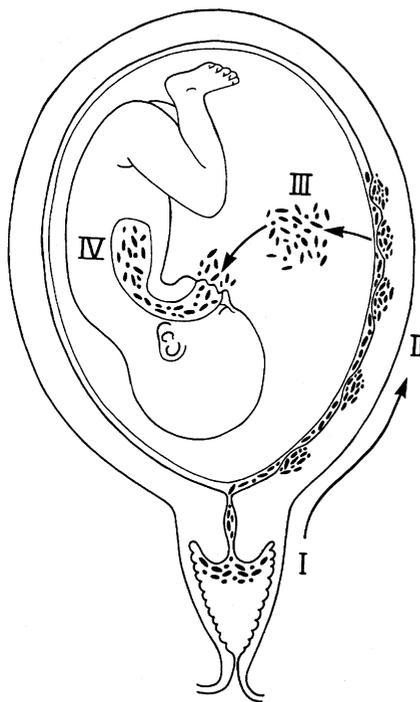

inoculum, and the presence of urinary tract infection. Subclinical or clinical chorioamnionitis results in a vigorous inflammatory response (cytokines and inflammatory cells) within the amniotic cavity. The cytokines produced in response to infection have a key role in parturition and may contribute to brain and lung injuries in the newborn infant (Grether and Nelson, 1997; Van Marter et al, 2000).

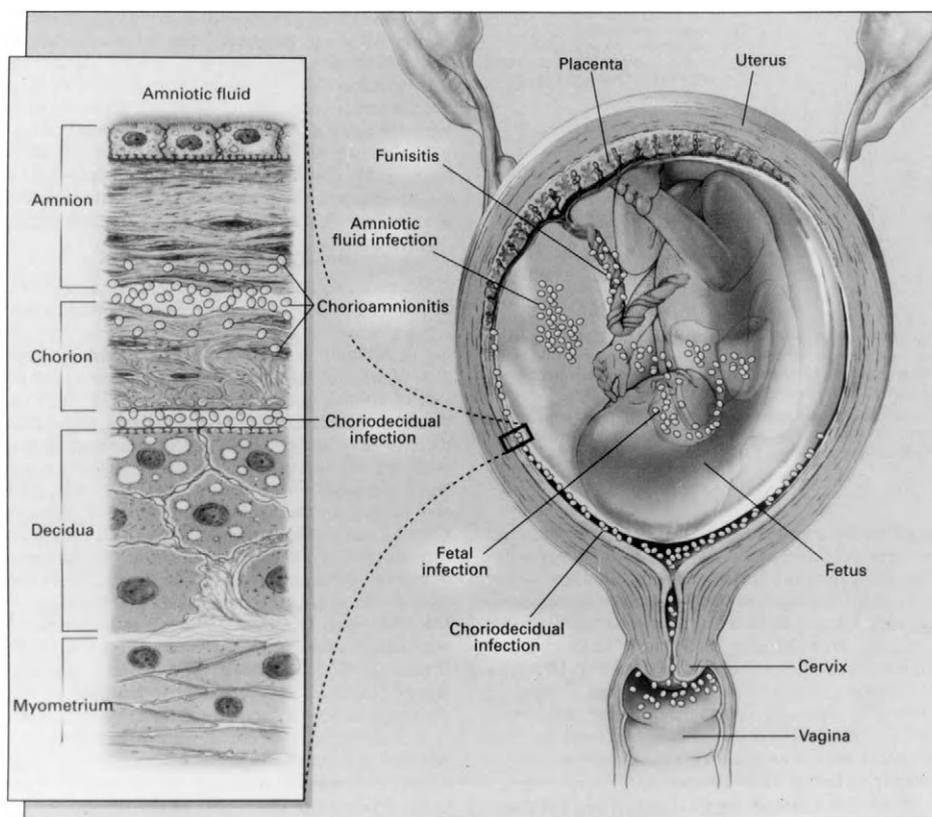

In infants presenting with immediate onset of respiratory distress and sepsis, it is certain that the infection

(bacteremia) must have begun antenatally (usually during labor and delivery). The fetus inhales the infected amniotic fluid, leading to pneumonia, blood stream invasion, and a systemic inflammatory response. Babies infected in this way exhibit the highest mortality rates. In babies who are initially asymptomatic, bacteremia can be somewhat delayed, although asymptomatic infants can be bacteremic (Escobar et al, 2000). Microorganisms acquired at the time of delivery colonize mucous membranes and proliferate locally before causing blood stream infection. Common sites of invasion are devitalized umbilical cord tissue and skin surfaces that have been compromised by monitoring or sampling (scalp monitoring, intravenous [IV] sites, etc.). The distinction between these two scenarios is important, because an early dose of antibiotics may effectively prevent overwhelming sepsis in an infant with the delayed presentation but will not do so in an infant whose sepsis began in utero. Transient bacteremia in the neonate is common, especially in babies undergoing procedures that bypass normal skin defense barriers (e.g., suctioning, intubation, or umbilical catheterization) (Storm, 1980). The bacteremia usually disappears within minutes. Persistent bacteremia occurs when the infant's local and systemic host defenses are overwhelmed.

The central cell in the cytokine response to bacterial sepsis is the activated macrophage (Fig. 39-4). Macrophages become activated when they come in contact with microbial cell wall products and toxins (e.g., endotoxin). Activated macrophages produce a variety of inflammatory substances (interleukins IL-1 $\beta$ , IL-6, and IL-8 and tumor necrosis factor- $\alpha$  [TNF- $\alpha$ ]) that increase vascular permeability, alter vascular tone, depress myocardial function, increase pulmonary vascular resistance, activate clotting systems, and mobilize and activate other phagocytic cells (allowing them to move via chemotaxis to sites of inflammation and kill bacteria) (see Fig. 39-4). Regulated production of cytokines allows the host to recover from the infectious episode. Unregulated cytokine responses increase both morbidity and mortality. Furthermore, when bacteremia is persistent, organisms are likely to disseminate and lodge in organs at distant sites (lungs, bone, central nervous system, kidney, etc.).

**FIGURE 39-2.** The sequence of events responsible for both early-onset and late-onset neonatal sepsis begins with colonization of the maternal genital tract. I, colonization of birth canal; II, upward spread of organisms leading to choriodecidualitis; III, development of chorioamnionitis; IV, inhalation and ingestion of contaminated amniotic fluid.

**FIGURE 39-3.** Organisms that inhabit the cervix, vagina, or rectum can spread upward into the amniotic cavity through intact or ruptured membranes and cause amnionitis. Initially, they spread into the choriodecidual space.

**TABLE 39-1**

**Vaginal Organisms and Conditions Associated with Spontaneous Preterm Labor and Preterm Premature Rupture of Membranes**

Condition	Associated Organism or Condition
Premature preterm rupture of membranes	<i>Neisseria gonorrhoeae</i> <i>Chlamydia trachomatis</i> <i>Trichomonas vaginalis</i> <i>Prevotella</i> spp. <i>Bacteroides</i> spp.
Preterm labor	Bacterial vaginosis <i>Ureaplasma urealyticum</i> <i>Mycoplasma hominis</i> <i>Gardnerella vaginalis</i> <i>Peptostreptococcus</i> <i>Bacteroides</i> spp.

**Epidemiology of Early-Onset Bacterial Infections**

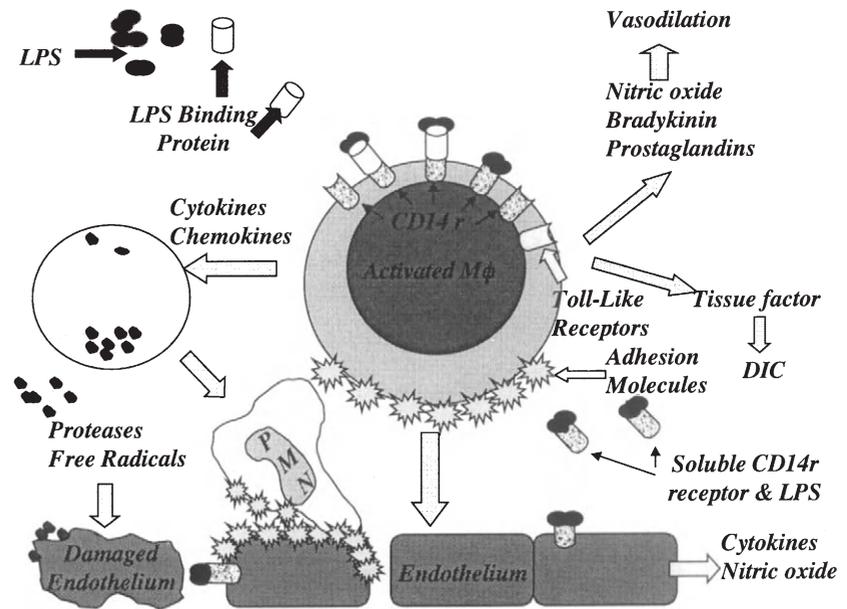

The incidence of early-onset bacterial infections ranges from 1 to 8 per 1000 live births (Klein, 2001). However, data now suggest that the incidence is declining as a result of intrapartum antibiotic therapy (Baltimore et al, 2001). In a surveillance study from Connecticut, in which the outcomes for 174,535 live births were recorded, the incidences of early-onset GBS sepsis and early-onset non-GBS sepsis

were 0.23 and 0.67 per 1000 live births, respectively (Baltimore et al, 2001).

Infants who experience early-onset sepsis commonly have one or more identifiable risk factors. The risk factors can be divided into the following four categories: host immunity, socioeconomic factors, obstetric and nursery practices, and health and nutrition of mothers. Prematurity is the single greatest risk factor for early-onset bacterial infections. The strong association between preterm birth and infection is related both to the reasons for preterm birth (e.g., chorioamnionitis) and host defense impairments that exist in all newborn babies but are greatest in extremely low-birth-weight (ELBW) infants (see Chapter 32). In a study of more than 32,000 infants by Boyer and colleagues (1983a), the attack rate for early-onset GBS sepsis in infants of birth weight less than 1000 g was 26 times that in term newborn infants and accounted for the greatest number of deaths. Additional risk factors for early-onset sepsis are colonization with known pathogens (e.g., GBS), chorioamnionitis, higher number of vaginal examinations during labor, and rupture of membranes for 18 hours or longer.

In a recent multicenter case-control study involving seven regional medical centers, 49% of infants with GBS and 79% of other infants with sepsis had one or more of the three major maternal risk factors already noted (signs and symptoms of chorioamnionitis, prolonged [ $>18$  hours] rupture of membranes, and colonization with GBS) (Schuchat et al, 2000). However, one must be cautious in using fever as the sole indicator of maternal infection, because fever is observed quite commonly in women who receive epidural anesthesia to alleviate pain during labor.

**FIGURE 39-4.** Macrophages become activated when they come in contact with microbial cell wall products and toxins (e.g., endotoxin). Activated macrophages produce a variety of inflammatory substances (interleukins IL-1 $\beta$ , IL-6, and IL-8; tumor necrosis factor- $\alpha$  [TNF- $\alpha$ ]) that increase vascular permeability, alter vascular tone, depress myocardial function, increase pulmonary vascular resistance, activate clotting systems, and mobilize and activate other phagocytic cells (allowing them to move via chemotaxis to sites of inflammation and kill bacteria). CD14r, CD14 receptor; DIC, disseminated intravascular coagulation; LPS, lipopolysaccharide; PMN, polymorphonuclear (leukocyte).

In a prospective study, Lieberman and colleagues (1997) found that fever occurred in 14.5% of women who did receive epidural anesthesia and in 1.0% of women who did not. For labors lasting more than 18 hours, the incidence of fever was 36%. These investigators calculated that 96.2% of intrapartum fevers, 85.6% of sepsis evaluations, and 87.5% of neonatal antibiotic treatment in term infants were associated with use of epidural anesthesia. In the epidural group, fever accounted for the sepsis evaluations in about one third of cases. Even among afebrile women, the use of epidural anesthesia is associated with a higher incidence of major and minor risk factors for neonatal sepsis—fetal tachycardia, low-grade temperature elevation, and prolonged rupture of membranes (Goetzl et al, 2001). Commonly accepted criteria for diagnosis of chorioamnionitis are listed in Table 39-2.

A number of other risk factors for early-onset sepsis has been identified. In several studies, a low Apgar score and need for resuscitation were associated with a higher incidence of sepsis (Gluck et al, 1966). Because of the strong association with chorioamnionitis, pPROM is a well-established risk factor for sepsis (Romero et al, 1999). Fortunately, the incidence of sepsis after pPROM can be reduced by administering antibiotics as soon as the membranes rupture (Kenyon et al, 2001a). Race appears to be

another important variable, and in several studies, black infants have exhibited higher rates of early-onset GBS sepsis than non-black infants (Schuchat et al, 1990). Data collected as part of the Collaborative Perinatal Research Study (n = 38,500 pregnancies) indicated that black women had higher rates of pPROM for longer than 24 hours, puerperal infection, and infants weighing less than 2500 g (Niswander and Gordon, 1972). The effect of race on the incidence of sepsis is complex and may relate to differences in nutrition, socioeconomic status, sexually transmitted diseases, or host immunity. Finally, in almost all studies, male infants have demonstrated a higher incidence of sepsis than female infants (Washburn et al, 1965). The immunologic basis for these differences is unknown.

### Group B Streptococcal Infections

Among bacterial agents known to cause sepsis in the neonate during the first week of life, Group B streptococci are unique for two reasons. First, despite numerous studies of the pathophysiology and epidemiology of maternal colonization and infant disease, the reason for the emergence of this pathogen as the leading cause of serious, lethal sepsis in the newborn is not known (Baker and Edwards, 1995). Secondly, GBS are the only bacterial pathogens, which have been demonstrated to respond to maternal intrapartum antibiotic prophylaxis with a significant reduction in the incidence of disease. (Carey et al, 2000; Locksmith and Duff, 2001; Schuchat, 2001).

Lancefield (1933) designated *Streptococcus agalactiae* as group B streptococci after a pandemic of streptococcal disease during World War I. Although the organism had been known to be the leading cause of mastitis in cattle since the 1800s, it was not recognized as a human pathogen until 1938, when Fry recovered the organism from three patients with puerperal sepsis. Before the 1960s, GBS was infrequently recognized as a cause of human disease. However, GBS emerged in the late 1960s

**TABLE 39-2**

#### Criteria for Diagnosis of Chorioamnionitis

1. Fever (temperature  $>37.8^{\circ}\text{C}$ ) plus two or more of the following:
  - a. Maternal tachycardia ( $>100$  beats/min)
  - b. Fetal tachycardia ( $>160$  beats/min)
  - c. Uterine tenderness
  - d. Malodorous or cloudy amniotic fluid
  - e. Maternal white blood cell count  $>15,000$  cells/mm<sup>3</sup>
2. No other site for infection

as the leading cause of neonatal sepsis in human newborn infants (Eickhoff et al, 1964).

Group B streptococci cause sepsis and other infections in newborns very early in life (early-onset sepsis) and also later in the newborn period and in infancy (late-onset sepsis). Early-onset disease was originally defined as that occurring during the first 5 days of life, and late-onset disease as that occurring at 10 days or later (Baker and Barrett, 1973). Subsequently, timing of the two forms of the disease has blurred (Baker and Edwards, 1995; Isaacs et al, 1996). All designations of timing have been empiric and independent of the epidemiology and clinical spectra of these two disease entities. Table 39–3 summarizes the features of early-onset and late-onset GBS sepsis.

Group B streptococci were first reported as the leading cause of neonatal sepsis in 1964 in a large Northeastern U.S. center by Eickhoff and colleagues. Subsequently, this same observation was made in many U.S. centers as well as in Great Britain, Scandinavia, and mainland Europe. The position of GBS as the leading cause of neonatal sepsis persisted until the implementation of prevention strategies in the late 1990s (see later). It has been suggested that shifts in the predominant subtypes of GBS causing disease in infants play a role in emergence of GBS as a major neonatal pathogen. However, this proposition has not been supported in seroepidemiologic studies (Lee et al, 2000; Lin et al, 1998).

### Vertical Transmission from Mothers to Infants

More than 98% of cases of early-onset GBS sepsis are the consequence of vertical transmission from the genital tract of the mother to the infant (Baker and Edwards, 1995). The mean rate of vertical transmission is about 50%. A very small number of cases are due to hematogenous transmission through the placenta. In these cases, the mother commonly displays signs and symptoms of chorioamnionitis—although hematogenous transmission does occur in the absence of symptoms. In cases of hematogenous transmission, results of maternal genital

cultures are usually negative, as is the case for the very rare occurrences of transmission from a health care worker or from a nonhuman vector (Davis et al, 1978).

Detection of maternal colonization presents an opportunity to identify infants at risk for early-onset GBS sepsis and offers an opportunity for intervention in the form of maternal treatment before delivery. Both antepartum and intrapartum types of antibiotic prophylaxis have been investigated; the U.S. Centers for Disease Control and Prevention (CDC) recommendations support an intrapartum regimen (see later). The following issues affect the accuracy of identifying women colonized with GBS: culturing methods, anatomic site of maternal culture specimens, and quantitation of cultures.

### Culturing Methods

The majority of studies using selective broth media containing antibiotics (e.g., nalidixic acid, gentamicin, colistin) demonstrate at least a two-fold greater yield of positive results for genital and rectal cultures from adults in comparison with nonselective methods (Baker et al, 1976; Gray et al, 1979). This greater yield is made possible by the suppression of overgrowth by co-colonizing bacteria in selective methods. It is noteworthy that standard laboratory methods for isolation of GBS from the blood and cerebrospinal fluid (CSF) of mothers and infants are fully adequate. In addition, use of nonselective media (standard blood agar plates) increases the yield of positive results from surface cultures in newborns during the first 24 to 48 hours of life, because the antibiotics in selective media are slightly inhibitory to GBS and most GBS surface isolates grow as pure cultures in the first 2 days of life (San Giovanni et al, 1987).

### Anatomic Site of Specimen Collection

Since 1977 there has been controversy in the literature regarding the best sampling site for identification of maternal colonization, genital or rectal (Badri et al, 1977; Anthony et al, 1981). The majority of studies reveals higher rates of rectal colonization (Baker and Edwards, 1995). However, Regan and colleagues (1987a), using culture methods that controlled for differences in behavior of lactobacilli at the two sites, found higher colonization rates at the genital site.

### Quantitation of Culture Results

“Heavy” colonization was first suggested by Bobitt and Ledger in 1976 as a factor likely to enhance vertical transmission. However, quantitative cultures are difficult to perform, and interest in obtaining them never achieved popularity. In contrast, semiquantitative screening is more feasible for most laboratories, and women with heavy colonization (3+ to 4+) are more likely to pass the microorganism to their infants (Ancona et al, 1980; Schuchat et al, 1994). In the Vaginal Infections and Prematurity (VIP) multicenter trial, a significantly greater rate of vertical transmission as well as higher incidences of preterm delivery and low birth weight were observed among women with heavy colonization (Regan et al, 1991).

TABLE 39–3

**Characteristics of Early-Onset and Late-Onset Group B Streptococcal Sepsis**

Characteristic	Early-Onset Sepsis	Late-Onset Sepsis
Age at onset	Birth through 5 day after birth	After day 7
Symptoms	Respiratory distress Apnea	Irritability Fever Poor feeding
Serotypes	All	All
Mode of transmission	Vertical	Nosocomial
Effect of intrapartum antibiotic prophylaxis recommended by the Centers for Disease Control and Prevention	Reduces incidence by 85%-90%	No effect

### **Maternal Colonization with Group B Streptococcal Infections**

In the United States, the prevalence of GBS in the genital or gastrointestinal tracts of pregnant women varies from 15% to 40% (Baker and Edwards, 1995). Carriage of GBS during pregnancy may be chronic, intermittent, or transient (Anthony et al, 1978). Therefore, a single culture of a specimen taken randomly during pregnancy may not be predictive of carriage at delivery. However, results of culture of specimens collected 1 to 5 weeks before delivery have a predictive value ranging from 60% to 100%, depending on site of culture (rectal, vaginal, or both) and interval between culture and delivery (Boyer et al, 1983b).

Although original studies reported no association between GBS colonization and risk factors for sepsis (Baker and Barrett, 1973), many subsequent reports have documented these associations (Bobitt et al, 1985; Regan et al, 1981; Stewardson-Krieger and Gotoff, 1978). Risk factors include preterm labor, preterm delivery, premature rupture of membranes, pPROM, prolonged rupture of membranes, and maternal fever. These risk factors form the basis of the CDC's consensus strategies for the intrapartum antibiotic prophylaxis risk factor-based strategy.

Other epidemiologic variables associated with an increased risk of maternal colonization are Hispanic race (both Mexican Americans and Caribbean Island Hispanics, especially patients of Dominican Republican Heritage) (Regan et al, 1987b), age less than 20 years, African-American ethnicity, and lower parity. In contrast, older age and lower parity, living with a partner (versus living alone), increased years of education, and smoking are associated with a reduced risk of colonization. Concurrent colonization with *Candida* species is associated with a higher risk of maternal colonization with GBS, but there is no relationship of GBS colonization with carriage of *C. trachomatis*, *Ureaplasma urealyticum*, *Trichomonas vaginalis*, or *M. hominis* (Regan et al, 1991).

### **Group B Streptococcal Sepsis in Neonates**

Only 1% to 2% of infants born to women who are colonized with GBS have early-onset sepsis. This incidence of infection rises with premature delivery (15%), prolonged (>18 hours) rupture of membranes (11%), presence of chorioamnionitis (6% to 20%), and twin pregnancy (35%). Other risk factors associated with early-onset sepsis are African-American race (Schuchat et al, 1990) and use of intrauterine monitoring (Davis et al, 1979).

Implementation of the CDC consensus strategies has lowered the incidence of sepsis in infants with these risk factors and changed the spectrum of risk factors describing early-onset sepsis (e.g., sepsis is more common among term than preterm infants) but has not yet altered GBS subtype distributions or prevalence in geographic locations.

Subtypes currently identified are Ia, II, III, IV, V, VI, VII, and VIII. Early studies of GBS disease in North America demonstrated a predominance of subtype III, which is thought also to be the most virulent subtype. It remains the most commonly isolated subtype causing meningitis in this country (Wilkinson, 1978). Since the 1970s, there has been a progressive change in predominance of subtypes,

with Ia now the leading cause of early-onset infection (Lin et al, 1998).

During the last decade, several new subtypes have been identified. Subtype V, initially isolated from nonpregnant adults testing positive for human immunodeficiency virus (HIV) in the United States, has become a common colonizing subtype among healthy, pregnant patients. It is most prevalent in the Northeastern United States (Lin et al, 1998). Subtype V has been reported to cause sepsis in very premature infants (Elliott et al, 1998; Rench and Baker, 1993).

Subtype IV is more commonly isolated in Europe, whereas subtypes VI and VIII predominate in Asia (Lachenauer et al, 1999; Lee et al, 2000). From an immunologic and public health perspective, the recognition of multiple new subtypes has confounded the efforts of investigators to develop an effective multivalent vaccine to prevent the disease in newborns.

### **Escherichia coli Infections**

*E. coli* is one of the most common pathogens causing sepsis and meningitis in the neonate. Although the antigenic structure of *E. coli* is complex (145 different somatic "O" antigens, 50 flagellar "H" antigens, and 80 capsular "K" antigens), the antigenic diversity of strains that cause neonatal sepsis and meningitis is limited. Eighty percent of the strains causing meningitis and 40% of the strains causing sepsis possess the K1 antigen (Mulder et al, 1984). It is noteworthy that the K1 polysaccharide is identical to the capsule of group B meningococci. Furthermore, the outer capsules of K1 *E. coli* and group B streptococci contain sialic acid, which may prevent activation of the alternative complement pathway. Other possible explanations for the virulence of this organism are lower concentrations of the ninth component of complement and reduced recognition by neutrophils. Approximately 20% to 30% of newborn babies are colonized with *E. coli*, and that percentage increases over the first few weeks of life (Peter and Nelson, 1978). Fifty percent of women at the time of delivery are colonized with *E. coli* that are K1 positive, and vertical transmission occurs 70% of the time (Sarff et al, 1975). Disease occurs in 1 in 100 to 200 colonized babies.

### **Listeria monocytogenes Infections**

*Listeria monocytogenes* is commonly found throughout the environment. Higher rates of colonization have been found among farmers and veterinarians. Almost all cases in humans come from the ingestion of contaminated food (Fleming et al, 1985). There are no differences in carriage rates between pregnant and nonpregnant individuals. Fecal carriage ranges from 1% in hospitalized patients to 5% in household contacts (Schlech, 1991; Schlech et al, 1983). *Listeria* can be transmitted to the fetus through a hematogenous (transplacental route) or ascending infection. Infections with *Listeria* that occur early in gestation result in septic abortion. Later in pregnancy (after the fifth month), infection with this organism results in the premature delivery of a stillborn or infected newborn. Approximately 70% of *Listeria*-infected pregnant women deliver before 35 weeks. An influenza-like illness in the

mother generally precedes delivery by 2 to 14 days and is demonstrable in about half of perinatal cases. During that time, the mother may be bacteremic. Treatment of *Listeria* sepsis during pregnancy can prevent infection in the fetus (Kalstone, 1991). *Listeria* tends to mimic GBS, with early-onset and late-onset presentations.

### Bacterial Pathogens

Since Dunham's original report in 1928, the bacteria responsible for early-onset neonatal sepsis have changed dramatically. However, the mechanisms responsible for the changes in incidence are not well understood. In the pre-antibiotic era, group A  $\beta$ -hemolytic streptococci accounted for the majority of perinatal infections. After the introduction of sulfonamides and then penicillin, gram-negative enteric organisms became the most common pathogens. In the 1950s, *Staphylococcus aureus* assumed a major dominance, followed once again by *E. coli* and gram-negative enterics in the 1960s. Beginning in the late 1960s, GBS (*S. agalactiae*) became the most common cause of neonatal sepsis in the United States. However, intrapartum antibiotic therapy has diminished the frequency of isolation of this pathogen.

Furthermore, there are regional differences in the kinds of organisms responsible for early-onset sepsis. These regional differences are important because they dictate the kinds of antibiotics used for empiric therapy. In the United States, the most common pathogens responsible for early-onset neonatal sepsis are *S. agalactiae* and *E. coli*. Other pathogens known to cause fulminant early-onset sepsis are *S. aureus*, *Haemophilus influenzae*, *Enterococcus* spp., *Streptococcus viridans*, *Klebsiella*, *Enterobacter* spp., *L. monocytogenes*, group A streptococci, and coagulase-negative staphylococci. There also, however, are dozens of bacteria known to be rare causes of early-onset neonatal sepsis.

### Clinical Manifestations

The clinical presentation of infants with early-onset bacterial sepsis is quite variable. The majority of infants present with respiratory distress and cardiovascular instability in the first 12 hours of life. In a subgroup of infected neonates, the signs appear after 12 hours of life. The delayed presentation in these infants suggests that the onset of bacteremia occurred at (or near) birth or during postnatal life. The signs of early-onset sepsis may be subtle (e.g., tachypnea) or overt (e.g., grunting, flaring, retractions). Almost any body system can be involved. Unfortunately, the signs of sepsis are nonspecific and common to many noninfectious disorders. Therefore, one must be cautious in ascribing an abnormal finding to a condition other than sepsis and must have a low threshold for initiating a sepsis evaluation. The common clinical signs of bacterial sepsis in the neonate are listed in Table 39-4.

Although the clinical manifestations of early-onset bacterial sepsis are nonspecific, a carefully performed physical examination is still the best way to identify infants with possible sepsis.

TABLE 39-4

### Clinical Signs of Neonatal Sepsis

Clinical Sign	% of Infants with Sign
Hyperthermia	51
Hypothermia	15
Respiratory distress	33
Apnea	22
Cyanosis	24
Jaundice	35
Hepatomegaly	33
Anorexia	28
Vomiting	25
Abdominal distention	17
Diarrhea	11

## Laboratory Testing

### General Concepts

One must consider four characteristics of laboratory tests when evaluating an infant for possible sepsis—sensitivity, specificity, positive predictive accuracy, and negative predictive accuracy. The *sensitivity* of a laboratory test is defined as the proportion of infants with proven (or probable) sepsis in whom the result is abnormal; its *specificity* is the proportion of healthy (noninfected) infants in whom the result is normal. A sensitive test will rarely miss an infant with sepsis, and a specific test will rarely misclassify an infant who is healthy.

Although tests that have both high sensitivity and high specificity are desirable, one must make tradeoffs in the real world between these two properties. Sensitivity is a desirable characteristic when the condition is serious and treatable, as sepsis in infants certainly is. Specificity is an important characteristic when false-positive test results can lead to harm. For example, if the therapy used to treat a condition has serious side effects (e.g., chemotherapeutics for malignancy), one must choose a laboratory test with high specificity. Sepsis is generally treated with antimicrobial agents that have a low toxicity. Therefore, high specificity is not as important as high sensitivity in the choice of tests to rule out sepsis. The relationship between sensitivity and specificity can be expressed using a receiver operator characteristic (ROC) curve. ROC curves are constructed by plotting the rate of true-positive results (sensitivity) against the rate of false-positive results (specificity) (Fig. 39-5). Tests that discriminate well are localized to the upper left corner of the curve. The ROC curve can help determine the best cut-off value (i.e., the best combination of sensitivity and specificity).

Positive and negative predictive accuracies are variables that help clinicians interpret the laboratory test once a result is known. *Positive predictive accuracy* is the probability that an infant with an abnormal laboratory test result is infected; *negative predictive accuracy* is the probability that an infant with a normal result is healthy (free of infection). The more

**FIGURE 39-5.** Receiver operator characteristic (ROC) curves are constructed by plotting the rate of true-positive results (sensitivity) against the rate of false-positive results (specificity).

sensitive a test, the greater its negative predictive value, and the more specific a test, the better its positive predictive value. Although we often order laboratory tests with the hope of identifying infants with sepsis, no single laboratory test or group of laboratory tests has a positive predictive value greater than 40%. In practice, the negative predictive value is a more important characteristic because it allows one to withhold or discontinue antibiotics when the probability of sepsis is low.

One other term deserves mention. The *likelihood ratio* is the likelihood that a given test result would be expected in an infant with sepsis compared with the likelihood that the same result would be expected in a healthy infant. Likelihood ratios focus on how likely a diagnostic test is to change our minds from what we thought before the test (pretest probability) to what we think afterward (post-test

probability). A likelihood ratio greater than 1 (positive likelihood ratio) increases the probability that the infant has the disease in question (e.g., sepsis), and a likelihood ratio less than 1 (negative likelihood ratio) decreases the probability that the infant is infected. Likelihood ratios greater than 10 or less than 0.1 are considered large (conclusive) changes from pretest to post-test probability. Likelihood ratios between 5 and 10 and between 0.1 and 0.2 are considered moderate shifts in pretest to post-test probability. The relationships among sensitivity, specificity, positive predictive accuracy, negative predictive accuracy, and likelihood ratio are shown in Figure 39-6.

**Cultures**

**Surface Cultures and Analysis of Gastric Aspirates**

Cultures of superficial body sites (external auditory canal, gastric aspirate, nasopharynx, groin, axilla, and umbilicus), or surface cultures, have traditionally been used to identify pathogens in sick neonates when other culture results are negative. Although some centers still use surface culture specimens to make clinical decisions regarding discontinuation of antimicrobial therapy, most do not (Shenoy et al, 2000). Evans and colleagues (1988) analyzed data from 24,584 cultures obtained from 3371 infants and found that the sensitivity, specificity, and positive predictive accuracy of surface cultures were 56%, 82%, and 7.5%, respectively. They concluded that surface cultures were of limited value in predicting the etiology of sepsis in neonates. Similarly, the examination of gastric aspirates for polymorphonuclear leukocytes (PMNs) has been used as a screening procedure for neonatal sepsis (Leibovich et al, 1987; Mims et al, 1972; Scanlon, 1972; Yeung and Tam, 1972). The presence of increased numbers of white blood cells has been thought to represent amnionitis and a fetal inflammatory response. However, a careful analysis of the origin of the cells in gastric aspirate has indicated a maternal origin

		Bacterial Infection Present		
		Yes	No	
Laboratory Test	Positive	TRUE POSITIVES (a)	FALSE POSITIVES (b)	POSITIVE PREDICTIVE VALUE (a)/(a+b)
	Negative	FALSE NEGATIVES (c)	TRUE NEGATIVES (d)	NEGATIVE PREDICTIVE VALUE (d)/(c+d)
		SENSITIVITY (a)/(a+c)	SPECIFICITY (d)/(b+d)	PREVALENCE (a+c)/(a+b+c+d)
		LIKELIHOOD RATIO, POSITIVE sensitivity/1-specificity	LIKELIHOOD RATIO, NEGATIVE 1-sensitivity/specificity	

**FIGURE 39-6.** Diagram of the relationships among sensitivity, specificity, positive predictive accuracy, negative predictive accuracy, and likelihood ratio.

(Vasan et al, 1977). Therefore, the presence of PMNs does not indicate fetal infection.

### **Blood Culture**

A positive blood culture result is the “gold standard” for detection of bacteremia in a neonate with suspected early-onset sepsis. However, the following variables affect the likelihood of recovering at least one colony-forming unit (CFU) in a blood culture specimen: (1) the number of CFUs in the blood at the time the culture specimen was obtained, (2) the culture techniques, (3) the volume of blood obtained, and (4) use of intrapartum antibiotics. Therefore, the blood culture is an imperfect reference standard. In one study, data obtained before the use of intrapartum therapy indicated that premortem blood culture results were positive in only 80% of infants in whom infection was proven by immediate postmortem cultures and autopsy (Squire et al, 1982). Furthermore, blood culture results are negative in up to 50% of neonates with a congenital bacterial pneumonia (positive tracheal aspirate culture result in the first 12 hours of life, and clinical signs) (Sherman et al, 1980). The use of intrapartum antibiotics has substantially reduced the number of positive blood culture results.

The number of CFUs is another important variable. In approximately 25% of infants with bacterial sepsis, the CFU count in the blood specimen is less than 5 CFU/mL (Dietzman et al, 1974). When the number of CFUs is that low, the volume of blood required to detect bacteremia is critical. In an *in vitro* study, Schelonka and associates (1996) demonstrated that when the CFU count in the blood specimen (original colony count) is 4 CFU/mL or less, a culture volume of 0.5 mL fails to detect at least one CFU 13% of the time. When the original colony count is 1 CFU/mL, the blood culture fails to detect bacteremia almost 60% of the time. Sending 1 mL of blood for culture will improve the recovery rates to 98% and 63% if the original colony counts are 4 CFU/mL and 1 CFU/mL, respectively. Unfortunately, the volume of neonatal blood sent for culture is frequently inadequate. In a study by Neal and colleagues (1986), 55% of neonatal blood specimens contained less than 0.5 mL of blood. Although 1 mL appears to be the ideal blood culture volume, it may be technically difficult to obtain in small, sick premature infants. In those circumstances, blood drawn through an indwelling arterial line appears to be an acceptable alternative (Cowett et al, 1976; Polin et al, 1981).

Another controversy is the time required for blood culture results to become positive. This is particularly relevant for the asymptomatic infant (or transiently symptomatic infant) who was started on antibiotic therapy because of risk factors for infection. In a study by Kumar and associates (2001), 97% of definite and “possible” bacterial pathogens were detected by 48 hours. The negative predictive value for isolation of definite bacterial pathogens was 99.8% at 48 hours. These data are similar to those reported by Garcia-Prats and coworkers (2000), who found that virtually all cultures growing clinically significant gram-positive and gram-negative organisms were positive by 36 hours (Garcia-Prats et al, 2000). In this study, there was

no difference in time to positivity between cultures of specimens collected “pre-therapy” and “post-therapy.” Therefore, in the term asymptomatic infant, it is reasonable to stop antibiotic therapy after 48 hours if culture results are negative *and* physical findings remain normal. In asymptomatic preterm infants started on antibiotic therapy because of risk factors for infection, a carefully performed physical examination is equally reassuring, but it is more difficult to do in these tiniest neonates. In such patients, the decision to continue or discontinue antibiotics is often based on results of other laboratory tests (see discussion of sepsis screens). Whenever the suspicion of sepsis is high (especially in a symptomatic infant), consideration should be given to continuing antibiotic therapy for a “complete course” despite a negative blood culture result (see later).

### **Urine Culture**

The rate of positive urine culture results in infants with early-onset sepsis is low. In the study by Visser and Hall (1979), the urine culture result was negative in eight of nine infants with early-onset sepsis in whom blood culture results were positive. In two other infants, the urine culture result was positive and the blood culture result was negative. Infants with late-onset sepsis had a higher rate of positive urine cultures. Similarly, DiGeronimo (1992) found only 1 infant with a positive urine culture result of 280 infants who were being evaluated for early-onset sepsis (16 of the infants had positive blood culture results), and no infants with negative blood culture results had bacteriuria.

Pyelonephritis in the neonate is thought to represent seeding of the kidney during an episode of bacteremia. Therefore, it makes intuitive sense that the blood culture result should be positive in any infant with a positive urine culture; however, this finding has not been substantiated in infants born to women who have received intrapartum antibiotic therapy. Given the low yield of positive urine culture results and costs of processing the specimens, urine culture should not be part of the traditional sepsis evaluation in the first 72 hours of life.

### **Cerebrospinal Fluid**

The controversies surrounding indications for lumbar puncture are discussed later. Lumbar puncture should be deferred in any infant with clinical instability or an uncorrected bleeding diathesis.

### **White Blood Count and Neutrophil Indices**

Total leukocyte counts are not very helpful in the diagnosis of neonatal sepsis (Schuchat et al, 1994). Normal counts range from 9000 to 30,000 cells/mm<sup>3</sup> at the time of birth, and differences in the site of sampling and the activity of the baby can affect this measurement. For example, in a study by Christensen and Rothstein (1979), venous blood leukocyte counts were 82% of simultaneously drawn capillary blood values, and arterial blood counts were 77% of capillary blood values. These investigators also reported that in samples collected after “violent crying,” white blood counts increased to 146% of baseline values and a “shift

to the left” occurred. Neutrophil indices—absolute neutrophil count (ANC), the absolute band count (immature neutrophil count), and the ratio of immature neutrophils to total neutrophils (I/T ratio)—have proved more useful than total leukocyte counts in the diagnosis of neonatal sepsis.

The reference ranges for each of these indices were established by Manroe and colleagues (Manroe, 1979). The lower limit or total neutrophil count is 1750 cells/mm<sup>3</sup> at birth and rises to 7200 cells/mm<sup>3</sup> by 12 hours of age. It then declines to approximately 1720 cells/mm<sup>3</sup> by 72 hours of age. The absolute band count undergoes similar changes postnatally. Peak values of 1400 cells/mm<sup>3</sup> occur at about 12 hours of life and then decline. In contrast, the I/T ratio is maximum at birth (0.16) and then declines to a value of 0.12 beyond age 72 hours. In this study, the mean gestational age of study infants was 38.9 weeks, and the mean weight was 2685 g. Mouzinho and coworkers (1994) published revised reference ranges for very low-birth-weight (VLBW) infants. They observed a wider reference range in total neutrophil counts for the VLBW population. The lower boundary ranged from 500 cells/mm<sup>3</sup> soon after birth to 2,200 cells/mm<sup>3</sup> by 18 to 20 hours of life. By day 5 of life, the lower boundary was 1,100 cells/mm<sup>3</sup>. These researchers found no differences in the I/T ratio or absolute immature neutrophil counts in VLBW infants.

Although normal values for neutrophil indices have been fairly well established, the cutoff values indicative of sepsis remain controversial. Table 39-5 lists suggested cutoff values for the ANC, absolute band count, and I/T ratio. It is important to note, however, that there is considerable overlap of these indices between healthy and infected newborns. Schelonka and colleagues (1994) determined normal values for neutrophil indices in healthy term infants. As noted previously, the upper limits for absolute band count and I/T ratio overlap with the suggested cutoff values. Furthermore, the inter-reader variability in the identification of immature neutrophils renders the value of the I/T ratio and absolute band count open to question (Schelonka et al, 1995).

The total neutrophil count is abnormal in about two thirds of infants with sepsis. However, a variety of clinical conditions can affect total neutrophil counts (Table 39-6). Neutropenia is the best predictor of sepsis, and neutrophilia does not correlate very well. Counts obtained in specimens collected immediately after birth have an impaired sensitivity for identification of infected newborns (Rozycki et al, 1987). Therefore, collection of the initial laboratory screen specimen should be delayed for several hours or a second screen specimen should be obtained at about 12-24 hours of life. The absolute band

count is an insensitive marker of sepsis but has a good positive predictive value and specificity. The I/T ratio has the best sensitivity of all the neutrophil indices (range 60% to 90%); however, a variety of perinatal conditions has been shown to affect this ratio (Manroe et al, 1979). The sensitivity, specificity, and positive and negative predictive values for the commonly used neutrophil indices are shown in Table 39-7.

### Platelet Counts

At the time of diagnosis of sepsis, about 25% of infants exhibit thrombocytopenia, and that percentage increases during the course of infection. The major mechanism responsible for thrombocytopenia in infected neonates is accelerated platelet destruction; a minority of infected infants has disseminated intravascular coagulation (DIC). In the absence of DIC, clinical bleeding abnormalities are rare.

### Acute Phase Reactants and Erythrocyte Sedimentation Rate

A wide variety of acute phase reactants has been used to identify infants with possible sepsis, including C-reactive protein (CRP), fibrinogen, ceruloplasmin, fibronectin, prealbumin, haptoglobin, and orosomucoid (Benitz et al, 1998; Gabay and Kushner, 1999; Sáez-Llorens and Lagrutta, 1993). Acute phase proteins are produced by hepatocytes in response to cytokine signals, principally IL-6. Gene expression for acute phase proteins is regulated mainly at the transcriptional level. Because the increase in acute phase proteins depends on an initial cytokine response, there is always some delay in the rise of these proteins. After an inflammatory stimulus (and after a delay of several hours) CRP and serum amyloid A are the first acute phase protein values to rise. The rise in the erythrocyte sedimentation rate (ESR) is slower and reflects elevated fibrinogen levels.

C-reactive protein is the most well studied acute phase protein in neonatal sepsis (Jaye and Waites, 1997). CRP was discovered in 1930 by Tillet and Francis in the sera of patients with pneumonia. It consists of five non-covalently bound identical subunits, each containing 187 amino acids, with one intrachain disulfide bond and no carbohydrate modifications. Monitoring of CRP levels has been widely promoted as a way to reduce the duration of antibiotic therapy in infants with suspected and proven sepsis (Bomela et al, 2000; Ehl et al, 1997; Philip and Mills, 2000). A CRP value of 10 mg/dL is generally accepted as the upper limit of normal, but some laboratories have used different cutoff values. The most widely used technique for measurement of CRP is laser nephelometry. Results can be available within 15 to 30 minutes and only 50  $\mu$ L of serum is needed.

The largest prospective study evaluating CRP in the diagnosis of neonatal infection was performed by Benitz and colleagues (1998). In this study, CRP was measured in 1002 infants with suspected early-onset sepsis at the time of initial evaluation (CRP #1) and on each of the next

**TABLE 39-5**

#### Neutrophil Value Suggestive of Infection

Neutropenia: neutrophil count <1750 cells/mm<sup>3</sup>  
 Ratio of immature to total neutrophil count >0.2  
 Absolute band count >2000 cells/mm<sup>3</sup>  
 Total white blood cell count <5000 cells/mm<sup>3</sup>

TABLE 39-6

## Frequency of Physical Findings in 49 Infants with Congenital Malaria

Complication	Frequency in Neonates with Following Abnormal Values*			
	Decrease in Total Neutrophils	Increase in Total Neutrophils	Increase in Total Immature Neutrophil Forms	Increased Ratio of Immature Forms to Total Neutrophil Count
Maternal hypertension	++++	0	+	+
Maternal fever, neonate healthy	0	++	+++	++++
≥6 hrs intrapartum oxytocin	0	++	++	++++
Asphyxia (5-min Apgar score ≤5)	+	++	++	+++
Meconium aspiration syndrome	0	++++	+++	++
Pneumothorax with uncomplicated hyaline membrane disease	0	++++	++++	++++
Seizures—no hypoglycemia, asphyxia, or central nervous system hemorrhage	0	+++	+++	++++
Prolonged (≥4 min) crying	0	++++	++++	++++
Asymptomatic blood glucose ≤30 mg/dL	0	++	+++	+++
Hemolytic disease	++	++	+++	++
Surgery	0	++++	++++	+++
High altitude	0	++++	++++	0

\*Frequency defined as follows: 0, not present; +, present in 0% to 25%; ++, present in 25% to 50%; +++, present in 50% to 75%; +++++, present in 75% to 100%.

two mornings (CRP #2 and CRP #3). CRP #1 was found to have a poor sensitivity (35.0%) for proven sepsis; this finding is not surprising, given the delayed rise in CRP. In contrast, CRP #2 had a sensitivity of 78.9% for proven sepsis. The sensitivity of CRP #2 and CRP #3 (excluding CRP #1) for proven sepsis was 88.9%; the negative predictive value was 99.7% for proven or probable early-onset sepsis. Positive predictive values were low (<10%); however, marked elevations of CRP (>6 mg/dL) were associated with a higher (60%) probability of sepsis. Therefore, like most diagnostic tests for early-onset sepsis, the high negative predictive accuracy of serial CRP determinations (performed 8 to 12 hours after birth) was helpful in deciding which infants did not require antibiotic

therapy and those in whom antibiotics could be discontinued after a brief course.

Determination of the erythrocyte sedimentation rate with the use of a micro-hematocrit tube was developed more than 50 years ago. During the first two weeks of life, an approximation of the upper limits of normal values for the ESR can be made by adding 2 or 3 to the age of the infant in days. The ESR is normal in most infants with non-infectious conditions, but significant elevations occur in infants with a Coombs-positive hemolytic anemia (Adler and Denton, 1975). The sensitivity of the ESR ranges from 30% to 70%. As for other measures of inflammation, there is a delay in the rise in ESR in infected neonates. Furthermore, once the ESR is elevated, the decline is very slow. However, the negative predictive accuracy of the micro-ESR is high (>95%), and in centers where CRP determinations are not available, it may be a suitable alternative.

TABLE 39-7

## Performance of Hematologic Tests in the Diagnosis of Sepsis

Parameter	Neutropenia	I/T > 0.2	Increased Band Count
Sensitivity (%)	38-96	90-100	63-67
Specificity (%)	61-92	50-78	69-77
PPV (%)	20-77	11-51	17-46
NPV (%)	96-99	99-100	95

I/T, ratio of immature neutrophil forms to total neutrophil count; PPV, positive predictive value; NPV, negative predictive value.

Data from Gerdes JS: Clinicopathologic approach to the diagnosis of neonatal sepsis. *Isr J Med Sci* 30:435, 1994.

## Cytokines

*Cytokines* are proteins, glycoproteins, and lipids that regulate the inflammatory response. A wide variety of cytokines has been identified in infants with sepsis, including IL-1, IL-6, IL-8, TNF- $\alpha$ , soluble IL-2 receptor, soluble intercellular adhesion molecule-1 (ICAM-1), soluble TNF- $\alpha$  receptor, E-selectin, IL-1 receptor antagonist, granulocyte-macrophage colony-stimulating factor (GM-CSF), and granulocyte CSF (G-CSF) (Mehr and Doyle, 2000).

The diagnostic value of IL-6 has been studied most extensively. Although the data are not definitive, the following generalizations about IL-6 and other cytokines in neonatal sepsis are possible:

1. There are marked variations in the assays used for cytokine determinations, which have resulted in variations in the cutoff values used to discriminate infected from noninfected infants.
2. The sensitivity of the IL-6 value is approximately 90%, and the negative predictive accuracy exceeds 95% (values for specificity have varied).
3. As the inflammatory response subsides, levels of IL-6 quickly return to a normal range (usually within 24 hours).
4. Persistent elevations of cytokines are associated with higher mortality.

A number of investigators has demonstrated that the combination of IL-6 and CRP determinations results in a higher sensitivity than either marker used alone (Doellner et al, 1998). IL-6 assays currently require hours to complete. Therefore, at present, cytokine determinations remain an unproven but promising diagnostic tool.

### Sepsis Screens

Because none of the diagnostic tests for sepsis is able to identify infants with proven sepsis with reasonable accuracy, investigators have used combinations of laboratory tests (neutrophil indices, measurements of acute phase proteins and ESR) to enhance the identification of infected neonates. Although these so-called sepsis screens do not have better positive predictive accuracy than individual laboratory tests, they have significantly better negative predictive accuracy and can provide greater reassurance that infection is not present. Philip and Hewitt (1980) utilized five tests—I/T ratio, absolute leukocyte count, CRP, micro-ESR, and haptoglobin—to screen infants admitted for suspected sepsis or meningitis. A positive sepsis screen result was defined as two or more abnormal test results. The sensitivity of the sepsis screen was 93%, and the positive predictive accuracy was 39%. When results of fewer than two tests were positive, the negative predictive accuracy was 99%.

Gerdes and Polin (1987) performed two sepsis screens 12 to 24 hours apart; the screens consisted of I/T ratio, white blood count, CRP, and micro-ESR. This method identified 100% of infected infants ( $n = 13$ ) and had a

negative predictive accuracy of 100%. With a hematologic scoring system employing seven variables, Rodwell and colleagues (1988, 1993) obtained similar results using a hematologic scoring system. Because of their high negative predictive accuracy, sepsis screens have been shown to result in a significant decrease in the use of antimicrobial agents. In addition, they permit discontinuation of antibiotic therapy at the earliest possible time with the greatest confidence.

## Diagnostic Approach to Neonates with Suspected Sepsis

### Symptomatic Infants

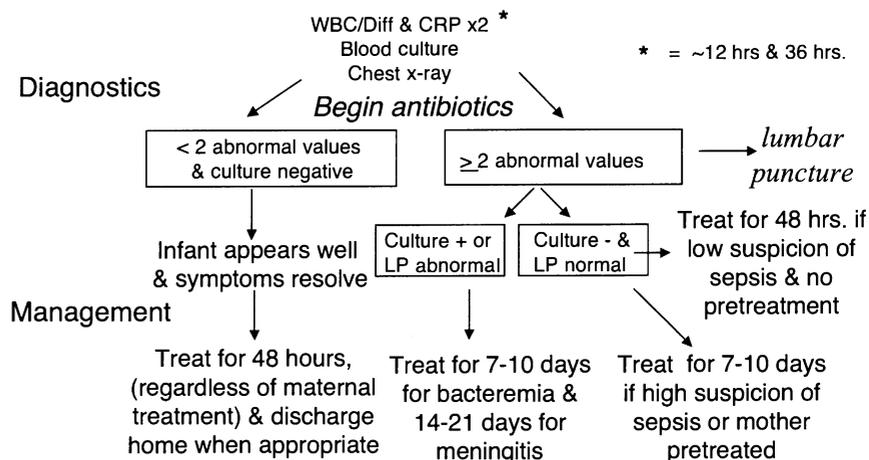

All symptomatic infants must be carefully evaluated for the possibility of sepsis, and most symptomatic infants are treated. Although the presence of risk factors should increase one's suspicion of sepsis, the absence of risk factors in a symptomatic infant is not totally reassuring. During the adjustment to postnatal life, some infants transiently exhibit abnormal signs (e.g., tachypnea) before becoming asymptomatic. Any infant who is still symptomatic at 6 hours of life should be treated as if infected. A suggested algorithm for the evaluation and treatment of symptomatic infants is shown in Figure 39-7. Antibiotic therapy can be stopped in a symptomatic infant when (1) the clinical suspicion of sepsis is low, (2) physical findings are normal at 48 hours of age, and (3) sepsis screen results remain negative.

### Asymptomatic Infants

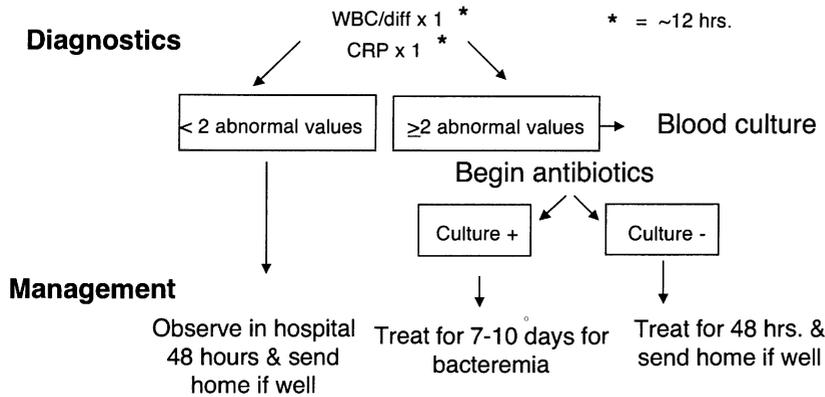

The management of asymptomatic infants born to mothers with risk factors for infection is controversial. Unfortunately, there are almost no prospective data to guide decision-making. A carefully performed physical examination is the most important part of the diagnostic work-up. Our recommendations for the management of asymptomatic infants born to women with risk factors for infection are shown in Figures 39-8 and 39-9. Recommendations for infants born at 35 weeks of gestation or later and for those

### Evaluation of Symptomatic Infants for Neonatal Sepsis

**FIGURE 39-7.** A suggested algorithm for the evaluation and treatment of symptomatic infants for neonatal sepsis. CRP, C-reactive protein value; LP, lumbar puncture (with examination of cerebrospinal fluid); Px, physical; WBC/Diff, white blood count with differential count.

*Evaluation of Asymptomatic Infants ≥ 35 weeks Gestation with > 1 Risk Factor for Neonatal Sepsis*

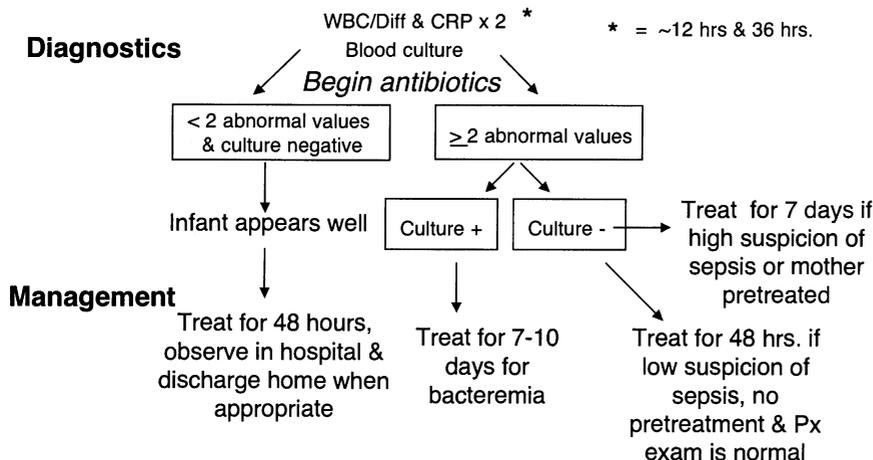

**FIGURE 39-8.** Recommendations for the management of asymptomatic infants born at 35 weeks of gestation or later to women with risk factors for infection. CRP, C-reactive protein value; WBC/Diff, white blood count with differential count.

born before 35 weeks of gestation are presented separately. As noted previously, the three main maternal risk factors for early-onset neonatal sepsis are colonization with GBS, signs and symptoms of chorioamnionitis, and prolonged (>18 hours) rupture of membranes. Intrapartum antibiotic therapy for women colonized with GBS is effective when administered more than 4 hours before delivery but does not guarantee that the infant will be well.

In asymptomatic infants born at or after 35 weeks of gestation to women with risk factors, there are two principal options, observation alone and observation plus diagnostic studies (see Fig. 39-8). The use of intrapartum antibiotics (more than 4 hours before delivery) is 90% effective when no other risk factors are present (Schrag et al, 2002). Therefore, observation alone is probably sufficient for asymptomatic infants born at or after 35 weeks of gestation to women who are colonized with GBS, have no other risk factors, and have received an appropriate antibiotic at least 4 hours before delivery. For any infant whose mother has other risk factors (PROM >18 hours or signs and symptoms of chorioamnionitis), we recommend

that a sepsis screen be performed, due to the difficulty of observing infants closely enough for the early, subtle signs of sepsis. The sepsis screen specimen should be drawn at 12 hours of life rather than immediately after birth, because of the greater likelihood of a positive result in an infected infant with the passage of time. If the result is positive, our recommendation is to obtain a blood culture and give antibiotic therapy until culture results are confirmed negative (48 hours). A positive sepsis screen result places the risk of bacteremia at about 40% (Gerdes, 1994). Escobar and colleagues (2000) identified 1275 asymptomatic infants (>2000 g) who were evaluated for early-onset sepsis because of risk factors. In the study, asymptomatic status reduced the probability of proven sepsis (adjusted odds ratio 0.26 (95% confidence interval [CI], 0.11 to 0.63); however, 1% of asymptomatic infants born to untreated women were infected, and 0.9% of infants born to women receiving intrapartum antibiotics were infected. Both of these rates are still ten times the rate seen in the general population. Overall, intrapartum antibiotic therapy decreased the percentage of babies who

*Evaluation of Asymptomatic Infants < 35 weeks Gestation with > 1 Risk Factor for Neonatal Sepsis*

**FIGURE 39-9.** Recommendations for the management of asymptomatic infants born before 35 weeks of gestation and born to women with risk factors for infection. CRP, C-reactive protein value; Px, physical; WBC/Diff, white blood count with differential count.

were critically ill ( $P = .001$ ) and infected ( $P = .066$ ). These researchers suggest that screening, treatment, and observation protocols cannot be based on asymptomatic status alone.

Recommendations for asymptomatic infants born before 35 weeks of gestation are shown in Figure 39–9. With increasing degrees of prematurity, the physical findings become more difficult to assess. Therefore, in an asymptomatic infant born before 35 weeks of gestation to a woman with any risk factors for sepsis, we recommend that broad-spectrum antibiotic therapy be started after a blood culture specimen has been obtained. Sepsis screen specimens should be obtained at 12 and 36 hours of life. We believe that if the infant remains asymptomatic (and appears well) and the results of culture and sepsis screens are negative, antibiotic therapy can be discontinued, and the infant observed. In the asymptomatic infant with a positive sepsis screen result, the decision to continue antibiotic therapy should be individualized. If the mother has received intrapartum antibiotics, blood culture results are less reliable, and such an infant should probably be given a complete course of therapy. If the mother has not received intrapartum antibiotics and appears well, antibiotic therapy can be discontinued, and the infant observed. The decision whether to perform a lumbar puncture for CSF analysis is discussed later.

### Clinical Spectrum of Disease

#### **Streptococcus agalactiae (Group B Streptococcus)**

The clinical picture of early-onset GBS sepsis is identical to that of early-onset sepsis due to other organisms. The case fatality rate is low in term infants, and morbid sequelae are rare. There are no characteristic physical findings. Furthermore, there are no distinguishing findings on complete blood count (CBC) or acute phase reactant determinations. Chest radiographs are indistinguishable from those seen in respiratory distress syndrome (RDS), transient tachypnea of the newborn, meconium aspiration syndrome, and pneumonia (Ablow, 1976).

#### **Staphylococcus aureus**

As already mentioned, *S. aureus* was the most common cause of neonatal sepsis in the 1950s; it was replaced by gram-negative enteric organisms (*E. coli*) and GBS. Staphylococci are responsible for a wide variety of serious infections in newborn infants, including breast abscess, furunculosis, osteomyelitis, endocarditis, and septic arthritis. Furthermore, phage group II organisms are capable of producing an exotoxin that cleaves the skin at the granular cell layer, causing toxic epidermal necrolysis, bullous impetigo, and a scarlatiniform rash. Most strains of *S. aureus* are sensitive to semisynthetic penicillins (e.g., methicillin), but methicillin-resistant strains of *S. aureus* (MRSA) have assumed an increasing importance. There are many potential reservoirs for MRSA in the nursery environment. Risk factors for colonization are birth weight less than 1500 g, prolonged hospital stay, and the presence of central venous catheter, thoracostomy tubes,

or shunts. MRSA generally cause nosocomial infections, and epidemics are not uncommon. Contact with the hands of colonized nursery personnel is usually how these organisms are spread. Coagulase-negative staphylococci can also cause early-onset bacterial sepsis; the clinical spectrum of disease is indistinguishable from that for other bacterial pathogens.

### **Listeria monocytogenes**

*L. monocytogenes* is responsible for early- and late-onset bacterial infections in a pattern similar to that seen with GBS. Infants with early-onset sepsis due to *Listeria* generally become symptomatic in the first day or two of life. There is often a history of an antecedent maternal illness (malaise, myalgia, and fever). Passage of meconium before birth is commonly noted. Infants infected with *Listeria* are generally indistinguishable from those infected with other pathogens; however a granulomatous rash has been described in critically ill infants with *L. monocytogenes* infection. Persistent pulmonary hypertension has also been observed in seriously ill infants. Laboratory features are non-specific. The mortality rate with early-onset disease is 25%.

### **Prevention**

#### **Intrapartum Antibiotic Prophylaxis**

##### **History**

In 1990, GBS infections caused an estimated 7600 serious illnesses and 310 deaths among U.S. infants 90 days or younger. Approximately 80% of these illnesses occurred in infants younger than 7 days—that is, those diagnosed with early-onset disease (Decreasing incidence, 1997). At that time and during the 2 years that followed, several well-designed studies demonstrated the efficacy of intrapartum antibiotic prophylaxis in reducing the incidence of early-onset GBS disease (Allen et al, 1993; Boyer and Gotoff, 1986). Professional and public demand encouraged the American Academy of Pediatrics (AAP) and the American College of Obstetricians and Gynecologists (ACOG) to publish guidelines for prevention of early-onset GBS sepsis (AAP, 1992; ACOG, 1992). The two organizations' recommendations differed in that one took a screening-based approach and the other a risk factor–based approach, leading to confusion.

In 1995, the CDC led representatives of the AAP and ACOG and other leaders in GBS research to develop a policy acceptable to all participants. In 1996, the CDC published consensus strategies recommending alternative strategies (“risk factor-based or culture-based”) for prevention of early-onset streptococcal sepsis (Prevention, 1996). Assessment of the CDC consensus strategies and other studies of intrapartum antibiotic prophylaxis have been confounded by noncompliance issues. Nevertheless, the impact of implementation has been dramatic. Active population-based surveillance in eight states from 1993 to 1998 demonstrated a decrease in attack rate of early-onset GBS sepsis from 1.7 to 0.6 per 1000 live births. This drop was associated with a 75% reduction in the (excess) incidence of disease among African-American infants. Projecting

the study findings to the entire United States, Schrag and colleagues (2000) estimated that 3900 cases of early-onset sepsis and 200 neonatal deaths were prevented by protocol-directed intrapartum antibiotic prophylaxis. In 2002, the CDC published new guidelines to take into account new information regarding the superiority of the culture-based strategy over the risk-based strategy (Prevention, 1996; Schrag et al, 2002).

### **Protocol—The “CDC Consensus Strategies”**

The CDC recommendations for intrapartum antibiotic prophylaxis to prevent early-onset group B streptococcal disease are summarized here (Schrag et al, 2002).

#### **Antepartum Culture-Based Strategy**

Originally, antepartum screening at 22 to 23 weeks and 35 to 37 weeks of gestation with the use of a combined vaginal-rectal swab specimen processed in selective media was advocated as the screening strategy. Later revisions of the screening strategy recommend screening only at 35 to 37 weeks of gestation. Antepartum treatment is recommended for women with the following characteristics:

- Previous infant with invasive disease
- GBS bacteriuria during pregnancy
- Positive GBS screening culture result during pregnancy (unless a planned cesarean delivery, in the absence of labor or amniotic membrane rupture, is performed)
- Unknown GBS status (culture not performed, culture incomplete, or results unknown) and any of the following features: delivery before 37 weeks of gestation, rupture of amniotic membranes for 18 hours or longer, and intrapartum temperature of 100.4° F (38° C) or higher.

#### **Intrapartum Management of Parturients**

Women who are able to receive penicillin should be given penicillin G, 5 million units as a loading IV dose followed by 2.5 million units q4h until delivery, or ampicillin, 2 g IV as a loading dose followed by 1 g q4h until delivery.

For any woman who is allergic to penicillin, the CDC recommends that during prenatal care, the history of penicillin allergy be assessed to determine whether the patient is at high risk for anaphylaxis (i.e., history of immediate hypersensitivity reactions). Women who *are not* at high risk for anaphylaxis should receive cefazolin, 2 g IV then 1 g IV q8h until delivery. Women who *are* at high risk for anaphylaxis should receive clindamycin, 900 mg IV q8h until delivery or erythromycin, 500 g IV q6h until delivery.

#### **Postnatal Management of Infants Born to Mothers Treated with Intrapartum Antibiotics**

The CDC guidelines recommend that all symptomatic infants undergo a full diagnostic evaluation, including CBC and differential, blood culture, and chest radiograph (if respiratory symptoms are present). If feasible, a lumbar puncture should be performed, and empiric therapy should be initiated with ampicillin and gentamicin. The duration of treatment might be as short as 48 to 72 hours, depending on the culture results and clinical course. The same recommendation (full diagnostic evaluation and treatment) is made for any infant born to a woman who has received

antibiotics for suspected chorioamnionitis. For asymptomatic infants born before 35 weeks of gestation to women who are culture positive for GBS, a limited evaluation (CBC with differential and blood culture) is recommended. If sepsis is suspected in this population, a full diagnostic evaluation and empiric therapy are suggested.

Asymptomatic infants born at or after 35 weeks of gestation to mothers who have received 4 or more hours of intrapartum antibiotic prophylaxis require no additional evaluation or therapy; however, observation for a minimum of 48 hours is recommended. Asymptomatic infants of the same gestational age whose mothers received less than 4 hours of intrapartum antibiotic prophylaxis should undergo a limited evaluation, consisting of a CBC with differential and a blood culture, and should be observed for a minimum of 48 hours. In selected circumstances (fully compliant family and adequate therapy), such an infant may be discharged earlier.

#### **Assessing the CDC Consensus Strategies—Noncompliance Issues, Cost-Versus-Benefit Analyses, Future Changes in Protocol**

Despite the initiation of the standardized protocols recommended by the AAP, CDC, and ACOG, there have been many noncompliance issues. Chandran and associates (2001) presented an observational study in which clinician compliance with nationally recommended guidelines was evaluated. For the combined risk factor-based and culture-based algorithm, clinical compliance with intrapartum prophylaxis ranged from 75% to 84%. Twenty-two percent of women received antibiotics that were not indicated. Among the women for whom antenatal cultures were indicated, only 65% underwent the tests. More significantly, only 9% of culture specimens were obtained from the anogenital site. Fourteen percent to 75% of infants underwent the guideline-suggested evaluation, and 61% to 94% remained hospitalized for a minimum of 48 hours. The failure to process cultures with selective media is another common noncompliance issue, but it may be improving (Adoption, 1998).

#### **Impact of Implementation of the CDC Consensus Strategies**

The primary outcome of the implementation of the CDC consensus strategies for prevention of early-onset neonatal GBS sepsis has been a steady and dramatic decrease in the incidence of the disease, with rates currently at 40% to 60% of those in the pre-implementation era. With few exceptions, however, there has not been any reduction in the incidence of early-onset sepsis due to other organisms (Isaacs and Royle, 1999). The majority of published reports also shows that intrapartum prophylaxis is not 100% effective; 10% of infants with positive blood culture results are born to treated mothers.

Initial concerns about the risks of implementing these strategies have proved unwarranted. The principal risks were maternal anaphylaxis (Schuchat et al, 2000) and emergence of infections in mothers and infants due to resistant organisms (e.g., *E coli*, *Enterococcus* spp.) (Chen et al, 2001; Towers et al, 1998). A study by the Neonatal Network of the National Institute of Child Health and Human Development (NICHD) demonstrated a change in the pathogens causing early-onset sepsis, with an increase in

sepsis due to *E. coli* from 3.2 to 6.8 per 1000 live births. Most (85%) *E. coli* isolates were resistant to ampicillin (Stoll et al, 2002).

### **Preterm Premature Rupture of Membranes**

It is generally accepted that intrauterine infection plays a primary role in the pathogenesis of pPROM and preterm delivery. Furthermore, there are strong associations among pPROM, positive amniotic fluid culture results, clinical signs of chorioamnionitis, and histologically confirmed chorioamnionitis. The relationship between lower genital tract colonization and pPROM is not as conclusive; however, several studies have demonstrated an association between colonization with various microorganisms (GBS, *U. urealyticum*, *G. vaginalis*, *Bacteroides* spp., *C. trachomatis*, and *T. vaginalis*) and pPROM. Although there have been numerous controlled trials examining the benefits of antibiotics in women with pPROM, only two studies have had sufficient power to evaluate neonatal morbidity. In 1997, the Maternal Fetal Network at the NICHD published the results of a multicenter trial (n = 614) in which women with pPROM (24 to 32 weeks of gestation) were randomly assigned to receive either antibiotic treatment (ampicillin or amoxicillin and erythromycin) for 1 week or placebo (Mercer et al, 1997). In the group receiving antibiotics, the incidence of clinical amnionitis was lower and gestation was significantly prolonged. Infants born to women treated with antibiotics exhibited lower incidences of respiratory distress syndrome and stage 2 or 3 necrotizing enterocolitis (NEC). Although the incidence of sepsis in infants younger than 72 hours was not reduced ( $P = .26$ ), the overall incidence of sepsis was significantly lower ( $P = .01$ ).

The ORACLE I study from the United Kingdom randomly assigned women with pPROM (n = 4286) to the following four treatment groups: amoxicillin–clavulanic acid, erythromycin, both antibiotics, or placebo (Kenyon et al, 2001a). Among 2260 singletons who were treated with erythromycin or placebo, the risk of death or major adverse outcome (chronic lung disease or major cerebral abnormality) was reduced. Use of erythromycin was associated with prolongation of pregnancy, reduced treatment with surfactant, and fewer positive blood culture results. There was no benefit to using amoxicillin–clavulanic acid with or without erythromycin; in fact, those combinations were associated with a higher risk of necrotizing enterocolitis. These studies suggest that administration of erythromycin for 7 to 10 days after pPROM offers substantial benefits to the preterm neonate and reduces the likelihood of sepsis.

### **Intravenous Immune Globulin for Prevention of Early-Onset Sepsis**

Reduced transplacental transfer of immunoglobulins (Ig) and decreased endogenous synthesis of IgG predispose premature infants to early-onset sepsis. This physiologic hypogammaglobulinemia provides a rationale for administering intravenous immune globulin (IVIG). However, few controlled studies of IVIG prophylaxis for early-onset sepsis have been undertaken.

Haque and colleagues (1986) studied VLBW ( $\leq 1500$  g) infants who were given either IVIG shortly after delivery or nothing (control). The rates of infection (mean age of onset 8 to 76 hours) were 16% in the control group and 4% in the treated group ( $P < .005$ ). Moreover, significantly higher serum Ig concentrations were found in the treated infants. Three randomized, placebo-controlled studies determined the overall incidence of both early-onset and late-onset infections in infants treated with IVIG since birth, in comparison with controls. Chirico and associates (1987) found a benefit of the treatment only in VLBW infants, whereas Conway and coworkers (1990) found no difference in sepsis incidence between treated and untreated infants when blood culture result was the diagnostic criterion. Sandberg and colleagues (2000) evaluated the effects of IVIG infusion in preterm infants with a plasma level of IgG less than 4 g/L at birth and were unable to demonstrate any benefit of the treatment.

### **Recombinant Cytokines for Prevention of Early-Onset Sepsis**

The recombinant forms of some hematopoietic cytokines have been cloned and purified and have been under clinical investigation for their possible role in modulating host defense in the prevention of neonatal sepsis. G-CSF has the ability to increase the number of circulating neutrophils and to augment the effectiveness of neutrophils and macrophages to kill infectious organisms.

Kocherlakota and La Gamma (1998) evaluated the ability of G-CSF to reverse neutropenia and reduce the incidence of early-onset sepsis in VLBW ventilator-dependent infants with preeclampsia-associated neutropenia. They found that the absolute neutrophil count (ANC) increased significantly in the treated infants in comparison with controls. Sepsis was observed in 2 of the 15 treated infants and in 7 of the 13 controls (13% and 54%, respectively;  $P < .05$ ).

## **Treatment**

### **Antimicrobial Therapy**

The decision to treat a newborn infant for possible sepsis is based on clinical signs or risk factors with or without confirmatory laboratory data. The choice of antibiotics for an infant with suspected early-onset sepsis depends on the predominant pathogens and the antibiotic sensitivity patterns for the microorganisms causing early-onset sepsis in a given region. The algorithms presented in Figures 39–7, 39–8, and 39–9 are meant to serve as guidelines for the diagnosis and management of infants with suspected sepsis. Decisions to discontinue antimicrobial therapy should be based on the level of suspicion for sepsis at the time treatment was begun, culture results, laboratory test results, and the clinical course of the infant. Therefore, when sepsis is highly suspected, antibiotics should be given for a “full course” even if culture results are negative.

Empiric therapy for early-onset sepsis generally uses combinations of antibiotics effective against gram-positive and gram-negative pathogens. The two most commonly used combinations are ampicillin with an aminoglycoside

(frequently gentamicin) and ampicillin with cefotaxime. Cefotaxime, a broad-spectrum third-generation cephalosporin, is used because of its reduced toxicity. However, the third-generation cephalosporins have been associated with rapid development of glycopeptide-resistant enterococci and with the selection of stably derepressed forms of  $\beta$ -lactamase-producing gram-negative bacteria (Bryan et al, 1985). Furthermore, none of the cephalosporins is effective against enterococci or *L. monocytogenes*.

After an organism has been isolated from culture, antibiotic therapy should be tailored according to its demonstrated sensitivities. *L. monocytogenes* is usually treated with ampicillin and an aminoglycoside until the blood culture result is negative. Enterococci are treated either with ampicillin and an aminoglycoside or with vancomycin, depending on sensitivity patterns. GBS can be safely treated with either ampicillin or penicillin. There are no data to suggest that the addition of an aminoglycoside improves morbidity or mortality in infants with bacteremia due to GBS. Most strains of *S. aureus* are resistant to ampicillin and penicillin because they produce  $\beta$ -lactamase. Therefore, infections with *S. aureus* are treated with penicillinase-resistant penicillins or cephalosporins. Methicillin-resistant *S. aureus* is sensitive to vancomycin. Gram-negative enteric organisms are generally sensitive to aminoglycosides. For gram-negative bacteria that are resistant to aminoglycosides, cefotaxime is a suitable alternative. Ceftriaxone is not commonly used because of the potential for displacement of bilirubin from albumin. *Pseudomonas aeruginosa* infections are commonly treated with ticarcillin or carbenicillin and an aminoglycoside, but most are also sensitive to ceftazidime.

Antibiotic therapy should be stopped as soon as the clinician believes the likelihood of infection is very low. Forty-eight hours are generally sufficient to determine that a blood culture result is truly negative. Infants with proven bacteremia (and without meningitis) are treated for 7 to 10 days. Dosing recommendations for commonly used antibiotics are presented in Appendix 1. Infants receiving potentially toxic antibiotics for more than 48 hours should undergo therapeutic drug monitoring.

### **Adjunctive Immunologic Therapies for Treatment of Early-Onset Sepsis**

In addition to conventional management (antibiotics and supportive care), adjunctive therapies, which attempt to modulate the immune status of the infant, have been investigated to reduce the mortality of neonatal sepsis. They include IVIG, granulocyte transfusions, and hematopoietic cytokines.

#### ***Intravenous Immune Globulin***

At the time of birth, the neonate has antibodies against any bacterial pathogens that the mother has been exposed to during her lifetime. These antibodies are actively transported across the placenta during the second half of gestation. There is very little endogenous production of antibody by the fetus unless infection occurs during fetal life (e.g., the TORCH [toxoplasmosis, other infections, rubella, cytomegalovirus, herpes simplex virus] infections).

Furthermore, preterm birth limits the amount of antibody the fetus receives. The lack of protective levels of antibody against specific pathogens significantly increases the susceptibility to infection and impairs the ability to recover from an infectious episode. For example, the absence of type-specific antibody against the capsular polysaccharide antigen of GBS is a significant risk factor for early-onset GBS sepsis (Baker and Kasper, 1976). For these reasons, the efficacy of administering IVIG as an adjunct treatment for neonatal sepsis has been investigated.

In 1994, Acunas and colleagues (1994) randomly assigned 67 infants with possible sepsis to receive either fresh frozen plasma or IVIG. Before that time, there were anecdotal reports on the benefits of administering fresh frozen plasma to infants with bacterial sepsis (Shigeoka et al, 1978). After 24 hours, these researchers found the plasma concentrations of immunoglobulins and IgG subclasses to be increased only in infants treated with IVIG, confirming the rationale for treatment with immunoglobulin rather than plasma. Sidiropoulos and associates (1986) conducted a randomized study to evaluate the use of IVIG in term and preterm neonates with bacterial sepsis. Study infants either received antibiotics alone or antibiotics plus IVIG for 6 days. There was no difference in overall mortality between the two groups; however, IVIG was found to significantly decrease the mortality in the preterm subgroup.

In 1988, Haque and coworkers investigated the use of an IgM-enriched immunoglobulin preparation. Infants in their study were randomly assigned to receive either antibiotic alone (controls) or antibiotic in combination with intravenous IgM-enriched immunoglobulin. Mortality due to sepsis was 20% in the control group but 3.3% in the group treated with the IgM preparation. In a second trial, the same group randomly assigned 130 term and preterm infants with suspected sepsis to receive a standard IVIG preparation, an IgM-enriched immunoglobulin, or supportive care alone (controls) for 4 days (Haque et al, 1995). Mortality from infection was 6.8% in the group receiving IgM-enriched immunoglobulin, 14.2% in the group given standard IVIG, and 25.5% in the control group. Although the overall mortality from sepsis was lower in the two immunoglobulin-treated groups than the control group, no advantages were demonstrated for administration of IgM-enriched therapy over standard IVIG.

Shenoi and associates (1999) reported a multicenter, placebo-controlled trial in which 58 term and preterm neonates were randomly assigned to receive IVIG or placebo. Although the placebo group contained a significantly greater number of babies with positive blood culture results (principally gram-negative organisms), no difference was found in mortality. Ohlsson and Lacy (2002) analyzed data from 13 randomized clinical trials in which infants with suspected sepsis were treated with supportive care alone or IVIG plus supportive care. Some of the trials were placebo-controlled. Although the mortality was lower with IVIG treatment in six studies ( $n = 318$ ) of infants in whom sepsis was suspected, there was no such reduction in mortality with IVIG in infants with subsequently proven infection ( $n = 262$ ). The analysis of the published studies was complicated by differences in design, IVIG preparation and dose, severity of infection, and infecting organisms. Ohlsson and Lacy (2002) concluded that there were insufficient data to

support the routine use of IVIG preparations to prevent death in suspected or proven infection in neonates.

Although data indicate that the use of IVIG in newborns appears safe, rare complications may occur. An outbreak of hepatitis C was reported in association with administration of IVIG (Flora et al, 1996), and dose-related immunosuppression with IVIG given at high doses (>2000 mg/kg) was detected in immunocompromised hosts (Cross et al, 1984). In addition, one report observed hemolysis in association with administration of IVIG to a neonate, secondary to an antigen-antibody reaction (Haque et al, 1988).

### **Granulocyte Transfusion**

The identification of functional and quantitative immaturity in neonatal phagocytic immunity has led investigators to postulate a role for granulocyte transfusions in the treatment of neonatal sepsis. In the early 1980s Laurenti and associates (1981) retrospectively analyzed data for infants who were given granulocyte transfusions as an adjuvant treatment for neonatal sepsis. A significant decrease in mortality (10% versus 72%) was observed, which was greatest in infants weighing less than 1500 g (10% versus 91%). A benefit of granulocyte transfusion was also demonstrated by Christensen and colleagues (1982), who performed a randomized controlled study on a population of neonates with overwhelming sepsis, neutropenia, and bone marrow neutrophil storage pool depletion. Survival was 100% in the seven treated neonates, and only 11% for the nine controls.

Both Baley and coworkers (1987) and Wheeler and associates (1987) evaluated the effects of stored buffy coat transfusion in neutropenic septic neonates. The total number of granulocytes transfused was approximately 50% less than in other studies. Neither of the studies was able to demonstrate effects on survival, and the researchers concluded that the efficacy of buffy coat transfusion remains questionable. Furthermore, in the study by Baley and coworkers, neutrophil storage pool depletion was rare among neutropenic infants.

In two studies published in 1984 and 1987, Cairo and associates demonstrated an increase in survival with granulocyte transfusions in infants with early-onset sepsis. These studies were unique, in that granulocytes were obtained by continuous-flow centrifugation and study patients received a total of five transfusions. In the first study, 23 septic and neutropenic infants (60% with positive blood culture results) were randomly assigned to receive either standard supportive care or granulocyte transfusions. Not one of the infants receiving granulocytes died, but mortality was 60% in the control group (Cairo et al, 1984). In 1992, the same group prospectively studied a population of neutropenic infants with early-onset sepsis in order to compare the effects of IVIG administration and granulocyte transfusion. Term and preterm infants, postnatal ages 3 to 8 days, were randomly selected to receive granulocyte transfusion or intravenous IVIG. Survival rate was 100% in the granulocyte-treated group and 64% in the IVIG-treated group (Cairo et al, 1992). A meta-analysis of 5 clinical studies designed to investigate the efficacy of granulocyte transfusion in

treatment of neonatal sepsis concluded that granulocyte transfusion did not provide a statistically significant benefit to neonates with culture-proven infections. (Vamvakas and Pineda, 1996).

### **Cytokines**

The recombinant forms of some hematopoietic growth factors have been investigated for their possible role in modulating host defense in infants, especially during periods of increased demand, such as overwhelming sepsis complicated by a low neutrophil count. G-CSF has a powerful ability to induce proliferation of neutrophil precursors and to mobilize neutrophils from the bone marrow into the circulation (Lieschke and Burgess, 1992a, 1992b). GM-CSF can prime term and preterm neutrophils for enhanced chemotaxis and respiratory burst responses (Jawson et al, 1994). Studies in newborn rats with induced sepsis have demonstrated that both G-CSF (Cairo et al, 1990) and GM-CSF (Frenck et al, 1990) improve survival.

In a controlled trial, Schibler and colleagues (1998) randomly assigned 20 infants with neutropenia and presumed early-onset sepsis to receive either G-CSF for 3 days or placebo. No significant differences in mortality were observed. Kocherlakota and La Gamma (1997) studied whether recombinant human G-CSF (rhG-CSF) could reverse sepsis-associated neutropenia and improve survival in early- and late-onset sepsis. Administration of rhG-CSF led to higher ANC than those seen in retrospectively selected, case-matched control patients with sepsis. In the early-onset sepsis group, 3 of the 5 neonates treated with antibiotics and supportive therapy died, but none of the neonates treated with rhG-CSF died. Miura and associates (2001) conducted a similar study in 44 preterm neonates with clinical diagnosis of early-onset sepsis. At 24 and 48 hours after treatment with G-CSF, the ANC significantly increased, but no effect on mortality was observed.

In a prospective controlled trial, 49 neutropenic infants with clinical signs of sepsis were randomly assigned to receive GM-CSF (for 7 consecutive days) or supportive care to determine whether G-CSF could reverse neutropenia and improve survival in early-onset sepsis (Bilgin et al, 2001). By day 7, the ANCs in the treated group were significantly higher than those in the control group. Furthermore, the mortality rate in the GM-CSF-treated group (10%) was significantly lower than in the control group (30%). In a small, randomized, placebo-controlled study of VLBW infants with neutropenia and clinical signs of sepsis, Bedford Russell and colleagues (2001) demonstrated that administration of rhG-CSF increased the ANC and lowered mortality. Bernstein and associates (2001) analyzed data from five randomized clinical trials in which infants with sepsis were treated with supportive care alone or a recombinant hematopoietic growth factor. Their analysis showed that the efficacy of G-CSF was unproven, even though there was a trend toward lower mortality. The lower-birth-weight neonates and neonates with neutropenia appeared most likely to benefit.

## NEONATAL BACTERIAL MENINGITIS\*

Neonatal bacterial meningitis remains a dreaded disease because of its mortality and its morbidity (in general terms, 20% and 50%, respectively; see prognosis discussion). As with sepsis, the incidence of purulent meningitis of the newborn infant varies among institutions and is higher in inner city hospitals, where prenatal care for the poor is suboptimal, and in complicated pregnancies and deliveries, especially those resulting in premature births. Incidence rates for neonatal meningitis are approximately one fourth to one tenth those for bacterial sepsis. The same pathogens that cause sepsis cause meningitis, with GBS and *E. coli* strains accounting for approximately 70% of all cases, and *L. monocytogenes* for an additional 5% in the first week of life. The other more common pathogens are *H. influenzae* and pneumococcus. Among infants who are hospitalized for longer than one week in neonatal intensive care units, *S. epidermidis* is the most common isolate. Risk factors for meningitis are identical to those for sepsis because bacteremia, if not actual sepsis, precedes seeding of the meninges with bacteria. Why some infants with sepsis also experience meningitis but most do not is not clear.

GBS meningitis usually manifests after the first several days of life, and the principal organism encountered in these infants is serotype III. The mortality rate is 20% to 40%. Streptococcal disease that occurs in the first 48 hours after delivery commonly manifests as acute respiratory distress with or without shock. Although the organism is frequently isolated from postmortem CSF cultures taken from these infants, histologic evidence of meningeal inflammation may be lacking (Franciosi et al, 1973).

Approximately 80% of all types of *E. coli* that cause meningitis possess the K1 antigen. The O18 and O7 somatic types and H6 and H7 flagellar types are most commonly associated with K1 strains cultured from CSF (Sarff et al, 1975). The presence, concentration, and persistence of this capsular polysaccharide antigen in CSF and blood of infants with meningitis correlate directly with the outcome of the disease (Franco et al, 1992). The concentration and persistence of interleukin-1 $\beta$  and TNF- $\alpha$ , the principal mediators of meningeal inflammation, correlate with an adverse outcome (Dodge, 1994; McCracken et al, 1989; Mustafa et al, 1989; Velasco et al, 1991). The mortality rates for neonatal *E. coli* meningitis vary from 20% to 30% in some centers to 50% to 60% in others. These figures have been relatively constant despite improvements in overall perinatal mortality.

### Pathology

The pathologic findings in neonatal meningitis are similar regardless of the bacterial etiology. The most consistent findings at necropsy of babies who die of meningitis are purulent exudate of the meninges and of the ependy-

mal surfaces of the ventricles associated with vascular inflammation. The inflammatory response of newborns is similar to that observed in adults with meningitis, except that babies have a paucity of plasma cells and lymphocytes during the subacute stage of meningeal reaction. Hydrocephalus and a noninfectious encephalopathy can be demonstrated in approximately 50% of infants who die of meningitis. Subdural effusions occur rarely in newborns; in contrast, this complication of meningitis is common in infants 3 to 12 months old. Varying degrees of phlebitis and arteritis of intracranial vessels can be found in all infants who die of meningitis. Thrombophlebitis with occlusion of veins may occur in the subependymal zones. K1 antigen has been demonstrated in the brain tissue of infants who die of *E. coli* K1 infection.

### Clinical Manifestations

The early signs and symptoms of neonatal meningitis are commonly indistinguishable from those of septicemia. Specific findings, such as stiff neck and Kernig and Brudzinski signs, are commonly absent (85% of the time) but should be sought because of their usefulness if present. Lethargy, feeding problems, and altered temperature are the most common presenting symptoms, and respiratory distress, anorexia, vomiting, apnea, jaundice, diarrhea, and abdominal distention are common findings. A bulging fontanelle may be a late sign of meningitis but can be confused with subgaleal hemorrhage, cephalohematoma, or caput succedaneum. Poor muscle tone (heel-to-head maneuver and vertical sling, for example) is extremely common for infants with either sepsis, meningitis, or both. Seizures are observed frequently and may be caused by direct central nervous system inflammation or may occur in association with hypoglycemia, hyponatremia, or hypocalcemia. Table 39–8 lists the differential diagnoses of infants presenting with the similar signs or symptoms of sepsis or meningitis.

### Diagnosis

Although analysis of the CSF is the gold standard for diagnosis of meningitis, it is imperfect for reasons similar to those previously discussed for blood cultures, and the interpretation of CSF cell counts in newborn infants may be difficult (Polk and Steele, 1988; Unhanand et al, 1993). Table 39–9 summarizes the characteristics of neonatal CSF for newborn infants as reviewed by Klein (2001). During the first week, the white cell count slowly diminishes in full-term infants but may remain high or may even increase in premature babies. Cell counts in the range of 0 to 10 cells/mm<sup>3</sup> are observed at 1 month of age. The percentage ratio of CSF glucose level to blood glucose level is 44% to more than 100% in both preterm and term infants. Although the CSF cell counts and protein and sugar concentrations from normal infants can overlap with those from infants with meningitis, less than 1% of babies with proven meningitis have totally normal results on a CSF analysis of a specimen from the initial lumbar puncture (Hristeva et al, 1993). Approximately 50% of all

Data from Klein JO: Bacterial sepsis and meningitis. In Remington JS, Klein JO (eds): *Infectious Diseases of the Fetus and Newborn Infant*, 5th ed. Philadelphia, WB Saunders, 2001, p. 966.

infants with positive results of CSF cultures for bacteria have negative blood culture results (Shattuck and Chonmaitree, 1992).

Stained smears of CSF must be examined carefully for every infant with suspected meningitis. Grossly clear fluid may contain few white blood cells and many bacteria. The stained smears from approximately 20% of newborns with proven meningitis are interpreted as showing no bacteria. As its name implies, *L. monocytogenes* commonly evokes a mononuclear cellular response in the CSF.

Difficult clinical choices must be made when (1) an infant is judged too unstable to undergo a lumbar puncture, (2) the puncture is traumatic or unproductive of fluid, or (3) the results of the CSF analysis are equivocal. Estimates of traumatic lumbar puncture, “dry tap,” and inadequate volume of CSF together are as high as 25% depending on the experience and persistence of those performing the procedure. In my experience, bloody or dry lumbar punctures are minimized, and hypoxemia is reduced, when the infant is placed in the flexed sitting position. For infants receiving ventilator therapy, less extreme hip flexion in the lateral position may minimize stress (Gleason et al, 1983; Weisman et al, 1983). Both preoxygenation through an increase in fractional inspired

oxygen (FiO<sub>2</sub>) and local anesthesia have merit and are standard procedures among caring clinicians and nurses. For an infant who is too unstable to undergo a lumbar puncture or after a “dry tap,” the clinician must rely on other features of the clinical picture and choose to treat for meningitis if those warrant it. Blood in the CSF does not necessarily indicate a traumatic puncture (meaning that a blood vessel has been nicked by the needle aiming for CSF). Depending on the ego of the clinician performing the procedure, other causes of blood in the CSF should be sought with more or less rigor.

## Therapy

It is the rare infant with meningitis who is not severely ill, and therefore, newborns with meningitis need multisystem, aggressive management in the setting of an intensive care unit. In addition to antibiotic therapy, these infants frequently require mechanical ventilation, compulsive fluid management to minimize the effects of cerebral edema and, inevitably, of capillary leak and inappropriate secretion of antidiuretic hormone (ADH), seizure control, vasopressor support, and cardiopulmonary monitoring. Selection of

‡Nine cases, 0-28 days.

Data from Klein JO: Bacterial sepsis and meningitis. In Remington JS, Klein JO: Infectious Diseases of the Fetus and Newborn Infant, 5th ed. Philadelphia, WB Saunders, 2001, p 973.

appropriate antibiotic therapy is based in part on the achievable CSF levels of these drugs in relation to the susceptibility of the organisms that cause the disease. The highest kanamycin and gentamicin concentrations in CSF are approximately 40% of the peak serum levels and are only equal to or slightly greater than the minimal inhibitory concentrations (MICs) for disease-causing coliform bacteria. In contrast, CSF penicillin and ampicillin concentrations may be only 10% of the corresponding peak serum levels, but these values are usually 10- to 100-fold higher than the greatest minimal inhibitory concentrations for group B streptococci and *L. monocytogenes*. The ability to attain CSF antimicrobial activity that is many times greater than is necessary to inhibit the pathogen may explain the rapid sterilization of CSF cultures from infants with gram-positive meningitis.

Delayed sterilization of CSF cultures from newborns with gram-negative meningitis may likewise be due to the low inhibitory and bactericidal CSF concentrations. Therefore, in some infants with coliform meningitis, one should alter the therapeutic regimens by adding a second antibiotic, selecting a different aminoglycoside, using one of the newer cephalosporin derivatives, or changing the route of administration. In addition, dosage and timing should be guided by renal, hepatic, and cardiopulmonary function. When possible, individualizing drug regimens on the basis of regular measurement of serum drug concentrations permits the attainment of therapeutic antibiotic effects and the avoidance of toxicity.

In the United States, ampicillin and either gentamicin or kanamycin are recommended as the initial therapy for neonatal meningitis. An alternative regimen of ampicillin and a cephalosporin (e.g., cefotaxime) can be used, but frequent use of such a regimen may lead to emergence of cephalosporin-resistant gram-negative bacterial isolates. Chloramphenicol, because of its capacity to diffuse readily into the CSF, has been used in neonatal meningitis and, with frequent measurement of blood levels.

It may be prudent to repeat a CSF examination and culture after initiation of therapy, especially if the clinical response is less than satisfactory. If organisms are seen on methylene blue-stained or gram-stained smears of the fluid, modification of the therapeutic regimen should be considered. In general, approximately 3 days are required for an antibiotic regimen to sterilize the CSF in infants with gram-negative meningitis. In infants with gram-positive meningitis, sterilization is usually seen within 36 to 48 hours. Neuroimaging should be considered to exclude parameningeal foci and abscess and to assist in the prognosis.

Some adjunctive therapies have been tried, and others appear promising, but none has widespread use at the present time. Neither intrathecal nor intraventricular administration of antibiotics significantly improves morbidity or mortality in infants with gram-negative meningitis. Although dexamethasone is clearly useful in experimental models of meningitis (Kim et al, 1995), it has not been proved useful in clinical trials for newborn infants (Daoud et al, 1999). New therapies that relate to inducible nitric oxide synthase or endothelin inhibition are being explored. These strategies aim at maintenance of adequate blood flow during inflammation and, thereby, minimization of ischemic injury, which

is of major importance in the disease process (Leib et al, 1998; Pfister et al, 2000).

Once the pathogen has been identified and the susceptibility study results are available, the single drug or combination of drugs that is most effective should be used. In general, penicillin or ampicillin is preferred for GBS infection; ampicillin with or without kanamycin or gentamicin for infection with *L. monocytogenes* and *Enterococcus*; ampicillin plus gentamicin or kanamycin for infection with coliform bacteria; and carbenicillin plus gentamicin for *Pseudomonas* infections. There is no precise method for determining the duration of antimicrobial therapy. A useful guide is to continue therapy for approximately 2 weeks after sterilization of CSF cultures or for a minimum of 2 weeks for gram-positive meningitis and 3 weeks for gram-negative meningitis, whichever is longer.

## Prognosis

The mortality rate in neonatal meningitis is high. The overall mortality rate remains approximately 20% to 50%, depending on the pathogen, the time of onset of disease, the degree of maturity of the patient, and the timing and adequacy of treatment. Short-term and long-term sequelae of neonatal meningitis occur frequently (Dodge, 1994; Edwards et al, 1985; Franco et al, 1992; Unhanand et al, 1993). The complications include brain abscess, communicating or noncommunicating hydrocephalus, subdural effusions, ventriculitis, deafness, and blindness. The extent of damage in survivors is in general related to the severity of the disease that is evident in the neonatal period. The spectrum of outcomes is not dissimilar from those for infants with moderate to severe asphyxia, in part because of the central nervous system ischemia related to the meningitis. Like infants with moderate asphyxia, the infant who has experienced meningitis may appear relatively normal at the time of discharge, and only after prolonged and careful follow-up do perceptual difficulties, reading problems, or signs of minimal brain damage become apparent. Approximately 40% to 50% of survivors have some evidence of neurologic damage, with severe damage obvious in 11%. Infants who survive neonatal meningitis should have regular audiology, language, and neurologic evaluations until they enter school (Edwards et al, 1985; Stevens et al, 2003).

## Nosocomial Infections in the Nursery

Ira Adams-Chapman and Barbara J. Stoll

Nosocomial infections are a significant cause of morbidity and late mortality among neonates (Stoll et al, 1996). There are numerous risk factors for acquiring a nosocomial infection, but the most important are prematurity, interventions associated with intensive care, and prolonged length of hospital stay. The duration of hospital stay is inversely related to birth weight and gestational age and directly related to comorbidities, such as respiratory disease and nosocomial infection (Mahieu et al, 2001a; Pittet et al, 1994). In addition to the greater financial burden of nosocomial infections, there is growing concern that the deleterious effects of the inflammatory response to infection may adversely affect long-term outcomes, including bronchopulmonary dysplasia and neurodevelopmental impairment (Adams-Chapman and Stoll, 2001; Gonzalez et al, 1996; Jobe and Ikegami, 1998; Leviton et al, 1999; Rojas et al, 1995; Stoll et al, 2003).

The growing numbers of surviving very low-birth-weight (VLBW) infants magnifies the effect of this problem. Clinicians must be aware of and make efforts to minimize exposure of newborns to known risk factors for infection. Continuous surveillance and monitoring of endemic nosocomial infection rates and patterns of responsible pathogens are necessary to establish a reference point in each nursery and facilitate early identification of epidemics. This also provides the framework for the design of intervention strategies to reduce nosocomial infections in the nursery.

### DEFINITIONS

Infections that manifest early in the first week of life are typically related to perinatal risk factors and vertical transmission from the mother. Nosocomial infections are more often related to patient colonization and environmental risk factors. Unfortunately, there is no specific postnatal age that distinguishes maternally transmitted infections from hospital-acquired infections (Baltimore, 1998). Most sources define nosocomial infections as infections occurring after 3 days of age (Baltimore, 1998; Stoll et al, 2002a). The Centers for Disease Control and Prevention (CDC) defines nosocomial infection as any infection that occurs after admission to the neonatal intensive care unit (NICU) and that was not transplacentally acquired (Garner et al, 1988). Other authorities suggest that nosocomial infections be defined as infections occurring more than 5 to 7 days after birth (Baltimore, 1998).

The lack of uniform definitions for nosocomial infections makes surveillance and comparisons between hospi-

tals difficult (Baltimore, 1998; Goldmann, 1989). The CDC has established uniform definitions for nosocomial infections in adult and neonatal patients, but these definitions are not universally accepted (Garner et al, 1988). Criteria for nosocomial infections common in the neonatal population are outlined in Table 40-1 (Garner et al, 1988). These definitions allow for comparisons between centers and serve as a tool to monitor quality improvement after instituting an intervention program. Of note, the diagnoses easiest to define and compare are blood culture-proven blood stream infections and necrotizing enterocolitis (NEC).

The majority of nosocomial infections in the neonatal population are blood stream infections associated with an intravascular device. Criteria for catheter-related blood stream infections (CRBSIs), as defined by the CDC, are (1) isolation of a recognized pathogen from one blood culture specimen or of a skin commensal from two blood culture specimens, (2) one or more clinical signs of infection, such as temperature instability, apnea, and bradycardia, and (3) presence of an intravascular device at the time the culture specimen is collected (Pearson, 1996).

### INCIDENCE

#### Well Baby Nursery

Nosocomial infections are uncommon in the well baby nursery. Accurate rates of nosocomial infection in the well baby nursery are difficult to ascertain because there is no systematic reporting or surveillance network for this issue; however, the incidence appears to be exquisitely low. Some researchers estimate rates of less than 1 per 100 patients discharged (Baltimore, 1998). Typical risk factors for acquiring a nosocomial infection, such as an invasive procedure and presence of an intravascular device, are uncommon in the healthy newborn population. Discharge from the hospital within 48 hours of birth and rooming-in practices have helped further decrease the risk of exposure in modern mother-baby units. Early discharge may further limit surveillance efforts, because patients may be discharged home before they become symptomatic from hospital-acquired infections (Goldmann, 1989).

#### Neonatal Intensive Care Unit

The majority of neonatal nosocomial infections occurs in term and preterm infants hospitalized in special care nurseries. It is difficult to determine and compare reports of endemic nosocomial infection rates in different NICU populations. Comparison of surveillance data between institutions is limited by differences in patient demographics (e.g., birth weight and gestational age distribution, underlying severity of disease, babies born in the hospital versus those born elsewhere), back transport policies, and the use of different definitions for nosocomial infection.

Among a cohort of 6215 VLBW infants (<1500 g) who were monitored by the National Institute of Child Health and Human Development (NICHD) Neonatal Research Network, 21% of those who survived beyond 3 days of age had at least one episode of late-onset sepsis (Stoll et al,

TABLE 40-1

**Definitions of Nosocomial Infections for Patients Younger than 12 Months, from the Centers for Disease Control and Prevention**

Nosocomial blood stream infections	<ol style="list-style-type: none"> <li>1. Recognized pathogen isolated from blood culture and pathogen is not related to infection at another site.</li> <li>2. Skin commensal isolated from two blood culture specimens on separate occasions or skin contaminant isolated from a patient with an intravascular device and clinical signs of infection (temperature instability, apnea, or bradycardia) and antimicrobial therapy is initiated.</li> <li>3. Clinical sepsis, defined as clinical signs of infection (temperature instability, hypotension, apnea, or bradycardia) without a recognized cause and all of the following: <ul style="list-style-type: none"> <li>Blood culture specimen not collected or result negative</li> <li>No apparent infection at another site</li> <li>Therapy instituted for sepsis</li> </ul> </li> </ol>
Pneumonia	<p>Chest radiograph with new or progressive infiltrate, cavitation, consolidation or pleural effusion and clinical evidence of increased respiratory secretions, purulent sputum or change in character of sputum</p> <p>Isolation of pathogens from transtracheal aspirate, bronchial washing or biopsy specimen</p> <p>Isolation of virus from secretions</p> <p>Histopathologic evidence of pneumonia</p>
Eye/ear/nose/throat infection	Superficial infections involving the eyes, external or middle ear, sinuses, or nares
Necrotizing enterocolitis	<p>Two of the following symptoms with no other recognized cause:</p> <p>Vomiting</p> <p>Abdominal distention or pre-feeding residuals and persistent microscopic and gross evidence of blood in the stool</p> <p>Radiographic findings consistent with pneumoperitoneum, pneumatosis intestinalis, or fixed bowel loops</p>

Modified from Garner JS, Jarvis WR, Emori TG, et al: CDC definitions for nosocomial infections, 1988. *J Infect Control* 16:128-140, 1988.

2002b). There was significant variability among the participating centers, with rates ranging from 10.6% to 31.7% at individual sites (Stoll et al, 2002b). Moreover, rates were inversely related to birth weight and gestational age, ranging from 43% for infants weighing 401 to 750 g at birth to 7% for infants weighing 1251 to 1500 g at birth. These data are similar to those reported by Brodie and colleagues (2000). In their study, 19% of 1354 infants weighing less than 1500 g at birth had nosocomial infections, and the rates were highest for infants at the lowest birth weights (39%, <750 g; 27%, 750-999 g; 10%, 1000-1499 g). A point prevalence survey conducted by the 29 level II to level IV nurseries participating in the Pediatric Prevention Network revealed a prevalence of 11.4% for nosocomial infection (Sohn, 2001).

Some investigators believe that reporting overall incidence rates may be misleading because of the wide varia-

tions in practice and patient populations in different units. Therefore, the National Nosocomial Infections Surveillance (NNIS) system monitors device-associated nosocomial infection rates by using an approach that accounts for variability in device utilization and length of hospital stay (Emori et al, 1991; Gaynes et al, 1996). These data are also stratified by birth weight categories and expressed as incidence density per 100 or 1000 patient-days. These two adjustments modify the relative risk on the basis of the severity of the illness and the duration of exposure to the risk factor. The small number of participating centers with high-risk nurseries confounds interpretation of NNIS data. However, these data are similar to institutional and collaborative epidemiologic data reported elsewhere. Rates of device-associated infections are presented in Table 40-2. These rates remained constant in the 1990s (Gaynes et al, 1996; National, 2000). The adverse effect of low birth

TABLE 40-2

**Rate of Device-Associated Nosocomial Infections**

Birth Weight (g)	Infections/1000 Device Days		VAP/1000 Vent Days	
	Gaynes et al (1999)	Stover et al (2001)	Gaynes et al (1996)	Stover et al (2001)
<1000	11.4	12.8	4.8	3.5
1001-1500	6.9	8.9	3.6	4.9
1501-2500	4.0	4.7	2.9	1.1
>2500	3.8	4.4	2.6	0.9

VAP, ventilator-associated pneumonia.

weight on the rate of infection is evident for catheter-related blood stream infections. Of interest, the rates of ventilator-associated pneumonia are more consistent across weight groups.

## ANATOMIC SITES OF INFECTION

### Well Baby Nursery

Nosocomial infections in the well baby nursery are most commonly superficial, involving the skin, mouth, or eyes. These infections include omphalitis, pustules, abscesses, and bullous impetigo (Goldmann, 1989). Nursery epidemics of diarrhea caused by bacterial and viral enteropathogens have been reported, but they occur infrequently (Goldmann, 1989).

### Neonatal Intensive Care Unit

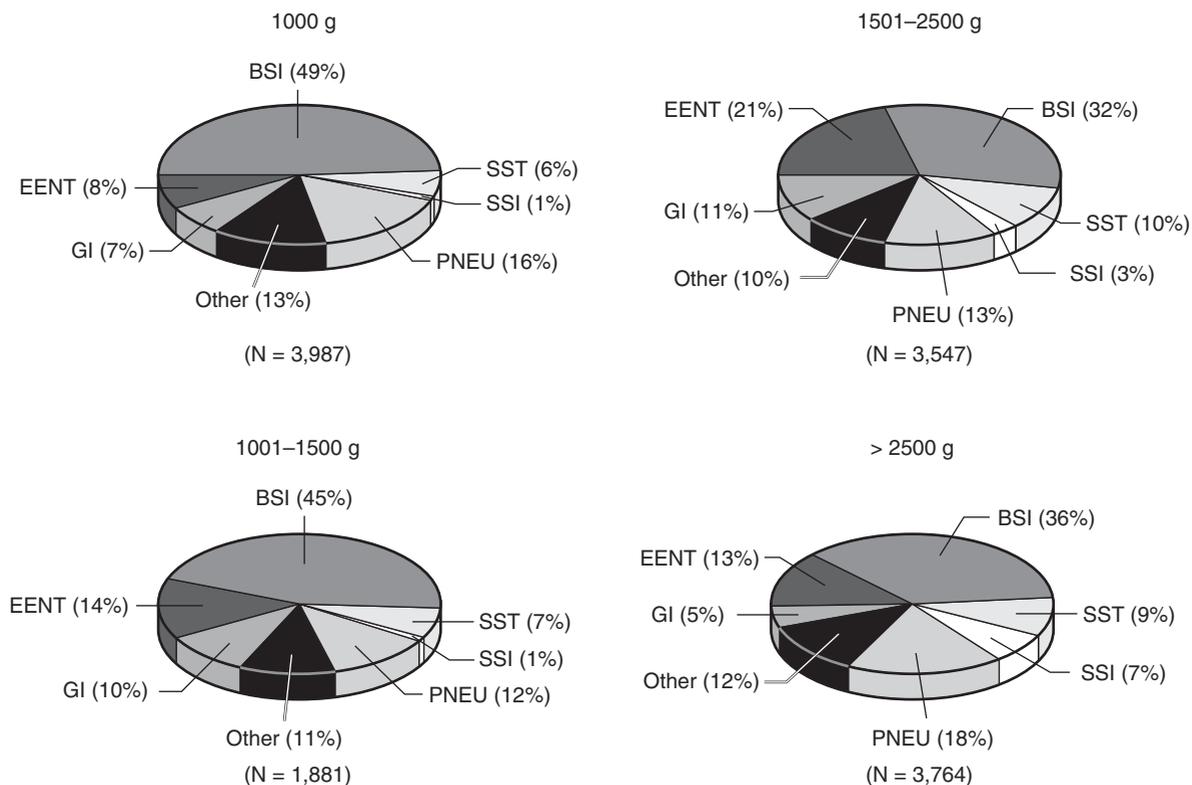

National and institutional surveillance data demonstrate that blood stream infections are responsible for the majority of nosocomial infections among NICU patients (Gaynes et al, 1996; National, 2000; Sohn et al, 2001). The remaining cases involve the respiratory tract, eye, ear, nose, and throat, or gastrointestinal tract (Fig. 40-1). Surveillance data for meningitis are limited. There are widespread differences in clinical practice regarding the inclusion of a lumbar puncture with cerebrospinal fluid analysis in the evaluation of an infant with suspected sepsis. Reports suggest that late-

onset meningitis may be underdiagnosed in the high-risk population of VLBW infants (Stoll et al, 2002b).

## RISK FACTORS

Some risk factors for acquiring a nosocomial infection are reflections of the patient population and cannot be modified. Other risk factors are directly related to the level of supportive care associated with intensive care medicine. Risk factors for nosocomial infection are lower gestational age and low birth weight; invasive procedures; invasive devices, especially intravascular catheters and endotracheal tubes; parenteral nutrition and intravenous lipids; colonization of skin, gastrointestinal tract, and airway with invasive organisms; selected drugs administered to the neonate; and issues surrounding nursery staffing, nursery crowding, and hand washing (Table 40-3) (Gaynes et al, 1996; Kawogoe et al, 2001; Stoll et al, 1996, 2002a; Stover et al, 1996; Suara et al, 2000). Minimizing exposure to known risk factors for infection is important to attempts to reduce the rate of nosocomial infections in the nursery.

The risk for development of a nosocomial infection is inversely related to gestational age and birth weight (Gaynes et al, 1996; Kawogoe et al, 2001; National, 2000; Stoll et al, 1996, 2002a; Stover et al, 1996; Suara et al, 2000). Previous reports estimate that there is a 3% higher risk of acquiring a nosocomial infection with each 500-g increment in birth weight (Goldmann, 1989). Infants with birth weights less than 1000 g have twice the rate of nosocomial blood stream

**FIGURE 40-1.** Distribution of nosocomial infections by site of infection. (Data from Gaynes RP, Edwards JR, Jarvis WR, et al: Nosocomial infections among neonates in high-risk nurseries in the United States. *Pediatrics* 98:357-361, 1996.)

TABLE 40-3

**Risk Factors for Acquiring Nosocomial Infection in the Neonatal Intensive Care Unit**

Prematurity
Low birth weight
Invasive device
Intravascular device (PIVC, umbilical catheter, PICC, CVC, PAL)
Mechanical ventilator
Urinary catheter
Ventriculoperitoneal shunt
Medications
Histamine <sub>2</sub> -blocking agents
Steroids
Others
Prolonged administration of hyperalimentation
Intralipid administration
Delayed enteral feedings
Feeding with formula rather than human milk
Inadequate nursery staffing and overcrowding
Poor compliance with handwashing

CVC, central venous catheter; PAL, percutaneous arterial line; PIVC, percutaneous intravenous catheter; PICC, peripherally inserted central catheter.

infections than infants with birth weights greater than 1000 g (Brodie et al, 2000; Gaynes et al, 1996; National, 2000; Stoll et al, 2002a; Stover et al, 1996). Severity of illness scores may be more predictive than birth weight alone, because they reflect physiologic stability and the cumulative need for intervention and invasive therapies (Goldmann, 1989; Gray et al, 1995).

The use of any type of invasive device increases the risk for infection. The most common invasive devices used in the nursery are intravascular catheters, mechanical ventilators, ventriculoperitoneal shunts, and urinary catheters. In general, the risk rises as the duration of exposure lengthens. Compared with adult patients, neonates are at higher risk for catheter-related blood stream infections and at lower risk for ventilator-associated and urinary tract infections. (Langley et al, 2001; National, 2000). These patterns correlate with the frequency with which these devices are used in the neonatal patient population.

Prolonged duration of mechanical ventilation is the primary risk factor for development of hospital-acquired pneumonia. Contamination of respiratory equipment—especially with gram-negative organisms that thrive in moist environments, such as *Acinetobacter*, *Pseudomonas*, and *Flavobacterium*—frequently lead to colonization of the respiratory tract. We speculate that aspiration of colonized gastric and oropharyngeal secretions around the uncuffed endotracheal tube may also occur. The various closed-system suctioning devices may decrease the risk of iatrogenic contamination during suctioning.

Intravascular devices commonly used in the neonatal population are peripheral intravenous catheters (PIVs), umbilical catheters, peripherally inserted central catheters (PICCs), surgically placed central venous catheters (CVCs) and percutaneous arterial catheters (PALs). Regardless of the type of device used, the rate of catheter-related blood stream infections is directly related to the number of days

catheters are in place and inversely related to the gestational age and birth weight of the patients (Gaynes et al, 1996; Kawogoe et al, 2001; National, 2000; Stoll et al, 2000a; Suara et al, 2000). Coagulase-negative staphylococci (CONS) remain the primary pathogens associated with catheter-related blood stream infections.

PIVs are the most commonly used device for vascular access in the neonate. In adults, removal of such catheters after 72 hours is recommended. Data in neonates are insufficient to recommend elective removal of PIVs after 72 hours, because studies have not shown a clear correlation between the higher colonization rate noted after 72 hours and an increased rate of catheter-related blood stream infection (Oishi, 2001; Pearson, 1996). Additional studies are needed to answer this question.

At present, data comparing the infection rates of the various types of intravascular catheters are limited. Theoretically, the risk should be lower for tunneled catheters because the Dacron cuff proximal to the exit site of a surgically placed catheter may inhibit the migration of organisms into the catheter tract (Mermel et al, 2001). Adult data suggest that tunneled catheters have lower infection rates than nontunneled catheters. This issue needs further study in the neonatal population, especially because PICCs are being used with greater frequency for long-term vascular access in neonates (Stoll et al, 2002a). A retrospective cohort study comparing infection rates between infants with PICCs with those with PIVs found no difference in the rates of catheter-related blood stream infection (Parellada et al, 1999).

The use of intravenous lipid emulsions (e.g., Intralipid) increases the risk for infection (Freeman et al, 1990). Lipid emulsions decrease the flow rate through the intravenous catheter and potentiate the growth and proliferation of some microorganisms. Lipid emulsions may interfere with host defense mechanisms by impairing the function of neutrophils and reticuloendothelial macrophages (Freeman et al, 1990; Langevin et al, 1999; Nugent, 1984). Extrinsic contamination has been reported but rarely occurs in the United States (Hernandez-Ramos et al, 2000). Freeman and associates (1990) reported that the use of a lipid emulsion was positively and independently predictive for the development of CONS bacteremia. Infants who demonstrated CONS sepsis were 5.8 times more likely to have been exposed to lipid emulsions. Administration of such emulsions has also been linked to a higher risk for nosocomial infection with *Candida* and *Malassezia* spp. in neonates (Long and Keyserling, 1985; Redline et al, 1985; Saiman et al, 2000).

Histamine-blocking agents and postnatally administered corticosteroids are the medications most commonly associated with an increased risk of nosocomial infections among newborns. It is hypothesized that the reduced gastric pH associated with the use of histamine<sub>2</sub>-blocking agents promotes bacterial overgrowth and invasion of pathogenic bacteria (Beck-Sague et al, 1994; Stoll et al, 1999). Others speculate that the use of these medications is a marker for infants with gastroesophageal reflux who may be at a higher risk for aspiration pneumonia (Stoll et al, 1999). Previously, dexamethasone was used in ventilator-dependent preterm infants to facilitate weaning from the ventilator and to minimize the risk of chronic lung

disease. Current data support minimizing use of this drug in VLBW infants, secondary to concerns of spontaneous bowel perforation and an adverse effect on growth and neurodevelopmental outcome (O'Shea et al, 1999; Stark et al, 2001, Vohr et al, 2000). The use of dexamethasone has been associated with an increased risk of infection in VLBW infants (Stoll et al, 1999, Yeh et al, 1997).

Nursery design and staffing influence the risk of infection. Overcrowding and larger workloads decrease compliance with hand washing and raise the risk of nosocomial infection (Archibald et al, 1997, Fridkin et al, 1996; Harbarth et al, 1999; Robert et al, 2000; Vicca, 1999). Inadequate numbers of staff and the use of temporary or inexperienced staff both adversely affect the rate of infection. The adverse impact of inadequate staffing and overcrowding were nicely demonstrated by Haley and Bregman (1982), who showed a relationship between nurse-to-patient ratio and colonization of patients with methicillin-resistant *Staphylococcus aureus* (MRSA). Fridkin and colleagues (1996) found that patient-to-nurse ratio was an independent predictor of development of a catheter-related blood stream infection. Furthermore, strategic nursery design and improvement in nursing staffing correlate with a lower rate of nosocomial infections (Gladstone et al, 1990).

### DISTRIBUTION BY PATHOGEN

The predominant pathogens responsible for nosocomial blood stream infections have changed over time. Goldmann (1989) proposed that these trends are explained by changes in the neonatal intensive care patient population and advancing technology. *S. aureus* was the most common nosocomial pathogen in the 1950s and 1960s. In the 1960s and 1970s, gram-negative organisms emerged as the predominant pathogens; globally, these organisms remain the most important pathogens responsible for nosocomial infections in the nursery (Stoll, 2001). National surveillance data indicate that CONS are currently the most common nosocomial pathogens (Gaynes et al, 1996; National, 2000) (Table 40-4). In the United States, the distribution of pathogens has not changed significantly over the past decade (Gaynes et al, 1996; Stoll et al, 1996, 2002a) (Table 40-5). Among a cohort of infants of birth weights less than 1500 g with late-onset infections, the NICHHD Neonatal Research Network reported that gram-positive organisms were responsible for 70% of cases, gram-negative organisms for 18%, and fungi for 12% (Stoll et al, 2002a). These findings are similar to those of a 10-year retrospective analysis of pathogens in a single center, in which gram-positive organisms caused 57% of late-onset infections (Karlowski et al, 2000). The distribution of infecting pathogens did not differ with birth weight or timing of infection (Stoll et al, 2002a).

For the clinician, understanding the specific colonization and resistance patterns in the individual NICU is perhaps more important than being aware of national trends. The emergence of nosocomial pathogens with antimicrobial resistance is a concern. In patients of all ages, reports estimate that 50% to 60% of nosocomial infections are caused by resistant organisms (Jones, 2001; Weinstein, 1998). Surveillance data indicate that the organisms show-

TABLE 40-4

#### Distribution of Pathogens Responsible for Blood Stream Infections

Pathogen	No.	%
Coagulase-negative staphylococci	3833	51.0
<i>Staphylococcus aureus</i>	563	7.5
Group B streptococcus	597	7.9
<i>Enterococcus</i> spp.	467	6.2
<i>Candida</i> spp.	518	6.9
<i>Escherichia coli</i>	326	4.3
Other <i>Streptococcus</i> spp.	205	2.7
<i>Enterobacter</i> spp.	219	2.9
<i>Klebsiella pneumoniae</i>	188	2.5

Data from Gaynes RP, Edwards JR, Jarvis WR, et al: Nosocomial infections among neonates in high-risk nurseries in the United States. *Pediatrics* 98:357-361, 1996.

ing patterns of increasing antibiotic resistance of importance to NICU patients are vancomycin-resistant enterococci (VRE), MRSA, and multidrug-resistant gram-negative organisms.

### Gram-Positive Bacteria

CONS are the most common endemic nosocomial pathogens in neonates (Brodie et al, 2000; Gaynes et al, 1996; Gray et al, 1995; National, 2000; Stoll et al, 2002a). The majority of CONS infections are blood stream infections.

TABLE 40-5

#### Common Pathogens Causing Nosocomial Infections

Gram-positive organisms	Coagulase-negative staphylococci <i>Staphylococcus aureus</i> <i>Enterococcus</i> spp. Group B <i>Streptococcus</i>
Gram-negative organisms	<i>Escherichia coli</i> <i>Klebsiella</i> <i>Pseudomonas</i> <i>Enterobacter</i> spp. <i>Serratia</i> <i>Haemophilus</i> spp. <i>Acinetobacter</i> <i>Salmonella</i>
Fungal organisms	<i>Candida albicans</i> <i>Candida parapsilosis</i> <i>Malassezia furfur</i>
Viral organisms	Respiratory syncytial virus Influenza Varicella zoster Rotavirus Enterovirus

Data from Gaynes RP, Edwards JR, Jarvis WR, et al: Nosocomial infections among neonates in high-risk nurseries in the United States. *Pediatrics* 98:357-361, 1996; and Stoll BJ, Hansen N, Fanaroff AA, et al: Late-onset sepsis in very-low-birth-weight neonates: The experience of the HICHHD Neonatal Research Network. *Pediatrics* 110:285-291, 2002.

Reported incidence ranges from 51% to 78% among VLBW infants (Gray et al, 1995; Isaacs et al, 1996; Stoll, 2002a; Stoll et al, 1996). Gray and colleagues (1995) reported a cumulative incidence of 17.5 episodes of CONS sepsis per 100 patient-days and an incidence density of 6.9 episodes of CONS sepsis per 1000 patient-days.

Known risk factors for CONS infection are low birth weight, lower gestational age, use of central venous catheters, prolonged administration of hyperalimentation, use of intravenous lipid emulsions, postnatal administration of corticosteroids, and prolonged hospital stay (Brodie et al, 2000; Freeman et al, 1990; Goldmann, 1989; Johnson-Robbins et al, 1996). CONS is the pathogen most commonly associated with catheter-related infections, partially because they produce capsular polysaccharide adhesin (poly-*N*-succinyl glucosamine), which enhances their ability to adhere to intravascular devices. Although preliminary studies suggest that prophylactic use of vancomycin reduces the risk of CONS catheter-related infections, this practice is not recommended because of the serious risk of encouraging antibiotic-resistant organisms, especially VRE and staphylococci.

Enterococci are responsible for both endemic and epidemic nosocomial infections in the NICU. Use of central venous catheters, prolonged hospital stay, and prior antibiotic use are recognized risk factors for colonization with these organisms. The gastrointestinal tract is often the primary source of infection; however, the pathogens are typically spread via the hands of health care workers or through environmental contamination. The widespread use of antibiotics has led to the emergence of VRE. There are published guidelines to prevent the spread of VRE, which include hand washing, isolation, barrier precautions, and cohorting of infected patients (Gross and Pujat, 2001; Recommendations, 1995). Educational programs to limit the indiscriminate use of antibiotics have been effective in decreasing the spread of VRE (Goldman et al, 1996; Isaacs, 2000).

*S. aureus* has caused epidemics in both the well baby nursery and the NICU. In the nursery, the major reservoir for staphylococci is colonized or infected infants. These infants transmit the organism to health care workers, who subsequently infect other infants. The skin, nares, and umbilicus are the most common sites of colonization. Unfortunately, routine surveillance cultures are not useful because colonization rates correlate poorly with infection rates. Studies in adult patients have shown that many patients who demonstrate *S. aureus* bacteremia were colonized with the identical strain at the time of admission to the hospital, suggesting that some of the infections with *S. aureus* are community acquired rather than hospital acquired (von Eiff et al, 2001). Similarly, health care workers may be colonized with a community-acquired strain of *S. aureus*, which they then transfer to vulnerable infants.

Group B streptococci (GBS) remain an important cause of late-onset infection in neonates. Intrapartum antibiotic treatment to prevent vertical transmission of GBS from a colonized mother to her infant has led to a dramatic decrease in early-onset GBS disease. In contrast, the incidence of late-onset GBS disease has remained unchanged, presumably because prophylaxis does not eradicate colonization of the genital tract or the environment.

## Gram-Negative Organisms

Gram-negative organisms are a particularly important cause of nosocomial blood stream infections, pneumonia, and meningitis because they generally cause severe disease. *Escherichia coli* is the most common gram-negative pathogen. Other gram-negative organisms responsible for nosocomial infections are *Klebsiella*, *Pseudomonas*, *Enterobacter*, *Acinetobacter*, *Serratia*, *Haemophilus* spp., and *Salmonella* spp. (see Table 40–5).

The attributable mortality is much higher for gram-negative infections than for gram-positive infections. Stoll and associates (2002a) report that infants with gram-negative infections had a 3.5-fold higher risk of death. Karlowicz and colleagues (2000) found that gram-negative infections were associated with fulminant death within 48 hours of a positive blood culture results in 69% of cases. *Pseudomonas* spp. appear to be particularly virulent, causing death in 42% to 75% of infected neonates (Karlowicz et al, 2000; Leigh et al, 1995; Stoll et al, 2002a).

## Fungal Organisms

Fungal infections are discussed in detail in Chapter 41.

Fungi are responsible for approximately 12% of nosocomial infections in the VLBW population (Makhoul et al, 2002; Stoll et al, 2002a). The reported incidence is 0.4 to 2 cases per 1000 live births (Benjamin et al, 2001; Makhoul et al, 2002). Rates and predominant fungal species vary among clinical centers. The smallest and most premature infants appear to be at the highest risk. Other identified risk factors are prolonged mechanical ventilation, use of broad-spectrum antibiotics, prolonged use of central venous catheters, and prior use of lipid emulsions (Benjamin et al, 2001; Long and Keyserling, 1985; Makhoul et al, 2002; Saiman et al, 2000).

## Viral Organisms

Viral organisms that cause nosocomial infection in the NICU are respiratory syncytial virus (RSV), influenza, varicella, rotavirus, and enterovirus. Isolated infections generally result from contact with infected caregivers or family members. Nursery epidemics may occur in addition to isolated individual cases.

## Respiratory Syncytial Virus

Careful hand washing is the most effective measure to prevent RSV infection.

Recommendations for prevention of RSV epidemics in the inpatient setting include cohorting of patients, barrier precautions, and careful hand washing (Goldmann, 2001; Hall, 2000; Karanfil et al, 1999; Mlinarvić-Galinović and Varda-Brkić, 2000; Snyderman et al, 1988). Rapid testing to detect the virus in nasal washings facilitates efforts to cohort infected patients, which has been shown to be an effective control measure (Madge et al, 1992; Snyderman et al, 1988). RSV is a fastidious organism capable of surviving on inanimate objects for prolonged periods; therefore, some authorities advocate the use of gowns and gloves

because of the increased risk of contamination through casual contact between the patient and the environment (Goldmann, 2001; Hall, 2000; Karanfil et al, 1999; Mlinarić-Galinović and Varda-Brkić, 2000). Several case reports have described the use of palivizumab, an RSV monoclonal antibody, to control nosocomial outbreaks; however, the efficacy of administering monthly injections to hospitalized patients has not been critically or systematically evaluated (Cox et al, 2001; Mačartney et al, 2000). Preterm infants born before 32 weeks of gestation and those with chronic lung disease remain at high risk for RSV infection after hospital discharge; therefore, the American Academy of Pediatrics (AAP) recommends that all high-risk infants (<32 weeks in gestational age, chronic lung disease, or asymptomatic acyanotic congenital heart disease, such as a patent ductus arteriosus or ventricular septal defect) receive palivizumab throughout the RSV season (AAP Committee, 1998; Meissner et al, 1999). These guidelines were updated in 2003 to also include patients with cyanotic congenital heart disease.

### **Influenza**

Influenza is spread primarily via airborne transmission. Hand washing and immunization of health care workers are the primary tools to prevent nosocomial spread of this virus (Nichol and Hauge, 1997). Most infection control guidelines recommend that every health care worker wear a mask during contact with infected patients. Although several drugs are available for the prophylaxis and treatment of influenza, they have not been studied in newborns and cannot be recommended at this time (Meissner, 2001). At risk infants should receive the influenza vaccine during the winter months.

### **Varicella**

Potential exposures and epidemics of nosocomial varicella have been reported. After exposure, the rate of disease transmission is higher in pediatric units than in neonatal units. The index case is typically an asymptomatic infected health care worker or family member who has had contact with a susceptible infant before the onset of clinical disease in the health care worker/family member. The incubation period lasts 14 to 16 days, and infected persons are contagious 24 to 48 hours before the appearance of the rash. The relative risk of infection varies according to the intensity of the exposure and the presence of maternal antibody. The majority of transplacental antibody transfer occurs during the third trimester, therefore most extremely preterm infants are born before this process is complete. ELBW infants may be at risk even if their mothers have documented titer of varicella antibodies. The AAP recommends administration of varicella zoster immune globulin (VZIG) to any newborn whose mother shows signs of varicella infection within 5 days before delivery or within 2 days after delivery. An exposed preterm infant born before 28 weeks of gestation or at less than 1000 g should receive immunoprophylaxis regardless of the mother's varicella history or serologic status. An exposed preterm infant born after 28 weeks of gestation should

receive VZIG only if the mother lacks clinical or serologic evidence of prior disease (AAP, 2000).

Airborne and contact precautions are recommended for all infants with active varicella disease for at least 5 days after vesicles appear and until all lesions have crusted. Airborne and contact precautions should be used for any exposed susceptible patient from 8 to 21 days after the exposure. Administration of VZIG potentially prolongs the incubation period; therefore, all exposed infants who receive this product should be isolated for up to 28 days after the exposure. An infant born to a mother with active varicella should be isolated for 21 days, or for 28 days if the infant received VZIG. The infants should also be isolated from the mother until all of her lesions have crusted.

### **Rotavirus**

Although rare, epidemics of rotavirus diarrhea may occur in the nursery (Jain and Glass, 2001; Lee et al, 2001; Widdowson et al, 2000). They are primarily due to inadequate hand washing and cross-contamination between patients. Standard and contact precautions should be adhered to throughout the duration of the illness. Some patients have prolonged fecal shedding of low concentrations of the virus; therefore, some infection control experts recommend contact precautions for the duration of the hospitalization of such patients. Rotavirus is an important cause of diarrhea in older infants and should be suspected with any apparent epidemic of diarrhea.

### **Enterovirus**

There are numerous serotypes of enteroviruses, including polioviruses, Coxsackie viruses A and B, and echovirus, as well as nonassigned subtypes (Chambon et al, 1999). Enterovirus infections have been described among neonates in the well baby nursery and the neonatal intensive care setting (Chambon et al, 1999; Isaacs et al, 1989; Sizun et al, 2000; Takami et al, 2000; Wreghitt et al, 1989). Both individual cases and epidemics can occur. The seasonal distribution of enterovirus infections in neonates mirrors what is seen in the community.

The clinical presentation associated with enteroviral infection is variable. Many patients are asymptomatic; however, several case reports describe overwhelming infection with multisystem organ dysfunction and death (Jankovic et al, 1999; Keyserling, 1997). Clinical manifestations of severe disease include meningoencephalitis, hepatic dysfunction, disseminated intravascular coagulation, myocarditis, pneumonitis, gastroenteritis, and muscle weakness (Abzug et al, 1993; Isaacs et al, 1989; Keyserling, 1997; Wreghitt et al, 1989). The severity of disease and the likelihood of death are often more pronounced in perinatally acquired cases than in nosocomially acquired cases, presumably related to the lack of maternal antibody present in the neonate (Isaacs et al, 1989; Modlin et al, 1981).

Infection control measures during an enteroviral epidemic include hand washing with alcohol-based preparations or antimicrobial soaps and cohorting of infected patients. Surveillance cultures of specimens from the throat and rectum may be helpful in identifying asymptomatic

colonized infants. Blood and cerebrospinal fluid cultures should be obtained in any patient with clinical symptoms of disease. Polymerase chain reaction (PCR) analysis is helpful in making a rapid diagnosis (Nigrovic, 2001). No antiviral agents are currently available to treat enteroviral infections in newborns (Nigrovic, 2001). Although commercially available intravenous immunoglobulin preparations have high levels of neutralizing antibodies to common enterovirus serotypes, there is no clear evidence that administration of immunoglobulin alters the process or outcome of enteroviral infection (Abzug et al, 1993; Dagan et al, 1983; Keyserling, 1997). The use of these products remains controversial in patients with enteroviral infection.

## EPIDEMICS

Numerous nursery epidemics have been reported. Common sources for infection are contaminated equipment (i.e., breast pump, thermometer, ventilator), environmental reservoirs, soaps, and lapses in hand hygiene practices (Focca et al, 2000; Hervas et al, 2001; Hoque et al, 2001; Jeong et al, 2001; Jones et al, 2000; McNeil et al, 2001; Reiss et al, 2000; van den Berg et al, 2000; Wisplinghoff et al, 2000; Yu et al, 2000). Clinicians must have a high index of suspicion to detect nursery outbreaks, especially when clusters of infections with unusual pathogens occur in a nursery. Continuous surveillance and monitoring of the endemic infection rate are crucial for determining when there has been a significant change in the baseline pattern of infection for a given nursery. Modern molecular technology facilitates identification and tracking of specific strains of bacteria to help determine the common source of infection (Chambon et al, 1999; Jeong et al, 2001; Jones et al, 2000; Takami et al, 2000).

Epidemics must be identified promptly, and immediate control measures instituted. Efforts should be made to identify the causal agent and the mode of transmission. Surveillance of staff may be necessary, even if they are asymptomatic. Reinforcement of hand-washing policies is of utmost importance. Cohorting of infected patients may be helpful in limiting the spread of organisms in the nursery. In an effort to minimize the risk of cross-contamination between patients, staff caring for colonized or infected infants should not care for infants who are not infected or colonized.

## INFECTION CONTROL

The CDC has developed a two-tier approach to infection control. Standard precautions should be used with all patient contact regardless of the underlying diagnosis or infectious status. These consist of universal precautions (designed to prevent blood and body fluid contamination) and body substance precautions (designed to prevent contamination with moist substances). Transmission-based precautions are necessary when a patient is infected with a known or suspected pathogen that is associated with a high risk of contamination via airborne or droplet transmission or contact with skin or contaminated surfaces (Garner, 1996).

The routine use of gowns is not an effective measure to decrease the endemic nosocomial infection rate in the nursery (Garner, 1996; Goldmann, 1989, 1991). Gowns should be used in specific circumstances in which the risk for

**TABLE 40-6**

### Guidelines for Sibling Visitation in the Nursery

- Siblings should not have been exposed to known communicable diseases (e.g., varicella).
- Siblings should not have fever or symptoms of acute illness (i.e., upper respiratory infection or gastroenteritis).
- Children should be supervised by their parents or a responsible adult during the entire visit.
- Children should be prepared in advance for the visit.

Adapted from the American Academy of Pediatrics Committee on the Fetus and Newborn. Postpartum (neonatal) sibling visitation. *Pediatrics* 76:650, 1985.

contamination is high or the infant is being held. Gowns should be changed after each patient encounter.

Visitation policies are nonrestrictive in most modern nurseries. Various regulatory agencies have developed guidelines for sibling visitation (Table 40-6) (AAP, 1985). Infection and colonization rates have not risen with use of the current standards. Siblings should be screened for infection or recent exposures prior to visitation.

## PREVENTION OF NOSOCOMIAL INFECTIONS

There will always be a baseline rate of nosocomial infection in the NICU because of inherent risk factors associated with the patient population, such as low birth weight, prematurity, and the need for supportive and invasive care. However, the wide variability of endemic nosocomial infection rates among centers with similar patient populations suggests that some risk factors are modifiable. Effective prevention strategies focus on these “modifiable” risks, such as strategic nursery design, adequate staffing, hand-washing compliance, minimization of catheter days, and promotion of enteral nutrition, especially with human milk (Adams-Chapman and Stoll, 2002; Goldmann, 1989; Horbar et al, 2001). Programs that include education and frequent feedback from staff, and active participation by health care providers at all levels are more likely to achieve sustained improvement in compliance. Monitoring and surveillance of the nosocomial infection rates in the nursery are also critical components of any prevention program (Table 40-7).

## Hand Hygiene

### Historic Perspective

Hand washing has clearly been shown to be the most effective and least expensive means of preventing the spread of nosocomial infection; however, even today, compliance with this simple practice is poor (Jarvis, 1994; Larson, 1999; Pittet, 2000; Pittet et al, 2000). Historically, the benefits of hand washing have been known since the early 19th century. Labarraque, a French pharmacist, was one of the first to demonstrate that cleansing the hands with solutions containing lime or soda could be used as disinfectants and antiseptics (Boyce et al, 2002). The issue was further elucidated by Ignaz Semmelweis, who noted that the mortality and puerperal infection rates were higher among women cared

TABLE 40-7

**Principles for the Prevention of Nosocomial Infection in the NICU**

- Observe recommendations for standard precautions with all patient contact
- Observe recommendations for transmission-based precautions as indicated:
  - Gowns
  - Gloves
  - Masks
  - Isolation
- Use good nursery design/engineering:
  - Appropriate nursing-to-patient ratio
  - Avoidance of overcrowding and excessive workload
  - Readily accessible sinks, antiseptic solutions, soaps, and paper towels
- Maintain hand-washing practices:
  - Improving hand-washing compliance
  - Washing of hands before and after each patient encounter
  - Appropriate use of soap, alcohol-based preparations, or antiseptic solutions
  - Alcohol-based antiseptic solution at each patients bedside
  - Emollients provided for nursery staff
  - Education and feedback for nursery staff
- Minimize risk of contamination of central venous catheters (CVCs):
  - Maximal sterile barrier precautions during CVC insertion
  - Local antisepsis with chlorhexidine gluconate
  - Minimal entries into the line for laboratory tests
  - Aseptic technique when entering the line
  - Minimal CVC days
  - Sterile preparation of all fluids to be administered via a CVC
- Provide meticulous skin care
- Encourage early and appropriate advancement of enteral feedings
- Provide education and feedback for nursery personnel
- Perform continuous monitoring and surveillance of nosocomial infection rates in the NICU

for by physicians than in those cared for by midwives. He postulated that the puerperal fever in these patients was caused by “cadaverous particles” transmitted from the autopsy suite on the hands of the students and physicians. After he instructed physicians to cleanse their hands with a chlorine solution between patients, the maternal infection and mortality rates dropped significantly (Boyce et al, 2002; Carter, 1983). This intervention represents the first clinical evidence suggesting that cleansing contaminated hands with an antiseptic agent was more effective than washing them with plain soap and water and that hand antisepsis could reduce the spread of contagious disease via the hands of health care workers (Boyce et al, 2002).

### **Guidelines for Hand Hygiene Practices in the Neonatal Intensive Care Unit**

#### ***Clinical Indications for Hand Hygiene***

Hand hygiene techniques are effective in decreasing the colonization rate of resident and transient flora and have been shown to reduce cross-contamination among patients. Several studies have shown that the hands of health care workers become contaminated during routine patient care activities, including “clean” procedures, such as lifting patients and checking vital signs, as well as during contact with intact skin (Casewell and Phillips, 1977; Pittet et al, 1999). Attempts have been made to stratify the type of activity with the likelihood of contamination, but they

have not been validated by quantitative bacterial contamination analysis. Direct patient contact and respiratory tract care seem to be particularly associated with contamination (Pittet et al, 1999). Organisms such as RSV, *S. aureus*, and gram-negative bacilli are able to survive on inanimate objects, so changing diapers or holding an infant infected with one of these organisms, and even touching items in the infant’s room, may result in contamination (Boyce et al, 2002; Goldmann, 1989; Hall, 2000).

Recommendations concerning indications for and the technique of hand washing are summarized in Table 40-8 (Boyce et al, 2002; Garner and Favero, 1986; Larson, 1995). Current recommendations strongly support the use of waterless alcohol-based preparations as the primary agents for hand hygiene except when the hands are soiled with organic material (Boyce et al, 2002).

#### ***Preparations for Hand Hygiene***

Washing the hands with soap causes suspension and mechanical removal of microorganisms and dirt from the hands. *Hand disinfection* refers to the same process but with the use of an antimicrobial product to kill or inhibit microorganisms. Table 40-9 compares properties of the various hand hygiene agents.

The cleansing activity of plain soap results from its detergent properties (Boyce et al, 2002). Hand washing with soap alone reduces bacterial colonization of the hands but has no significant antimicrobial activity and is ineffective at

TABLE 40-8

**Recommendations for Hand Hygiene Practices in the NICU\***

Indications for handwashing	<ul style="list-style-type: none"> <li>▪ Wash hands with a non-antimicrobial soap or an antimicrobial soap and water when hands are visibly soiled or contaminated with proteinaceous material.</li> <li>▪ If the hands are not visibly soiled, alcohol-based waterless antiseptic agents are strongly preferred for routine decontamination of hands in all other clinical situations.</li> <li>▪ Alcohol-based waterless antiseptic agents should be available at each patient area and other convenient locations, and in individual pocket-sized containers for health care providers.</li> <li>▪ Antimicrobial soaps may be considered in settings with few time constraints and easy access to hand hygiene facilities.</li> <li>▪ Decontaminate hands after contact with intact patient skin (i.e., checking pulse or lifting).</li> <li>▪ Decontaminate hands after contact with body fluids or excretions, mucous membranes, non-intact skin, or wounds.</li> <li>▪ Decontaminate hands before applying sterile gloves or inserting a central intravascular catheter.</li> <li>▪ Decontaminate hands before inserting indwelling urinary catheters or other invasive devices not requiring surgical procedures.</li> <li>▪ Decontaminate hands after removing gloves.</li> <li>▪ Decontaminate hands before caring for patients with severe neutropenia or severe immunosuppression.</li> <li>▪ Decontaminate hands after contact with inanimate objects in the immediate vicinity of the patient.</li> </ul>
Recommended techniques for hand hygiene	<ul style="list-style-type: none"> <li>▪ When using a waterless antiseptic agent, apply enough of the product to cover all surfaces of the hands and fingers, and rub hands together until they are dry. Each manufacturer has guidelines for the volume to be used; in general, however, enough should be applied such that it takes 15 to 25 seconds to dry.</li> <li>▪ When using a non-antimicrobial or antimicrobial soap, wet hands, apply 3 to 5 mL of solution to the hands, and rub for at least 15 seconds. Be sure to cover all surfaces of the hands and fingers. Rinse hands with warm water, and dry thoroughly. Foot pedals or towels should be used to turn off the water</li> </ul>

Adapted from Boyce, 2002.

removing pathogenic flora. Soaps containing antimicrobial agents are typically used in the NICU environment.

The antimicrobial activity of alcohol stems from its ability to denature proteins (Boyce et al, 2002). Because proteins are not readily denatured in the absence of water; solutions containing 50% to 80% alcohol are most effective (Boyce, 2000; Boyce et al, 2002). Alcohol has a rapid onset of action and reduces bacterial colonization but has no residual activity. The efficacy of alcohol-based products is influenced by the type of alcohol used, concentration, contact time, volume used, and whether the hands are wet when the product is applied (Boyce et al, 2002; Mackintosh and Hoffman, 1984). When used in adequate amounts, alcohol is usually more effective than other hand hygiene products (Boyce, 2000; Boyce et al, 2002).

Chlorhexidine gluconate is a cationic bis-biguanide whose antimicrobial activity is due to attachment and disruption of cytoplasmic membranes (Boyce et al, 2002). The onset of action is slower than the alcohol-based preparations; however its major benefit is the persistent antimicrobial activity, which may last up to 6 hours after application (Boyce et al, 2002; Larson, 1995). Varying percentages of this product have been added to other hand hygiene preparations, especially the alcohol-based preparations to confer greater residual activity.

Hexachlorophene is a bisphenol compound with bacteriostatic properties. Its activity is due to its ability to inactivate essential enzymes systems. It has good activity against *S. aureus* but weak activity against gram-negative bacteria, fungi, and *Mycobacterium tuberculosis*. Hexachlorophene also has residual activity. Hexachlorophene was used for routine bathing of newborn infants until 1972, when the U.S. Food and Drug Administration (FDA) warned against its use because infants bathed in the 3% solution were found to have cystic degeneration of the cerebral white matter (Shuman et al, 1975). This product should be used only on term infants during a severe outbreak of *S. aureus*. Most experts recommend diluting the material 1:4 with water to minimize the risk of systemic absorption.

Iodine and iodophors penetrate the cell walls of organisms, impairing protein synthesis and altering the cellular membranes (Boyce et al, 2002). The amount of iodine present determines the level of antimicrobial activity. Combining iodine with polymers (i.e., povidone or poloxamers) increases the solubility, promotes sustained release of iodine, and decreases skin irritation. The activity of this product is affected by pH, exposure time, temperature, presence of organic (blood or sputum) or inorganic material, and the concentration of iodine.

TABLE 40-9

**Antimicrobial Spectrum and Characteristics of Hand Hygiene Antiseptic Agents\***

Group	Gram-Positive Bacteria	Gram-Negative Bacteria	Mycobacteria	Fungi	Viruses	Speed of Action	Comments
Alcohols	+++	+++	+++	+++	+++	Fast	Optimum concentration 60%-90% No persistent activity
Chlorhexidine (2% and 4% aqueous)	+++	+++	+	+	+++	Intermediate	Persistent activity Rare allergic reactions
Iodine compounds	+++	+++	+++	++	+++	Intermediate	Causes skin burns Usually too irritating for hand hygiene

### Compliance

Despite the fact that the benefits of hand washing have been reported since the 19th century, compliance with hand-washing protocols remains unacceptably low. The overall compliance rate is approximately 40% (Pittet, 2000). Reported barriers to compliance with hand hygiene recommendations include skin irritation, poor accessibility of sinks or cleansing agents, greater priority for patient needs, insufficient time, heavy workload and understaffing, and lack of information (Table 40-10). A common misconception is that using gloves obviates adequate hand hygiene. Leakage and contamination of gloves have been reported (Boyce et al, 2002; Larson, 1995). Disposable single-use gloves should be removed after each patient encounter, and hands should be washed before and after their use.

Hand hygiene is extremely cost effective. The additional hospital charges associated with a single nosocomial infection almost equal the yearly hand hygiene budget. Pittet and colleagues (2000) estimated the cost of a hand hygiene intervention program to be less than \$57,000 per year. Assuming that only 25% of the observed decrease in infections was

attributable to improved hand hygiene practices, they estimated a savings of \$2,100 for every infection averted.

### Prevention of Catheter-Related Blood Stream Infections

The care and maintenance of central venous catheters may affect the risk of catheter-related blood stream infection. Before insertion of an intravascular device, attempted sterilization of the skin insertion site is of utmost importance. The recommended technique for skin antisepsis is to use two consecutive 10-second applications or a single 30-second application of the selected antibacterial agent. Sterile water rather than alcohol should be used to remove antiseptics from the skin. Providone-iodine (10%) solution is commonly used for skin antisepsis; however, recent reports suggest that chlorhexidine gluconate is more effective at decreasing skin colonization and subsequent CRBSI in adults as well as colonization of peripheral intravenous catheters in neonates (Darmstadt and Dinulos, 2000; Garland et al, 1995).

Hub colonization and repeated entry into the line for administration of medications or collection of specimens

TABLE 40-10

**Factors Influencing Compliance with Hand Hygiene Practices**

Observed risk factors for poor adherence to recommended practices	Physician status (rather than a nurse) Nursing assistant status (rather than a nurse) Working in an intensive care unit Working during the week compared with the weekend Wearing gowns and gloves Automated sink Activities with high risk of contamination High numbers of indications for hand hygiene per hour of patient care
Self-reported factors for poor adherence to recommended practices	Agents irritating or drying Inconvenient location of sinks and supplies Inadequate supply of soap, paper, etc. Too busy/patient needs take priority Perceived low risk of acquiring infection Gloves obviate the need for hand hygiene Lack of knowledge of guidelines and recommendations Disagreement with recommendations

Data from Pittet D: Improving compliance with hand hygiene in hospitals. *Infect Control Hosp Epidemiol* 21: 381-386, 2000; and Boyce JM: Using alcohol for hand antiseptics: Dispelling old myths. *Infect Control Hosp Epidemiol* 21: 438-441, 2000.

for laboratory studies are both associated with an increased risk for infection. Salzman and coworkers (1993) conducted a prospective study in which surveillance cultures of catheter hubs were performed three times per week, and blood cultures and hub cultures were conducted for any suspected episode of sepsis. These investigators found that 54% of 28 episodes of CRBSI were preceded by or coincided with colonization of the catheter hub with the same pathogen. Mahieu and associates (2001b) reported that catheter manipulation for blood sampling and fluid or tubing changes raised the risk of colonization. Despite the lack of large randomized controlled trials, the available data suggest that the use of heparin is associated with a lower risk of bacterial colonization and thrombosis (Appelgren et al, 1996; Mahieu et al, 2001b). It is hypothesized that heparin prevents bacteria from adhering to the catheter and that the preservatives in heparin preparations have some limited antibacterial properties.

Various products have been designed to decrease the risk of catheter-related infection in adult patients. Although data on their use are promising, many of the currently available

products are not specifically designed for the neonate, and their safety and efficacy have not been tested in this patient population. Antiseptic- or antibiotic-impregnated catheters have been shown to significantly decrease the risk of CRBSI in adults (Elliott, 2000; Marin et al, 2000; Pai et al, 2000; Tennenberg et al, 1997; Veenestra et al, 1999). Pierce and colleagues (2000) reported that pediatric patients randomly assigned to the use of a heparin-bonded device had a lower incidence of CRBSI than controls (4% versus 33%;  $P < .005$ ). Studies are in progress to evaluate the efficacy of antibiotic lock therapy in neonates. Johnson and associates (1994) treated a small group of pediatric patients with CRBSIs with antibiotic lock therapy for 10 days. They reported that 10 out of 12 catheters were salvaged. There are very limited data describing the use of antibiotic lock therapy in neonates. Garland and coworkers (2002) randomly assigned 82 VLBW infants to saline control or vancomycin antibiotic lock therapy of catheters in an effort to prevent CRBSI. These researchers found a significantly lower incidence density of catheter-related infections, no evidence of toxicity, and no cases of VRE in the neonates receiving antibiotic lock therapy.

**Umbilical Cord Care**

Umbilical cord infections remain a significant cause of neonatal mortality in developing nations, although not in the United States (Zupan and Garner, 2001). In clinical practice, there are numerous approaches to umbilical cord care in the healthy term infant because the available data are insufficient to recommend the use of a specific agent or regimen (Zupan and Garner, 2001). Most authorities agree that the umbilical cord should be separated from the placenta with the use of good aseptic technique. Subsequently, some experts recommend "natural drying," but others support the use of an antiseptic agent such as alcohol, silver sulfadiazine, chlorhexidine, triple dye, or gentian violet (Darmstadt et al, 2000; Hsu et al, 1999; Pezzati et al, 2002; Zupan and Garner, 2001). Hexachlorophene and iodine are used sparingly because of concerns about their systemic absorption and toxicity. Studies have shown that antiseptic products decrease umbilical cord colonization. Unfortunately, this decrease has not clearly resulted in a lower incidence of umbilical cord infections. In a meta-analysis that included "no intervention" as an alternative, Zupan and Garner (2001) were unable to determine which regimen was superior. In general, they found that time to cord separation is prolonged when antiseptics are used, but there were no significant differences in the incidence of infection or death with the use of a particular agent for cord care.

**Skin Care**

The skin of VLBW preterm infants is immature and functions as an ineffective barrier to prevent transepidermal loss of water and invasion of bacteria. The stratum corneum (the outermost layer of skin) has both mechanical and chemical properties that decrease the risk of infection (Darmstadt and Dinulos, 2000). This layer of skin matures

at approximately 32 weeks of gestation. In a prematurely born neonate, the maturation process is accelerated and is usually complete by 2 to 4 weeks after birth (Darmstadt and Dinulos, 2000).

Unfortunately, there is no consensus on the most effective skin care practices for VLBW infants (Baker et al, 1999; Munson et al, 1999). Neonatologists had hoped that the application of a topical emollient would be the “magic bullet” to protect the developing epidermal layer, reduce the risk of infection, and prevent transepidermal water loss. Several studies have documented that such a practice decreases water loss; however, there was no significant reduction in nosocomial infection in VLBW infants randomly assigned to receive routine application of one emollient product (Aquaphor) in a study performed by Edwards and colleagues (2001). Infants randomly assigned to emollient therapy had more nosocomial blood stream infections, particularly with CONS. This difference was most evident in infants with birth weights of 501 to 750 g.

The efficacy of other topical agents warrants further study. Efforts to prevent traumatic injury to the skin of VLBW infants include the use of transparent dressing over bony prominences, semipermeable barriers between the skin and adhesive tape, and water-activated electrodes and the avoidance of agents such as tincture of benzoin, mastisol, and adhesive removers (Adams-Chapman and Stoll, 2002; Darmstadt and Dinulos, 2000; Hoath and Narendran, 2000).

## MANAGEMENT OF NOSOCOMIAL INFECTIONS

### Catheter-Related Blood Stream Infections

Management of neonates with CRBSIs is problematic because of the limited intravenous access in most such patients as well as the lack of consensus among clinicians. Current recommendations for adults regarding catheter removal with associated CRBSI suggest the removal of nontunneled central venous catheters (umbilical venous catheters, PICCs) associated with bacteremia or fungemia, unless the pathogen is CONS (Mermel et al, 2001). A patient with a catheter-related infection due to CONS should undergo catheter removal if culture results are persistently positive or if the patient is unstable (Benjamin et al, 2001; Karlowicz et al, 2000).

Benjamin and colleagues (2001) retrospectively reviewed data on infants with CRBSIs and compared outcomes in patients in whom catheters were removed at the onset of infection with those in whom catheters remained in place. Forty-six percent (59 of 128) of infants in whom catheter sterilization was attempted had complications, compared with 8% (2 of 25) of those in whom catheters were removed. In particular, infants with gram-negative infections were more likely to have complications if their catheters remained in place. A study of infants with CRBSIs due to CONS found no difference in the complication or mortality rate in patients in whom removal of the catheter was delayed (Karlowicz et al, 2000). Such patients were more likely to have persistently positive culture results (43%, versus 13% for immediate catheter removal), and the attempt to retain the catheter was never successful if culture results remained positive for more than 4 days.

Further prospective randomized trials are needed to validate these observational data.

### Antibiotic and Adjunctive Therapies

Antibiotic therapy effective against a culture-proven or suspected pathogen is the primary treatment for nosocomial infections. Awareness of the colonization patterns for a particular infant or a nursery influence the choice of antibiotics. One should consider coverage for *Pseudomonas* spp. or other resistant gram-negative organisms in patients with a rapid clinical deterioration (Karlowski et al, 2000; Stoll et al, 2002a).

Many high-risk neonates with late-onset infections have evidence of multisystem organ dysfunction. Supportive therapy (i.e., colloid infusions, ionotropic agents, mechanical ventilation) should be used as indicated by the clinical status of the patient.

A meta-analysis of the prophylactic use of intravenous immune globulin (IVIG) in preterm neonates found only a 3% reduction in nosocomial infection and no reduction in mortality (Modi and Carr, 2000; Ohlsson and Lacy, 2001a). The benefit in patients with culture-proven sepsis remains unclear, and IVIG is therefore not recommended for routine use in such patients (Modi and Carr, 2000). Some authorities speculate that the benefit of IVIG would be greater if products containing high concentrations of specific antibodies against pathogens frequently responsible for neonatal infections were developed (Hill, 2000; Ohlsson and Lacy, 2001b; Weisman et al, 1994). Hemopoietic colony-stimulating factors (G-CSF and GM-CSF) are effective in raising the neutrophil count but have not consistently decreased nosocomial infection rates or mortality (Modi and Carr, 2000; Modi et al, 2001). Studies are being conducted in adults to evaluate the efficacy of administering various cytokine preparations known to modulate the inflammatory response.

## CONCLUSION

Interventions to reduce nosocomial infection are urgently needed. Infants with nosocomial infections have significantly longer hospital stays (79 versus 60 days;  $P < .001$ ) and higher hospital costs (Gray et al, 1995; Mahieu et al, 2001a; Pittet et al, 1994; Stoll et al, 2002a). The higher costs are primarily secondary to daily hospital charges and pharmaceutical fees (Mahieu et al, 2001a). The attributable cost of nosocomial infection has been estimated to be approximately \$40,000 per adult case and \$1200 per neonatal case (Mahieu et al, 2001a; Pittet et al, 1994). The magnitude of these costs is significant, especially when one considers the growing number of surviving VLBW infants, who are at the highest risk for acquiring a nosocomial infection. Moreover, infants who experience a nosocomial infection are significantly more likely to die than are those who remain uninfected (Stoll et al, 1996, 2002a).

A variety of new therapeutic alternatives are currently being investigated. Clinicians must continue to focus on developing effective prevention strategies, including strict hand-washing policies, minimal use of invasive devices, promotion of enteral nutrition surveillance of infection patterns, and education for the nursery staff.

# Fungal Infections in the Neonatal Intensive Care Unit

Margaret K. Hostetter

## OVERVIEW OF FUNGAL INFECTION IN THE NEWBORN

Invasive fungal infection occurs in approximately 6% to 7% of all infants admitted to the neonatal intensive care unit (NICU) (Stoll et al, 1996), but the incidence is inversely correlated with birth weight: the lower the birth weight, the greater the risk of invasive fungal infection. For example, in a survey of 2847 infants from six different nurseries, the risk of candidemia in infants weighing less than 800 g was 8%; the risk fell to 3% for infants weighing 801 to 1000 g, to 1% for infants weighing 1101 to 1500 g, and to 0.31% for infants weighing more than 1500 g (Saiman et al, 2000). According to these data, the infant weighing 800 g or less has a 25-fold increased risk of invasive candidemia. This markedly increased risk correlates with a mortality rate exceeding 25% in most studies (Chapman and Faix, 2000; Saxen et al, 1995; Weese-Mayer et al, 1987).

Colonization with ubiquitous fungal species occurs in at least 25% of very low-birth-weight (VLBW) infants (Baley et al, 1986), and both the number of *Candida* organisms in the gastrointestinal tract (Pappu-Katikaneni et al, 1990) and colonization at sites such as endotracheal tubes (Rowen et al, 1994) have been correlated with increased risk of invasive disease due to *Candida* species. Prospective studies correlating colonization by other fungal genera (e.g., *Aspergillus*, *Malassezia*) with risk of invasive disease have not been done.

Host factors that contribute to the susceptibility of the NICU infant to fungal infection include birth weight of less than 1500 g, 5-minute Apgar scores of less than 5, disruption of cutaneous barriers by percutaneous catheters (Faix et al, 1989; Saiman et al, 2000; Stoll et al, 1996), and relative immunocompromise ascribable to reduced numbers of T cells, impaired neutrophil number and function, and reduced levels of complement (Rebuck et al, 1995; Zach and Hostetter, 1989). Concomitants of nursery care that are thought to increase the risk of fungal infections include prolonged use of antimicrobials (especially third-generation cephalosporins), indwelling central venous catheters, abdominal surgery, parenteral nutrition, parenteral lipid formulations, histamine H<sub>2</sub> receptor antagonists, endo-

tracheal intubation, and length of stay more than 1 week (Saiman et al, 2000).

This combination of factors has made *Candida* the third most common cause of late-onset sepsis in the NICU. Other fungi encountered include the non-*albicans* species *Candida parapsilosis*, *Candida glabrata*, and *Candida lusitanae*; *Aspergillus fumigatus* and *Aspergillus flavus*; and *Malassezia furfur* and *Malassezia pachydermatis*. All of these fungi have in common a ready ability to colonize the infant's gastrointestinal tract (*Candida albicans*), the skin of caregivers (*Candida parapsilosis*, *M. furfur* or *M. pachydermatis*), various parenteral nutrition formulations (*Candida* and *Malassezia* species), and sinks, drainage pipes, air ducts, or new construction (*Aspergillus* species). Of interest, the yeast *Cryptococcus neoformans* and the fungi *Histoplasma capsulatum*, *Blastomyces dermatitidis*, and *Coccidioides immitis* are virtually never seen in the NICU.

## INFECTIONS DUE TO CANDIDA SPECIES

### Risk Factors and Epidemiology

Approximately 7% of infants weighing less than 1500 g will develop evidence of invasive candidal disease such as candidemia or disseminated candidiasis. This relatively high incidence contrasts with the logarithmically smaller incidence (0.6%) of candidemia in infants weighing more than 2500 g; most of these infants acquire blood-borne candidal infection in association with congenital anomalies, especially those of the gastrointestinal tract (Rabalais et al, 1996).

A number of environmental factors other than birth weight and gestational age are thought to facilitate colonization with *Candida* species as stated above. Hand carriage of *C. albicans* was found in approximately 5% of health care workers; *C. parapsilosis* was present in 19%.

Of interest, a number of variables appear not to be associated with candidal colonization, including use of antibiotics in the mother, premature rupture of the membranes, the infant's gender, intubation, use of antimicrobial agents other than third-generation cephalosporins in the infant, surgical procedures, and frequency of intubation (Saiman et al, 2001). The role of some environmental factors is controversial. One study found that infants receiving intravenous hydrocortisone were approximately 7 times as likely as uninfected infants to develop disseminated candidal infection within the first 35 days of life (Botas et al, 1995). Use of topical petrolatum was associated with systemic candidal infection in a case-control study (Campbell et al, 2000). Table 41-1 shows the typical species involved in colonization versus candidemia.

### Congenital Candidiasis

Presenting within the first 24 hours of life in both full-term and premature infants, congenital candidiasis, a very rare entity, manifests as a deeply erythematous skin rash in the setting of pronounced neutrophilia, with white

TABLE 41-1

Colonization and Disease Due to *Candida*

Species	Percent of Cases		
	Colonization (n = 486/2157)	Candidemia (n = 35/2847)	Disseminated Candidiasis (n = 19)
<i>Candida albicans</i>	62%	63%	68%
<i>Candida parapsilosis</i>	32%	29%	32%
Other <i>Candida</i> spp.	6%	8%	

Data from Saiman 2001; Saiman 2000; Noyola, 2001.

blood cell (WBC) counts often rising to 50,000/mm<sup>3</sup> or more. In the full-term infant, the infection appears to be limited to the dermatologic involvement, and desquamation typically ensues within 2 to 3 days. Although the condition appears extremely painful and is reminiscent of staphylococcal scalded skin syndrome, full-term infants remain stable and continue to feed well.

In contrast, congenital candidiasis in the premature infant is a life-threatening condition (Dvorak and Gvaller, 1966; Johnson et al, 1981). Again, the clinical manifestations develop within the first 24 hours of life, but the rash is often accompanied by multiple pustules, as well as hazy infiltrates on chest radiograph. Results of blood cultures may be positive on occasion. The premature infant is thought to acquire the organism from inhalation of infected amniotic fluid; the accompanying pneumonitis is the most frequent cause of death, even in the face of rapid diagnosis and initiation of systemic antifungal therapy with amphotericin B.

Diagnosis in both premature and full-term infants requires the visualization of the organism on Gram stain of a skin swab or a smear from an opened pustule. On rare occasions, the placenta has yielded the diagnosis. In full-term infants, cultures of blood, urine, and cerebrospinal fluid (CSF) are negative, and chest radiographic findings are normal. In premature infants, chest radiographs show fluffy infiltrates that can be confused with hyaline membrane disease, and the child may have accompanying candidemia.

Treatment for the full-term infant requires only the full-body application of antifungal creams containing either nystatin or azoles such as miconazole or clotrimazole. In the premature infant, systemic treatment with amphotericin B at a dose of 1 mg/kg is mandatory, but respiratory involvement all too frequently heralds death despite antifungal therapy.

## Local Infections with *Candida* Species

### Wound Infections

Local infections due to *Candida* species occur mainly at wound sites and in the urinary tract. Candidal peritonitis may be seen in the rare infant receiving chronic ambulatory peritoneal dialysis. This entity also can occur in patients with necrotizing enterocolitis as a consequence of

intestinal perforation and contamination of the peritoneal cavity. In this context, candidal peritonitis typically presages death.

Because *Candida* species may colonize the skin of patients or caregivers, isolation of *Candida* from a skin swab should not necessarily be construed as evidence for a wound infection. Visualization of the organism in polymorphonuclear leukocytes on Gram stain is a more convincing finding.

### Candidal Infection of the Urinary Tract

The growth of *Candida* species from urinary samples collected by bag is not a reliable indicator of infection (Lundstrom and Sobel, 2001). Isolation of *Candida* species from a catheterized specimen or suprapubic aspiration is a reliable indicator of infection, although asymptomatic colonization of urinary catheters, stents, or nephrostomy tubes can be difficult to distinguish from true infection.

The presence of candiduria in the NICU infant is associated with renal candidiasis—the latter manifested by cortical abscesses or fungal mycelia in the collecting system (“fungus balls”)—nearly half the time (Bryant et al, 1999). Thus, in contrast to older children or adults, the finding of candiduria in the NICU infant should prompt blood cultures and renal imaging at the very least. If blood cultures prove to be positive, a full evaluation for disseminated candidiasis should be undertaken (see below). It is important to remember that almost 50% of premature infants with candiduria will have upper tract disease that may progress to frank obstruction if fungal mycelia occlude the calyces (Bryant et al, 1999).

Diagnosis requires the isolation of *Candida* species from suprapubic aspiration or catheterized urine specimens. Because of the high prevalence of associated upper tract disease, imaging of the kidneys by ultrasonography should be performed on isolation of the organism from a sterile urine specimen. Only about half of patients who eventually develop upper tract manifestations will display them on the first ultrasound study (Bryant et al, 1999). Therefore, follow-up imaging is recommended both to ensure the clearance of fungal mycelia, if initially present, and to monitor for later development of this complication. Unfortunately, no standard interval for monitoring has been proposed. However, in the infant who remains

persistently funguric or candiduric, a negative result on a single ultrasound examination should not be considered presumptive evidence of cure.

Removal of a colonized urinary catheter may suffice for management of a patient without pyuria or systemic symptoms. Disease confined to the lower tract is best treated with oral azoles (e.g., fluconazole, 4 to 6 mg/kg/day). Treatment of upper tract disease requires systemic amphotericin B. In adults, less than 10% of candiduric patients develop candidemia; in the premature infant, this number is thought to be considerably higher. Therefore, the growth of *Candida* species from a urine specimen collected under sterile conditions demands a thorough search for systemic foci.

### Candidal Peritonitis

*Candida* peritonitis typically develops as a consequence of bowel perforation or rarely as a complication of peritoneal dialysis. In the former situation, multiple organisms such as gram-negative rods and enterococci also may be involved, and the neonate is at risk for sepsis with any one of them (Johnson et al, 1980). Resected tissue from infants suffering from a newly reported entity called “invasive *Candida* enteritis of the newborn” shows penetrating candidal hyphae at the site of an intestinal perforation; this finding is thought by some investigators to be distinct from candidal peritonitis accompanying necrotizing enterocolitis (Bond et al, 2000). Peritonitis associated with a peritoneal dialysis catheter usually occurs as an isolated process, and the outcome is much better.

Diagnosis requires visualization of the organism on a Gram stain of peritoneal fluid obtained by sterile technique or culture of the organism from the same source. Isolation of *Candida* species from the peritoneal fluid should always prompt a search for bowel perforation, either by radiology or by surgical exploration, depending on the clinical circumstances.

Treatment of *Candida* peritonitis due to necrotizing enterocolitis or bowel perforation requires surgical evaluation, supportive therapy, and pharmacologic coverage for all contaminating microorganisms in the peritoneal fluid. The typical regimen may include ampicillin and an aminoglycoside for enterococci and gram-negative rods, clindamycin for anaerobes, and systemic antifungal therapy, most likely with amphotericin B. The isolation of *Candida* species from peritoneal dialysate can be treated with a short course (for 7 to 10 days) of parenteral amphotericin B therapy in a dose of 0.3 to 0.5 mg/kg/day after removal of the catheter. The catheter typically can be reinserted within 24 to 48 hours, once the Gram stain is free of yeast cells.

### Candidemia/Line Infections

The association between prematurity and blood-borne candidal infections has been recognized since the 1980s (Baley et al, 1984; Faix et al, 1989). From that time up to the present, the incidence of candidemia has escalated from 25 to 123 cases per 10,000 NICU admissions (Kossoff et al, 1998; Saiman et al, 2000). *Candida* species

are the third most frequent cause of late-onset sepsis, accounting for approximately 9% of infections in this category (Stoll et al, 1996). The median time of onset is at approximately 30 days of age (Baley et al, 1984). In a large multicenter study, colonization of the gastrointestinal tract preceded candidemia in 43% of cases, a frequency suggesting that other sites of colonization, such as intravascular catheters or endotracheal tubes, may contribute to the risk of candidemia (Saiman et al, 2000).

A variety of nonspecific clinical symptoms may be associated with this presentation of candidal disease, including respiratory decompensation, feeding intolerance, temperature instability, and mild thrombocytopenia. It is unclear whether this last manifestation relates more to the use of heparin in central venous catheters or to the presence of *Candida* species in the blood stream.

Although *C. albicans* and *C. parapsilosis* account for almost 90% of candidemias (see Table 41–1), other species such as *C. krusei* are increasing in prevalence and may be resistant to azoles (Faix, 1992; Huang et al, 1999). Despite the emergence of less sensitive species, however, morbidity and mortality rates are highest with *C. albicans* infection (Bayley et al, 1984; Faix, 1992).

*Candida* species isolated from a blood culture should never be regarded as a contaminant but should prompt an immediate search for evidence of disseminated disease, which occurs in approximately 10% of premature newborns (Noyola et al, 2001; Patriquin et al, 1980). A thorough evaluation includes ophthalmologic examination and ultrasonography of the heart, venous system, and abdomen. When lumbar puncture is performed in the evaluation for disseminated candidiasis, as many as 50% of candidemic infants may be found to have associated meningitis (Faix, 1992). Moreover, even with the prompt removal of the central venous catheter and institution of appropriate doses of antifungal therapy, a substantial proportion of infants may exhibit prolonged candidemia lasting 1 to 3 weeks (Chapman and Faix, 2000).

Numerous studies have shown that central venous catheters should be removed within 24 hours after the diagnosis of candidemia (Karlwicz et al, 2000); in particular, removal of the central venous catheter within 3 days is associated with a significantly shorter median duration of candidemia (3 versus 6 days) and a reduced mortality rate (0% versus 39%). Many experts recommend routine echocardiograms for patients with central venous catheters to look for catheter-associated thrombi prior to removal of the catheter.

The rapid institution of parenteral amphotericin B to a maximum dose of 1 to 1.5 mg/kg/day is of paramount importance. The lower dose is favored for candidemia, but the higher dose may be necessary for accompanying meningitis or disseminated disease. No more than 24 hours should elapse before the infant is receiving a dose of 0.7 to 1 mg/kg/day. Accompanying meningitis, if documented, should prompt the addition of 5-fluorocytosine in doses of approximately 25 mg/kg/day. Levels of this drug should be monitored in the newborn and kept at 25–50 µg/mL to avert bone marrow suppression or hepatotoxicity.

A rise in creatinine occurs in more than 80% of older patients receiving amphotericin B (Bennett, 1974), but

infants in the NICU appear in large part to be protected against this complication. However, infants demonstrating a twofold rise in creatinine, evidence of tubular compromise, or renal tubular acidosis may benefit from use of one of the liposomal amphotericin preparations. One such agent, AmBisome, has been used in neonates (Juster-Reicher et al, 2000; Weitkamp et al, 1998). The particles in at least one other liposomal preparation appear to be too large to penetrate the adult kidney (Hell et al, 1999), and this author has seen a premature newborn whose persistent candiduria failed to resolve until the liposomal preparation (Abelcet) was changed to amphotericin B desoxycholate. If the central venous catheter is promptly removed and there is no evidence of dissemination, the duration of therapy is typically 10 to 14 days after the blood culture becomes negative (Donowitz and Hendley, 1995).

A recent prospective study of 100 premature newborns weighing less than 1000 g at birth has shown that 6 weeks of prophylaxis with intravenous fluconazole in an escalating dosage regimen (3 mg/kg, divided, every third day for 2 weeks; then every other day for 2 weeks; then every day for 2 weeks) reduced both colonization and infection in the treatment group. The incidence of candidemia was approximately 20% in the placebo group and zero in the treatment group (Kaufman et al, 2001). Although resistance to fluconazole did not emerge during the 6 months of the study, at least one institution in a separate multi-site, prospective study of candidemia reported three *C. albicans* isolates that were resistant to fluconazole (minimal inhibitory concentration [MIC] greater than 64 µg/mL) (Saiman et al, 2000).

Molecular genotyping must be employed in attempting to differentiate a temporally related cluster of candidal infections from a true outbreak caused by a common source. Any of several methods of sufficient sensitivity and specificity may be utilized, but genotyping that relies solely on restriction fragment patterns frequently gives rise to erroneous conclusions (Faix et al, 1995; Vazquez et al, 1997).

### Disseminated Candidiasis

Mortality rates approach 30% for disseminated candidiasis, a dreaded complication of candidal infection. Once again, *C. albicans* is the leading pathogen. Organ involvement is most common in the vascular tree at catheter sites (15.2%), followed by the kidneys (7.7%) (Noyola et al, 2001; Patriquin et al, 1980). Eye involvement occurs in approximately 6% of infants. Thrombi within the vascular bed may be particularly difficult to eradicate with antifungal therapy; infants with right atrial thrombi may benefit from atriotomy (Foker et al, 1984). Other sites rarely involved include the liver (Noyola et al, 2001), spleen (Kretschmer et al, 1968), and skeletal system (Adler et al, 1972; Brill et al, 1979; Dan, 1983; Diament et al, 1982; Ho et al, 1989; Pittard et al, 1976; Pope, 1982; Svirsky-Fein et al, 1979; Ward et al, 1983). In infection of the bones and joints in premature newborns, *Candida* species typically are the second most likely pathogen, preceded by *Staphylococcus aureus* (Ho et al, 1989).

Both prospective and retrospective studies have established that *C. albicans* carries higher morbidity and mortality rates than those associated with *C. parapsilosis* (Faix, 1992; Saxen et al, 1995). Premature newborns infected with *C. albicans* have a considerably higher risk of prolonged fungemia, in many cases lasting more than 7 days (Chapman and Faix, 2000). Reasons underlying this propensity to delayed clearance despite adequate systemic antifungal therapy are poorly understood but may involve an insufficient cytokine response or immaturities of reticuloendothelial clearance (Mehr and Doyle, 2000). In animal models, tumor necrosis factor-α (TNF-α) appears to be the cytokine best correlated with clearance (Choi et al, 2001), but levels in premature infants are highly variable (Ng et al, 1997).

## INFECTIONS ASCRIBABLE TO OTHER FUNGI

### Invasive Fungal Dermatitis

Invasive fungal dermatitis typically manifests in the infant weighing less than 1000 g, who displays macerated or bruise-like lesions that are contaminated with fungal species. In the initial report, *C. albicans* was identified in three of seven confirmed cases; *C. parapsilosis*, *C. tropicalis*, *Trichosporon beigeli*, *Curvularia*, or *A. niger* or *A. fumigatus* were cultured from the remainder (Rowen et al, 1995). Among cases considered “probable,” seven of eight had *C. albicans*. Systemic complications including fungemia, meningitis, or infection of the urinary tract occurred in four of seven confirmed cases and in seven of eight probable cases. In more cases than controls, the patient had received postnatal steroids and had had prolonged hyperglycemia. Disseminated infection occurred in 69% of the cases, all ascribable to *Candida* species.

Diagnosis requires a skin biopsy demonstrating fungal invasion beyond the stratum corneum or a positive potassium hydroxide preparation of skin scrapings; growth of the identical organism from an otherwise sterile site (blood, CSF, or urine obtained via supra pubic aspiration) is confirmatory. Treatment requires systemic doses of amphotericin B in the range of 0.7 to 1.0 mg/kg/day; in those infants who do not develop systemic infection, oral therapy with fluconazole or topical antifungal creams may suffice. Parenteral therapy is advisable for pathogens like *Aspergillus*, and repeated skin biopsies may be necessary to define duration of therapy.

### Line Infections Due to Lipophilic Organisms

*M. furfur* and *M. pachydermatis* are lipophilic organisms commonly carried on the skin, even in patients without tinea versicolor (Marcon and Powell, 1992). Cutaneous colonization can infect hyperalimentation fluids or parenteral lipid formulations. Infants typically present with mild but nonspecific symptoms: respiratory decompensation, glucose intolerance, or thrombocytopenia (Dankner et al, 1987; Stuart and Lane, 1992). Diagnosis requires isolation of the organism from blood by growth on fungal medium overlaid with olive oil, because *Malassezia* species will not grow in the absence of lipids (Marcon et al, 1986). Removal of the central venous catheter usually suffices

for therapy, although some experts recommend the addition of amphotericin B in doses of 0.5 mg/kg/day for 7 days.

## Miscellaneous Fungal Infections

### *Aspergillus* Infections

Most infections with *Aspergillus* occur in severely immunocompromised patients such as those with DiGeorge syndrome or myeloperoxidase deficiency (Chiang et al, 2000; Marcinkowski et al, 2000), but disseminated disease has occurred in premature newborns without additional immunologic abnormalities (Rowen et al, 1992). Rare cases of *Aspergillus* osteomyelitis or brain abscess also have been reported (Marcinkowski et al, 2000; Simpson et al, 1977). Diagnosis requires isolation of the fungus from a normally sterile tissue site or visualization by Gomori-methenamine silver stain on biopsy of infected tissue. Of note, a commercially available ELISA for diagnosis of aspergillosis on serum specimens had an 83% rate of false-positives in premature newborns (Siemann et al, 1998). Treatment requires systemic amphotericin B in doses of 1.0 to 1.5 mg/kg/day. Fungistatic agents such as the triazoles are not recommended for treatment of aspergillosis. There is no published experience with itraconazole or voriconazole in the premature newborn.

### *Trichosporon beigelii* Infection

In a cluster of five neonatal cases of infection caused by *T. beigelii*, a yeast found ubiquitously in soil, no common source was identified (Fisher et al, 1993). Two of three premature infants infected with this organism died. Resistance to achievable concentrations of amphotericin B complicates therapy.

# RESPIRATORY SYSTEM

Editor: ROBERTA A. BALLARD

## CHAPTER 42

### Lung Development: Embryology, Growth, Maturation, and Developmental Biology

Susan Guttentag and Philip L. Ballard

The primary function of the lung is to accomplish exchange of oxygen and carbon dioxide, to accommodate the needs of aerobic cellular respiration. Oxygen consumption in the adult human ranges from 250 mL/minute at rest to 5500 mL/minute at peak exercise (reviewed in Warburton et al, 2000). To accommodate these needs, a large surface area, up to 70 m<sup>2</sup>, and a thin alveolar-capillary membrane are required. Therefore, a primary component of lung organogenesis is to expand the lung surface area to meet these needs, a process known as *lung branching morphogenesis*. A second goal of lung organogenesis is to minimize the alveolar-capillary membrane, coordinating the development of an extensive capillary network with a thin, expansive alveolar epithelial surface. A third goal of lung development is production of a protective aqueous barrier overlying the delicate alveolar epithelium that is constantly exposed to air. This liquid layer, however, creates a surface tension sufficient to collapse alveoli in the course of air breathing. Hence, another goal of lung development is to produce a surface-active agent, or surfactant, to reduce surface tension, thereby preventing alveolar collapse, or atelectasis, at end-expiratory alveolar volumes. This allows for air to remain within the lung at end-expiration, the functional residual capacity, which significantly reduces the work required to generate the next breath.

The trachea, airways, and alveoli are in constant contact with the external environment. Consequently, with every inhalation these epithelial surfaces come into contact with large numbers of microorganisms and toxic particles. Another important goal of lung organogenesis is to develop mechanisms for clearance of microorganisms and allergens that may result in epithelial infection or injury (Crouch and Wright, 2001).

Finally, the lung needs to develop defenses against non-particulate substances that are potentially harmful. Oxygen, so critical to cellular function, can be the source of harmful reactive oxygen species (Chabot et al, 1998). Inhaled pollutants also must be detoxified by the lung. The lung, like other organs, has multiple strategies for handling reactive oxygen species and toxic metabolites to minimize tissue damage.

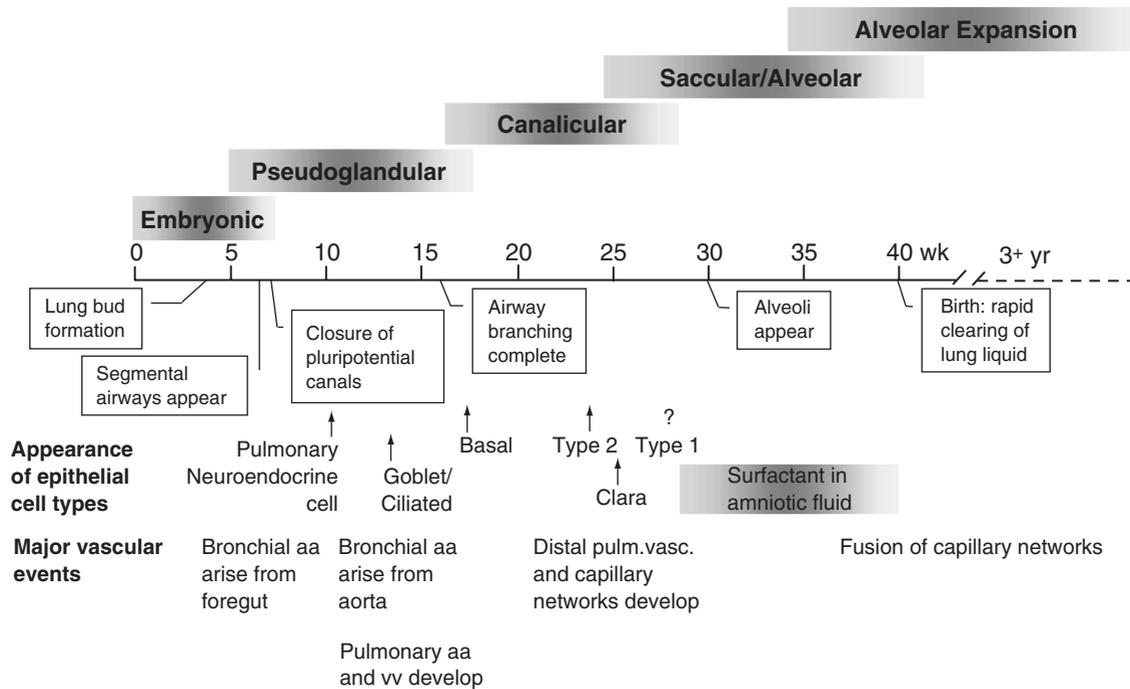

Appropriate development and integration of these lung functions are critical to the health and survival of newborn infants. This chapter focuses on developmental aspects of each function that place the premature neonate at increased risk for lung injury and disease.

#### DEVELOPMENT OF GAS EXCHANGE SURFACE

Lung formation begins early in human gestation (by day 25) and growth extends well into childhood, reaching completion by approximately 8 years of age (Davies and Reid, 1970). Lung development can be organized into five stages: embryonic, pseudoglandular, canalicular, terminal sac, and alveolar. The timing of these stages is somewhat imprecise, however, and considerable overlap may occur between stages (Hislop and Reid, 1981). Figure 42–1 shows a time line for fetal and postnatal lung development that incorporates salient events in the development of airway, alveolar, and vascular components as a reference for the discussion that follows. Because of the interrelatedness of these events, it is possible to examine how disruptions in the developmental program can have profound effects on lung morphogenesis. Disruption in the final common pathway of altered lung development often results in pulmonary hypoplasia. Table 42–1 lists genetic defects and disorders associated with pulmonary malformations, organized by mechanism of disease. Pulmonary hypoplasia can result from primary defects in lung morphogenesis as well as from neurologic diseases associated with decreased fetal breathing movements, derangements of the chest wall that restrict fetal breathing movements, renal disorders that compromise amniotic fluid volume and thereby restrict fetal breathing, or space-occupying masses that restrict lung growth. In each case, disorders that manifest early in fetal development have the most profound effects on lung development, resulting in the most severe pulmonary hypoplasia.

#### The Embryonic Phase

The lung bud develops initially as a laryngotracheal groove of the ventral foregut at 25 days of human gestation; within a few days, the groove closes in such a fashion that the only

**FIGURE 42-1.** Timeline for fetal and postnatal lung development that incorporates salient events in the development of airway and alveolar and vascular components. aa, vv, arteries, veins.

remaining luminal attachment to the foregut is in the region of the developing hypopharynx and larynx. The lung bud, consisting of epithelium and surrounding mesenchyme, then begins the first of a series of dichotomous branchings that give rise to the conducting airways and five primordial lung lobes (two on the left and three on the right).

The process of branching morphogenesis requires extensive communication between the cells lining the tubular lung bud and those cells contained within the invested mesenchyme (reviewed in Kaplan, 2000; Warburton et al, 2000). Classic recombination experiments using mesenchyme dissected away from the epithelium of either the trachea or more distal bronchi indicate that the mesenchyme plays an important role in dictating the branching pattern and cell fate of the expanding epithelium (Shannon and Deterding, 1997). Branching involves growth arrest of the epithelial cells at branch points, with continued or accelerated growth of epithelial cells lateral to branch points (Hogan and Yingling, 1998). This is governed by the expression of transcription factors that in turn control the expression of growth factors and their receptors—for example, Sonic hedgehog, secreted from epithelial cells, and its receptor patched (Ptc) on adjacent mesenchyme cells—in a complex array of both positive and negative feedback loops. Activation of Ptc results in the release of an intracellular gene product smoothed (Smo), which activates the Gli family of transcription factors. Although the downstream targets for this signaling pathway are unclear, the net result is local proliferation of mesenchymal cells at the tips of the growing epithelial tubules. The Gli family of transcription factors also are necessary for dorsolateral patterning that separates the trachea from the esophagus. Left-right asymmetry of the lung, studied in mice, is governed by another family of

transcription factors related to transforming growth factor- $\beta$  (TGF- $\beta$ ), specifically, lefty 1 and 2, nodal, and gdf1 (Rankin et al, 2000).

Tracheoesophageal fistulas and tracheal atresia and stenosis result from errors in partitioning of the laryngo-tracheal groove. Transgenic mouse models have shown that targeted knockout of genes encoding Gli family members recapitulates these developmental errors and may contribute to these malformations (Rankin et al, 2000; Warburton et al, 2000). Failure of partitioning of the lung bud also can result in pulmonary agenesis, typically of the right lung.

### The Pseudoglandular and Canalicular Phases

Branching continues such that by 7 weeks, the trachea and the segmental and subsegmental bronchi are evident, marking the end of the embryonic phase. The pseudoglandular phase extends from 7 to 16 weeks of human gestation. By the end of 16 weeks, all bronchial divisions are complete, resulting in a total of 16 divisions responsible for gas conduction. The canalicular phase, extending from 16 to 28 weeks, is marked by the development of the rudimentary gas exchange units that are no longer invested with supportive cartilaginous structures. Furthermore, parallel development of vascular structures occurs to supply ever-increasing numbers of potential air spaces.

Successive branching of the lung bud is dependent on a number of growth factors and transcription factors (reviewed in Kaplan, 2000; Warburton et al, 2000). A critical component is the mesenchymal product fibroblast growth factor-10 (FGF-10) and its receptor fibroblast growth factor receptor-2 (FGFR-2) on epithelial cells. The

**Genetic Disorders and Syndromes Associated with Pulmonary Abnormalities**

<b>Genetic Condition</b>	<b>Pulmonary Abnormality</b>	<b>Associated Finding(s)</b>	<b>OMIM Ref.*</b>
<b>Syndromes Associated with Primary Defects in Lung Development</b>			
Trisomy 21	Pulmonary hypoplasia, tracheoesophageal fistula, alveolar dysplasia	Chylothorax	
Trisomy 18	Pulmonary malsegmentation to aplasia of right lung; tracheoesophageal fistula		
Trisomy 13	Situs inversus of lungs; calcified pulmonary arterioles; congenital diaphragmatic hernia		
Pallister-Hall syndrome	Laryngeal cleft, dysplastic tracheal cartilage, absent lung, abnormal lung lobation	Hypoplasia/absent epiglottis	146510
Pfeiffer syndrome	Tracheal stenosis, laryngotracheomalacia	Broad short thumbs and big toes; FGFR-2 defects	101600
Smith-Lemli-Opitz syndrome type II	Unilobar lung	Postaxial polydactyly, cleft palate, cataracts, heart disease	268670
G syndrome, Opitz-Frias syndrome	Laryngotracheoesophageal cleft	Hypertelorism, hoarse cry; X-linked	145410
Hydroletharus syndrome	Tracheal stenosis, abnormal lung lobation		236680
Lung agenesis	May be bilateral; if unilateral, usually right is missing		601612
Type 1 total anomalous pulmonary venous return	Unilateral pulmonary hypoplasia	Total anomalous pulmonary venous return	106700
Thymic aplasia with fetal death	Unilateral pulmonary agenesis, pulmonary hypoplasia	No parathyroid tissue, truncus arteriosus	274210
Matthew-Wood syndrome	Pulmonary hypoplasia	Anophthalmia, microphthalmia	601186
Familial pulmonary hypoplasia	Pulmonary hypoplasia		265430
Larsen-like syndrome, lethal type	Pulmonary hypoplasia, tracheomalacia	Collagen fiber dysmaturity	245650
Aphalangy with hemivertebrae	Pulmonary hypoplasia	Aphalangy of hands, feet	207620
<b>Syndromes Associated with Hypotonia and Decreased Fetal Breathing</b>			
Pena-Shokeir syndrome type I	Pulmonary hypoplasia	Fetal akinesia sequence	208150
COFS syndrome (Pena-Shokeir syndrome type II)	Pulmonary hypoplasia	Hypotonia, large ears, arthrogryposis, camptodactyly	214150
Myasthenia gravis	Pulmonary hypoplasia	Similar to fetal akinesia sequence	254200
<b>Syndromes Associated with Restriction of Thoracic Volume</b>			
Pulmonary cystic lymphangiectasis	Pulmonary hypoplasia	Bilateral chylothoraces	265300
Lethal congenital contracture syndrome	Pulmonary hypoplasia	Contractures, short thorax, hydrops	253310
Tight skin contracture syndrome	Pulmonary hypoplasia	Contractures, tight thin skin	275210
Pterygium syndrome	Pulmonary hypoplasia	Arthrogryposis	265000
Spondylospinal thoracic dysostosis	Pulmonary hypoplasia	Arthrogryposis, micrognathia	601809
Jeune asphyxiating thoracic dystrophy	Pulmonary hypoplasia	Small narrow thorax, polydactyly, hepatic and renal abnormalities	208500
Neonatal osseous dysplasia I	Pulmonary hypoplasia, laryngeal stenosis, tracheobronchomalacia	Skeletal dysplasia	256060
Short rib-polydactyly syndrome types II and IV	Pulmonary hypoplasia	Hydrops, narrow chest	269860 263520
Osteosclerotic bone dysplasia, lethal	Pulmonary hypoplasia	Craniofacial defects, osteosclerosis	259775

expression of FGFR-2 in key positions along the expanding tubule determines the location of primary, secondary, and tertiary branches. In another complex feedback network, FGF-10 signaling from the epithelium also induces the expression of bone morphogenetic protein-4 (BMP-4), another member of the TGF- $\beta$  superfamily, by the mesenchyme, which inhibits epithelial proliferation, thus limiting tubule length. Other families of growth and transcription factors assist in the regulation of lung morphogenesis, including the epithelial growth factor (EGF)/EGF receptor family, insulin-like growth factors/receptors, platelet-derived growth factors and their receptors, and other members of the TGF- $\beta$  superfamily. The complex interplay of these networks is reviewed elsewhere (Cardoso, 1995; Costa et al, 2001). Components of extracellular matrix are vital to branching morphogenesis and microvascular development by influencing cell adhesion, cell shape, and cytoskeletal organization, as well as providing a scaffold for cell-cell signaling (Dunsmore and Rannels, 1996). For example, interference in the assembly of fibronectin matrix, which is thought to provide positional information for cell migrations, inhibits branching in embryonic lungs.

Errors in the developmental program during the later embryonic and/or pseudoglandular stages may result in a form of pulmonary hypoplasia that is characterized by decreased numbers of bronchial segments that contain an appropriate number of alveoli per bronchiole as indicated by radial alveolar counting (Hislop and Reid, 1981). Congenital diaphragmatic hernia results from a developmen-

tal error in this period. Closure of the pleuripertoneal canals occurs by 7 weeks of gestation, thereby separating the pleural from the peritoneal cavity. Failure of closure results in a diaphragmatic defect permitting continuity between these spaces. With this defect, at 10 weeks, when the midgut returns to the peritoneal cavity, abdominal contents are free to pass into the thoracic cavity and restrict the space into which the lung grows. The molecular mechanisms governing the development of the pleuroperitoneal folds and their closure, and the migration of myoblasts into these membranes to form the diaphragm, are poorly understood. Administration of nitrofen, a herbicide with structural similarity to thyroid hormone, early in rodent gestation induces unilateral or bilateral diaphragmatic defects. This line of evidence has been a valuable model of congenital diaphragmatic hernia.

As branching morphogenesis continues, maturation of more proximal epithelium follows. Some of the same growth factors modulating branching also influence cell fate of the once-undifferentiated epithelium. Thyroid transcription factor-1 (TTF-1), a product of the *Nkx2.1* gene, plays an important role in embryonic lung branching; transgenic mice null for *Nkx2.1* exhibit complete absence of lung branching (reviewed in Cardoso, 1995). However, *Nkx2.1* also plays a prominent role in establishing cell fate, specifically of alveolar type II cells. The physiologic role of endogenous corticosteroids, thyroid hormones, and potentially other circulating hormones is limited to modulation of the rate of differentiation of both mesenchymal and

epithelial cells after completion of airway branching. This role is well illustrated for glucocorticoids by the arrest of lung cellular differentiation at about fetal day 16, after branching morphogenesis is complete, in transgenic mice with knockout of either corticotrophin-releasing hormone or glucocorticoid receptor (Muglia et al, 1995; Schmid et al, 1995).

### The Terminal Sac and Alveolar Phases

The *acinus* is the gas exchange unit of the lung and encompasses a respiratory bronchiole and all of its associated alveolar ducts and alveoli (West, 1990). A terminal bronchiole with all of its associated acinar structures constitutes a *lobule*. Ultimately, the zone of gas exchange will attain a surface area of 50 to 100 m<sup>2</sup>, with a volume of 2.5 to 3.0 L in the adult human. Branching of the most distal air spaces continues on a more limited basis during the terminal sac and alveolar phases, finally achieving a total of 23 airway subdivisions by the end of the terminal sac phase, while evolution of the relationships between the air spaces, capillaries, and mesenchyme takes on more significance.

Lengthening and widening of the terminal sacs serve to expand the surface area available for gas exchange. Each saccule will give rise to two to three alveolar ducts, further expanding the available surface area. The expansion of surface area and luminal volume compresses the interstitium, bringing the capillary networks in close proximity to potential air spaces, thereby promoting alveolar development and later capillary bed fusion. At this stage, a complete capillary network is available for each acinus, effectively creating a double circulation between acini. Capillary networks investing separate acini will fuse as the interstitium separating alveoli thins toward birth, a process that is not complete until 18 months of postnatal age.

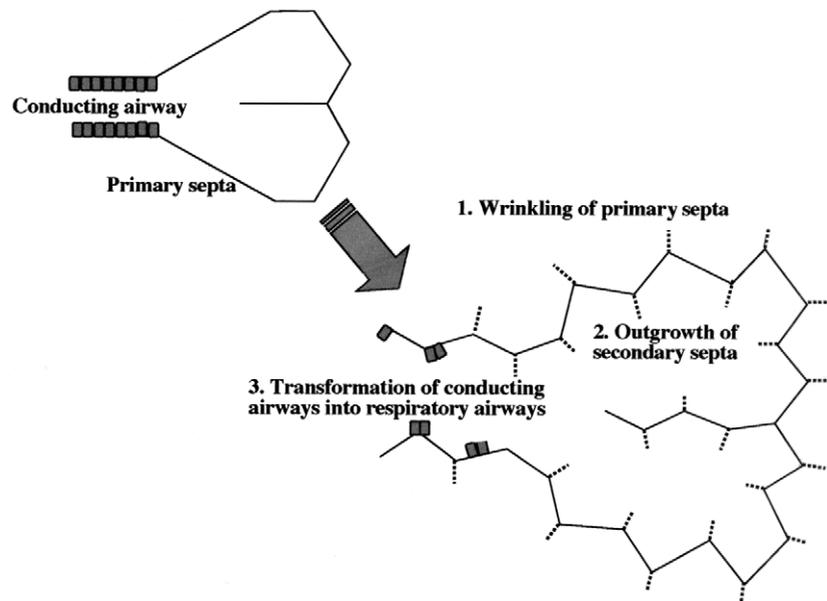

The basement membrane and interstitial extracellular matrix components appear to play important roles in alveologenesis as well as in the differentiation of types I and II epithelial cells (Dunsmore and Rannels, 1996; Wright et al, 1999). Production of elastic fibers, composed of elastin and microfibrillar proteins, begins at mid-gestation and extends through the neonatal period (reviewed in Dunsmore and Rannels, 1996; Mariani et al, 1997; Schuger, 1997). Elastin is a polymer of cross-linked tropoelastin precursor protein and constitutes approximately 90% of the mass of the fibers. A variety of glycoproteins makes up the microfibrils that serve as a scaffold for elastin deposition. Elastin, localized to the walls of alveoli and pulmonary vessels, allows for repetitive deformations in the shape and size of these structures. Excess elastin or diminished content of elastin in diseases such as pulmonary hypertension and fibrotic conditions can severely compromise the strength and formation of blood vessels and alveoli.

The alveolar basement membrane includes laminin, entactin, types IV and V collagen, chondroitin sulfate and chondroitin sulfate proteoglycan, heparan sulfate proteoglycans, and fibronectin. Basement membrane components are important in the regulation of epithelial differentiation into surfactant-producing type II cells and the thin type I cell that participates in gas exchange and alveolar fluid homeostasis. The local concentration of basement membrane

components may regulate the location of type II cells (at the corners of alveoli) and the relative ratio of types I and II alveolar cells. There is evidence that the type II cell basement membrane is discontinuous, allowing maintenance of direct cell-cell interactions with cells of the interstitium, specifically fibroblasts (Adamson, 1992). In addition, *in vitro* studies have shown that extracellular matrix can have dramatic effects on maintenance of type II cell phenotype in isolated cell culture. The developmental program governing extracellular matrix composition during alveolar epithelial cell differentiation probably is recapitulated after epithelial damage by airborne or blood-borne toxic agents. Because type II cells are the source of type I cells after injury, alterations in extracellular matrix composition are essential to reconstitute a functional, differentiated alveolar lining. Moreover, aberrant signaling during the repair process may lead to abnormalities in extracellular matrix deposition and reconstitution of the alveolar lining, thereby contributing to the pathobiology of lung diseases such as bronchopulmonary dysplasia. The interplay of extracellular matrix (ECM) components and proteases involved in the remodeling of ECM reinforces the dynamic nature of ECM during lung development and injury repair (reviewed in Parks and Shapiro, 2001). For example, the aberrant alveologenesis that occurs in EGF receptor-knockout mice is associated with a dramatic reduction in matrix metalloproteinase-2 (MMP-2). The MMP-2-knockout mouse model phenocopies the alveolar defects of the EGF receptor knockout, indicating that the abnormal alveologenesis of the EGF receptor knockout is due in part to abnormal modulation of ECM components (Kheradmand et al, 2002).

The development of primary alveoli is followed by a further expansion of the gas exchange surface area through the formation of septa, or secondary crests. Primitive saccules develop low ridges that subdivide the saccule into an alveolar duct (primary septa) and outpouchings between the ridges (secondary septa) (Fig. 42-2). Regions destined for secondary septation exhibit increased elastin deposition (Mariani et al, 1997). Septa contain a connective tissue core separating two capillary membranes, suggesting that the septum is formed by the folding of the capillary on itself. This folding occurs in regions in which the double capillary network is preserved between acini or, alternatively, at pleural surfaces or adjacent to large blood vessels and conducting airways. Septation also leads to the development of the pores of Kohn, allowing gaseous continuity between acini.

There is controversy regarding the completion of alveolarization. Current estimates suggest that the formation of new alveoli is complete by approximately 2 to 3 years of postnatal life, achieving a total of between 200 million and 600 million alveoli (Davies and Reid, 1970). Lung growth is not complete at this stage, however. Between 4 years of age and adulthood, there is extensive linear growth, which includes expansion of the thoracic cavity. Increased intrathoracic volume increases the negative pressure generated by diaphragmatic excursions, thereby allowing three-dimensional stretch of alveoli, which increases alveolar volume. In total, lung volume increases 23-fold between birth and adulthood. The capillary bed expands at a greater pace, achieving a 34-fold expansion over the same period. Thus, compared with adult lung, the term

**FIGURE 42-2.** Primary and secondary septa.

newborn has relatively less lung volume per kilogram of body weight, increased interstitial components relative to air space, and a smaller capillary bed.

The physiologic factors regulating growth of the lung during postnatal life are not well understood. Treatment of animals with corticosteroids, can reduce lung weight through direct effects on cell replication (e.g., in newborn rats) and indirectly in the fetus by accelerating placental senescence and impairing function (Okajima et al, 2001; Tschanz et al, 1995). Postnatally, lung growth is stimulated after partial pneumonectomy but there is little information on mediating agents and mechanism of action (Holmes and Thurlbeck, 1979).

### PHYSICAL FACTORS INFLUENCING LUNG DEVELOPMENT

The role of physical factors in modulating lung size is well established. Normal growth requires adequate space in the chest cavity and appropriate tonic and cyclic distending forces. Genetic defects that compromise the thoracic skeleton are associated with pulmonary hypoplasia as a result of the restriction of intrathoracic space. In animal models, denervation of the diaphragm to eliminate fetal breathing movements also is associated with pulmonary hypoplasia. Finally, manipulation of fetal lung fluid volume can modulate lung growth in utero, although the mechanisms for this effect remain unclear.

#### Fetal Lung Fluid

In fetal animals, lung growth is reduced by maneuvers such as cervical spinal cord transection (denervating the diaphragm); removing a portion of the rib cage, thereby reducing chest wall rigidity; chronic drainage of amniotic fluid; and tracheostomy that allows free efflux of lung fluid. The common thread is reduction of the tonic or cyclic stretch imposed on the developing lung (Dobbs and

Gutierrez, 2001). In contrast, tracheal occlusion, which increases intraluminal pressure, increases lung dry weight. These and other experimental observations have led to the proposal that fetal breathing movements retard loss of lung liquid and maintain lung expansion in the face of decreased upper airway resistance, whereas during periods of nonbreathing there is tonic inflation secondary to laryngeal abduction (Harding, 1984; Harding et al, 1986). Both of these stretching events may stimulate production of growth-mediating factors such as insulin-like growth factor-II and platelet-derived growth factor B by lung fibroblasts. The mechanisms by which mechanical forces are transduced into epithelial cell proliferation and differentiation are largely unexplored.

Fetal lung fluid is a product of the epithelial lining of the developing lung (reviewed in Hooper and Harding, 1995). Its composition is distinct from that of both amniotic fluid and plasma, as illustrated in Table 42-2. The increased chloride content of fetal lung fluid as compared with serum is due to the ability of the tracheal and distal pulmonary epithelium to actively secrete chloride into the potential air spaces. The identity of the chloride pump remains unclear; however, its action can be inhibited by a variety of mediators, including beta-adrenergic agonists, arginine vasopressin, and prostaglandin E<sub>2</sub>. Production of fetal lung fluid averages 4 to 6 mL/kg/hour. Because of the resistance imparted by laryngeal abduction, fluid accumulates to a total volume of 20 to 30 mL/kg during gestation, providing end-expiratory pressure of approximately 4 cm H<sub>2</sub>O.

Despite the importance of fetal lung fluid to lung growth and development, the transition to an air-breathing environment must be coupled with the conversion from a secretory pulmonary epithelium to one that is absorptive. Enhanced sodium transport across the alveolar epithelium is in part responsible for this change. Much evidence suggests that induction of components of the epithelial sodium channels (ENaC) around the time of birth is a major factor in promoting sodium transport,

TABLE 42-2

**Composition of Human Fetal Lung Liquid Compared with Other Body Fluids**

Component	Lung Liquid	Interstitial Fluid	Plasma	Amniotic Fluid
Sodium (mEq/L)	150	147	150	113
Potassium (mEq/L)	6.3	4.8	4.8	7.6
Chloride (mEq/L)	157	107	107	87
Bicarbonate (mEq/L)	3	25	24	19
pH	6.27	7.31	7.34	7.02
Protein (g/dL)	0.03	3.27	4.09	0.10

with water passively following the movement of sodium (reviewed in Jain, 1999). Transgenic knockout animals devoid of the  $\alpha$  subunit of ENaC die at birth due to failure to clear fetal lung fluid. The  $\alpha$ -ENaC subunit is dramatically up-regulated just before birth, whereas the  $\beta$  and  $\gamma$  subunits are not up-regulated until shortly after birth. Induction of ENaC components occurs at a transcriptional level in response to changes in ECM components, glucocorticoids, aldosterone, and oxygen. By contrast, agents that increase intracellular cyclic adenosine monophosphate (cAMP) levels (i.e., beta agonists, phosphodiesterase inhibitors, and cAMP analogues), although not increasing the number of sodium channels, increase the probability of a channel being open to sodium transport as a result of phosphorylation of the subunits.

Water channels, consisting of aquaporins, also are induced during the late fetal period to facilitate fluid movement (Song et al, 2000). Aquaporin 5 is expressed by alveolar type I cells, whereas aquaporin 4 is expressed in airway epithelial cells and aquaporin 1 in pulmonary endothelial cells. In contrast with the  $\alpha$ -ENaC  $-/-$  mice, newborn transgenic animals deficient in aquaporin 5 or both 5 and 1 survive despite reduced water permeabilities (reviewed in Verkman et al, 2000).

On delivery of the head and neck, continued uterine contractions on the fetal thorax promote expulsion of bulk fluid from the fetal lung. The absence of uterine contractions is associated with an increased incidence of retained fetal lung fluid in infants delivered by cesarean section without the benefit of labor. However, animal studies have shown that the magnitude of the benefit of thoracic compression during labor is modest (reviewed in Bland, 2001). The primary mechanism by which labor facilitates clearance of lung fluid, thereby reducing the incidence of transient tachypnea of the newborn, is through hormonal effects on fluid clearance, such as  $\alpha$ -ENaC, especially through catecholamines. The onset of air breathing, associated with increased intrathoracic negative pressure, assists in the clearance of residual fetal lung fluid into the loose interstitial tissues surrounding alveoli. Fluid is then reabsorbed via lymphatics and pulmonary blood vessels.

**Fetal Breathing Movements**

Fetal breathing is an essential stimulus for lung growth and for successful respiratory effort after birth (Blanco, 1994; Harding, 1997). Fetal breathing is readily detectable as early as 10 weeks of gestation in the human fetus. Fetal breathing occurs for 10% to 20% of the time at 24 to 28 weeks and for 30% to 40% of the time after 30 weeks of gestation. Originating from the diaphragm, fetal breathing is erratic in frequency and amplitude, and changes throughout gestation. The volume of fluid moved is small and insufficient to be cleared from the trachea. Respiratory rates ranging from 30 to 70 breaths/minute, in addition to periods of apnea of up to 2 hours, have been recorded. Sustained periods of fetal breathing increase in duration with advancing gestation. The frequency of fetal breathing varies with sleep state (inhibited during quiet sleep) and exhibits diurnal variation, with the lowest rates recorded early in the morning. Fetal breathing is hormonally responsive, and the inhibition of fetal breathing at the onset of labor is attributed to the action of increased circulating prostaglandins (Rigatto, 1996). Similarly, maternal medications can influence the frequency of fetal breathing movements. Central nervous system stimulants (e.g., caffeine, amphetamines) are associated with increased fetal breathing, whereas depressants (e.g., anesthetics, narcotics, ethanol) are associated with decreased fetal breathing. Maternal smoking is associated with reduced fetal breathing, largely as a result of the associated relative hypoxemia. Animal studies have clearly shown that permanent cessation of fetal breathing, regardless of the insult, is associated with impaired fetal lung growth. However, the impact of short-term alterations in frequency and amplitude of fetal breathing on fetal lung development is unknown.

After delivery, the breathing pattern changes from episodic and erratic to continuous and regular. There are several mechanisms by which postnatal breathing patterns are established (Jansen and Chernick, 1991). Animal studies suggest that delivery triggers the withdrawal of inhibitory signaling on the midbrain. Similarly, it has been suggested that withdrawal of a placental inhibitory factor is in part responsible for the initiation of continuous breathing, although no substance has been identified to date. Skin cooling and a concomitant reduction in core temperature are potent sensory stimuli for initiating and maintaining continuous breathing. The most detailed studies, however, have been related to the roles of oxygen and carbon dioxide in postnatal breathing. Central and peripheral chemoreceptors are reset with the onset of continuous breathing, allowing for increased sensitivity to  $PCO_2$  immediately after birth as a primary mechanism for continuous breathing. By contrast, hypoxemia does not appear to play a role in maintaining continuous breathing for several days postnatally.

**LUNG EPITHELIAL CELL DIFFERENTIATION**

As branching morphogenesis proceeds, the epithelium lining the successive generations of airways and, ultimately, alveoli give rise to specialized cells that participate

in gas exchange, mucociliary clearance, and host defense. Differentiation proceeds in a centrifugal fashion from proximal to distal air spaces, lagging behind branching. Temporal as well as contextual signals foster the regionalization of epithelial cell types.

### Proximal Airways

The airway epithelial cells are tall and columnar, decreasing to a more cuboidal appearance in the most distal segments (Jeffrey, 1998). The endodermal epithelial lining cells of the conducting airways differentiate into four cell types: ciliated, mucus-secreting goblet, indeterminate, and basal cells. A fifth cell, the pulmonary neuroendocrine cell, is not endodermal in origin but originates from neural crest cells migrating into the lung during development (reviewed in Warburton et al, 1998). Cartilaginous support of the tracheobronchial tree begins and proceeds in a centrifugal fashion, beginning in the primitive trachea at approximately 10 weeks and proceeding to the most distal terminal bronchioles by approximately 25 weeks.

### Distal Airways

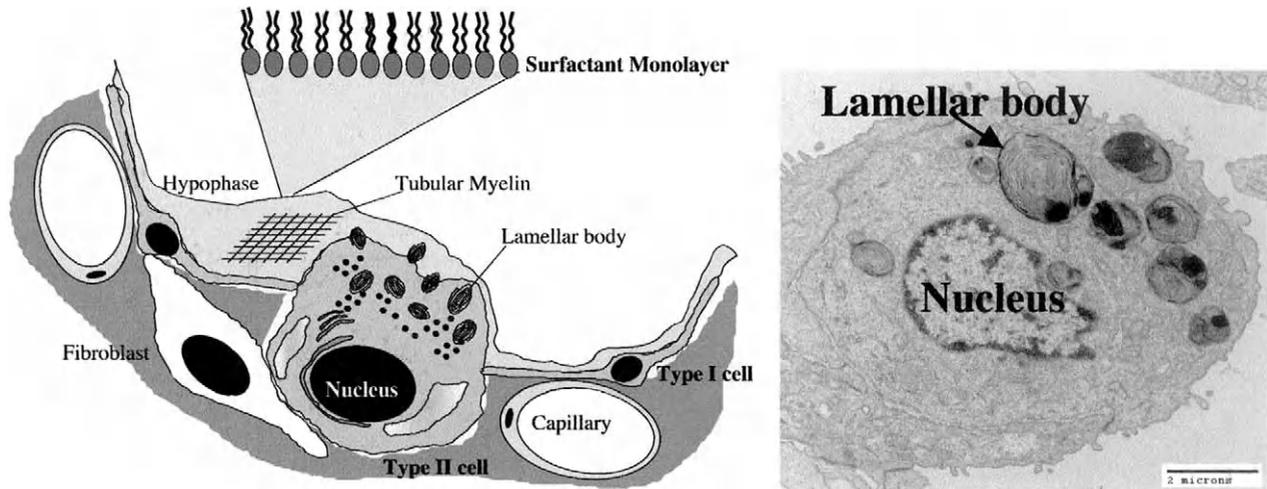

The bronchiolar epithelium differs from the more proximal airway epithelium in the contribution of Clara cells to the epithelial cell population. The nonciliated, secretory Clara cell is found in increasing numbers and density down the conducting airways, such that the Clara cell is the most abundant cell of the terminal bronchiole (reviewed in Massaro et al, 1994; Plopper, 1997). Clara cells are critical to the host defense and detoxification functions of the lung. This specialized cell produces the highest levels of cytochrome P-450 and flavin mono-oxygenases of the 40 known lung cell types. These enzyme systems are important in detoxification but also participate in the bioactivation of procarcinogens, placing the Clara cell in a delicate balance between these two activities. Accordingly, Clara cells are one of the primary targets of toxic metabolites. Other important products of the Clara cell include Clara cell secretory protein (CCSP or CC10); surfactant proteins A, B, and D (SP-A, SP-B, SP-D); leukocyte protease inhibitor; and a trypsin-like protease. CC10, SP-A, and SP-D have important roles in regulating inflammatory responses within the lung, both from pathogens and allergens. Despite SP-B immunoreactivity, Clara cells are incapable of completing the proteolysis of SP-B to its mature, surface-active form, implying that the other products of SP-B processing have additional function in the airways. The secretion of antiproteases from Clara cells indicates that these cells play an important role in maintaining the protease-antiprotease balance in the lung. Clara cells are detected in proximal bronchi as early as 15 weeks of gestation, appearing in scattered bronchioles by 18 weeks. Between 23 and 34 weeks, there is a dramatic increase in Clara cell numbers as well as in CC10 expression in distal bronchioles. Although transcription factors known to be important in type II cell differentiation and in the expression of type II cell-specific genes also control the expression of Clara cell-specific genes (e.g., TTF-1,

GATA6), little is known about the regulation of Clara cell differentiation. However, like type II cells, the Clara cell is responsive to injury, proliferating in response to epithelial injury and transdifferentiating into ciliated epithelial cells to repopulate the airway.

### Alveolar Epithelium

During months 4 to 6 of gestation, the epithelial cells lining the acini begin to differentiate further (Brody and Williams, 1992; Mallampalli et al, 1997). The cuboidal epithelial cells accumulate large glycogen stores and develop small vesicles containing loose lamellae. In cells destined to become type II cells, lamellar bodies become larger, more numerous, and more densely packed with surfactant phospholipids and proteins, whereas those cells destined to become type I cells, on losing their relationship to mesenchymal fibroblasts, lose the prelamellar vesicles and thin progressively, thereby adopting a phenotype more suitable for gas exchange. Type I and type II cells are readily identified early in the terminal sac stage of fetal lung development. Induction of the components of pulmonary surfactant results in the increased synthesis and storage of surfactant in the increasing numbers of lamellar bodies within type II cells (Fig. 42-3). From approximately 24 weeks of human gestation, the acini and the alveolar-capillary membrane are sufficiently developed to support gas exchange, but the limiting factor for successful air breathing is the maturation of the surfactant system.

Differentiation of precursor epithelial cells into type II cells, and subsequently into type I cells, is under both negative and positive regulation, and these effects occur primarily through altered gene expression. Type II cell differentiation *in vitro* is blocked by TGF- $\beta$ , which acts in part by restricting the availability of transcription factors (e.g., TTF-1, hepatic nuclear factor-3) that are required for synthesis of type II cell-specific genes. It is likely that TGF and other growth-promoting factors inhibit the differentiation process in developing lung *in vivo*; in later gestation, a decline in level or activity of these factors promotes cell differentiation. Glucocorticoids and agents that stimulate production of cAMP antagonize TGF- $\beta$  effects and stimulate cell differentiation through induction and repression of specific genes. In culture systems, these hormones cause precocious development of type II cells, inducing approximately 2% of genes that are expressed in lung epithelial cells. The spectrum of the hormonal response includes proteins of all categories of structural and functional activity in addition to type II cell-specific genes such as surfactant components. A number of transcription factors is induced, some with known function related to surfactant production (e.g., TTF-1, CAAT enhancer-binding protein), and these in turn control expression of target genes. Regulation of gene transcription involves many different proteins that often interact with each other and/or nucleic acid. Categories of these nuclear proteins include transcription factors, coactivators, corepressors, histones, enzymes that modify nuclear proteins, DNA or RNA, proteins of the transcriptional machinery (e.g., RNA polymerase), and receptors for ligands such as corticosteroids and retinoic

**FIGURE 42-3.** Lamellar bodies within type II cells.

acid. Clearly, regulation of epithelial cell differentiation is a complex molecular process that incorporates actions of a variety of signaling molecules and target genes.

### Surfactant

After bulk removal of fetal lung fluid at birth, a thin layer of lung liquid remains to protect the delicate alveolar epithelium. The surface tension generated by this aqueous layer opposes alveolar inflation and promotes alveolar collapse at the low alveolar volumes at end-expiration. The film of surfactant at the air-liquid interface lowers surface tension as alveolar surface area decreases, thereby preventing alveolar collapse, maintaining functional residual capacity, and lowering the force required for subsequent alveolar inflation.

Surfactant is a mixture of phospholipids, neutral lipids, and proteins that are synthesized, packaged, and secreted by alveolar type II cells (reviewed in Hawgood and Clements, 1990) (Table 42-3). Storage of surfactant occurs in a lysosome-derived, membrane-bound organelle, the lamellar body, which undergoes regulated secretion in response to a variety of stimuli, most of which result in increased intracellular calcium levels. In the alveolus, surfactant phospho-

lipids undergo transition through an extracellular storage form, tubular myelin, in association with SP-A and SP-B. The hydrophobic SP-B and SP-C are necessary to liberate surfactant phospholipids from this structure and to order phospholipids in the monolayer at the air-liquid interface. Phospholipid and protein components are recycled out of the monolayer and back into the alveolar type II cell, where they can be repackaged into lamellar bodies. Alternatively, alveolar macrophages are able to phagocytize and degrade surfactant components (Wright, 1990).

The predominant surfactant phospholipid is disaturated phosphatidylcholine (specifically, dipalmitoyl phosphatidylcholine [DPPC]), with the remaining phospholipids consisting of monounsaturated phosphatidylcholine and other phospholipids (Rooney, 1989). Disaturated phospholipids are compressible, allowing for packing of the surface film at end-expiration that reduces surface tension to nearly zero. The amounts of DPPC and phosphatidylglycerol in fetal lung increase with advancing gestation due to increased activity of enzymes responsible for phospholipid synthesis. The expression and activity of enzymes of the choline incorporation pathway, the predominant pathway for surfactant phospholipid synthesis, not only are developmentally regulated but are also induced by hormones, specifically glucocorticoids, thyroid hormone, and agents that increase intracellular cAMP.

Surfactant contains a group of specific proteins with functions relevant to many of the primary functions of the lung (Kuroki and Voelker, 1994). The four surfactant proteins—SP-A, SP-B, SP-C, and SP-D—are subdivided on the basis of their physical characteristics into hydrophobic (SP-B and SP-C) and hydrophilic (SP-A and SP-D) proteins. The hydrophobic surfactant proteins play a major role in the surface-active properties of surfactant, whereas the primary roles of the hydrophilic surfactant proteins are in host defense (see later on) and surfactant clearance and metabolism. SP-B is a secretory protein that exhibits strong association with membranes; SP-C contains a membrane-spanning domain that integrates the protein into phospholipid layers (reviewed in Weaver and Conkright, 2001). Both are synthesized as large precursor pro-proteins that undergo extensive post-translational

**TABLE 42-3**

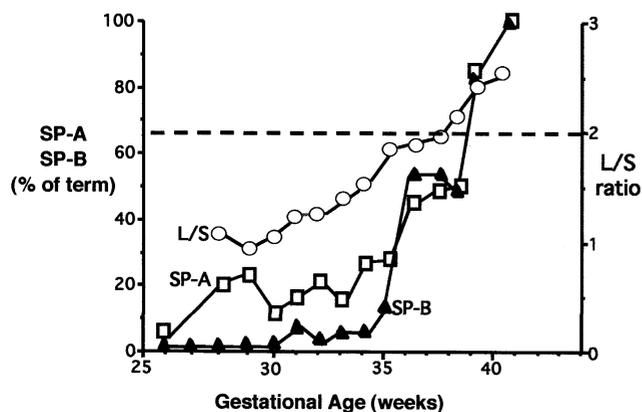

#### Composition of Pulmonary Surfactant

Component	Percentage (by weight)
Lipid	90
Saturated phosphatidylcholine	45
Unsaturated phosphatidylcholine	25

Neutral lipids	10
Protein	10
Surfactant proteins	5
Serum proteins	5

processing through the secretory pathway, ultimately leading to the lamellar body. SP-B is essential for the process of lamellar body genesis, and the alveolar type II cells of infants with inherited deficiency of SP-B are devoid of lamellar bodies. Lamellar bodies are the site of final events in SP-C processing, and infants with inherited deficiency of SP-B are therefore deficient in mature SP-C, instead accumulating a larger precursor of SP-C. Thus, patients with inherited deficiency of SP-B, despite having relatively normal surfactant phospholipid profiles, make a pulmonary surfactant with very poor surface tension properties due to the combined defects in SP-B and SP-C synthesis. Together, the hydrophobic proteins facilitate the release of surfactant phospholipid from tubular myelin to the surface monolayer and promote spreading of lipids in the film and film stability at the end-expiration (Veldhuizen and Haagsman, 2000).

SP-B and SP-C exhibit developmental and hormonal regulation of expression (reviewed in Mendelson, 2000). In human fetuses, SP-C mRNA is detected as early as 12 weeks of gestation and SP-B mRNA by 14 weeks of gestation, yet the mature proteins are not detectable in fetal lung tissue until after 24 weeks of gestation. Furthermore, SP-B protein is not detectable in amniotic fluid until after 30 weeks of gestation (Fig. 42-4), increasing toward term (Pryhuber et al, 1991). This is due to developmental regulation of post-translational events in the proteolytic processing of pro-SP-B and pro-SP-C. Consequently, infants delivered prematurely have reduced levels of both surface-active components of surfactant, phospholipid, and hydrophobic surfactant proteins.

In the absence of adequate amounts of mature pulmonary surfactant, preterm infants develop progressive atelectasis and respiratory distress syndrome. The rate of type II cell differentiation and, secondarily, of surfactant production by the fetal lung, is modulated by levels of endogenous corticosteroids and is accelerated by administration of glucocorticoid (Mendelson, 2000). The response of the surfactant system to glucocorticoid involves all of the lipid and protein components and occurs primarily through increased gene expression, thus representing precocious maturation mimicking the normal developmental pattern and processes. Glucocorticoids probably also enhance matu-

**FIGURE 42-4.** Levels of SP-A and SP-B proteins in amniotic fluid plotted against gestational age.

ration of other cell types, as well as the extracellular matrix, but these effects are less well characterized. Endogenous thyroid hormones, prostaglandins, and catecholamines also have stimulatory effects on type II cell maturation as well as clearance of lung fluid at birth. Certain cytokines (e.g., tumor necrosis factor- $\alpha$  [TNF- $\alpha$ ], TGF- $\beta$ ) inhibit surfactant production in experimental systems and may down-regulate surfactant in conditions such as sepsis and inflammation. A partial list of hormones capable of inducing or inhibiting surfactant components is presented in Table 42-4.

## Development of the Pulmonary Vasculature

The pulmonary vasculature consists of the vascular supply to the acini and the bronchial circulation (Burri, 1997). Branching of the pulmonary arteries follows branching of bronchi and bronchioli up to the acinar level, and for each airway branch, the pulmonary artery branches are 2 to 3 times more numerous. Pulmonary venous development occurs in the connective tissue septa between airway branches and parallel arterial divisions. The proximal pulmonary arteries and veins develop through the process of

**TABLE 42-4**

### Regulators of Alveolar Type II Cell Differentiation

Agent	Proposed Physiologic Role
<b>Inducers</b>	
Glucocorticoids (cortisol)	Major endogenous modulator of alveolar development and surfactant production
Beta-adrenergic agonists (epinephrine) Cyclic AMP	Increase surfactant production and secretion, especially during labor and delivery
Thyroid hormones (T <sub>3</sub> , T <sub>4</sub> )	Enhance glucocorticoid effects on lipid synthesis
Retinoic acid	May interact with glucocorticoids to regulate lipid and SP-B production
Bombesin-related peptides Parathyroid hormone-related protein (PTHrP)	May contribute to surfactant lipid synthesis
<b>Inhibitors</b>	
Protein kinase C activators (proinflammatory cytokines)	Inhibit surfactant protein gene transcription during infection, inflammation
TGF- $\beta$ family	Inhibit type II cell maturation during early gestation and with inflammation
TNF- $\alpha$	Inhibit SP-B and SP-C gene transcription during infection
Insulin	Inhibit surfactant protein gene transcription in infants of diabetic mothers with poorly controlled disease
Dihydrotestosterone	Delayed type II cell maturation in males

SP-B, SP-C, surfactant proteins B, C; T<sub>3</sub>, triiodothyronine; T<sub>4</sub>, thyroxine; TGF, transforming growth factor; TNF, tumor necrosis factor.

angiogenesis, whereby new vascular structures arise from existing vessels; endothelial cells migrate out and organize to form a central lumen, thereby extending the length of the existing vessel. The second vascular supply to the lung, the bronchial circulation, arises first from the dorsal aorta in close proximity to the celiac axis (6 weeks) and is then replaced by definitive bronchial arteries arising from the aorta by 12 weeks. Persistence of rudimentary bronchial arteries is associated with developmental anomalies such as pulmonary sequestration.

The capillary network investing the acinus expands to match the increasing surface area of the developing acinar structures. Unlike the preacinar and resistance arteries that are present by 28 weeks of gestation, which arise through the process of *angiogenesis*, the more distal pulmonary vascular plexus arises *de novo* from the mesoderm surrounding the developing lung bud, a process known as *vasculogenesis* (reviewed in Baldwin, 1996). Angioblasts within the mesenchyme surrounding the acini differentiate into endothelial cells, proliferate, and organize into clusters that send out endothelial cells to establish a lumen. This network ultimately connects to the developing pulmonary arteries and veins. Alveolar-capillary dysplasia, an unusual and fatal cause of respiratory failure in the term neonate, is the result of developmental errors that prevent the appropriate interconnection of these vascular networks. Thinning of the interstitial mesenchyme surrounding the capillary network proceeds such that by 28 weeks, the alveolar-capillary membrane is similar in thickness to that in the adult (0.6  $\mu\text{m}$ ).

Muscularization of the preacinar and resistance arteries extends through the canalicular stage to term (reviewed in Stenmark and Mecham, 1997). The developing endothelial cells recruit smooth muscle cells and pericyte precursors, which are important in maintaining vascular integrity, through the action of growth factors such as angiopoietin-1. Muscularization normally occurs from pulmonary arteries to the level of the terminal bronchiole and is minimal in the vessels supplying respiratory bronchioles. Abnormal extension of smooth muscle along arterioles supplying acinar structures occurs in infants dying from persistent pulmonary hypertension of the newborn and in severe bronchopulmonary dysplasia.

## DEVELOPMENT OF PULMONARY HOST DEFENSE

The adult human lung takes in approximately 7 L/minute of air contaminated with a variety of potential pathogens and particulates that can cause epithelial injury. An integrated system of host defense maintains the sterility and integrity of the gas exchange surface. The proximal and distal airway epithelia play a major role in clearance of potential pathogens. Components of mucociliary clearance appear at 11 to 13 weeks in human gestation with the differentiation of ciliated epithelial cells and the expression of mucus in mucus-secreting goblet cells within the epithelium as well as submucosal glands. The number of goblet cells peaks in mid-gestation (30% to 35% of total airway epithelial cells), decreasing toward term to levels lower than in adults and then increasing after birth. The postnatal increase in goblet cells occurs after preterm birth as

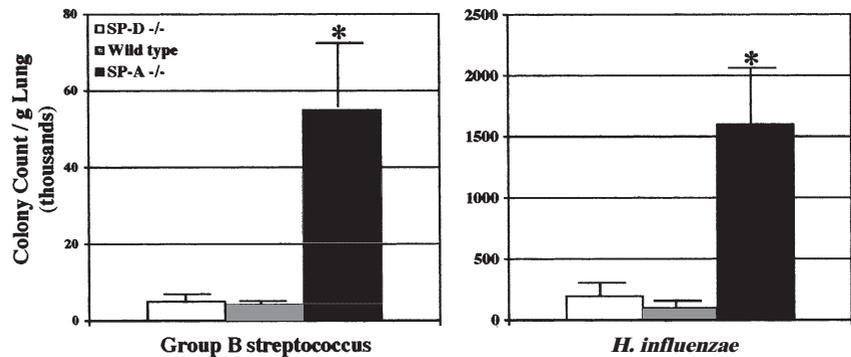

well, resulting in greater numbers of goblet cells in preterm infants than in term infants. Therefore, premature infants are prone to more mucus production in smaller airways than term infants and have relatively fewer ciliated cells to assist in mobilization of secretions.

A number of microbial defense molecules are produced and secreted into the airways. They include lysozyme, C-reactive protein, lactoferrin (Wilmott et al, 2000), defensins (Weiss, 1994), cathelicidins (Lehrer and Ganz, 2002), and collectins. Collectins are molecules possessing collagen-like domains and a calcium-dependent lectin domain that recognizes and binds carbohydrates on proteins and lipids. The lung collectins, the hydrophilic SP-A and SP-D, are secreted by epithelial cells lining airways (Clara cells) and alveoli (type II cells) (reviewed in Crouch and Wright, 2001; McCormack and Whitsett, 2002). They interact with microorganisms, inflammatory cells, and leukocytes to facilitate clearance of microorganisms from the air space. They interact in similar ways with inhaled pollens and other antigens to facilitate clearance and to modulate allergic responses.

The basis for the interactions of the lung collectins with microbes and antigens centers on the binding of sugars by the lectin domain, or carbohydrate recognition domain (Hakansson and Reid, 2000). Differences in the structure of the carbohydrate recognition domain provide SP-A and SP-D with altered affinities for different sugar molecules, allowing complementary functions and improving the diversity of microbial interactions. Collectins enhance the uptake of microorganisms and antigens in part through aggregation of multiple organisms by the carbohydrate recognition domain. Each individual collectin trimerizes through interactions between the collagen-like domains. The trimers further associate into octadecamers (six groups of 3) in the case of SP-A, conferring an appearance similar to a bouquet of tulips, or dodecamers (four groups of 3) in the case of SP-D, which associate in the form of a cross. This arrangement of SP-D facilitates the aggregation of multiple organisms and inflammatory cell surface receptors. Studies of the role(s) of the lung collectins in pulmonary infections have been greatly aided by the availability of knockout mouse models. Interactions with gram-negative organisms frequently depend on the ability of SP-A and SP-D to bind lipopolysaccharide, whereas the mechanism of SP-A interactions with gram-positive organisms, including group B beta-hemolytic streptococci, are not as clear (Fig. 42-5). Both collectins bind a variety of fungi as well as *Pneumocystis carinii* and play an important role in inhibiting a variety of respiratory viruses, including influenza A virus and respiratory syncytial virus.

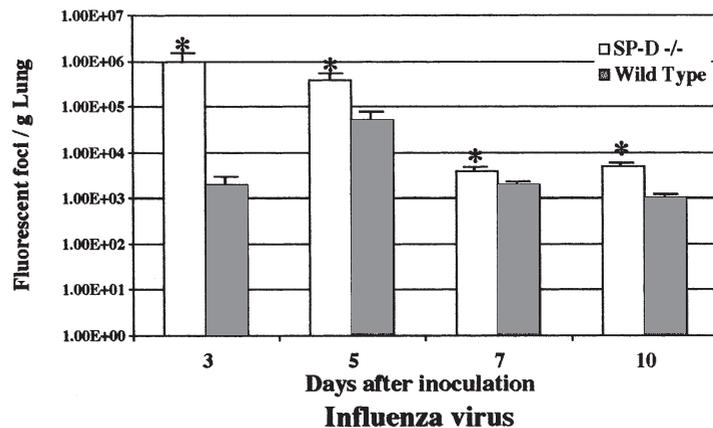

The lung collectins also modulate the functions of a variety of immune cells, including macrophages, neutrophils, eosinophils, and lymphocytes (Wright, 1997). In addition to opsonizing microorganisms, functions of the lung collectins include stimulating chemotaxis of macrophages and neutrophils, enhancing cytokine production by macrophages and eosinophils, attenuating lymphocyte responses, and modulating the production of reactive oxygen and nitrogen species used in killing microorganisms.

Two highly homologous SP-A genes (*SPA1* and *SPA2*) lie in close proximity to the SP-D gene on chromosome 10 in

A

B

the human. Like the hydrophobic surfactant proteins, SP-A and SP-D exhibit both developmental and hormonal regulation of expression (reviewed in Mendelson, 2000). In human fetuses, SP-A mRNA is undetectable before 20 weeks of gestation, and SP-A protein is first detectable in amniotic fluid by 30 weeks (see Fig. 42-4), increasing toward term (Pryhuber et al, 1991). In humans, SP-A gene expression is induced by cAMP and glucocorticoids, although the response to glucocorticoids is biphasic, showing attenuation at higher doses. Retinoids, insulin, and growth factors such as TGF- $\beta$  and TNF- $\alpha$  inhibit SP-A gene expression. SP-A is produced and secreted by both alveolar type II cells and bronchiolar Clara cells. SP-D is produced in tracheobronchial glands as well as by type II and Clara cells. Like SP-A, SP-D levels in human lung are quite low during the second trimester (Dulkerian et al, 1996), increase toward term, and are detectable in amniotic fluid (Miyamura et al, 1994). Levels of both SP-A and SP-D increase markedly in the first days after preterm birth.

### Development of Detoxification Systems

Although oxygen is essential to cellular processes, excessive oxygen is damaging through direct toxicity of oxygen free radicals or indirectly from altered physiologic processes (reviewed in Weinberger et al, 2002). The lung is particularly susceptible to the damaging effects of free radicals. Oxygen free radicals are byproducts of the electron transport reactions of mitochondria that generate adenosine triphosphate (ATP) from molecular oxygen.

Superoxide, produced by reduction of molecular oxygen with the addition of a single electron, is formed by all cells and occurs in high concentrations in phagocytic cells to facilitate the killing of microorganisms. Hydrogen peroxide is generated from the transfer of a single electron to superoxide. Hydroxyl radicals are generated from the interaction of hydrogen peroxide with superoxide. The free electrons of each of these species of free radicals can interact with membrane lipids resulting in lipid peroxidation, with proteins to oxidize sulfhydryl groups, and with DNA causing direct damage. This leads to damage of airway and alveolar epithelial cells as well as capillary endothelial cells. Compromise of epithelial integrity leads to interstitial and air space edema, followed by infiltration of neutrophils. The damaged alveolar epithelium heals through proliferation of the alveolar type II cell and can be accompanied by various degrees of pulmonary fibrosis.

Hyperoxia is a potent regulator of a variety of processes. Prolonged exposure to oxygen results in influx of neutrophils into the lung. Oxygen regulates the activity of plasminogen activator inhibitor-1 and other proteases and antiproteases within the air spaces, thereby modulating the destructive effects of proteases elaborated from inflammatory cells. Oxygen can also regulate growth responses by inhibiting the secretion of growth factors and reducing DNA synthesis. Therefore, it is understandable that oxygen toxicity is a central component of bronchopulmonary dysplasia.

Multiple defenses exist to attenuate the effects of oxygen free radicals in the lung. Enzymes such as superoxide dismutase, glutathione peroxidase, and catalase catalyze

the detoxification of superoxide and hydrogen peroxide. Vitamins, especially vitamin E, and other antioxidants such as beta-carotene, selenium, and taurine assist in the trapping of free radicals. The fetal lung is exposed to oxygen tensions of 20 to 25 mm Hg in utero, and the transition to air breathing is associated with a four- to sevenfold increase in oxygen tension, presenting a significant oxidant stress. Animal studies indicate that many of the antioxidant enzymes are induced before term delivery, and limited data suggest that the same is true for human fetuses (reviewed in Weinberger et al, 2002). Premature animals fail to up-regulate antioxidant enzymes in response to oxygen-induced lung injury (Frank and Sosenko, 1991). Thus, preterm infants are more significantly compromised in antioxidant defenses, and because of the need for oxygen in the treatment of respiratory distress syndrome, they are more susceptible to oxygen toxicity.

### SUMMARY

Lung branching morphogenesis is coordinated with both epithelial cell proliferation and pulmonary vascular development to provide a large surface area and thin alveolar-capillary membrane for gas exchange. Many of

the syndromes listed in Table 42–1 illustrate how abnormalities of early fetal lung development compromise gas exchange as a result of pulmonary hypoplasia. Although the fetal lung developmental program requires an array of transcription factors, hormones, and growth factors promoting branching morphogenesis, lung growth is equally dependent on intact neural input to modulate fetal breathing, stability of an appropriate-size thorax, and the production of adequate lung and amniotic fluid. Although it occurs late in fetal lung development, maturation of the surfactant system also is crucial to the transition to air breathing. Furthermore, the maturation of the host defense and detoxification systems minimizes the effects of increased oxygen tension and exposure to potential pathogens accompanying the transition to air breathing. Premature birth affects all of these functions, as illustrated in Table 42–5. Bronchopulmonary dysplasia is the end result of multiple injuries to the underdeveloped lungs of premature newborns that further compromise postnatal growth and development and impair function. Thus, integrated approaches to therapy that reflect the interdependency of these lung functions, rather than single “therapeutic bullets,” will have the most promise for minimizing the impact of premature birth on childhood and, ultimately, adult lung function.

**TABLE 42-5**

#### Impact of Pregnancy Abnormalities, Prematurity, and Infant Lung Disease on Lung Development and Maturation

Event	Impact	Potential Consequence(s)
Development of conducting airways	<i>Branching</i> : no effect; completed to level of the respiratory bronchi by 24 weeks <i>Tone</i> : Increased secondary to lung disease in part reflecting developmental deficiency of nitric oxide and proliferation of smooth muscle cells	None Increased airways resistance
Alveolization	Variable inhibition depending on timing of delivery and severity of lung disease; also may be compromised by excess glucocorticoids	Reduced lung growth and total lung surface area with increased alveolar size (hypoplasia with emphysemic changes); impaired pulmonary function
Development of alveolocapillary membrane	Approaches adult diameter by week 24; glucocorticoids induce precocious thinning	Underdevelopment impairs gas exchange and contributes to RDS
Type II cell differentiation	Variable immaturity and deficient surfactant production depending on timing of delivery; induced by antenatal glucocorticoids	Developmental deficiency of surfactant content and composition results in RDS
Hydrophobic surfactant proteins (SP-B, SP-C)	Variable deficiency depending on timing of delivery and infection; necessary for lamellar body formation and optimal surfactant function	High alveolar surface tension; RDS
Hydrophilic surfactant proteins (SP-A, SP-D)	Variable deficiency depending on timing of delivery; participate in lung host defense and immunomodulation	Compromised ability to clear microorganisms from airways/alveolar space; pneumonia Unmodulated inflammatory response contributes to chronic lung disease
Type I cell differentiation	Variable deficiency depending on timing of delivery and type II cell hyperplasia secondary to lung disease; cells develop from type II cells	Thickened epithelium impairs gas exchange
Clara cell differentiation	Variable deficiency depending on timing of delivery; reduction in number of cells	Impaired antioxidant and antimicrobial defenses; may contribute to chronic lung disease and pneumonia

TABLE 42-5

**Impact of Pregnancy Abnormalities, Prematurity, and Infant Lung Disease on Lung Development and Maturation—Cont'd**

Event	Impact	Potential Consequence(s)
Induction of antioxidant systems	Low expression until just prior to term	Lung injury from oxidant stress exacerbated by need for increased oxygen
Mucociliary clearance	Goblet cells decrease in number toward term	Increased mucus production may obstruct small airways
Development of pulmonary capillary bed	Normally parallels alveolar development; thus, variable effects depending on timing of delivery and severity of lung disease	In the extreme, alveolar capillary dysplasia; probably associated with variable degrees of impaired gas exchange; pulmonary hypertension
Pulmonary arteries	Medial hypertrophy and increased muscularization of peripheral vessels with lung disease	Pulmonary hypertension associated with chronic lung disease
Fetal lung liquid	<i>Fluid loss:</i> variable effects depending on magnitude and duration of fluid loss as well as timing of delivery; reduced content occurs secondary to prolonged premature rupture of membranes or intrinsic defect in fluid secretion <i>Fluid retention:</i> Hormone surges near term and labor promote reabsorption before delivery	Pulmonary hypoplasia
Fetal breathing movements	Contribute to lung growth; reduced movements associated with severe neurologic impairment and asphyxia Postnatal transition to regular respiratory pattern disrupted with premature delivery	Apnea of prematurity
Respiratory musculature	Underdeveloped and easily fatigued in premature newborn	Apnea of prematurity

RDS, respiratory distress syndrome.

## Control of Breathing

Thomas N. Hansen and Anthony Corbet

Rhythmic breathing is maintained by alternating discharges of inspiratory and expiratory neurons, located diffusely in the medulla oblongata, and is activated by nonspecific neuronal traffic in the brainstem. One concept is that expiratory neurons discharge continuously under the influence of the reticular activating system, but rhythmic breathing is produced by the central inspiratory activator, which intermittently discharges and temporarily inhibits expiratory neurons (Cohen, 1979). Some of the inspiratory neurons are organized into the nucleus paragigantocellularis lateralis, thought to be the central inspiratory activator, and located close to the central chemoreceptors on the ventral surface of the medulla (Von Euler, 1983).

In adults, inspiration is active, and expiration is passive. Expiration is divided into two phases. In the first phase, a group of inspiratory neurons apply postinspiratory “braking” to slow exhalation. In the second phase, exhalation continues passively, or it is accelerated by contraction of expiratory muscles. The main inspiratory muscles are the diaphragm, intercostals, and upper airway abductors. The main expiratory muscles are intercostal and abdominal groups, which accelerate expiration, and upper airway adductors, which retard expiration by narrowing the larynx.

Inspiration is controlled by an “off switch” (Fig. 43–1). During inspiration, the augmenting discharge of the central inspiratory activator to inspiratory motor neurons and specialized  $R_b$  neurons suddenly causes the off switch neurons to discharge, transiently inhibiting the central inspiratory activator and allowing passive exhalation. The off switch also is controlled by the pulmonary volume sensors and the rostral pontine pneumotaxic center, which together decrease the depth and increase the rate of breathing (Kosch et al, 1986). The threshold of the off switch, and thus the depth and rate of breathing, are modulated up or down from a number of sources: peripheral chemoreceptors, central chemoreceptors, chest wall proprioceptors, hypothalamus, and cerebral cortex (Von Euler, 1983).

The respiratory control mechanisms develop progressively throughout gestation and infancy, so the system does not attain maturity until late in the first year of life. During quiet sleep, modulation of breathing is metabolic, through central and peripheral chemoreceptors, which sense, respectively,  $PCO_2$  and  $PO_2$ . During active sleep and wakefulness, there are additional behavioral controls such as crying, sucking, and gross body motions (Schulte, 1977; Thach et al, 1978).

## FETAL BREATHING

After many years of controversy, it is now established that the fetus breathes (Dawes, 1973). This breathing activity, which is essentially diaphragmatic, is present for 30% to 35% of the time in mothers examined with a real-time ultrasound scanner (Patrick et al, 1978). It is irregular in rate and amplitude; recorded rates in the human fetus range between 30 and 70 breaths/minute. The tidal volume of lung liquid is small, quite insufficient to clear the dead space. Owing to active lung liquid secretion, the net flow of liquid is out of the lung. Periods of apnea may last as long as 1 hour in the normal human fetus. In the lamb, breathing occurs during active sleep, associated with low-voltage electrocortical activity, and breathing is inhibited during quiet sleep, associated with high-voltage electrocortical activity. There appears to be a circadian rhythm, breathing activity being lowest in the early morning and rising during the afternoon to peak in the early evening (Dawes, 1974). Fetal breathing has been detected as early as 10 weeks of gestation. Fetal breathing is suppressed, however, during late pregnancy as labor approaches, probably due to a progressive rise of plasma prostaglandins (Kitterman et al, 1983), and remains suppressed during active labor (Boylan and Lewis, 1980).

Fetal breathing is increased by drugs that stimulate the central nervous system, such as caffeine, isoproterenol, serotonin, and substance P, and it is inhibited by anesthetics, narcotics, barbiturates, ethanol, and smoking (Manning, 1977). Fetal breathing also is inhibited by prostaglandins, endorphins, and adenosine. The inhibitory effect of maternal ethanol ingestion is mediated by prostaglandins (Smith et al, 1990). Hypoglycemia or maternal fasting is associated with decreased fetal breathing, whereas it is stimulated after maternal meals and by hyperglycemia.

Mild fetal hypoxemia severely depresses fetal breathing, by acting at a midbrain inhibitor, but more severe fetal hypoxemia induces primitive deep gasping by a direct action on the medulla. It is believed that the hypoxia-sensitive carotid body peripheral chemoreceptors are active in the fetus and provide a constant stimulus to breathing (Murai et al, 1985), but their effect on the central respiratory neurons is easily overridden by high-voltage electrocortical activity (quiet sleep) acting through the midbrain inhibitor or, under certain conditions, by endogenous depressants such as prostaglandins, endorphins, or adenosine, which may be present at high levels in the blood stream (Jansen and Chernick, 1988). Adenosine may be released under conditions of hypoxia, and adenosine antagonists such as theophylline have been found to decrease the depressant effect of hypoxia on ventilatory drive (Darnall, 1985; Runold et al, 1989). The hypoxic response with depression of fetal breathing may be blocked with dopamine antagonists (Lagercrantz, 1992), which suggests that a dopaminergic pathway may connect the midbrain inhibitor with the respiratory centers in the medulla.

Hypercarbia has a rapid stimulatory effect on fetal breathing, this effect being exerted by increased hydrogen ion concentration at central chemoreceptors on the surface

CO<sub>2</sub>, about which little is known, and there must still be a reversal of the midbrain inhibition produced by the high-voltage electrocortical state, perhaps induced by increased brainstem neuronal traffic. In addition, clamping the umbilical cord at birth may cut off the supply of a placental inhibitor, possibly prostaglandin, endorphin, or adenosine, and this may facilitate the onset of breathing. It has been demonstrated in the fetal lamb in which breathing has been stimulated by a cord clamp, that when the cord is unclamped, breathing is soon inhibited (Adamson et al, 1987). Injection of a placental extract also produces inhibition of fetal breathing (Alvaro et al, 1993); the inhibitor may be a prostaglandin (Adamson et al, 1991), and recent evidence suggests that adenosine may be important (Herlenius et al, 2002). The conclusion must be that no single factor is responsible for the onset of continuous breathing at birth (Jansen and Chernick, 1988). In summary, hypoxemia does not play a role for several days after birth; hypercarbia probably is most important, but there must be a very rapid resetting of the central chemoreceptor threshold for PCO<sub>2</sub>. In addition, the action of the midbrain inhibitor during the high-voltage electrocortical state must be abolished by increased neuronal traffic in the brainstem; and there must be removal of an unknown placental inhibitor.

### CONTROL OF BREATHING IN THE FULL-TERM NEWBORN INFANT

In adults, it is well known that mild hypoxia and hypercarbia stimulate breathing. The ventilatory response to hypercarbia in the full-term newborn is considered to be similar to that in the adult, but the response to hypoxia is more complex.

As discussed previously, before birth, mild hypoxia inhibits breathing, due to stimulation of the midbrain inhibitor. The term newborn infant responds to decreased oxygen by a transient weak hyperpnea, followed by a relative ventilatory depression of variable magnitude (Brady and Ceruti, 1966). This phenomenon suggests rapid exhaustion of the peripheral chemoreceptor in the face of moderate hypoxic respiratory center depression produced by the midbrain inhibitor. This biphasic response to hypoxia persists for a few days after birth in the full-term infant. In addition to the effect of the midbrain inhibitor, adenosine, released by hypoxia, also may be responsible for the depressed hypoxic ventilatory response (Koos and Matsuda, 1990).

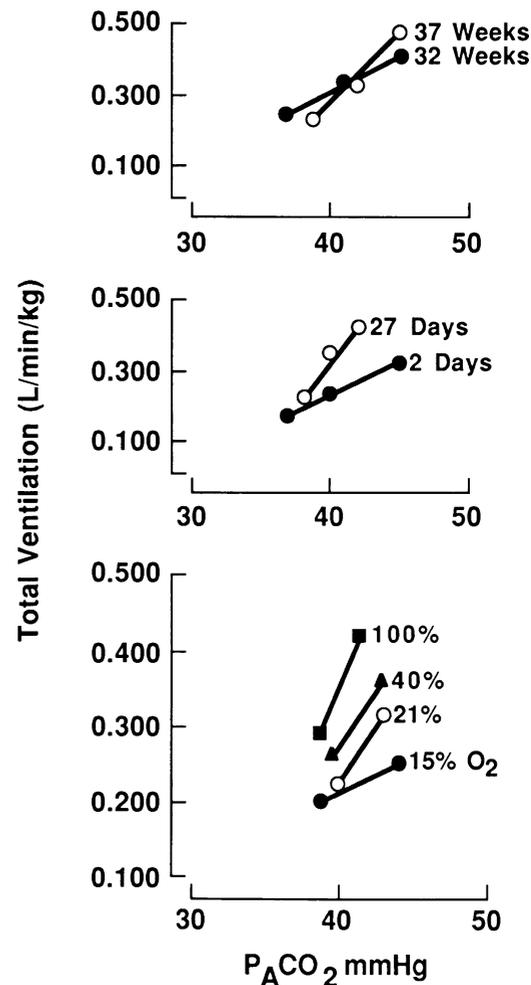

If the term infant at age 2 to 6 hours is given 100% oxygen to breathe, no change in ventilation occurs, as would be expected in the normal adult; the absence of a transient depression suggests that the peripheral chemoreceptor is not functional and has not undergone upward resetting of the threshold from the low level operating in the fetus (Hertzberg and Lagercrantz, 1987). If the term infant older than a few days is given 100% oxygen to breathe, there is a transient depression of ventilation (Rigatto and Brady, 1972); this suggests that the normal expected activity of the peripheral chemoreceptor appears by 2 days of age in the full-term infant. The occurrence of mild apnea episodes is not uncommon in healthy term infants on the first day of life.

### CONTROL OF BREATHING IN THE PREMATURE INFANT

The sensitivity of the central chemoreceptor to CO<sub>2</sub> is reduced in premature infants and increases progressively with gestational age to adult levels by full term (Rigatto, 1977; Rigatto et al, 1975b). Higher oxygen concentrations increase sensitivity, and hypoxemia decreases sensitivity to CO<sub>2</sub> (Rigatto et al, 1975c). In small premature infants, adult levels of sensitivity are reached by 4 weeks of postnatal age (Fig. 43-2).

Although full-term infants have a biphasic response to hypoxia, in small preterm infants, there is no initial hyperpnea, only a sustained decrease in ventilatory activity (Alvaro et al, 1992). This finding indicates that peripheral chemoreceptor function is even worse in preterm infants.

In preterm infants given 100% oxygen, the peripheral chemoreceptor response initially is absent, but it improves

**FIGURE 43-2.** The relationship between ventilatory sensitivity to carbon dioxide and gestational age (**top panel**), postnatal age (**middle panel**), and the concentration of inspired oxygen (**bottom panel**). (From Rigatto H, Brady J, Verduzco RT: Chemoreceptor reflexes in preterm infants: The effect of gestational and postnatal age on the ventilatory response to inhaled carbon dioxide. *Pediatrics* 55:614, 1975; and Rigatto H, Verduzco RT, Cates DB: Effects of O<sub>2</sub> on the ventilatory response to CO<sub>2</sub> in preterm infants. *J Appl Physiol* 39:896, 1975.)

with time, and by 2 weeks of postnatal age the response is as good as that seen in term infants (Lagercrantz, 1992). Thus, the main problem in premature infants may be that the peripheral chemoreceptor function is relatively weak, at least in the first few weeks of life.

In larger premature infants, the central hypoxic depression of ventilation, mediated by the midbrain inhibitor, also disappears about 2 to 3 weeks after birth, when the mature response of sustained hypoxic stimulation of ventilation mediated by the peripheral chemoreceptor becomes dominant (Rigatto et al, 1975a). However, in very small premature infants, Martin and colleagues (1998) demonstrated that this insufficiency was persistent through 4 to 8 weeks of postnatal age and contributed to a prolonged vulnerability to depression of breathing.

### THE ROLE OF STRETCH RECEPTORS

Evidence for the presence of a Hering-Breuer reflex in newborn infants has been obtained, and the strength of the reflex increases with gestational age until term (Gerhardt and Bancalari, 1981), but declines after birth (Bodegard et al, 1969). The Hering-Breuer reflex is mediated by stretch and irritant receptors. The function of stretch receptors is to increase inspiratory flow and tidal volume without changing inspiration time (Haddad and Mellins, 1977). This means that stretch receptors increase the output of the respiratory center. The function of irritant receptors is to shorten inspiration and expiration times and to reduce tidal volume without changing inspiratory flow. The irritant receptors must operate the off switch neurons (see Fig. 43–1), but have no effect on respiratory center output. The combined activity of stretch and irritant receptors, the volume sensor, shortens both inspiration and expiration, reduces tidal volume, and increases the inspiratory flow. Thus, the increasing activity of the Hering-Breuer reflex throughout gestation is consistent with a maturational increase of respiratory drive induced by the stretch receptors, and may play a role in the reduced ventilatory drive seen in preterm infants.

### PERIODIC BREATHING

A periodic breathing pattern consists of breathing for 10 to 15 seconds followed by apnea for 5 to 10 seconds, without change of heart rate or skin color. The net effect may be hypoventilation (Rigatto and Brady, 1972). This pattern is common at high altitude and is abolished by supplemental oxygen (Graham et al, 1950) and by continuous positive airway pressure (CPAP). The more premature the infant, the more frequent its occurrence, but to a lesser extent it persists in term infants and during early infancy (Hoppenbrouwers et al, 1977). Periodic breathing does not occur during the first 2 days of life (Barrington and Finer, 1990) and is more frequent during active sleep. The prognosis is excellent, so no treatment is required. Although it initially was thought that periodic breathing was associated with a high risk for apnea of prematurity (Daily et al, 1969), this concept has been questioned by Barrington and Finer (1990), who found that periodic breathing does not immediately precede significant apnea spells in preterm infants.

Theoretical models suggest that periodic breathing is due to an imbalance between the peripheral and the central chemoreceptor effects on ventilatory drive (Khoo et al, 1982). Investigators have shown that periodic breathing in newborn guinea pigs can be induced by suppression of the central chemoreceptor, and then abolished by restoration of the balance with suppression of the peripheral chemoreceptor (Wennergren and Wennergren, 1983). In humans at high altitude, with spontaneous periodic breathing due to hypoxic stimulation of the peripheral chemoreceptor, stimulation of the central chemoreceptor with acetazolamide abolished periodic breathing, whereas further stimulation of the peripheral chemoreceptor with almitrine increased periodic breathing (Hackett et al, 1987). The hypothesis of Barrington and Finer (1990) is that periodic breathing in premature infants is often due to excessive stimulation by the peripheral chemoreceptor, promoting an imbalance; this concept is consistent with their observation that periodic breathing is not observed in the first 2 days of life, when the peripheral chemoreceptor is inactive, but is common thereafter, when the peripheral chemoreceptor is reset and again functional.

### APNEA OF PREMATURITY

During episodes of apnea, there is a cessation of respiratory activity—exchange of oxygen and carbon dioxide. This means that the term *apnea* is applied to the absence of both air flow and breathing effort (so-called central apnea) and also to the absence of air flow with breathing effort present (so-called obstructive apnea).

Apneic spells usually seen in infants are episodic and random (Daily et al, 1969). Episodes prolonged for 20 seconds or more or those accompanied by bradycardia or color change (desaturation) are considered significant. Perlman and Volpe (1985) have described the cerebral ischemia that accompanies severe bradycardia with a heart rate of less than 80 beats/minute. On neurodevelopmental follow-up evaluation, infants with significant apnea of prematurity do not perform as well as do similar premature infants without recurrent apneas (Cheung et al, 1999; Kitchen et al, 1987; Tudehope et al, 1986). The diagnosis of apnea of prematurity can be made only after the exclusion of all other causes of recurrent apnea.

The incidence of apneic spells is inversely related to gestational age (Henderson-Smart, 1981). Although commonly stated otherwise, apneic episodes frequently start on the first day of life (Barrington and Finer, 1991; Henderson-Smart, 1981). In many infants, only bradycardia is recognized by the hospital staff, but polygraphic recordings indicate that bradycardia is nearly always preceded by apnea (Dransfield et al, 1983). It is thought that 40% of the episodes are central or diaphragmatic, 10% are obstructive, and 50% are mixed, which may indicate either obstructive followed by central apnea (Martin et al, 1986) or central followed by obstructive apnea (Butcher-Puech et al, 1985). In an individual infant, one type tends to predominate. Central apneas tend to be shorter, whereas obstruction tends to prolong the episode and accelerate the onset of bradycardia. Obstructive apneas are particularly common on the first day of life in premature infants (Barrington and Finer, 1991).

Apnea of prematurity usually resolves by 38 weeks of postconceptional age, but sometimes resolution is delayed until 42 weeks; now that so many very small infants survive, it may be even more prolonged. In many infants there is a good correlation between the attainment of full nipple feeds and the cessation of apnea episodes (Darnall et al, 1997); but just as poor nipple feeding may be prolonged so may apnea be prolonged. In very small premature infants of 24 to 28 weeks of gestation, apnea of prematurity often is prolonged past full-term gestation (Eichenwald et al, 1997), especially if the infant has neurologic dysfunction (Cheung et al, 1999). In a recent study, infants who were still experiencing routine hospital monitor alarms at the time of possible hospital discharge were found to have lower oxygen saturation levels than those in similar infants who were not having routine hospital monitor alarms (Di Fiore et al, 2001); continuous pneumogram recordings showed that although occurrence rates for apneas were nearly the same, desaturation and bradycardia events were more likely in infants who had lower resting oxygen saturation levels (95%) in room air than in those who had normal resting oxygen saturation levels (99%). The investigators suggested that those with lower oxygen levels and more monitor alarms may have subtle residual lung disease or possibly increased neurologic dysfunction. In infants with prolonged apnea of prematurity, often sent home on apnea monitors, apnea, desaturation, and bradycardia events persist for up to 6 months or longer (Silvestri et al, 1994).

It was once thought that bradycardia was not related to hypoxemia (Hiatt et al, 1981), but rather had a central brainstem origin (Schulte, 1977) or was a reflex response to the cessation of lung inflation (Gabriel and Albani, 1976). Henderson-Smart and colleagues (1986) however, concluded that episodes of bradycardia were associated with oxygen desaturation, and Poets and associates (1993) confirmed this. In 80 premature infants, just before discharge from the hospital, 193 episodes of bradycardia were recorded; 83% were associated with apnea episodes, and 86% were associated with oxygen desaturation; when all three occurred together, the sequence of events was apnea followed by desaturation followed by bradycardia. The median interval between the onset of apnea and the onset of desaturation was 1 second, and between the onset of apnea and the onset of bradycardia the interval was 5 seconds. Although in such circumstances the bradycardia may be due to a direct effect on the heart, the short time interval suggests that the bradycardia is a peripheral chemoreceptor response to hypoxemia, as suggested by earlier workers (Storrs, 1977). There was no evidence that the onset of apnea and that of bradycardia were simultaneous, as would be expected in a lung or brainstem reflex.

### Pathogenesis

The cause of apnea of prematurity is unknown, but a number of theories have been considered for central, diaphragmatic, and obstructive apneas. The neurons of the central pattern generator are poorly myelinated and have a reduced number of dendrites and synaptic connections, thus impairing the capability for sustained ventilatory drive. Prolonged auditory conduction times have been

demonstrated in infants with apnea, a problem assumed to reflect the function of the medulla in general (Henderson-Smart et al, 1983).

Along similar lines, because infants with apnea of prematurity have a deficiency of catecholamine excretion in the urine, other investigators have suggested a neurotransmitter deficiency (Kattwinkel et al, 1976b). Infants with apnea of prematurity have a decreased ventilatory response to CO<sub>2</sub> inhalation in comparison with premature infants of the same gestation without apnea of prematurity (Gerhardt and Bancalari, 1984a).

The chest wall of premature infants is highly compliant, so considerably more work is performed to generate adequate tidal ventilation. This results in substrate depletion and diaphragmatic failure from fatigue. Evidence for fatigue has been shown by examination of the diaphragmatic electromyogram (Muller et al, 1979).

There is some evidence that the diaphragm may activate before the upper airway abductors, which would predispose to upper airway closure during inspiration. The same problem may occur if abductor activation is insufficient (Mathew, 1985). Because airway obstruction imposes a load on the inspiratory muscles, the ability to load-compensate is important. It has been shown that load compensation is poor in small premature infants and increases as term is approached (Gerhardt and Bancalari, 1982). The poor load compensation is due to the high degree of compliance of the chest wall and the presence of an intercostal phrenic inhibitory reflex, which is activated by chest distortion and also shortens the duration of inspiration (Gerhardt and Bancalari, 1984b). This problem predisposes the infant to obstructive apnea, especially under conditions of excessive neck flexion, when the upper airway tends to narrow, and in the supine position, when the tongue falls backward.

### Relation to Sleep State

Most apneas occur during active sleep (Schulte, 1977) and are less common during states of quiet sleep or wakefulness. During active sleep, there is a low-voltage electrocortical state, as well as decreased arousal from sleep, decreased muscular tone, absence of upper airway adductor activity, decreased respiratory drive, irregular breathing, and inspiratory chest wall distortion. The loss of chest wall muscle tone and airway adductor activity causes a 30% reduction in lung volume and a decreased arterial PO<sub>2</sub> (Henderson-Smart and Read, 1979). Reduced ventilatory drive causes a slight elevation in arterial PCO<sub>2</sub>. The ventilatory response to hypoxia is depressed during active sleep, much more than in quiet sleep. The ventilatory sensitivity to CO<sub>2</sub> also is thought to be more depressed in active sleep (Rigatto, 1982). The newborn and the premature infant are asleep 80% of the time, compared with the adult, who is asleep for 30% of the time. More than 50% of sleep is active in the small premature infant, and the mature amount of 20% is not reached until 6 months of age (Bryan and Bryan, 1986).

### Treatment

All infants at risk for apnea should have a heart rate monitor; monitoring should be continued until the infant is at least 34 weeks of postconceptional age, or after that time

until the infant has been free of bradycardia for 1 week. Heart rate monitors are preferred because apnea without bradycardia is not significant apnea, obstructive apnea with bradycardia is detected reliably, and false alarms are infrequent. Most monitors in the neonatal intensive care unit also include an apnea monitor; the principal objections to the apnea monitor alone are that it misses obstructive apnea with the infant breathing, and it may confuse bradycardia with large stroke volumes for breathing. It has become common to monitor with pulse oximetry because of the importance of both oxygen desaturation and heart rate.

Because respiratory center output is dependent on general neuronal traffic, cutaneous stimulation is effective (Kattwinkel et al, 1975). The use of oscillation water beds has been helpful sometimes (Korner et al, 1975). It is reasonable to maintain the patient in the prone position (Kurlak et al, 1994) because in this position there is a significant reduction in the duration of episodes of desaturation and bradycardia. Even in larger premature infants nearing hospital discharge, there may be advantages to the prone position in the form of improved oxygenation and a better ventilatory response to hypercarbia (Martin et al, 1995). Because diaphragmatic fatigue has been implicated, it is essential to maintain the circulation and a general state of good nutrition; the infusion of amino acids may increase the ventilatory response to hypoxia and hypercarbia (Soliz et al, 1994).

If the patient is hypoxemic, oxygen supplementation is essential, but there is no evidence that significant apnea is reduced if the patient is hyperoxygenated, and harm to the immature retina may be inflicted with such a strategy. Upton and colleagues (1991), using pulse oximetry, found that if the baseline oxygen saturation was higher, the desaturation produced by apnea tended to be less severe, and it was less likely that bradycardia would result. In apneas without bradycardia, the median baseline oxygen saturation was 95% and the median reduction with apnea was 5%, whereas for those apneas with bradycardia, the median baseline oxygen saturation was 92% and the median reduction was 9%. Upton and colleagues concluded that it is important to keep the premature infant with recurrent apneas relatively well oxygenated. Pulse oximeters vary in their ability to detect hyperoxemia (arterial  $PO_2$  greater than 90 mm Hg), but with one commonly used instrument, Adams and coworkers (1994) found that setting the upper limit at 95% detected nearly all instances of hyperoxemia. If the infant must be given occasional bag-mask ventilation, it is important to ensure that the oxygen concentration remains stable and is not increased.

Because an oxygen hood interferes with access to the infant, many centers prefer to use nasal cannulas to administer oxygen, usually at a flow of 1 to 2 L/minute, with use of blended oxygen to maintain the pulse oximeter reading in the range of 92% to 96% saturation. Some evidence suggests that nasal cannula therapy may lead to correction of chest wall distortion, with less asynchrony between chest and abdomen, resulting in a more efficient breathing strategy (Locke et al, 1993), perhaps by producing a small amount of continuous distending pressure in the nasopharynx; although this pressure may seem unreg-

ulated, pulmonary air leak complications have never been reported with this simple technique.

Most infants are treated with methylxanthines, which have been demonstrated to be effective in controlled trials (Murat et al, 1981). Because caffeine produces less tachycardia, has a more favorable therapeutic index, and produces less erratic blood level fluctuations, it may be preferred over theophylline (Aranda and Turmen, 1979). There is some evidence that theophylline, but not caffeine, decreases cerebral blood flow in premature infants (Pryds and Schneider, 1991; Saliba et al, 1989); high doses of caffeine may decrease cerebral and intestinal blood flow (Hoecker et al, 2002), perhaps related to antagonism of adenosine receptors. Theophylline may increase the metabolic rate (Walther et al, 1990), which may retard weight gain; increased oxygen consumption may be detrimental if organ blood flow is reduced at the same time. A significant fraction of theophylline is methylated to caffeine in premature infants (Aranda and Turmen, 1979). In a significant number of patients who do not respond to theophylline, a good response is obtained with caffeine (Davis et al, 1987). In a comparative trial, Larsen and colleagues (1995) found caffeine to be equally effective but associated with less tachycardia and less feeding intolerance than were found with theophylline. Either drug may be given for 2 weeks and then stopped to observe whether apnea has ceased, or it may be continued until 32 to 34 weeks of postconceptional age, by which time the problem of apnea has frequently resolved. Infants should not be discharged before caffeine or theophylline has been eliminated because there is evidence that theophylline is effective at quite low levels. Methylxanthines may increase  $CO_2$  sensitivity, decrease diaphragmatic fatigue, and improve load compensation (Gerhardt et al, 1983). Methylxanthines reduce the ventilatory depression following hypoxia by blocking adenosine receptors (Lopes et al, 1994). Some investigators have suggested that theophylline increases the activity of the peripheral chemoreceptors in term infants (Cattarossi et al, 1993), which is consistent with experimental evidence in peripheral chemoreceptor-denervated lambs treated with caffeine (Blanchard et al, 1986).

The other mainstay of treatment is nasal CPAP (Kattwinkel et al, 1975). Although the effect of 5 cm  $H_2O$  should be tried, frequently as much as 8 to 10 cm  $H_2O$  is necessary for satisfactory control, perhaps because many of these infants have chest cage insufficiency and a low lung volume. Infants may be fed by continuous gastric infusion during this procedure. Care should be taken not to depress the circulation; the chest radiograph should be reviewed periodically to avoid overdistingending the lungs. It has been postulated that CPAP provides increased ventilatory drive by directly stimulating the pulmonary stretch receptors (DiMarco et al, 1981; Speidel and Dunn, 1976), but this hypothesis could not be confirmed in premature infants by measurements of the rate of inspiratory flow (Krauss et al, 1986). Also, Krauss and colleagues could not find any improvement in the ventilatory response to inhaled  $CO_2$ . Other investigators consider that obstructive and mixed apneas are selectively relieved by CPAP (Miller et al, 1985), which suggests that CPAP may work by supporting the pharynx. Using fiberoptic laryngoscopy, it has been

demonstrated that nasal CPAP produces dilation of the larynx in premature infants (Gaon et al, 1999). In addition, CPAP prevents chest wall distortion during inspiration (Locke et al, 1991), which may improve the efficiency of ventilation and suppress the intercostal phrenic inhibitory reflex; improved load compensation in small premature infants on CPAP has been demonstrated (Martin et al, 1977). Some centers use nasal cannula therapy with high flow (1.0 to 2.0 L/minute) as a simple form of nasal CPAP. In a controlled clinical trial, it has been shown that esophageal pressures generated with this technique are equivalent to levels generated with conventional nasal CPAP, and that the occurrence rate for apnea was similar (Sreenan et al, 2001b), indicating an improvement. Nasal humidification should be maintained with frequent nasal saline drops.

Another drug that has proved useful is doxapram (Barrington et al, 1987). At low doses, it stimulates the peripheral chemoreceptors, whereas at higher doses, it stimulates the respiratory center directly. In the United States, the preparation contains 0.9% benzyl alcohol as a preservative, but at a dose of 0.5 mg/kg/hour, the amount of benzyl alcohol administered is only 5.4 mg/kg/day, which is far below the levels associated with toxicity in premature infants (Barrington and Finer, 1986). Doxapram should be reserved for infants who fail to respond to optimal xanthine and CPAP therapy, in whom mechanical ventilation would be the next step; methylxanthine therapy should be continued during doxapram infusion (Eyal et al, 1985). In addition, doxapram should not be used in the first week of life or if the serum bilirubin is high, because an association with intraventricular hemorrhage and kernicterus has been reported (Jardine and Rogers, 1988). The drug may be started at 1.0 mg/kg/hour for a few hours as a loading dose, which may then be decreased to 0.5 mg/kg/hour. Higher doses may sometimes be associated with side effects, such as abdominal distention, increased gastric residuals, irritability, hyperglycemia, and mild hypertension (Hayakawa et al, 1986). Poets and colleagues (1999) treated small premature infants not responding to high levels of caffeine with intravenous (0.5 to 2.0 mg/kg/hour) or enteral (2 to 8 mg/kg every 2 hours) doxapram and described a significant reduction in the occurrence of apnea, desaturation, and bradycardia. Enteral administration was not tolerated in one third of the patients. Doxapram is quite widely used in Japan; a controlled trial in preterm infants who did not respond to xanthines showed an approximate 80% reduction in apnea with low-dose doxapram (0.2 to 1.0 mg/kg/hour) and only minimal side effects (Yamazaki et al, 2001). Doxapram may be associated with a moderate prolongation of the Q-Tc interval, and use of electrocardiographic monitoring has been suggested (Maillard et al, 2001). A recent case-control study suggested that isolated mental delay may occur in infants treated with longer courses of doxapram (Sreenan et al, 2001a), but a causal relationship was not proved.

It has been reported that inhalation of 0.5% to 1.5% carbon dioxide is effective at reducing the number of apnea spells in premature infants (Al-Aif et al, 2001). There was no change in transcutaneous PCO<sub>2</sub> levels, presumably because minute ventilation was increased.

### **Movement-Related Apnea Episodes**

Mathew and associates (1991) observed a high incidence of apneas during squirming motions associated especially with arousal from sleep; they suggested that as many as one third of apneas in premature infants may be of this type. Using esophageal pressure measurements, Abu-Osba and coworkers (1982) showed that these motions were associated with increased abdominal expiratory muscle activity against a closed glottis (i.e., Valsalva maneuvers); they also observed some obstructed inspiratory breaths during squirming motions (i.e., Müller maneuvers). These episodes may be associated with greatly reduced minute ventilation and severe oxygen desaturation and bradycardia. These spells are unlikely to respond to methylxanthine therapy. A similar phenomenon without glottic closure may occur in infants on slow-rate mechanical ventilation.

### **Cyanotic Spells without Apnea in Preterm Infants: "V/Q Spells"**

In a study by Poets and colleagues (1993), about 15% of premature infants had episodes of bradycardia, which were associated with appropriate nasal air flow but significant oxygen desaturation. The rate at which oxygen desaturation developed was even more rapid with these spells than during apnea (Samuels et al, 1992). Poets and colleagues (1992) considered the likely causes of this phenomenon and concluded that there is sudden ventilation-perfusion (V/Q) mismatching secondary to peripheral airway dysfunction. The latter may respond to CPAP therapy or increased positive end-expiratory pressure (PEEP) if the infant is on a ventilator, but this has not been proved. Poets and colleagues (1995) also have described episodes of severe oxygen desaturation without bradycardia, without apnea, and without squirming motions, but they were not sure of the cause; they suggested that premature infants born at less than 32 weeks of gestation should be monitored with pulse oximeters until at least 36 weeks of postconceptional age. This recommendation is based on the frequency of these episodes and the inability of apnea and heart rate monitors to detect them reliably. Upton and coworkers (1991) also described many episodes of desaturation without bradycardia in premature infants and suggested that pulse oximetry may be the best way to monitor premature infants; it is more important to detect the effect of apnea on the heart rate and oxygen saturation than it is to detect the apnea itself.

Adams and colleagues (1997) analyzed similar episodes in premature infants using respiratory inductance plethysmography and concluded that many spells with air flow present were associated with reduced tidal breath volumes and hypopnea. Potential consequences could include small peripheral airway dysfunction, secondary V/Q mismatching, and oxygen desaturation.

Bolivar and coworkers (1995) described episodes of oxygen desaturation in premature infants on mechanical ventilation; these episodes were preceded by increased positive esophageal pressure resulting from active expiratory efforts, presumably produced during attempts at crying. The presence of an endotracheal tube prevented the larynx from closing and allowed the lung volume to decrease

suddenly, causing a decrease in lung compliance and an increase in airway resistance; then continued mechanical ventilation or spontaneous breathing was relatively ineffective during a period of severe oxygen desaturation. These investigators suggested that increased positive end-expiratory pressure (PEEP) might be effective, that further sedation might prevent the attempts at crying, and that extubation would allow the larynx to function properly to maintain the lung volume and peripheral airway patency.

### SYMPTOMATIC RECURRENT APNEA EVENTS

Apnea events are a frequent manifestation of general problems in newborn and premature infants (Kattwinkel, 1977). The more common underlying disorders or conditions are (1) local infection such as a scalp abscess; (2) bacteremia or septicemia; (3) necrotizing enterocolitis; (4) hypoxic-ischemic encephalopathy; (5) intracranial hemorrhage, posthemorrhagic hydrocephalus, and periventricular leukomalacia; (6) patent ductus arteriosus with a large left-to-right shunt; (7) gastroesophageal reflux; (8) hypoglycemia; (9) hypocalcemia; (10) anemia; (11) drugs or anesthesia; (12) environmental overheating; (13) any condition causing hypoxemia or hypovolemia; and (14) causes of upper airway obstruction such as nasal stenosis, choanal atresia, or vocal cord paralysis. These should be excluded and appropriately treated before a diagnosis of apnea of prematurity is made.

#### Apnea Associated with Infection

Small premature infants commonly have systemic infections, and the initial sign is often an increased frequency of apnea episodes. Such infections include *Staphylococcus epidermidis* bacteremia associated with venous catheters, *Candida* fungal sepsis associated with vaginal delivery and dexamethasone administration, and respiratory syncytial virus pneumonia associated with bronchopulmonary dysplasia and nosocomial spread. It is imperative that infection be definitively ruled out or diagnosed and treated in all cases of recurrent apnea events. This is an important part of clinical practice with premature infants. For suspected infection it is usual to take blood specimens for culture, examine the white cell count, and start antibiotics. The removal of indwelling catheters always becomes an important consideration.

#### Apnea Associated with Gastroesophageal Reflux

It has been established that visible postfeeding regurgitation of formula into the pharynx or mouth is associated with an increased incidence of apnea in premature infants (Menon et al, 1985); the explanation for the reflux is considered to be an activation of the laryngeal chemoreflex by gastric fluids (Thach, 1997). This phenomenon has suggested that covert gastroesophageal reflux to the level of the mid-esophagus, which is common in small premature infants, may be associated with recurrent apnea; treatment with theophylline may exacerbate the reflux, making the situation worse. Several polygraphic studies in premature infants have failed to

demonstrate a temporal relationship between episodes of apnea and episodes of acid reflux into the lower or mid-esophagus (Ajuriaguerra et al, 1991; Newell et al, 1989; Walsh et al, 1981). Examining older infants, Paton and colleagues (1990) concluded that although reflux and apnea may coexist in the same patient, acid events in the lower esophagus do not precede apnea events.

Newell and colleagues (1989) showed in a small subgroup of infants with xanthine-resistant apnea of prematurity that effective control of gastroesophageal reflux with use of a thickened formula and a more upright position was associated with a significant reduction in the number of apneic spells. Of importance, this reduction was not immediate but delayed by 1 to 2 days following treatment; also, the improvement was obtained without the use of cisapride or other drugs. It has been suggested that the decreased number of apneas was due to the resolution of esophagitis (Booth, 1992).

Barrington and colleagues (2002) found no relationship between acid reflux events and apnea events in premature infants just prior to discharge from the hospital. Arad-Cohen and associates (2000) also found in older infants that most apneas were not related to reflux, but when apnea and reflux occurred close together, the apnea event preceded the reflux event. It seems more logical that apnea and desaturation would lead to relaxation of the gastroesophageal junction, explaining why formula is often found in the pharynx of infants suctioned during an apnea event.

Other investigators have suggested that the pH probe method may not be sufficiently sensitive, as it does not detect non-acid reflux events (Wenzl et al, 2001); they have used the intraluminal impedance technique in larger infants to detect esophageal volume changes with reflux and claim this method to be more reliable. Using similar impedance methodology in premature infants, Peter and colleagues (2002) found no temporal relationship between apnea, desaturation, or bradycardia and lower esophageal reflux events.

It has become common practice in many centers to treat xanthine-resistant apnea of prematurity with metoclopramide, cisapride, and other antireflux agents, although no controlled trials have established the efficacy of these drugs in preventing apnea. Some evidence does suggest that cisapride is effective at reducing reflux in small premature infants (Ariagno et al, 2001), as in older infants. Kimball and Carlton (2001) performed a retrospective chart review in a large number of premature infants and found that the number of apneas in the 5 days after starting cisapride or metoclopramide was not less than the number of apneas during the 5 days before therapy. It is extremely doubtful if these drugs have an important role to play in the management of recurrent apnea events. Cisapride is currently restricted by the Food and Drug Administration (FDA) to only investigational use, related to an associated Q-T prolongation with possibly an increased risk for cardiac arrhythmias (Dubin et al, 2001).

#### Apnea Associated with Anemia of Prematurity

Agreement is lacking on the problem of anemia of prematurity and its relationship to recurrent apnea. In many centers, blood transfusion is standard policy in premature

infants with a hematocrit of less than 30%, and in any infant with signs of anemia, such as tachycardia, tachypnea, or episodes of apnea or bradycardia. Keyes and associates (1989) found no relationship between hematocrits of 19% to 64% and any of these signs, and found no consistent changes after transfusion. However, Joshi and colleagues (1987) found a significant reduction in the incidence of brief and intermediate apneas, and in the incidence of bradycardias, after transfusion. Other investigators have reported similar results (DeMaio et al, 1989). Ross and coworkers (1989) conducted a controlled trial of blood transfusion in a group of infants who all met the aforementioned criteria for transfusion. After transfusion there was a significant reduction in the heart rate, in the number of apnea and bradycardia episodes, and in the blood lactate levels in comparison with the group not transfused. Stute and coworkers (1995) found a significant reduction in the number of apneas and the number of bradycardias during the 3 days after transfusion in small premature infants.

### **Apnea Associated with Anesthesia**

Premature infants who undergo surgery with general anesthesia frequently have major recurrent apnea episodes for a few days after the procedure; the most common case is that of bilateral inguinal hernia repair (William et al, 2001). This susceptibility to apnea may persist until 50 to 60 weeks of postconceptional age, so older premature infants must be appropriately observed and treated for apnea following anesthesia (Scherer, 1991). Spinal anesthesia may be a better choice than general anesthesia when possible (Krane et al, 1995).

### **Apnea Associated with Immunizations**

An increased incidence of apneas is sometimes associated with routine vaccinations given at 2 months of postconceptional age (Stalker, 2000). Botham and colleagues (1997) described a group of preterm infants born at 24 to 31 weeks of gestation; only 1 infant had apnea before the diphtheria-tetanus-pertussis (DTP) injection, but 17 infants had apnea events afterward.

### **Apnea Associated with Respiratory Syncytial Virus Infection**

Premature infants who have respiratory syncytial virus (RSV) infections frequently have recurrent apnea episodes accompanied by nasalitis and increased secretions in the pharynx. Lindgren and colleagues (1992) have described a hyperresponsive laryngeal chemoreflex in RSV-infected lambs with nasalitis and increased tracheal secretions.

## **FEEDING HYPOXEMIA**

Feeding hypoxemia (also called feeding apnea, feeding desaturation, and feeding bradycardia) is frequent in premature infants given nipple feeds too soon but sometimes occurs in term infants (Hanlon et al, 1997; Rosen et al,

1984). During sucking and swallowing, ventilation is severely impaired (Shivpuri et al, 1983). The rapid onset of bradycardia is thought to be reflex in origin, whereas the delayed onset of bradycardia is due to oxygen desaturation. Feeding hypoxemia resolves with maturation, usually by 44 weeks of postconceptional age but occasionally as late as 54 weeks. Infants are treated by frequent interruptions during a feed, by supplemental oxygen while feeding, and in extreme cases by gavage. Sometimes, atropine before feeds may be helpful for treating the rapid-onset reflex bradycardia (Kattwinkel et al, 1976a). These events are not sleep related and should be differentiated from events associated with apnea of prematurity. With a knowledgeable, trained mother, feeding events should not delay discharge from the hospital.

## **CONGENITAL HYPOVENTILATION SYNDROME**

Although congenital hypoventilation syndrome—an uncommon condition—is more frequently described in older infants (Brouillette et al, 1990), the severe form occurs in newborns and may need attention in the delivery room or the newborn nursery. These infants have significant hypoventilation with small tidal volumes and prolonged apneas while asleep, but tend to have more normal ventilation while awake. There is little evidence of a response to asphyxia, so severe oxygen desaturation and hypercarbia develop without signs of an increased effort to breathe. Because the arousal responses may be present but the ventilatory responses to hypoxia and hypercarbia are absent, it is thought that this condition is caused by a failure to integrate signals from the central and peripheral chemoreceptors into the respiratory centers (Marcus et al, 1991). Findings on sonography, computed tomography (CT), and magnetic resonance imaging (MRI) studies of the head usually are normal initially (Weese-Mayer et al, 1988); the auditory brainstem responses may be abnormal. No respiratory stimulant drugs have been found to be effective (Oren et al, 1986), at least in the severe newborn type of this syndrome, and most infants require prolonged home mechanical ventilation with a tracheostomy. Phrenic nerve pacemakers may be useful sometimes (Brouillette et al, 1983), but because the upper airway muscles are not activated by the phrenic nerve, a tracheostomy is still necessary. Initially the ventilator may be needed for much of the day, but some improvement may be noted at about the age of 6 months, after which the infant may need the ventilator only at night while sleeping (Oren et al, 1987). Some of these infants may have Hirschsprung disease (O'Dell et al, 1987), a dysautonomia syndrome, or a neuroblastoma (Lambert et al, 2000), suggesting a more widespread problem. Seizure disorder, mild cerebral atrophy, and developmental delay may occur, possibly as a result of multiple asphyxial episodes. Many families cope with management of these children surprisingly well, and some of the children may even go to school (Marcus et al, 1991).

Acquired forms of central hypoventilation syndrome may be associated with the Arnold-Chiari syndrome (Choi et al, 1999), hypoxic-ischemic encephalopathy, meningitis, brain tumor, and metabolic brain disease. Examples of the

obesity-hypoventilation syndrome have not been reported in the newborn.

### APNEA OF INFANCY

Isolated apneas 5 to 15 seconds in duration, with or without periodic breathing, occur commonly in term infants during the first 6 months of life (Richards et al, 1984). There is no associated bradycardia or color change, and the episodes resolve spontaneously. Certain infants have significant apneas, usually more than 20 seconds in duration but sometimes shorter, and nearly always associated with bradycardia or skin color change. These too usually resolve spontaneously. The diagnosis of apnea of infancy is reserved for apneas with onset after 38 weeks of gestation, to distinguish them from apnea of prematurity persisting until 42 weeks of postconceptional age (Consensus Statement, 1987).

Usually after discharge from the nursery, some infants with apnea of infancy have an acute life-threatening event (ALTE), necessitating resuscitation by vigorous stimulation or positive pressure ventilation (Consensus Statement, 1987). Apnea of infancy is just one cause of an ALTE, perhaps representing 50% of the cases. Other causes include gastroesophageal reflux, pharyngeal incoordination, convulsions, infection, heart disease, breath-holding spells, central hypoventilation syndrome, central nervous system abnormality, and accidental or intentional smothering by the mother. Many infants with an ALTE, after appropriate investigation to exclude other causes, are considered to have *near-miss sudden infant death syndrome* (SIDS). Investigation of these infants, by a 24-hour recording of their breathing, reveals that they have an increased incidence of periodic breathing, brief apneas, and prolonged apneas, when compared with control infants (Guilleminault et al, 1979). It is not clear whether the infants had the same abnormalities before their ALTE, which were simply not recognized, but that scenario seems quite likely. A significant number of these infants later die suddenly; it seems reasonable to consider that they died of apnea of infancy with a fatal episode of ALTE.

### SUDDEN INFANT DEATH SYNDROME

SIDS describes the sudden unexpected death of an infant, which is unexplained by history, by a thorough death scene investigation, and by an adequate autopsy (Consensus Statement, 1987). Death occurs during sleep, most commonly at night. The incidence in the United States is 0.8 per 1000 live births (1995 data). It is a major cause of infant mortality, with a peak incidence between 2 and 4 months of age, and it is much less common after 6 months of age. Environmental risk factors include prone sleeping position, exposure to tobacco smoke, overheating, and upper respiratory infections. Other risk factors are soft bedding, bed sharing, and bottle feeding, although they may not be independent variables. A recent study found that parental bed sharing was not a factor if the infant was sleeping in the supine position (Gessner et al, 2001).

The occurrence rate for SIDS is 3 to 4 times higher in all premature infants, and 10 times higher in very low-

birth-weight infants, but the increased risk is not related to apnea of prematurity (Hodgman, 1998). Subsequent siblings of infants who die of SIDS may be at increased risk for SIDS.

Considerations in the differential diagnosis include accidental suffocation, deliberate infanticide, congenital brain abnormalities, cardiac conduction defects, and rare metabolic disorders of fatty acid oxidation. It must be emphasized that the diagnosis of SIDS is one of exclusion. The autopsy evaluation is remarkable for subtle findings, pulmonary congestion, and multiple petechial hemorrhages on the surface of the lungs, thymus, and pericardium—signs of suffocation that suggest deep breaths against an obstructed airway.

### The Prolonged Q-T Syndrome Hypothesis

One hypothesis is that infants who die of SIDS have a prolonged corrected Q-T interval in the electrocardiogram (ECG) and die from a cardiac arrhythmia. Schwartz and colleagues (1998) examined the ECGs of 34,000 infants on day 4 of life. In 12 of 24 infants (50%) who subsequently died of SIDS, the Q-Tc was longer than 440 msec. Of those who did not die of SIDS, only 2.5% had a Q-Tc longer than 440 msec. Other investigators have examined this problem and not found similar results (Southall et al, 1986). Infants with the true long Q-T syndrome die with syncopal spells and ventricular tachycardia episodes. There is no evidence that infants with SIDS die with such cardiac arrhythmias; recordings at the time of death suggest severe sinus bradycardia from hypoxia (Meny et al, 1994). Death by cardiac arrhythmia would not explain the characteristic autopsy findings of SIDS. As a screening procedure for detecting high SIDS risk, analysis of the Q-T interval would not be efficient; the positive test predictive value would be only 1.5%. In view of the absence of any reliable preventive treatment for this problem, it does not seem prudent to subject millions of infants to routine ECG examinations (Hoffman and Lister, 1999). The long Q-T syndrome may be associated with sodium channel gene mutations; in a postmortem molecular analysis of 93 cases of SIDS, only 2 infants had such a gene mutation (Ackerman et al, 2001). Infants who die of a cardiac arrhythmia with the long Q-T syndrome should be considered in a separate category.

### Apnea of Infancy Hypothesis

A more widely accepted hypothesis has been that these infants die from obstructive apnea and that they have apnea of infancy before their demise. However, infants with apnea of infancy, diagnosed by pneumogram, who have not yet experienced an ALTE, have only a slightly increased risk for SIDS over that in the general population. If infants with apnea of infancy have a single ALTE, the risk for sudden death increases to 4%, and if they have several ALTE episodes the risk is enormous. Nevertheless, only 7% of infants diagnosed with SIDS have a preceding ALTE. In a study examining breathing patterns obtained with 24-hour recordings at the time of discharge from the birth hospital, nonselected infants destined to die of SIDS did not have a breathing pattern significantly different

from that in closely matched infants who did not die of SIDS (Southall et al, 1982). Infants who die of SIDS seldom have a prior diagnosis of apnea of infancy or prolonged apnea of prematurity. It seems reasonable to conclude that the apnea of infancy hypothesis for SIDS remains unproved, and that SIDS and apnea of infancy should be considered separate problems. Thus, an infant who dies suddenly after episodes of apnea of infancy should be considered not to have died of SIDS but to have died of apnea of infancy with an ALTE.

### A Variation of the Apnea Hypothesis

Although the apnea of infancy hypothesis is widely discredited, a recent study in Belgium found that in pneumograms performed at ages 1 to 4 months, short obstructive and mixed sleep apneas were more common in infants destined to die of SIDS than in control infants (Kato et al, 2001). Such episodes are common in early infancy; they are mild and nonthreatening and do not warrant a diagnosis of apnea of infancy, in which the recorded events are more prolonged and severe. Consistent with this reported mild ventilatory instability, there is evidence that the medullary arcuate nucleus of infants who die of SIDS is hypoplastic and manifests reduced neuronal density (Matturri et al, 2000). The arcuate nucleus corresponds to the site of central chemoreceptor cells in experimental animals such as the rat. In addition, in the arcuate nucleus of infants who die of SIDS, there is reduced muscurinic receptor binding (Kinney et al, 1995) and reduced serotonergic receptor binding (Panigrahy et al, 2000). This finding is unique to this site in infants who die of SIDS. In other infants who die of chronic oxygen insufficiency not related to SIDS, the same defect often is found, but it occurs without specificity in many other sets of neurons; it does not occur in infants who die of other causes without chronic oxygen deprivation. Although not established, a defect in central chemoreception is a likely cause for SIDS.

### Prone Sleeping Position and Further Hypotheses About SIDS

The evidence that the prone sleeping position is associated with an increased incidence of SIDS is convincing. An American Academy of Pediatrics Task Force on sleeping position and SIDS recommended that infants should sleep in the supine or lateral position (Kattwinkel et al, 1992). The relative risk of SIDS associated with the prone sleeping position ranges from 3.5 to 9.3 in seven reported studies; no study has reported a relative risk of less than 1.0 (Guntheroth and Spiers, 1992). Critical review of reports from several countries has shown that previously observed large reductions in the SIDS rate with supine or lateral positioning were sustained over time; further reductions in the incidence of prone positioning were accompanied by further reductions in the incidence of SIDS (Centers for Disease Control and Prevention, 1996; Hunt, 1994). It was concluded that the supine position was not associated with an increase in complications such as upper airway obstruction or aspiration pneumonia, as had been believed previously (Hunt and Shannon, 1992; Malloy, 2002).

The decreased incidence of SIDS is more marked with supine than with lateral positioning (Fleming et al, 1996; Wigfield et al, 1992); while asleep, the infant placed in the side position may roll into the prone position. The lateral position is no longer recommended (AAP Task Force, 1996). It is emphasized that the American Academy of Pediatrics recommendations do not apply to small premature infants, to infants with significant gastroesophageal reflux, or to those with craniofacial abnormalities such as the Pierre Robin syndrome or laryngomalacia; such infants may do better sleeping in the prone position.

No consensus on the cause of the problem with prone positioning has been developed, but several suggestions have been published that constitute further related hypotheses for the cause of SIDS.

### *The Face-Down Sleeping Hypothesis*

Chiodini and Thach (1993) showed that the prone position may be associated with rebreathing and hypoxia; this is especially true when the infant assumes a persistent face-down position, a not uncommon occurrence, and when the infant sleeps on soft bedding with pillows, rather than on a firm mattress. These authors could find little evidence for the development of any airway obstruction, but the development of hypoxia was significant. Associated with rebreathing, the reduction of inspired oxygen was significantly greater than the increased inspired carbon dioxide (Patel et al, 2001), and there was a related increase in minute ventilation. Waters and colleagues (1996) found a high incidence of face-down position among older infants, but noted that periodic arousals with head turning prevented serious hypercarbia in most cases. Constantin and associates (1999) noted that the face-down position was uncommon in older premature infants near the time of discharge; it may be that such infants are not prone to SIDS until they are old enough to move their head into the face-down position, at which time they become dependent on an adequate arousal response.

### *The Decreased Arousability Hypothesis*

Kahn and coworkers (1993) demonstrated that the prone position was associated with significantly fewer and shorter arousals from sleep. During obstructive apneas, an arousal or deep sigh response is significantly more frequent in the supine position than in the prone position (Groswasser et al, 2001). Decreased arousability in the prone sleeping position is independent of quiet or active sleep (Goto et al, 1999; Home et al, 2001). It seems possible that an insufficient arousal response to serious hypoxia, during sleep in the prone position, may be an important factor in SIDS. Nevertheless, the occurrence of airway obstruction in SIDS is poorly explained.

### *The Laryngeal Chemoreflex Hypothesis*

Jeffery and colleagues (1999) showed in normal term infants that small pharyngeal infusions of water caused markedly slower swallowing and breathing rates in the prone position, but little change in the supine position. Larger infusions in piglets under similar conditions caused more severe apneas and sometimes death. These investigators hypothesized that any or all of three

factors may be operating: (1) prone position, (2) active sleep, and (3) laryngeal chemoreflex activity. All three may dominate in early infancy, the time of peak occurrence for SIDS. Later in infancy, infants roll on their backs, sleep becomes predominantly quiet rather than active, and the chemoreflex is attenuated with maturation. In the supine position, the pyriform fossae on either side of the larynx are available to store pharyngeal fluid and may protect the upper airway. In the prone position, the esophagus is superior to the larynx, so fluid may flow easily over the laryngeal chemoreceptors, initiating apnea with bradycardia. Under these circumstances it is reasonable that the glottis or larynx may close, causing airway obstruction. It has been suggested that the airway obstruction is due to laryngospasm caused by reflux of acid gastric contents into the pharynx, a phenomenon that has been demonstrated repeatedly in newborn dogs (Duke et al, 2001).

Other environmental factors important in SIDS also may play parts: smoking, nasalitis, and overheating. Nicotine exposure in lambs is associated with reduced arousal responses and reduced ventilatory responses to hypoxemia (Hafstrom et al, 2000). Pooled secretions in upper respiratory infections may stimulate the laryngeal chemoreflex, and this may be accentuated by overheating (Jeffery et al, 1999), but diminished in the supine sleeping position (Lindgren, 1999).

In view of the strong evidence about the prone sleeping position, infants in the normal newborn nursery should be placed in the supine position. SIDS has been reported in the newborn infant in the hospital (Burchfield and Rawlings, 1993). Premature infants accustomed to sleeping prone should be encouraged into the supine position before being discharged; in the supine position, premature infants are more arousable (Goto et al, 1999). Mothers should be appropriately advised of the advantages of the supine position. The “Back to Sleep” campaign was initiated in 1994 by the National Institute of Child Health and Human Development to inform health care professionals and families of this important recommendation. There is evidence that health care professionals, families, and day care centers do not always follow this advice (Paris et al, 2001; Pollack et al, 2002), so there is considerable room for improvement.

### HOME APNEA MONITORING PROGRAMS

Controversy remains about whether some infants should have apnea monitoring at home. Infants may be candidates for home monitoring if they have unresolved apnea of prematurity or unresolved apnea of infancy or are considered to be at increased risk for SIDS. The hope of those who use home monitors is that the occurrence of ALTE or SIDS will be reduced by appropriate caretaker interventions. Parents must be skilled in the use of the monitor, in the interpretation of frequent false alarms, and in cardiopulmonary resuscitation. There is no evidence that home apnea monitoring reduces the number of deaths or the number of ALTE episodes in any of these conditions, and the incidence of SIDS remains unchanged related to the use of home monitors.

### Discharge Pneumogram for Premature Infants

The pneumogram performed in premature infants at the time of discharge appears to be of no help in deciding whom to monitor for SIDS and should not be used for this purpose (Consensus Statement, 1987). In one British study, 4% of 1157 premature infants discharged from the hospital had previously unrecognized prolonged apneas on the predischarge pneumogram. None of the infants with later SIDS had prolonged apneas at discharge, and none with prolonged apneas at discharge had SIDS (Southall et al, 1982). Some clinicians perform a predischarge pneumogram to assess the risk for an ALTE. Barrington and associates (1996) performed a pneumogram in small premature infants believed to be ready for discharge from intensive care. In a few with worrisome apneas, discharge was delayed until the recordings improved, but in the end, most infants had less worrisome apneas recorded just prior to discharge, and all infants were sent home without a home apnea monitor. During a 6-month follow-up period, only 3 of 176 infants had an ALTE, and the predischarge pneumogram could not distinguish these 3 infants from the others without an ALTE. Some authors justify the predischarge pneumogram because it may detect undiagnosed apneas (Razi et al, 1999); however, the significance of such apneas not detected clinically by the nursing staff is currently uncertain (Martin and Fanaroff, 1998). Some inconclusive evidence has been found in favor of the predischarge pneumogram under certain circumstances. Subhani and colleagues (2000) examined the predischarge event recordings of 106 infants, but all of the infants were still on caffeine for apnea of prematurity. These investigators found that 74 infants had normal recordings and none had complications at follow-up, whereas in 32 infants, the recordings were not considered normal and 3 infants had an ALTE after discharge. It was not claimed that those 3 infants with an ALTE could be differentiated from the 29 other infants with an abnormal pneumogram and no ALTE. Furthermore, criteria for indicating an abnormal pneumogram are not established at this time. Di Fiore and colleagues (2001) concluded that infants who continue to have clinical monitor alarms near the time of discharge have relatively short apnea events, but they are more prone to desaturation and bradycardia events because they have residual lung disease with lower oxygen saturation levels, or because they have subtle neurodevelopmental dysfunction.

Despite lack of conclusive evidence, some institutions still perform a pneumogram in most small premature infants before discharge, usually if there is a history of recurrent apnea events and even if the apneas appear to be resolved. If persistent apnea events are found, depending on the severity, infants may be kept in the hospital longer, they may be discharged home without a monitor, or they may be discharged home on a monitor with the apparent hope of preventing an ALTE. However, many institutions take a different approach: They keep premature infants in the hospital for 5 to 7 days after the last apnea event observed by the hospital staff and then discharge the infant without a home apnea monitor. Darnall and colleagues (1997) concluded that it is reasonable to wait for up to 8 days after an apnea event before discharging the premature infant

without a monitor. In larger premature infants, Eichenwald and associates (2001) concluded that an interval of 5 to 6 days was appropriate before discharge without a home monitor. A national survey showed that home apnea monitoring is not the standard of care (Meadows et al, 1992), and that there is no evidence that the home apnea monitoring strategy prevents any deaths. Surprisingly, there is no evidence that use of the home monitor accelerates discharge and reduces the length of hospitalization (Sychowski et al, 2001); it takes additional time in the hospital to prepare the family for use of the monitor. However, despite lack of evidence, use of monitors is widely supported in the community, and in making decisions about their use, it may be unwise to alienate an anxious and insistent family. If an infant is sent home on caffeine, it seems reasonable to use a home monitor, especially as the drug should be discontinued a month or so after discharge.

### The CHIME Project

As mandated by Congress, a large multicenter study is being conducted by the Collaborative Home Infant Monitoring Evaluation (CHIME) group. The aim is to reach a better understanding of apnea events in early infancy and to explore the possible role of home monitoring in the prevention of SIDS. A new and improved monitor is used; it includes pulse oximetry and respiratory inductance plethysmography for evaluating both central and obstructive apneas (Weese-Mayer et al, 2000). Data from this group indicate that the median level of fractional oxygen saturation in healthy term infants in the first 6 months of life is 98%, with the lower limit at 95% (Hunt et al, 1999). Transient desaturations of more than 10% were common, found in 60% of the infants, and nearly always were associated with brief apneas. The desaturations decreased in frequency as the infants approached the age of 6 months. These data confirm the earlier studies by Poets and colleagues (1991), who found that desaturations to less than 80% associated with apneas were common in healthy infants.

The CHIME group has reported a comparison of four groups of infants: (1) healthy full-term infants, (2) discharged preterm infants, (3) siblings of infants who died of SIDS, and (4) infants who had a recent ALTE (Ramanathan et al, 2001). The latter three groups were considered to be at increased risk for SIDS. The authors adopted arbitrary definitions that can be approximated as follows: *conventional events* were apneas of 20 or more seconds or bradycardias with heart rates of less than 80 beats/minute for at least 15 seconds; *extreme events* were apneas of 30 or more seconds or bradycardias with heart rates of less than 60 beats/minute for at least 10 seconds. Conventional events occurred in 31% of all infants, and extreme events occurred in an additional 10% of infants. Conventional events were quite common, and occurrence rates were similar in all four groups of infants. Extreme events were common only in the preterm infant group and only up to 43 weeks of postconceptional age, well before the peak incidence of SIDS. There was a high frequency of obstructive apneas without bradycardias, which

would not be detected by commercial home monitors using transthoracic impedance; about 50% of extreme events had no bradycardia even with oxygen desaturation. There are no data confirming that even the extreme events documented in this study, especially those without bradycardia, would have any deleterious effects or predictive values.

It is not known what effect parental interventions may have had on the data. However, based on about 700,000 hours of monitoring, events described as abnormal by many authorities were actually quite common even in healthy term infants during the first 6 months of life, as well as in premature infants. For commercial home monitors, if they are to be used without better evidence for their efficacy, it is clear that technical improvements must be made and that much broader limits for normal breathing behavior must be accepted. Jobe (2001), among others, has called for a radical reduction in the use of home apnea monitors for the purpose of preventing SIDS.

# Pulmonary Physiology of the Newborn

Thomas N. Hansen and Anthony Corbet

## LUNG MECHANICS AND LUNG VOLUMES

The lungs possess physical, or mechanical, properties that resist inflation, such as elastic recoil, resistance, and inertance. The dynamic interaction between these properties determines the effort that must be exerted during spontaneous breathing and the resting and extreme values for the volume of gas in the lung.

### Elastic Recoil

The lung contains elastic tissues that must be stretched for lung inflation to occur. Hooke's law requires that the pressure needed to inflate the lung must be proportional to the volume of inflation (Fig. 44-1). Conventionally, volume of inflation is plotted on the  $y$ -axis, and the distending pressure is plotted on the  $x$ -axis. In this way, the constant of proportionality is volume divided by pressure, or *lung compliance*. Throughout the range of tidal ventilation, the relationship between pressure and volume is linear. At higher lung volumes, as the lung reaches its elastic limit (*total lung capacity* [TLC]), this relationship plateaus.

The lungs and the chest wall function as a unit (the respiratory system) coupled with the interface between the parietal and the visceral pleura. The tendency for the lung to collapse at rest is balanced by the outward recoil of the chest wall, resulting in a negative (subatmospheric) intrapleural pressure. The volume at which this balance occurs is the functional residual capacity (FRC). Inflation of the respiratory system above FRC requires a positive distending pressure that, at higher lung volumes, must overcome the elastic recoil of both the lung and the chest wall. Deflation below FRC requires an active expiratory maneuver. Residual volume (RV) is defined as the volume of air that cannot be expired with a forced deflation.

As depicted in Figure 44-1, the relative compliance of the lung of the newborn is similar to that of the adult lung (Krieger, 1963); however, the infant's chest wall compliance (Table 44-1) is greater than the adult's (see Fig. 44-1), and the pleural pressure is only slightly subatmospheric. Measurements of lung and chest wall compliance suggest that the newborn should have a lower percent RV and a lower percent FRC than in the adult. In fact, the percent FRC in the newborn is equal to the adult's, and the infant's percent RV is slightly greater. This seeming paradox exists because FRC and RV are measured while the infant is breathing, and predictions from the pressure volume curves assume

that there is no air movement and passive relaxation of all respiratory muscles (Bryan and England, 1984). Data suggest two mechanisms by which the newborn can maintain a normal FRC during spontaneous breathing: (1) by maintaining inspiratory muscle activity throughout expiration and splinting the chest wall or (2) by increasing expiratory resistance by glottic narrowing. The reason for the elevated RV is not entirely clear, but it could result from airway closure during an active expiration as part of a crying vital capacity maneuver.

### Resistance

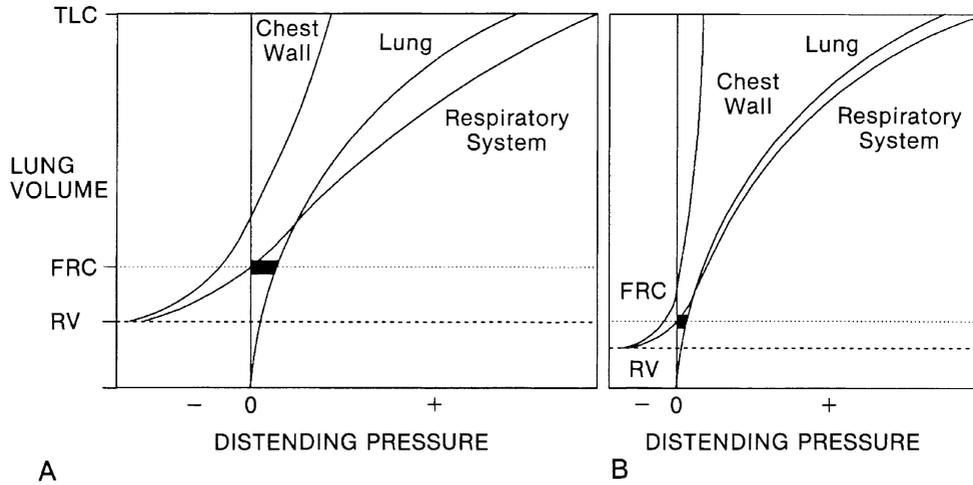

Resistance to gas flow arises because of friction between gas molecules and the walls of airways (*airway resistance*) and because of friction between the tissues of the lung and the chest wall (*viscous tissue resistance*). Airway resistance represents approximately 80% of the total resistance of the respiratory system (Polgar and String, 1966). In the newborn, nasal resistance represents nearly half the total airway resistance; in the adult, it accounts for about 65% of the airway resistance (Polgar and Kong, 1965).

Gas flows only in response to a pressure gradient (Fig. 44-2). During laminar flow, the pressure difference needed to force gas through the airway is directly related to the flow rate times a constant—airway resistance. During turbulent flow, however, this pressure is directly proportional to a constant times the flow rate squared. Gas flow becomes turbulent at branch points in airways, at sites of obstruction, and with high flow rates. Turbulence occurs whenever flow increases to a point that Reynolds' number exceeds 2000. This dimensionless number is directly proportional to the volumetric flow rate and gas density, and it is inversely proportional to the radius of the tube and gas viscosity. Obviously, turbulent flow is most likely to occur in the central airways, where volumetric flow is high, rather than in lung periphery, where flow is distributed across a large number of airways. Both types of flow exist in the lung, so the net pressure drop is calculated as follows (Pedley et al, 1977):

$$\Delta P = (K_1 \times \dot{V}) + (K_2 \times \dot{V}^2) \quad (1)$$

It is possible to take advantage of the differences between laminar and turbulent flows to determine the site of airway obstruction in the lung. If obstruction to gas flow is in the central airways, turbulent flow is affected the most. Because turbulent gas flow is density dependent, allowing the patient to breathe a less dense gas (such as helium mixed with oxygen) reduces the resistance to gas flow. If the site of obstruction is peripheral, the mixture of helium and oxygen does not appreciably affect resistance.

Inflation of the lung increases the length of airways and might therefore be expected to increase airway resistance. Lung inflation also increases airway diameter, however. Because airway resistance varies with the fourth to fifth power of the radius of the airway, the effects of changes in airway diameter dominate, and resistance is inversely proportional to lung volume (Rodarte and Rehder, 1986). Similarly, airway resistance is lower during inspiration than during

**FIGURE 44-1.** This is an idealized plot of volume as a function of distending pressure for the lung, chest wall, and respiratory system (lung plus chest wall) of an adult (A) and an infant (B). These curves are derived by instilling or removing a measured volume of gas from the lung and allowing the respiratory system to come to rest against a shuttered airway. At this point, only elastic forces are acting on the respiratory system, and airway pressure is equal to alveolar pressure. Intrapleural pressure can be measured using an esophageal balloon. Because airway pressure is equal to alveolar pressure, the distending pressure for the lung can be measured as *airway pressure – intrapleural pressure*. The distending pressure for the chest wall is *intrapleural pressure – atmospheric pressure*, and the distending pressure for the respiratory system is *airway pressure – atmospheric pressure*. Compliance is the change in volume divided by the change in distending pressure. The shaded area is the resting intrapleural pressure at functional residual capacity (FRC). Lung volumes depicted include residual volume (RV), functional residual capacity (FRC), and total lung capacity (TLC).

expiration because of the effects of changes in intrapleural pressure on airway diameter. During inspiration, pleural pressure becomes negative, and a distending pressure is applied across the lung. This distending pressure increases airway diameter as well as alveolar diameter and decreases the resistance to gas flow. During expiration, pleural pressure increases and airways are compressed. Collapse of airways is

opposed by their cartilaginous support and by the pressure exerted by gas in their lumina. During passive expiration, these defenses are sufficient to prevent airway closure. When intrapleural pressure is high during active expiration, airways may collapse, and gas may be trapped in the lung. This problem may be accentuated in the small preterm infant with poorly supported central airways.

**TABLE 44-1**

<b>Lung Volumes and Mechanics in the Normal Newborn</b>	
<b>Lung Volumes</b>	<b>mL/kg</b>
Total lung capacity	63
Functional residual capacity	30
Residual volume	23
Tidal volume	6
<b>Compliance</b>	<b>mL/cm H<sub>2</sub>O</b>
Total respiratory system	3
Chest wall	20
Lung	4
<b>Resistance</b>	<b>cm H<sub>2</sub>O/mL/sec</b>
Total pulmonary resistance	0.03-0.04

Data from Cook et al, 1957; Gerhardt and Bancalari, 1980; Polgar and Promadhat, 1971; Polgar and String, 1966; Reynolds and Etsten, 1966.

**Inertance**

Gas and tissues in the respiratory system also resist accelerations in flow. Inertance is a property that is negligible during quiet breathing and physiologically significant only at rapid respiratory rates.

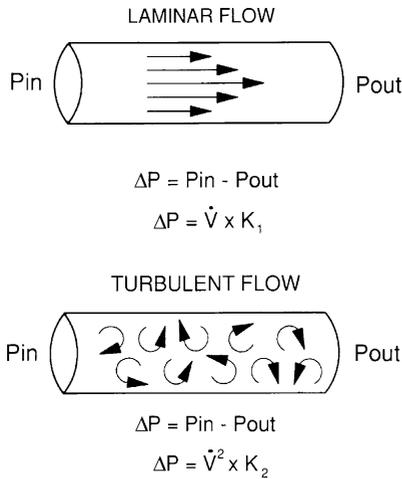

**Dynamic Interaction**

Compliance, resistance, and inertance all interact during spontaneous breathing (Fig. 44-3). This interaction is described by the equation of motion for the respiratory system:

$$P(t) = (V[t] \times 1/C) + (\dot{V}[t] \times R) + (\ddot{V}[t] \times I) \quad (2)$$

where P(t) is the driving pressure at time t, V[t] is the lung volume above FRC, C is the respiratory system compliance,  $\dot{V}[t]$  is the rate of gas flow, R is the resistance of the respiratory system,  $\ddot{V}[t]$  is the rate of acceleration of gas in the airways, and I is the inertance of the respiratory system. If I is neglected, the equation simplifies to:

$$P(t) = (V[t] \times 1/C) + (\dot{V}[t] \times R) \quad (3)$$

**FIGURE 44-2.** Gas flow ( $\dot{V}$ ) through tubular structures occurs only in the presence of a pressure gradient ( $P_{in} > P_{out}$ ). For laminar flow,  $P$  is directly proportional to

$$\Delta P = \dot{V} \times (8 \times L \times \mu) / (\pi \times r^4)$$

In this case, the constant of proportionality ( $K_1$ ) is directly related to the length of the airway ( $L$ ) and the viscosity of the gas ( $\mu$ ) and indirectly proportional to the fourth power of the radius of the airway ( $r$ ).

For turbulent flow,  $\Delta P$  is proportional to  $\dot{V}^2$ . The constant of proportionality ( $K_2$ ) is directly proportional to the length of the airway and the density of the gas and inversely proportional to the fifth power of the radius of the airway.

At times of zero gas flow (end-expiration and end-inspiration), the equation further simplifies to:

$$P(t) = (V[t] \times 1/C) \text{ and } C = V(t)/P(t) \quad (4)$$

This series of equations and Figure 44-3 demonstrate that at points of no gas flow (end-expiration and end-inspiration), only elastic forces are operating on the lung. During inflation or deflation of the lung, however, both elastic and resistive forces are important.

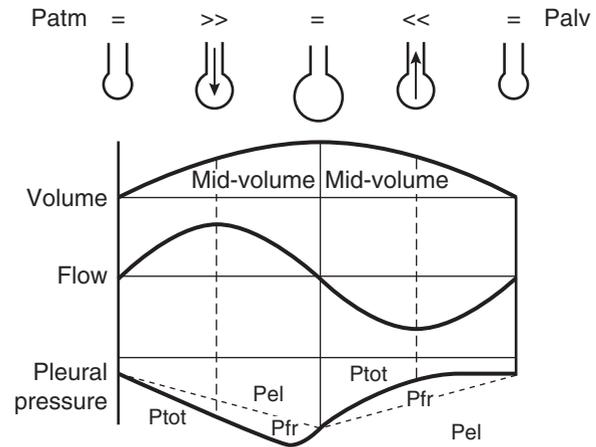

Although the solution to the equation of motion for the respiratory system is beyond the scope of this discussion, the behavior of the respiratory system during passive exhalation is a special situation for which a solution can be obtained relatively easily (Lesouef et al, 1984; McIlroy et al, 1963). Before a passive exhalation maneuver, the infant is given a positive pressure breath, and the airway is occluded—invoking the Hering-Breuer reflex and a brief apnea. Airway pressure is measured, and the occlusion is released. Expired gas flow is measured using a pneumotachometer and integrated to volume; flow is then plotted as a function of volume (Fig. 44-4A). During a passive exhalation, there are no external forces acting on the respiratory system ( $P[t] = 0$ ), so the equation of motion simplifies to:

$$(V[t] \times 1/C) + (\dot{V}[t] \times R) = 0$$

Rearranging gives

$$\dot{V}(t) = (-1/[RC]) \times V(t) \quad (5)$$

This equation states that during passive exhalation, flow plotted against volume is a straight line with slope  $-1/(RC)$ .

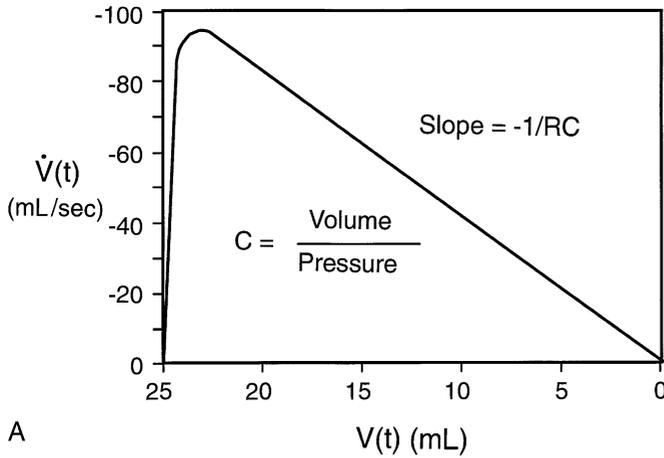

**FIGURE 44-3.** Gas flows from the atmosphere into the lung only if atmospheric pressure ( $P_{atm}$ ) is greater than alveolar pressure ( $P_{alv}$ ). At end-expiration, when  $P_{atm}$  equals  $P_{alv}$ , there is no gas movement into or out of the lung. During a spontaneous inspiration, the diaphragm contracts, the chest wall expands, and the volume in the intrathoracic space increases. As a result, pleural pressure ( $P_{pl}$ ) decreases relative to  $P_{atm}$ , and a gradient is created between  $P_{pl}$  and  $P_{alv}$ , distending the lung, increasing alveolar volume, and decreasing  $P_{alv}$ . A gradient also is created between  $P_{atm}$  and  $P_{alv}$ , and gas flows from the atmosphere into the alveolar space. The rate of gas flow increases rapidly, reaches a maximum (peak flow), and then decreases as the alveolus fills with gas and  $P_{alv}$  approaches  $P_{atm}$ . At peak inspiration,  $P_{alv}$  equals  $P_{atm}$ , and lung volume is at its maximum, as is  $P_{pl}$ . The curved solid line connecting end-expiration to end-inspiration is the total driving pressure for inspiration ( $P_{tot}$ ). The dotted line represents the pressure needed to overcome elastic forces alone ( $P_{el}$ ). The difference between the two lines is the pressure dissipated overcoming flow-resistive forces ( $P_{fr}$ ). During exhalation, this cycle is reversed.

The quantity  $RC$  has units of time and is termed the *respiratory time constant* ( $Trs$ ).  $Trs$  defines the rate at which the lung deflates during a passive exhalation (see Fig. 44-4). Time constants affect the rate of lung inflation in the same manner in which they affect lung deflation (see Chapter 45).

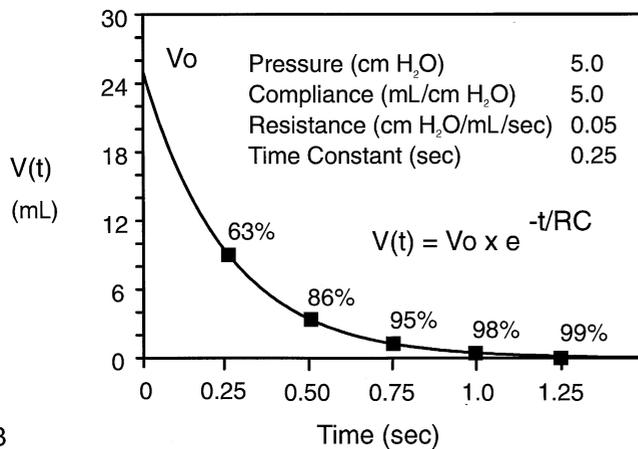

### Measurements of Lung Mechanics

A true measurement of static lung compliance requires instilling a known volume of gas into the lung and then measuring airway pressure at equilibrium in the absence of respiratory muscle activity (see Fig. 44-1) (McCann et al, 1987). This technique is used to measure compliance during the passive exhalation maneuver described previously (see Fig. 44-4). Another technique for measuring compliance takes advantage of the fact that gas flow is transiently equal to zero at end-inspiration and end-expiration (see Fig. 44-3). Compliance is calculated by dividing the change in volume between these two points by the concomitant change in distending pressure. Because the measurement is made while the infant is breathing, it is termed *dynamic compliance*. In the normal infant, dynamic compliance should be equal to static compliance.

As was mentioned earlier, measurements of compliance are affected by lung size. For example, if a distending

A

B

**FIGURE 44-4.** A, Plot of flow of gas out of the lung,  $\dot{V}_t$ , versus volume of gas remaining in the lung,  $V(t)$ , for a passive exhalation. Flow of gas out of the lung is negative by convention. After an initial sharp increase, flow decreases linearly as the lung empties. Static compliance of the respiratory system is obtained by dividing the exhaled volume by the airway pressure at the beginning of the passive exhalation. Resistance is calculated from the slope of the flow volume plot,  $-(1/RC)$ , and the compliance. This technique has the advantages of not requiring measurements of pleural pressure and being relatively unaffected by chest wall distortion. B,  $V(t)$  is plotted as a function of time for a passive exhalation. The graph is an exponential with the equation

$$V(t) = V_0 \times e^{-t/(R \times C)}$$

$V_0$  is the starting volume, and  $e$  is a mathematical constant (roughly 2.72). For this example, the time constant of the respiratory system ( $Trs$ ) is roughly 0.25 second. Calculations show that when exhalation persists for a time equal to one time constant ( $t = 0.25 \text{ sec} = 1 \times Trs$ ), 63% of the gas in the lung is exhaled. For  $t = 2Trs$ , 86% of the gas is exhaled; for  $3Trs$ , 95%; for  $4Trs$ , 98%; and for  $5Trs$ , 99%. If expiration is interrupted before a time  $t = 3Trs$ , gas is trapped in the lung.

pressure of 5 cm H<sub>2</sub>O results in a 25-mL increase in lung volume in a newborn, calculated lung compliance is 5 mL/cm H<sub>2</sub>O. In an adult, the same distending pressure of 5 cm H<sub>2</sub>O increases the lung volume by roughly 500 mL, and calculated compliance is 100 mL/cm H<sub>2</sub>O. Although the calculated lung compliances are different, the forces needed to carry out tidal ventilation are similar (i.e., lung

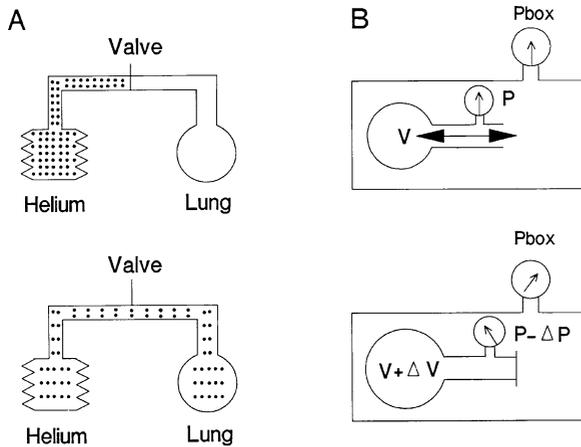

function is normal in both circumstances). This example points out that if lung compliances are to be compared, they must be corrected for size. This is usually performed by dividing compliance by resting lung volume to get *specific compliance*. For the newborn, resting lung volume is roughly 100 mL, so specific compliance is 0.05 mL/cm H<sub>2</sub>O/mL lung volume. For the adult, resting lung volume is nearly 2000 mL, so specific compliance is 0.05 mL/cm H<sub>2</sub>O/mL lung volume—identical to that in the newborn.

Lung compliance changes with volume history, meaning that it decreases with fixed tidal volumes and increases after deep breaths that recruit air spaces that may have been poorly ventilated or atelectatic. The periodic sigh in spontaneous breathing is associated with an increase in lung compliance and in oxygenation.

Many respiratory disorders result in nonhomogeneous increases in small airway resistance in the lung. Therefore, if lung compliance remains relatively uniform, the product of resistance and compliance ( $Trs$ ) varies throughout the lung. During lung inflation, units with normal resistance have the lowest  $Trs$  and fill rapidly. Units with high resistance have a longer  $Trs$  and fill more slowly. At rapid respiratory rates, when the duration of inspiration is short, only those lung units with a short  $Trs$  are ventilated. In effect, the ventilated lung becomes smaller. As discussed earlier, as the lung becomes smaller, its measured compliance decreases. Therefore, in infants with ventilation inhomogeneities, dynamic lung compliance decreases as respiratory rate increases. This decrease in lung compliance with increasing respiratory rate is termed *frequency dependence of compliance* and is suggestive of inhomogeneous small airway obstruction.

Resistance of the total respiratory system can be measured using the passive exhalation technique described previously (see Fig. 44-4), or it can be calculated from measurements of distending pressure, volume, and flow (see Fig. 44-3). Points of equal volume are chosen during inspiration and expiration. The gas flow and the distending pressure are measured at each point. The pressure needed to overcome elastic forces should be the same for inspiration and expiration; therefore, these pressures cancel out each other. Total resistance, consequently, is equal to distending pressure at the inspiratory point minus distending pressure at the expiratory point, divided by the sum of the respective inspiratory and expiratory point gas flows. Investigators have calculated compliance and resistance by measuring distending pressure, gas flow, and volume (see Fig. 44-3), then fitting these measurements to the equation of motion (see Equation 3) using multiple linear regression techniques, and solving for the coefficients  $1/C$  and  $R$  (Bhutani et al, 1988).

FRC is measured by inert gas dilution techniques (helium dilution) or inert gas displacement (nitrogen washout) (Fig. 44-5). Both of these techniques measure gas that communicates with the airways. The total volume of gas in the thorax at end-expiration (thoracic gas volume [TGV]) can be measured using a body plethysmograph and applying Boyle's law. This technique measures all gas in the thorax—even trapped gas that is not in contact with the airways. Obviously, FRC measured by inert gas dilution is less than TGV if significant volumes of trapped gas are present.

**FIGURE 44-5.** **A**, Measurement of functional residual capacity (FRC) by helium dilution. At end-exhalation, the infant breathes from a bag containing a known volume ( $V_{\text{bag}}$ ) and (initial) concentration of helium ( $\text{He}_i$ ) in oxygen. The gas in the infant's lungs dilutes the helium-oxygen mixture to a new concentration ( $\text{He}_f$ ):  $\text{FRC} = \text{Bag volume} \times (\text{He}_i - \text{He}_f) / \text{He}_f$ . **B**, Measurement of thoracic gas volume (TGV) using a plethysmograph. The infant breathes spontaneously in a sealed body plethysmograph. At end-exhalation, the airway is closed with a shutter. As the infant attempts to inspire against the shutter, the volume of the thorax increases and airway pressure decreases. The increase in volume of the thorax can be measured from the change in the pressure inside the plethysmograph (Pbox). By Boyle's law:  $P \times \text{TGV} = (P - \Delta P) \times (\text{TGV} + \Delta V)$ , where  $P$  is atmospheric pressure,  $(P - \Delta P)$  is airway pressure during occlusion, and  $(\text{TGV} + \Delta V)$  is thoracic volume during occlusion. Therefore,  $\text{TGV} = (P - \Delta P) \times \Delta V / \Delta P$ . Because  $\Delta P$  is small compared with  $P$ , this can be simplified to  $\text{TGV} = P \times \Delta V / \Delta P$ .

## ALVEOLAR VENTILATION

The tissues of the body continuously consume  $\text{O}_2$  and produce  $\text{CO}_2$  (Fig. 44-6). The primary function of the circulation is to pick up  $\text{O}_2$  from the lungs and deliver it to the tissues, then to pick up  $\text{CO}_2$  from the tissues and deliver it to the lungs. The exchange of  $\text{O}_2$  and  $\text{CO}_2$  with the blood occurs within the alveolar volume of the lungs. The alveolar volume acts as a "large sink" from which  $\text{O}_2$  is continuously extracted by the blood and to which  $\text{CO}_2$  is continuously added. This mechanism for acquiring  $\text{O}_2$  from the atmosphere and excreting  $\text{CO}_2$  into the atmosphere is the *alveolar ventilation* (Slonim and Hamilton, 1987).

The alveolar volume of the lung includes all lung units capable of exchanging gas with mixed venous blood: respiratory bronchioles, alveolar ducts, and alveoli. Because the conducting airways do not participate in gas exchange, they constitute the *anatomic dead space* ( $V_D$ ). At end exhalation, the FRC is the sum of the volume of gas in the alveolar volume and in the anatomic dead space. During normal breathing, the amount of gas entering and leaving the lung with each breath is the tidal volume ( $V_T$ ):

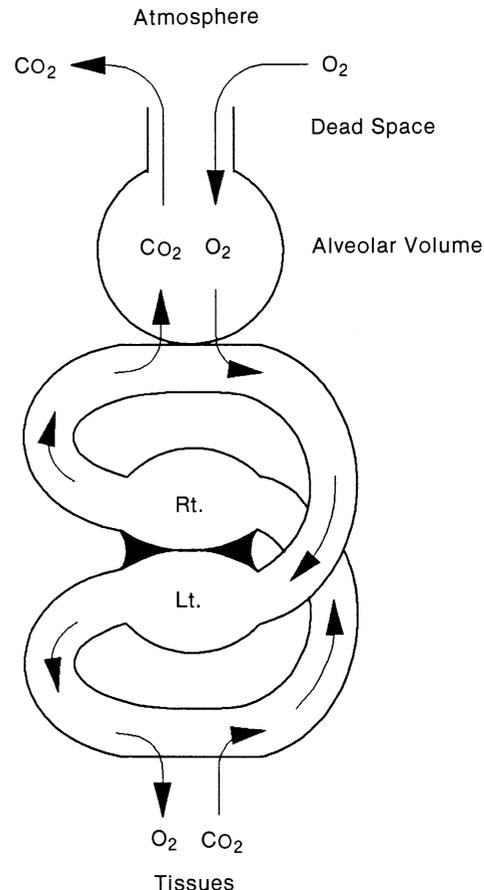

$$V_T \times \text{respiratory rate (RR)} = \text{minute ventilation } (\dot{V})$$

Part of each  $V_T$  is wasted ventilation because it moves gas into and out of the  $V_D$ . Therefore, alveolar ventilation ( $\dot{V}_A$ ) can be expressed as:

$$\dot{V}_A = (V_T - V_D) \times \text{RR} \quad (6)$$

Alveolar ventilation is an intermittent process, whereas gas exchange between the alveolar space and the blood occurs continuously. Because arterial  $\text{O}_2$  and  $\text{CO}_2$  tensions ( $\text{PaO}_2$  and  $\text{PaCO}_2$ ) are roughly equal to the  $\text{O}_2$  and  $\text{CO}_2$  tensions within the alveolar space, these fluctuations in breathing could result in intermittent hypoxemia and hypercarbia. Fortunately the lung has a large buffer—the FRC. The FRC is four to five times as large as the  $V_T$ ; therefore, only a fraction of the total gas in the lung is exchanged during normal breathing. This large buffer continues to supply  $\text{O}_2$  to the blood during expiration and acts as a sump to accept  $\text{CO}_2$  from the blood, so alveolar  $\text{O}_2$  and  $\text{CO}_2$  tensions ( $\text{PAO}_2$  and  $\text{PACO}_2$ ) change little throughout the ventilatory cycle.

Alveolar ventilation is linked tightly to metabolism. When alveolar ventilation is uncoupled from the body's metabolic rate, hypoventilation or hyperventilation results. During hypoventilation, less  $\text{O}_2$  is added to the alveolar space than is removed by the blood, and less  $\text{CO}_2$  is removed from the alveolar space than is added by the blood. As a result,  $\text{PAO}_2$  decreases and  $\text{PACO}_2$  increases. The net result of hypoventi-

**FIGURE 44-6.** Schematic showing coupling of alveolar ventilation to tissue oxygen consumption.

lation is hypoxemia and hypercapnia. Administering supplemental O<sub>2</sub> increases the quantity of O<sub>2</sub> in each breath delivered to the alveolar space, and it may prevent arterial hypoxemia. For example, suppose a 1-kg male infant has a V<sub>T</sub> of 6 mL, an anatomic V<sub>D</sub> of 2 mL, and a respiratory rate of 40 breaths/minute. His alveolar ventilation is 160 mL/minute ([6 mL - 2 mL] × 40/min). If he breathes room air (21% O<sub>2</sub>), he delivers 33.6 mL of O<sub>2</sub> to the alveolar space every minute (160 mL/min × 0.21). If he maintains the same V<sub>T</sub> but breathes only 20 times per minute, his alveolar ventilation decreases to 80 mL/minute, only 16.8 mL of O<sub>2</sub> (80 mL/min × 0.21) is delivered to the alveolar space each minute, and his P<sub>AO<sub>2</sub></sub> and P<sub>aO<sub>2</sub></sub> decrease. If he is allowed to breathe 50% O<sub>2</sub>, O<sub>2</sub> delivery to the alveolar space increases to 40 mL/minute (80 mL/min × 0.50), and both his P<sub>AO<sub>2</sub></sub> and P<sub>aO<sub>2</sub></sub> increase. Because O<sub>2</sub> administration has no effect on the accumulation of CO<sub>2</sub>, it does not prevent hypercapnia.

Hyperventilation delivers more O<sub>2</sub> to the alveolar space than can be removed by the blood and removes more CO<sub>2</sub> than can be added by the blood. As a result, P<sub>AO<sub>2</sub></sub> increases and P<sub>ACO<sub>2</sub></sub> decreases.

Measurements of alveolar ventilation and anatomic V<sub>D</sub> in the infant rely on the relationship between CO<sub>2</sub> production ( $\dot{V}CO_2$ ),  $\dot{V}_A$ , and P<sub>ACO<sub>2</sub></sub>. The mathematical expression of this relationship states (Cook et al, 1955):

$$F_{ACO_2} = \dot{V}CO_2 / \dot{V}_A \quad (7)$$

F<sub>ACO<sub>2</sub></sub> is the fraction of CO<sub>2</sub> in total alveolar gas, or

$$F_{ACO_2} = P_{ACO_2} / (P_B - 47) \quad (8)$$

P<sub>B</sub> is the barometric pressure, and 47 mm Hg is the vapor pressure of water at body temperature. Therefore,

$$\dot{V}_A = [\dot{V}CO_2 \times (P_B - 47)] / P_{ACO_2} \quad (9)$$

If minute ventilation ( $\dot{V}$ ) is measured, dead space ventilation ( $\dot{V}_D$ ) is calculated as:

$$\dot{V}_D = \dot{V} - \dot{V}_A \quad (10)$$

V<sub>D</sub> volume is calculated by dividing by the respiratory rate.

This method measures the anatomic V<sub>D</sub> in the lung. As seen in the next section, portions of some gas exchanging units in the lung can also function as V<sub>D</sub>; therefore, the total V<sub>D</sub>, or the physiologic V<sub>D</sub>, may be greater than the anatomic V<sub>D</sub>. Physiologic V<sub>D</sub> is calculated by substituting P<sub>aCO<sub>2</sub></sub> into Equation 9 for P<sub>ACO<sub>2</sub></sub>. When P<sub>aCO<sub>2</sub></sub> = P<sub>ACO<sub>2</sub></sub>, all the V<sub>D</sub> is anatomic V<sub>D</sub>, and the gas-exchanging units are all functioning normally. As physiologic V<sub>D</sub> increases, however, P<sub>aCO<sub>2</sub></sub> increases relative to P<sub>ACO<sub>2</sub></sub>. Therefore, the difference between P<sub>aCO<sub>2</sub></sub> and P<sub>ACO<sub>2</sub></sub> (the aA.DCO<sub>2</sub>) is a measure of efficiency of gas exchange in the lung.

For clinical purposes,  $\dot{V}CO_2$  in Equation 9 is assumed to be a constant, so that  $\dot{V}_A$  is proportional to 1/P<sub>aCO<sub>2</sub></sub>. Thus, increased P<sub>aCO<sub>2</sub></sub> means that alveolar ventilation has decreased; decreased P<sub>aCO<sub>2</sub></sub> means that alveolar ventilation has increased.

## VENTILATION-PERFUSION RELATIONSHIPS

Under ideal circumstances, ventilation and perfusion of the lung are evenly matched ( $\dot{V}/\dot{Q} = 1$ ), both in the lung as a whole and in each individual air space. The air spaces

receive O<sub>2</sub> from the inspired gas and CO<sub>2</sub> from the blood. O<sub>2</sub> is transported into the blood, while CO<sub>2</sub> is transported to the atmosphere. Even though  $\dot{V}/\dot{Q}$  is 1, CO<sub>2</sub> and O<sub>2</sub> are exchanged in the lung at the same ratio at which they are exchanged in the tissues: A little less CO<sub>2</sub> is transported out than O<sub>2</sub> is transported in, so the respiratory exchange ratio R equals 0.8. If there is no diffusion defect, the gas composition of the air spaces and the blood comes into equilibrium. N<sub>2</sub> makes up the balance of dry gas. The sum of partial pressures of all gases in the air spaces must equal atmospheric pressure. The ideal alveolar gas composition is as follows: P<sub>O<sub>2</sub></sub> = 100, P<sub>CO<sub>2</sub></sub> = 40, P<sub>N<sub>2</sub></sub> = 573, and P<sub>H<sub>2</sub>O</sub> = 47, all in mm Hg, at an atmospheric pressure of 760 mm Hg. The ideal arterial blood composition is the same. Therefore, differences between alveolar and arterial gas compositions under ideal circumstances all are zero. Knowing the values for P<sub>aCO<sub>2</sub></sub> and inspired gas, ideal alveolar gas composition can be calculated from the alveolar gas equations (Farhi, 1966):

$$P_{AO_2} = P_{IO_2} - P_{ACO_2} \times [F_{IO_2} + (1 - F_{IO_2})/R] \quad (11)$$

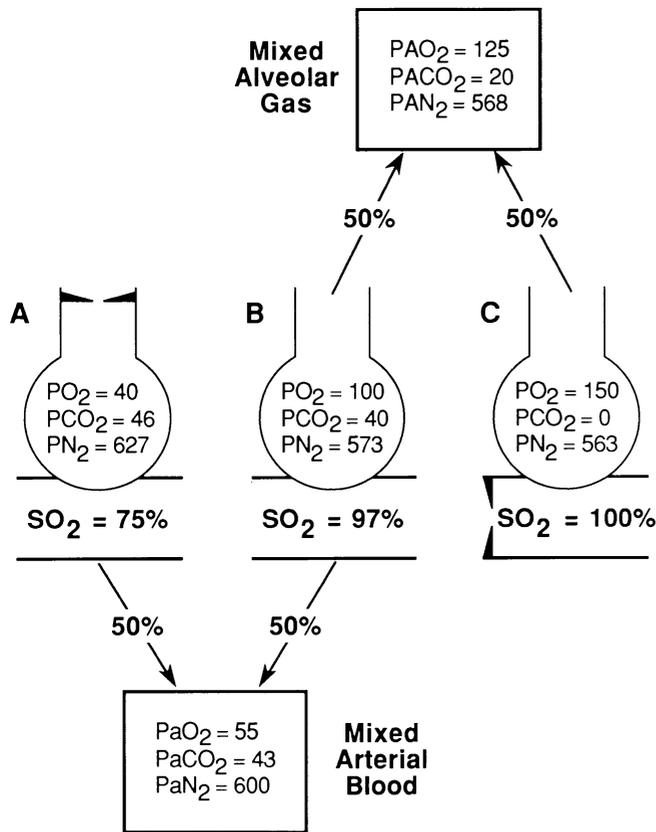

where

$$P_{IO_2} = F_{IO_2} \times (P_B - P_{H_2O}) \quad (12)$$

$$P_{AN_2} = F_{IN_2} \times [P_{ACO_2} \times (1 - R)/R + (P_B - P_{H_2O})] \quad (13)$$

Under normal circumstances and certainly in the presence of lung disease, this ideal situation does not exist; some air spaces receive more ventilation than perfusion, and others receive more perfusion than ventilation. A reduction of ventilation may occur because of atelectasis, alveolar fluid, or airway narrowing. Reduced ventilation in one part of the lung may cause increased ventilation elsewhere. A reduction of perfusion may occur if air spaces are collapsed or overdistended or because of gravitational effects, and increased perfusion may occur in congenital heart disease. As with ventilation, reduced perfusion in one part of the lung may cause increased perfusion in other regions. If an air space is relatively overventilated (high  $\dot{V}/\dot{Q}$ ), its gas composition tends toward that of inspired gas, which in the case of room air is P<sub>O<sub>2</sub></sub> = 150 mm Hg and P<sub>CO<sub>2</sub></sub> = 0 mm Hg. If an air space is relatively underventilated (low  $\dot{V}/\dot{Q}$ ), its gas composition tends toward that of mixed venous blood, which is P<sub>O<sub>2</sub></sub> = 40 mm Hg and P<sub>CO<sub>2</sub></sub> = 46 mm Hg. What counts is the  $\dot{V}/\dot{Q}$  ratio, not absolute values of  $\dot{V}$  or  $\dot{Q}$  (West, 1986).

To understand  $\dot{V}/\dot{Q}$  imbalance, it is common to view the lung as a three-compartment model (Fig. 44-7), in which  $\dot{V}/\dot{Q} = 0$  (see Fig. 44-7A),  $\dot{V}/\dot{Q} = 1$  (see Fig. 44-7B), and  $\dot{V}/\dot{Q} = \text{infinity}$  for the three compartments, respectively (see Fig. 44-7C). The O<sub>2</sub> saturation of blood in each compartment depends on the P<sub>O<sub>2</sub></sub> and the O<sub>2</sub> dissociation curve. For illustrative purposes, in a badly diseased lung, 50% of ventilation goes to  $\dot{V}/\dot{Q} = 1$  and 50% to  $\dot{V}/\dot{Q} = \text{infinity}$ , whereas 50% of perfusion goes to  $\dot{V}/\dot{Q} = 1$  and 50% to  $\dot{V}/\dot{Q} = 0$ . Perfusion of  $\dot{V}/\dot{Q} = 0$  causes venous admixture, whereas ventilation of  $\dot{V}/\dot{Q} = \text{infinity}$  causes alveolar V<sub>D</sub>. The mixed alveolar gas composition is easily calculated as the mean. For mixed arterial blood, the P<sub>O<sub>2</sub></sub> must be read from the O<sub>2</sub> dissociation curve, but because the CO<sub>2</sub> dissociation curve is fairly linear, the values for CO<sub>2</sub> are easily calculated as the mean. The abnormalities in distribution of  $\dot{V}$  and  $\dot{Q}$  have created an Aa.DO<sub>2</sub> = 70, aA.DCO<sub>2</sub> = 23, and aA.DN<sub>2</sub> = 32 mm Hg (see Fig. 44-7). The Aa.DO<sub>2</sub>

**FIGURE 44-7.** Three-compartment model of the lung with  $\dot{V}/\dot{Q} = 0$  (A),  $\dot{V}/\dot{Q} = 1$  (B), and  $\dot{V}/\dot{Q} = \text{infinity}$  (C). The inspired gas is room air, and B is the ideal compartment. The sum of alveolar gas partial pressures is always 713 mm Hg. SO<sub>2</sub> is oxygen saturation in capillary blood. PaO<sub>2</sub> is read from the oxygen dissociation curve for a saturation of 86%. By calculated differences, Aa.DO<sub>2</sub> is 70 mm Hg, aA.DCO<sub>2</sub> is 23 mm Hg, and aA.DN<sub>2</sub> is 32 mm Hg.

is greater than the sum of the other two because the O<sub>2</sub> dissociation curve is not linear. Of course, the situation in most lungs is not as extreme as the one illustrated. From this case, however, it can be seen that

1. Open low  $\dot{V}/\dot{Q}$  units produce increased Aa.DO<sub>2</sub>, significant hypoxemia, and increased aA.DN<sub>2</sub>, but because they are poorly ventilated and have a PCO<sub>2</sub> close to the ideal value, they do not change the aA.DCO<sub>2</sub> significantly.
2. High  $\dot{V}/\dot{Q}$  units produce increased Aa.DO<sub>2</sub> without hypoxemia and increased aA.DCO<sub>2</sub>, but because they are poorly perfused and have a PN<sub>2</sub> close to the ideal value, they do not change the aA.DN<sub>2</sub> significantly.

For the calculation of Aa.DO<sub>2</sub> and aA.DN<sub>2</sub>, it is customary to calculate the ideal alveolar gas composition for O<sub>2</sub> and N<sub>2</sub> from the alveolar gas equations and use these values with those measured for arterial PO<sub>2</sub> and PN<sub>2</sub>. This approach emphasizes that part of the Aa.DO<sub>2</sub> and aA.DN<sub>2</sub> responsible for hypoxemia. For aA.DCO<sub>2</sub>, both arterial and mixed alveolar samples are required.

In the newborn, a fourth compartment in the model is important. A significant part of the venous return may be shunted from right to left at the foramen ovale, ductus arteriosus, pulmonary arteriovenous vessels, or lung mes-

enchyme without airway development, thus adding mixed venous to mixed arterial blood. This substantially increases the Aa.DO<sub>2</sub> but has little effect on aA.DCO<sub>2</sub> and no effect on aA.DN<sub>2</sub>. The reason for the lack of effect on aA.DN<sub>2</sub> is that there is no significant exchange of N<sub>2</sub> in the body, so venous and arterial PN<sub>2</sub> are the same. The effect on aA.DCO<sub>2</sub> is small because venous PCO<sub>2</sub> is only slightly higher than arterial. From this analysis, it can be seen that hypoxemia is produced by a true right-to-left shunt and open low  $\dot{V}/\dot{Q}$  units. Diffusional problems are not thought to be important in the newborn. Hypoxemia may be modeled as a venous admixture, the part of mixed venous blood expressed as a fraction of cardiac output, that when added to blood equilibrated with an ideal lung would produce the measured arterial oxygen saturation. It is calculated as follows:

$$\dot{Q}_{va}/\dot{Q}_t = (C\dot{c}O_2 - C\dot{a}O_2)/(C\dot{c}O_2 - C\bar{v}O_2) \quad (14)$$

where  $\dot{Q}_{va}/\dot{Q}_t$  = venous admixture, CO<sub>2</sub> = oxygen content,  $\dot{c}$  = pulmonary capillary, a = arterial, and  $\bar{v}$  = mixed venous blood. For practical application, CO<sub>2</sub> is calculated from a constant a $\bar{v}$ .O<sub>2</sub> difference, which does introduce an error.

If an infant breathes 100% O<sub>2</sub> for 15 minutes, most N<sub>2</sub> is washed out of the lung, and the PO<sub>2</sub> in open low  $\dot{V}/\dot{Q}$  units becomes so high that associated blood is 100% saturated with O<sub>2</sub>. The remaining venous admixture is attributed to true right-to-left shunt ( $\dot{Q}_s/\dot{Q}_t$ ). If an infant has the total venous admixture  $\dot{Q}_{va}/\dot{Q}_t$  measured while breathing room air and then the true shunt ( $\dot{Q}_s/\dot{Q}_t$ ) measured while breathing 100% O<sub>2</sub>, the venous admixture due to open low  $\dot{V}/\dot{Q}$  units ( $\dot{Q}_o/\dot{Q}_t$ ) can be calculated as the difference. The venous admixture due to open low  $\dot{V}/\dot{Q}$  units also can be calculated from the aA.DN<sub>2</sub> (Markello et al, 1972):

$$\dot{Q}_o/\dot{Q}_t = (PaN_2 - PAN_2)/(PON_2 - PAN_2) \quad (15)$$

where PON<sub>2</sub> is the PN<sub>2</sub> in the  $\dot{V}/\dot{Q} = 0$  units (see Fig. 44-7), and PaN<sub>2</sub> is measured and PAN<sub>2</sub> is the ideal value calculated from the alveolar gas equation. In newborns with a significant value for true shunt, this value really represents venous admixture as a fraction of effective pulmonary blood flow ( $\dot{Q}_o/\dot{Q}\dot{c}$ ). A better estimate for  $\dot{Q}_o/\dot{Q}_t$  can be obtained from simple arithmetic (Corbet et al, 1974):

$$\dot{Q}_o/\dot{Q}_t = (\dot{Q}_o/\dot{Q}\dot{c}) \times (1 - \dot{Q}_{va}/\dot{Q}_t)/(1 - (\dot{Q}_o/\dot{Q}\dot{c})) \quad (16)$$

The true right-to-left shunt can then be estimated without 100% O<sub>2</sub> breathing, using the equation:

$$\dot{Q}_s/\dot{Q}_t = \dot{Q}_{va}/\dot{Q}_t - \dot{Q}_o/\dot{Q}_t \quad (17)$$

The normal values for the various indices of ventilation-perfusion imbalance in normal newborn infants are shown in Table 44-2.

## HEART-LUNG INTERACTION

### Effects of the Lung on the Heart

There exists considerable potential for the lung to affect the heart. Because they share the thoracic cavity, changes in intrathoracic pressure accompanying lung inflation are

transmitted directly to the heart. In addition, all of the blood leaving the right ventricle must traverse the pulmonary vascular bed, so changes in pulmonary vascular resistance may greatly affect right ventricular function.

### Effects of Changes in Intrathoracic Pressure on the Heart

#### Negative Intrathoracic Pressure

During spontaneous inspiratory efforts, the chest wall and diaphragm move outward, intrathoracic volume increases, and intrathoracic pressure decreases (Fig. 44-8A). The heart also resides within the thoracic cavity and is subject to the same negative intrathoracic pressure during inspiration. With a decrease in intrathoracic pressure, the heart increases in volume, and the pressure within its chambers decreases relative to atmospheric pressure. Analogous to the lung, when the pressure within the heart decreases, blood is literally sucked back into the heart from systemic veins and arteries. On the right side of the

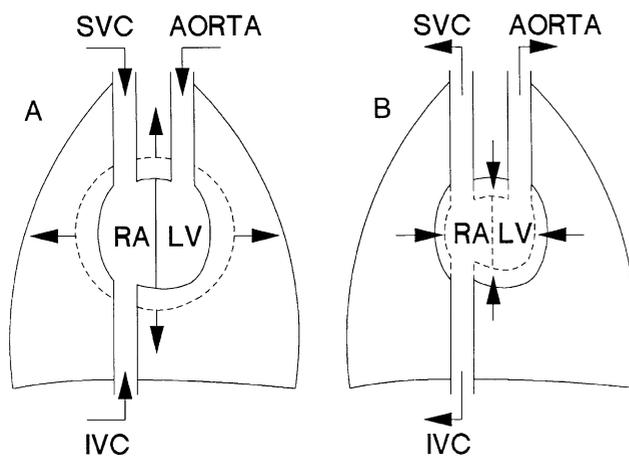

heart, the phenomenon serves to increase the flow of blood from systemic veins into the right atrium, increasing right ventricular preload and ventricular output. On the left side of the heart, ventricular ejection is impaired. During systole, the left ventricle must overcome not only the load imposed by the systemic vascular resistance but also the additional load imposed by the negative intrathoracic pressure (McGregor, 1979).

In infants with normal lungs, spontaneous respiratory efforts result in relatively small swings in pleural pressure (2 to 3 mm Hg) that have little effect on the pressure within the heart. With airway obstruction or parenchyma lung disease, however, swings in pleural pressure can be much greater (5 to 20 mm Hg), and systemic arterial pressure may fluctuate as much as 5 to 20 mm Hg, depending on where in the respiratory cycle ventricular systole occurs. In older children with asthma or some other form of airway obstruction, these fluctuations in blood pressure constitute pulsus paradoxus and are indicative of severe airway obstruction.

#### Positive Intrathoracic Pressure

During positive pressure ventilation, the lung inflates and pushes the chest wall and diaphragm outward (see Fig. 44-8B). This outward push generates a pressure in the thoracic space that is greater than atmospheric pressure. The magnitude of the increase (relative transmission of airway pressure to the pleural space) is determined by the volume of lung inflation (which in turn is determined by the airway pressure and lung compliance) and by the compliance of the chest wall and diaphragm. If the lung is compliant and the chest wall rigid, little airway pressure is lost inflating the lung, but considerable pressure is generated in the thoracic cavity as the lung attempts to push the rigid chest wall outward. In this instance, intrathoracic pressure (intrapleural pressure) is much greater than atmospheric and in fact nearly equal to airway pressure. If the lung is poorly compliant and the chest wall highly compliant, most of the airway pressure is dissipated in efforts to inflate the lungs, and little is transmitted to the thoracic cavity.

The effects of positive intrathoracic pressure on the heart are opposite to those of negative intrathoracic pressure. The heart is compressed by the lungs and chest wall, and blood is squeezed out of the heart and the thoracic cavity. Return of blood from systemic veins is impaired, and right ventricular preload and output decrease. If the increase in intrathoracic pressure coincides with ventricular systole,

**FIGURE 44-8.** **A**, Negative intrathoracic pressure increases the volume of the heart and decreases the pressure within the chambers. This facilitates return of blood from the superior vena cava (SVC) and inferior vena cava (IVC) to the right atrium (RA) and impedes ejection of blood from the left ventricle (LV) into the extrathoracic aorta. **B**, Positive intrathoracic pressure decreases the volume of the heart and increases pressure within its chambers. This impedes blood return to the right atrium and augments ejection of blood from the left ventricle.

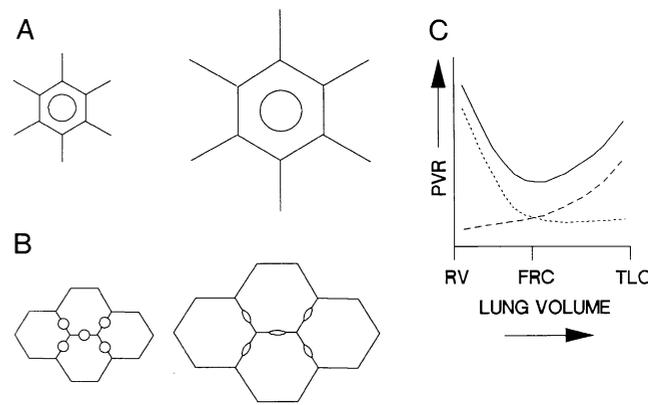

the effect is to augment left ventricular ejection and reduce the load on the left ventricle.

In the infant undergoing positive pressure ventilation, the degree to which lung inflation compromises venous return is related to the relative compliances of the lung and chest wall. If the infant's lung is poorly compliant and the chest wall is compliant, as in hyaline membrane disease, there is little effect of lung inflation on venous return. If the infant's lung is normally compliant but tight abdominal distention prevents descent of the diaphragm, intrathoracic pressure increases dramatically during positive pressure ventilation, and venous return and cardiac output can be impaired. This mechanism may help explain the circulatory instability of infants after repair of gastroschisis or omphalocele. A similar situation may arise in the preterm infant with pulmonary interstitial emphysema and massive lung overinflation. In this case, the heart is tightly compressed between the hyperinflated lungs, the other structures of the mediastinum, and the diaphragm. Venous return may be severely limited and venous pressures so increased that massive peripheral edema often accompanies the reduction in cardiac output.

Although the effects of increased pleural pressure on the right atrium are detrimental, the effects on the left ventricle may be extremely beneficial (Niemann et al, 1980). During cardiopulmonary resuscitation, the chest wall is compressed against the lung, and intrathoracic pressure increases. Because the left ventricle is in the thorax, left ventricular pressure increases as well. A gradient is created favoring flow of blood out of the ventricle and thorax and into the extrathoracic systemic circulation. Between chest compressions, elastic recoil causes the chest wall to pull away from the lung and heart, decreasing pleural pressure and favoring return of venous blood and priming the heart for the next chest compression. A similar phenomenon may result in augmentation of systemic pressure when ventilator breaths coincide with ventricular systole.

### Effect of Lung Inflation on Pulmonary Vascular Resistance

The pulmonary interstitium comprises three different interconnected connective tissue compartments, each containing a different element of the pulmonary circulation (Fishman, 1986). The first—the perivascular cuffs—consists of a sheath of fibers that contain the precapillary pulmonary arteries, lymphatics, and bronchi. The second consists of the intersegmental and interlobular septa and contains pulmonary veins and additional lymphatics. The third connects these two within the alveolar septa and contains the majority of the pulmonary capillaries. The first and second compartments represent the extra-alveolar interstitium, whereas the third represents the alveolar interstitium. The perivascular cuffs are surrounded by alveoli and expand during lung inflation (Fig. 44-9A). As a result, pressure within each cuff decreases, distending extra-alveolar blood vessels and decreasing their resistance to blood flow. The alveolar interstitium lies between adjacent alveoli and contains the majority of gas-exchanging vessels in the lung. These vessels are exposed to alveolar pressure on both sides and during lung inflation (see

**FIGURE 44-9.** **A,** Effects of lung inflation on extra-alveolar vessels. **B,** Effects of lung inflation on alveolar vessels. **C,** Effect of lung volume on pulmonary vascular resistance (PVR) (solid line). Inflation is from residual volume (RV) to functional residual capacity (FRC) to total lung capacity (TLC). Dashed line represents alveolar vessels; dotted line represents extra-alveolar vessels.

Fig. 44-9B) are compressed so that their resistance to blood flow increases.

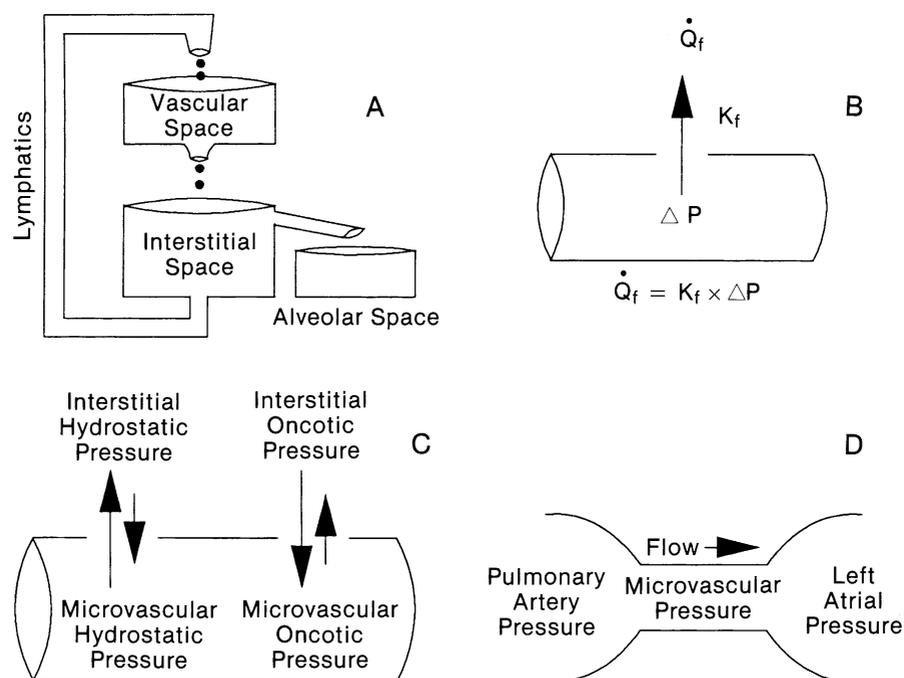

Therefore, during lung inflation (see Fig. 44-9C), the resistance in extra-alveolar vessels (dotted line) decreases, while resistance in alveolar vessels (dashed line) increases. As a result, the overall pulmonary vascular resistance (solid line) decreases initially, with lung inflation reaching its nadir at FRC, and then increases with further inflation.

If transition from intrauterine life to extrauterine life is to be successful, after birth all of the right ventricular output must traverse the pulmonary vascular bed. To some extent, this adaptation is facilitated by a reduction in pulmonary vascular resistance that occurs with inflation of the lungs (see Fig. 44-9) to a stable FRC. Inflation of the lung beyond FRC increases pulmonary vascular resistance. If care is not taken during positive pressure ventilation, it is possible to inflate the lung to the point at which alveolar vessels close and blood flow through the lung is impaired. When this occurs, either cardiac output decreases or the blood bypasses the lung via the foramen ovale or ductus arteriosus. Clinically, this is manifested as circulatory insufficiency from impaired right ventricular output or hypoxemia from right-to-left shunting of blood, or both.

## Effects of the Heart on the Lung

### Pulmonary Edema

Pulmonary edema is the abnormal accumulation of water and solute in the interstitial and alveolar spaces of the lung (Bland and Hansen, 1985; Staub, 1974). In the lung, fluid is filtered from capillaries in the alveolar septa into the alveolar interstitium (Fig. 44-10A) and then siphoned into the lower pressure extra-alveolar interstitium. The extra-alveolar interstitium contains the pulmonary lymphatics, and under normal conditions, they remove fluid from the lung so that there is no net accumulation in the interstitium. Pulmonary edema results only when the rate of fluid filtration exceeds the rate of lymphatic removal. This can occur by one of only

**FIGURE 44-10.** **A**, In the lung, fluid is continuously filtered out of vessels in the microcirculation into the interstitium and then returned to the intravascular compartment by the lymphatics. *Only when the rate of filtration exceeds the rate of lymphatic removal can fluid accumulate in the interstitium.* Spillover of fluid into the alveolar space occurs only when the interstitial space fills or when the alveolar membrane is damaged. **B**, Fluid flows out of vessels at a flow rate ( $f$ ) that is equal to the driving pressure for fluid flow ( $\Delta P$ ) times the filtration coefficient ( $K_f$ ):  $\dot{Q}_f = K_f \times \Delta P$ .  $K_f$  can be thought of as the relative permeability of the vascular bed to fluid flux.  $K_f$  in the normal lung is a small number, so that despite a driving pressure of roughly 5 mm Hg, the net rate of fluid filtration is approximately 1 to 2 mL/kg/hour. **C**, The driving pressure for fluid flow out of the microvascular bed represents a balance of two sets of pressures. Within the blood vessel, hydrostatic pressure tends to push fluid out of the vessel into the interstitium. This pressure is partially opposed by a smaller hydrostatic pressure within the interstitium pushing fluid back into the blood vessel. Within the blood vessel, there also exists a discrete oncotic pressure resulting predominantly from intravascular albumin, which tends to draw fluid from the interstitium back into the blood vessel. This pressure is partially opposed by an interstitial oncotic pressure tending to draw fluid from the blood vessel into the interstitium. **D**, The intravascular hydrostatic pressure must be less than pulmonary artery pressure ( $P_{pa}$ ) for blood to flow into the microvascular bed and greater than left atrial pressure ( $P_{la}$ ) for blood to flow out. Intravascular pressure within the microvascular bed is roughly equal to  $0.4(P_{pa} - P_{la}) + P_{la}$ . The interstitial hydrostatic pressure is roughly equal to alveolar pressure. The intravascular oncotic pressure can be calculated from the plasma albumin concentration. The interstitial oncotic pressure is roughly two thirds of the intravascular oncotic pressure. The balance of these pressures favors filtration out of the vessel (in the normal lamb, this pressure is roughly 5 mm Hg).

three mechanisms (see Fig. 44-10B): (1) the driving pressure for fluid filtration (filtration pressure) increases, (2) the permeability of the vascular bed (and hence the filtration coefficient  $K_f$ ) increases, or (3) lymphatic drainage decreases.

### Increased Driving Pressure

Filtration pressure can be increased by increased intravascular hydrostatic pressure, decreased interstitial hydrostatic pressure, decreased intravascular oncotic pressure, or increased interstitial oncotic pressure (see

Figs. 44-10C and D). By far the most common cause of increased filtration pressure is increased intravascular hydrostatic pressure (Table 44-3). In the newborn, intravascular hydrostatic pressure increases with increased left atrial pressure from volume overload or with any of a number of congenital and acquired heart defects. In the preterm and term newborn, evidence suggests that alterations in pulmonary blood flow that are independent of any change in left atrial pressure also may influence fluid filtration in the lung. Preterm infants with patent ductus arteriosus and left-to-right shunts exhibit signs of respiratory insufficiency before they develop any

TABLE 44-3

**Increased Intravascular Hydrostatic Pressure****Increased Left Atrial Pressure**

- Intravascular volume overload
  - Overzealous fluid administration

  - Left-sided obstructive lesions
  - Left-to-right shunts
  - Myocardiopathies

**Increased Pulmonary Blood Flow**

- Normal pulmonary vascular bed
  - Patent ductus arteriosus
  - Increased cardiac output
- Reduced pulmonary vascular bed
  - Bronchopulmonary dysplasia
  - Pulmonary hypoplasia

evidence of heart failure, and experiments performed in newborn lambs show that fluid filtration in the lung can be increased by increasing pulmonary blood flow without increasing left atrial pressure (Feltz and Hansen, 1986). In the newborn with a diminished pulmonary vascular bed, either from lung injury or from hypoplasia, cardiac output appropriate for body size may represent a relative overperfusion of the lung and can result in increased fluid filtration. This phenomenon has been invoked to explain the lung edema that often complicates the clinical course in the infant with bronchopulmonary dysplasia.

The exact cause of pulmonary edema that accompanies severe hypoxia or asphyxia in the newborn is still a controversial issue. Data suggest that it is the result of increased filtration pressure and not the result of any alteration in permeability. Heart failure accounts for some of the increased filtration pressure following severe asphyxia. In addition, there may be some element of pulmonary venous constriction. Finally, evidence indicates that hypoxia and acidosis may redistribute pulmonary blood flow to a smaller portion of the lung and result in relative overperfusion and edema, similar to that seen with anatomic loss of vascular bed (Hansen et al, 1984).

Several investigators have suggested that upper airway obstruction may cause pulmonary edema by decreasing interstitial hydrostatic pressure relative to intravascular hydrostatic pressure. Other workers suggest, however, that with airway obstruction vascular pressures decrease with intrapleural pressure in such a way that filtration pressure remains unchanged (Hansen et al, 1985).

Hypoproteinemia in infants results in a decrease in intravascular oncotic pressure. Its effects on filtration pressure, however, are blunted by the simultaneous decrease in protein concentration in the interstitial space of the lung. As a result, edema is unlikely to occur unless hydrostatic pressure also increases (Hazinski et al, 1986).

**Increased Permeability**

Another possible mechanism for increased fluid filtration in the lung is a change in the permeability of the microvascular membrane to protein. In this form of edema, the sieving properties of the microvascular endothelium are altered so that  $K_f$  increases, and patients may develop pulmonary edema despite relatively normal vascular pressures (Albertine, 1985). Furthermore, even small changes in vascular pressures can result in a dramatic worsening of pulmonary status. High-permeability pulmonary edema usually implies either direct or indirect injury to the capillary endothelium of the lung. Direct injuries result from local effects of an inhaled toxin such as oxygen. Indirect injuries imply that the initial insult occurs elsewhere in the body and that the lung injury occurs secondarily. An example of indirect lung injury is that due to sepsis: Neutrophils activated by bacterial toxins attack endothelial cells in the lung and increase permeability to water and protein (Brigham et al, 1974). Indirect injuries usually involve blood-borne mediators such as leukocytes, leukotrienes, histamine, or bradykinin. Alveolar overdistention can also cause high-permeability pulmonary edema, presumably by direct injury of the pulmonary vascular bed. This type of vascular injury probably accounts for some of the edema that accompanies diseases such as hyaline membrane disease and bronchopulmonary dysplasia, in which maldistribution of ventilation results in areas of alveolar overdistention (Carlton et al, 1990).

**Decreased Lymphatic Drainage**

In the normal lung, the rate of lung lymph flow is equal to the net rate of fluid filtration, and as long as lymphatic function can keep up with the rate of fluid filtration, water does not accumulate in the lung. Although lymphatics can actively pump fluid against a pressure gradient, studies show that this ability is limited and that lung lymph flow varies inversely with the outflow pressure (pressure in the superior vena cava). Several groups of investigators have demonstrated that, in the presence of an increased rate of transvascular fluid filtration, the rate of fluid accumulation in the lung is substantially greater if systemic venous pressure is increased (Drake et al, 1985). Recent data suggest that the ability of the lymphatics to pump against an outflow pressure is impaired in the fetus and newborn. In fact, in fetal lambs, lymph flow ceases at an outflow pressure of roughly 15 mm Hg (Johnson et al, 1996). This explains why pulmonary edema often complicates the clinical course in infants with bronchopulmonary dysplasia and cor pulmonale and explains the particular problem of edema with pleural effusions complicating the postoperative course in patients following cavopulmonary shunt placement.

More recently, investigators have shown that the ability of the lymphatics to pump can be affected by other mediators, with pumping increased by alpha-adrenergics and certain leukotrienes and impaired by nitric oxide, beta-adrenergics (Von Der Weid, 2001), and products of hemolysis (Elias et al, 1990).

### Congenital Pulmonary Lymphangiectasis

Congenital pulmonary lymphangiectasis is a rare form of pulmonary lymphatic dysfunction that can be categorized as (1) that associated with congenital heart disease and (2) that not associated with congenital heart disease. The cardiac anomalies may include hypoplastic left heart syndrome, total anomalous pulmonary venous drainage, and pulmonary stenosis, including Noonan syndrome (France and Brown, 1971). The type that does not include associated cardiac anomalies may be of early or late onset and has a wide spectrum of severity. In some affected children, the lesion is asymptomatic, whereas in others, it can lead to severe respiratory failure, usually in the first hours after birth but sometimes during the first weeks or months of life. Most infants with this condition die early in the neonatal period. Pulmonary lymphangiectasis has been reported twice as often in males and has been seen in families (Scott Emaukpor et al, 1981).

Usually the radiologist is the first to suggest the diagnosis, after observing dilated lymphatic vessels and sometimes small accumulations of pleural fluid on the chest radiograph. The older infant may have no symptoms or mild to moderate tachypnea with varying degrees of hypoxemia. If pleural fluid has accumulated, examination of the fluid is important. If the infant has received milk feedings, pleural fluid is chylous; otherwise, there is an elevation in mononuclear cells and moderate protein of up to about 4%. These findings in the absence of fever or other signs of systemic illness are diagnostic of impaired lymphatic drainage.

Lung biopsy probably is not indicated and can be hazardous because once the distended lymphatic channels are severed, they can leak fluid for weeks. Only if the diagnosis is in doubt is open lung biopsy appropriate.

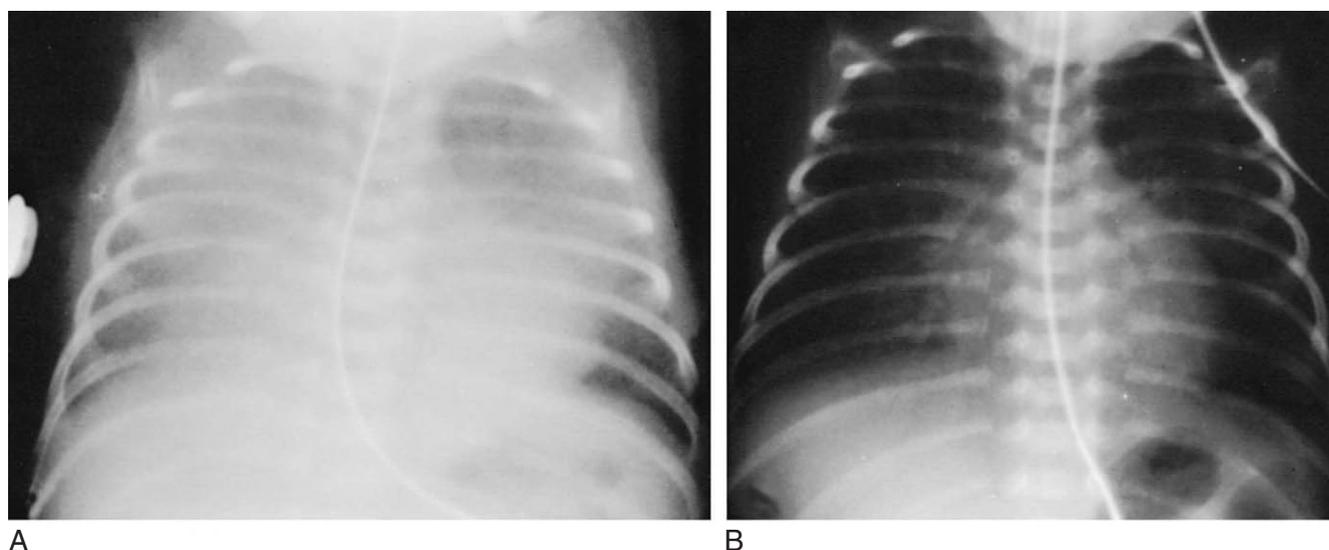

In non-cardiac lesion-associated diffuse lymphangiectasis, only supportive treatment is available. The long-term prognosis depends on the severity of the lesion, but this form of pulmonary lymphangiectasis is compatible with asymptomatic life as an adult (Wohl, 1989).

### Symptoms of Pulmonary Edema

As discussed previously, fluid filtered into the alveolar interstitium ordinarily moves rapidly along pressure gradients into the extra-alveolar interstitium, where it is removed by the lymphatics. A delay in this process at birth can result in clinical transient respiratory distress (see Chapter 47). The extra-alveolar interstitium has a large storage capacity. Fluid does not begin to spill over into the alveoli and airways until total lung water has increased by more than 50%, unless the alveolar membrane is damaged. Therefore, the first signs and symptoms of pulmonary edema are related to the presence of extra fluid in the interstitial cuffs of tissue that surround airways. As fluid builds up in these cuffs, airways are compressed, and signs of obstructive lung disease develop. The chest may appear hyperinflated, and auscultation reveals rales, rhonchi, and a prolonged expiration. Early in the course, chest radiographs reveal lung overinflation and an accumulation of fluid in the extra-alveolar interstitium—evident as linear densities of fluid that extend from the hilum to the periphery of the lung (the so called sunburst appearance) and fluid in the fissures. With more severe edema, fluffy densities appear throughout the lung as alveoli fill with fluid (Fig. 44–11). Heart size may be increased in infants with edema from increased intravascular pressure. Initially, infants present with increased PaCO<sub>2</sub> secondary to impaired ventilation. Later, PaO<sub>2</sub> decreases secondary to ventilation-perfusion mismatching and alveolar flooding. In adults, a ratio of protein concentration in tracheal aspirate to that in plasma greater than 0.5 may help to differentiate high-permeability pulmonary edema from high-pressure pulmonary edema (Fein et al, 1979).

### Treatment of Pulmonary Edema

Treatment of pulmonary edema is directed at relieving hypoxemia and lowering vascular pressures. Hypoxemia should be treated with the administration of oxygen and,

**FIGURE 44–11.** A, Preterm infant with a large patent ductus arteriosus and pulmonary edema. B, The same infant 24 hours after the patent ductus arteriosus was closed by administration of indomethacin.

if necessary, positive pressure ventilation. Positive end-expiratory pressure frequently improves oxygenation in persons with pulmonary edema by improving ventilation-perfusion matching within the lung. Available evidence suggests that positive pressure ventilation does *not* reduce the rate of transvascular fluid filtration in the lung (Woolverton et al, 1978). Optimal treatment of pulmonary edema requires correction of the underlying cause. In infants with patent ductus arteriosus (see Fig. 44–11) or other heart disease amenable to surgery, this is often easily accomplished. In cases of permeability edema or edema from nonsurgical heart defects, correction of the underlying cause may not be possible. In these instances, the only remaining option is to lower vascular pressures (even in permeability edema, lowering vascular pressures lowers the rate of fluid filtration and may also improve lymphatic function). This can be accomplished by lowering circulating blood volume by use of diuretics and fluid restriction, by improving myocardial function with the use of digitalis or other inotropic agents, or in severe cases by using a systemic vasodilator to reduce afterload and lower vascular pressures directly.

More recent data suggest that clearance of fluid from the alveolar space may be accelerated by beta-adrenergic agents (Frank et al, 2000) and by dopamine (Saldias et al, 1999). Whether these agents will have any clinical efficacy remains to be determined.

### **Pulmonary Hemorrhage**

Landing (1957) described pulmonary hemorrhage in 68% of lungs of 125 consecutive infants who died in the first week of life; massive pulmonary hemorrhage was found in 17.8% of neonatal autopsies at the Johns Hopkins Hospital (Rowe and Avery, 1966). Fedrick and Butler (1971) judged massive pulmonary hemorrhage to be the principal cause of death in about 9% of neonatal autopsies.

#### **Etiology and Pathogenesis**

Pulmonary hemorrhage usually occurs between days 2 and 4 of life in infants who are receiving mechanical ventilation. It has been associated with a wide variety of predisposing factors, including prematurity, asphyxia, overwhelming sepsis, intrauterine growth restriction/retardation, massive aspiration, severe hypothermia, severe Rh hemolytic disease, congenital heart disease, and coagulopathies. It is often associated with central nervous system injury, such as asphyxia or intracranial hemorrhage. Cole and associates (1973) studied a group of infants with pulmonary hemorrhage to determine the clinical circumstances under which the illness occurred as well as the hematocrit and protein compositions of fluid obtained from lung effluent and arterial or venous blood. Their results indicated that the lung effluent was, in most cases, hemorrhagic edema fluid and not whole blood (i.e., as indicated by hematocrit values significantly lower than those of whole blood). In addition, they did not find that coagulation disorders initiated the condition but probably served to exacerbate it in some cases. They postulated that the important precipitating factor was acute left ventricular failure caused by asphyxia or other events that might increase the filtration pressure, thereby

injuring the capillary endothelium of the lung. Thus, pulmonary hemorrhage may be considered to represent the extreme form of high-permeability pulmonary edema.

Pulmonary edema following central nervous system injury probably results from increased hydrostatic pressure and some increase in vascular permeability (Malik, 1985). With the massive sympathetic discharge that accompanies central nervous system injury, left atrial pressure increases, and pulmonary arteries and veins constrict. As a result, microvascular pressure increases dramatically, damaging the microvascular endothelium, increasing its permeability to proteins and red blood cells. In infants with overwhelming sepsis and endotoxin production, increased microvascular permeability is apparent in the pulmonary circulation as well, undoubtedly contributing to the massive pulmonary hemorrhage sometimes seen in this group of patients. Pulmonary hemorrhage also has been described occasionally in the presence of a large patent ductus arteriosus, with a left-to-right shunt that results in high flow and high pressure injurious to the vascular bed.

Pulmonary hemorrhage also is associated with surfactant replacement therapy. Presumably the hemorrhage results from the rapid increase in pulmonary blood flow that accompanies improved lung function after surfactant therapy. The contribution of the patent ductus arteriosus to this increased blood flow remains to be determined. A meta-analysis suggests that surfactant replacement may be associated with an increased risk of pulmonary hemorrhage. This risk, however, is still extremely small compared with the known benefits of surfactant replacement (Pappin et al, 1994; Raju and Langenberg, 1993).

#### **Diagnosis**

Infants with any of the conditions mentioned previously should be observed carefully for possible pulmonary hemorrhage. Particular note should be made of any blood-stained fluid from endotracheal tube aspirates, especially if repeated suctioning shows an increase in the amount of hemorrhagic fluid. The infant's chest radiograph may show the fluffy appearance of pulmonary edema in addition to the underlying pathologic process, and the infant may have increased respiratory distress. Frank pulmonary hemorrhage, when it occurs, is an acute emergency, and the fluid has the appearance of fresh blood being pumped directly from the vascular system, although hematocrit values for the fluid are at least 15 to 20 points lower than the hematocrit of circulating blood, in keeping with hemorrhagic pulmonary edema.

#### **Treatment**

Effective treatment of pulmonary hemorrhage requires (1) clearing the airway of blood to allow ventilation; (2) use of adequate mean airway pressure, particularly end-expiratory pressure; (3) resisting the temptation to administer large volumes of blood, because in most cases the infant has not had a large loss of volume, so that administration of excessive volume exacerbates the increase in left atrial pressure and hemorrhagic pulmonary edema; rather, red cell replacement should be done as a slow administration of packed cells after the infant's pulmonary status has been stabilized; and (4) evaluation of the possibility of coagulopathy and administration of vitamin K and platelets, if appropriate.

## Principles of Respiratory Monitoring and Therapy

Thomas N. Hansen, Anthony Corbet,  
Alfred L. Gest, and Alicia A. Moise

### OXYGEN THERAPY

In an emergency, high concentrations of oxygen may be administered by face mask, head hood, or endotracheal tube for the relief of cyanosis. If administration of oxygen must be continued beyond the emergency, it should be warmed, humidified, and delivered by a flow proportioner connected to compressed sources of air and oxygen. The concentration of oxygen should be analyzed continuously or at least every hour, using an oxygen analyzer that is calibrated with air and oxygen every 8 hours. The use of oxygen therapy beyond the emergency period should be monitored continuously by measuring oxygen saturation using a pulse oximeter or oxygen tension using a transcutaneous  $PO_2$  electrode. When this is not possible, oxygen should be given in a concentration just sufficient to abolish central cyanosis; within a few hours, arrangements should be made for appropriate measurements. In older infants, it has become common to administer oxygen by nasal cannula, with adjustments to either the flow or the concentration, according to the results of pulse oximetry.

### Monitoring Oxygen Therapy

#### Indwelling Catheters

In infants with significant respiratory distress, it is common to monitor oxygen therapy during the first few days of life using an umbilical artery catheter. For most infants, the arterial oxygen pressure ( $PaO_2$ ) should be maintained between 50 and 70 mm Hg, but in some patients with labile pulmonary hypertension, it may be necessary to keep the  $PaO_2$  slightly higher. For infants requiring high ventilator pressures, however, levels between 30 and 40 mm Hg may be accepted, provided that the circulatory status is well maintained and metabolic acidosis does not occur.

The reported complications of umbilical artery catheters include perforation, vasospasm, thrombosis, embolism, and infection. The most obvious sign of vasospasm is ischemia of the ipsilateral leg, and if this persists after a brief period of warming the contralateral leg, the catheter should be removed. During a difficult insertion procedure, it is possible (although this rarely occurs) to perforate the umbilical artery and enter the peritoneum, with consequent hemoperi-

toneum and hemorrhagic shock. By far the most frequently feared complication is thrombosis, and small thrombi, as documented by contrast aortography, may develop around the catheter in up to 95% of infants (Neal et al, 1972). Minute emboli may explain transient episodes of ischemia that later result in bluish discoloration of the toes. Clinical evidence of obstruction to a mesenteric, renal, pelvic, or femoral artery or to the aorta itself is comparatively uncommon but has been found in 13% of autopsy cases (Cochran, 1976). Suggestive evidence was found serendipitously by Jackson and coworkers (1987) that aortic thrombosis, detected by ultrasound examination, is more common after 11 days than after 4 days of catheterization. Infants with thrombosis can usually be managed conservatively with removal of the catheter and supportive care. Renovascular hypertension may occur, necessitating antihypertensive therapy. The condition usually resolves in time (Caplan et al, 1989). Another significant complication of umbilical arterial catheterization is infection, with sepsis occurring in 5% of cases (Landers et al, 1991). The incidence, however, is clearly higher (13%) if the catheter remains in place more than 14 days. Although the umbilical artery catheter is the easiest and most reliable way to monitor oxygen therapy, the need for arterial access should always be weighed against the inherent risks of an indwelling line when a decision is made to leave a catheter in place for more than a few days.

As an alternative to the umbilical artery catheter, short catheters inserted percutaneously or by cut-down procedure into the radial, posterior tibial, or dorsalis pedis artery are now widely used. These catheters sometimes function only a few days to a week, but the rates of infection and other complications are quite low.

Unfortunately, these measurements of  $PaO_2$  are intermittent and represent conditions at only a single point in time. Information derived from continuous estimates of arterial oxygenation using noninvasive devices has shown that arterial oxygenation can vary significantly over time. As a result, changes in oxygen therapy should be based on data from a continuous monitoring device as well as intermittent determinations of arterial oxygen tension ( $PAO_2$ ).

#### Intermittent Punctures

Arterial samples can be obtained by percutaneous needle aspiration of brachial, radial, or temporal arteries. Unfortunately, unless the sample is obtained immediately on penetration, the infant will become agitated and the measurement will not reflect steady-state oxygenation.

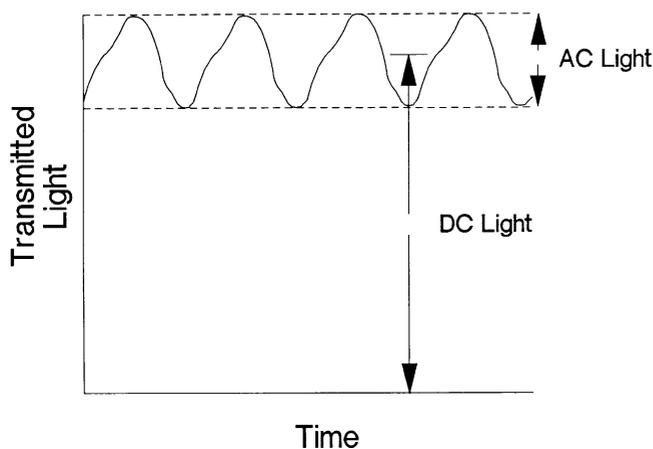

“Arterialized” capillary blood samples also have been used to monitor oxygen therapy. These measurements require that the extremity be heated to 43° to 44° C and that blood be collected free-flowing and under anaerobic conditions. These conditions are extremely difficult to reproduce in clinical situations. In addition, this technique almost always disturbs the infant, causing actual arterial oxygenation to fall. As a result, estimates of  $PaO_2$  from capillary samples are notoriously unreliable, and capillary sampling is not recommended.

## Noninvasive Monitors

### Pulse Oximeter

Pulse oximetry is now the standard noninvasive technique for monitoring oxygen therapy. In fact, pulse oximeters are now incorporated into most bedside monitors, and pulse oximeter estimates of arterial oxygen saturation ( $SpO_2$ ) are considered by some authorities to be the “fifth vital sign.” The pulse oximeter takes advantage of differences in light absorption between oxyhemoglobin and reduced hemoglobin in the red and infrared spectra (Fig. 45–1) (Pologe, 1987; Wukitsch, 1987). In the red region of the spectrum, reduced hemoglobin absorbs more light than oxyhemoglobin, whereas in the infrared region, oxyhemoglobin absorbs more light than reduced hemoglobin. Total light absorption (at any wavelength) is the sum of the independent absorptions. For whole blood, the ratio of absorption in the red region to that in the infrared region (see Fig. 45–1) decreases as oxygen saturation ( $SaO_2$ ) increases.

Pulse oximeters are easy to calibrate and apply. They do not require heat, have a rapid response time, and are not affected by skin thickness. Although the pulse oximeter assumes that there are only two types of hemoglobin present in arterial blood, a consistent effect of fetal hemoglobin

**FIGURE 45–1.** The pulse oximeter uses light-emitting diodes (LEDs) to send pulses of light of two different wavelengths through tissue containing a peripheral artery. A photodiode located opposite the LEDs measures the intensity of the transmitted light. At each wavelength, the light transmitted to the diode consists of two components: (1) an alternating current (AC) component, in which the intensity of transmitted light changes with the volume of blood (light absorber) in the artery, and (2) a direct current (DC) or constant component that results from light being transmitted through the tissues without being absorbed or scattered. The pulse oximeter measures the intensity of transmitted light as it illuminates one LED and then the other and then switches both off. With both LEDs off, the oximeter can measure and correct for the effects of external light incident on the photodiode. These cycles occur 480 times per second. The pulse oximeter focuses on the pulse-added component of the transmitted light by dividing the AC component by the DC component at each wavelength and creating the ratio  $R = (AC_{Red}/DC_{Red})/(AC_{Ir}/DC_{Ir})$ . (See text.) In this way, it ignores absorbances of venous blood, tissue, and pigmentation.

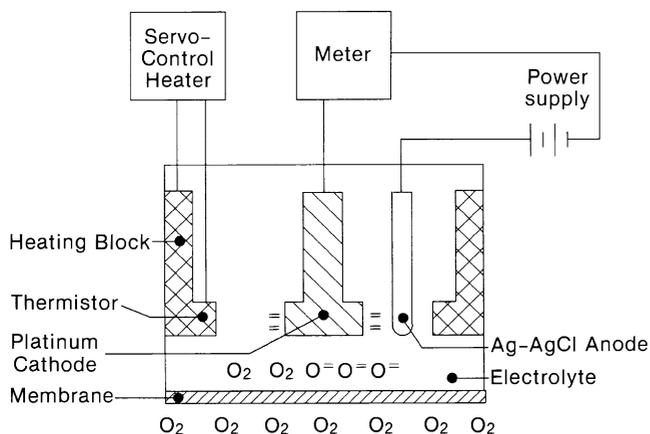

on the relationship between oxygen saturation measured by the pulse oximeter and arterial oxygen saturation has not been demonstrated (Jennis and Peabody, 1987; Ramanathan et al, 1987). In the presence of methemoglobin, the pulse oximeter will overestimate  $SaO_2$ , especially as actual  $SaO_2$  decreases (Barker et al, 1989). Similarly, in the presence of carboxyhemoglobin, the  $SpO_2$  will consistently overestimate actual  $SaO_2$  (Barker and Tremper, 1987).

The alternating current (AC) signal detected by the pulse oximeter is small compared with the direct current (DC) background, so if changes in tissue perfusion reduce arterial pulsations, the pulse oximeter cannot function. In addition, motion artifacts can be confused with pulsatile flow resulting in  $SpO_2$  values that are significantly different from the actual  $SaO_2$ . The magnitude of this error will be influenced by the magnitude of the movement, the degree of arterial pulsation, and venous oxygen saturation (Hay, 2000). Recently, signal-processing algorithms have been developed that have substantially reduced the number of “false hypoxemia” and “false bradycardia” episodes. The SET (signal extraction technology) algorithm validates measurements of  $SpO_2$  using spectral data obtained before, during, and after movements to match measurements of  $SpO_2$  to the frequency domain of the patient’s heart rate. In one study, this algorithm reduced the number of episodes of false alarms by 86% (Hay et al, 2002).

Although  $PaO_2$  can be roughly calculated from  $SaO_2$ , particularly at higher ranges of saturation, the range of  $PaO_2$  values for any given confidence interval of saturations can be broad. A recent survey suggested that more than 70% of neonatal units were setting the upper alarm limit on the pulse oximeter at 96% or greater, and 32% were using 100% as the upper alarm limit (Vijayakumar et al, 1997). These upper limits will miss many, if not most, hyperoxic episodes. Poets and colleagues (1993) have shown that the upper alarm limit must be set at 95% to identify 95% of hyperoxic episodes while allowing the  $PaO_2$  to be kept at greater than 60 mm Hg. Adams and coworkers (1994) found that an upper limit of 94% was necessary to detect 95% of hyperoxic episodes in their unit and that setting the limit at 95% allowed them to detect only 89% of hyperoxic episodes. Each center should generate acceptable ranges for  $SaO_2$  for given clinical conditions. For example, if the goal is to keep  $PaO_2$  between 50 and 80 mm Hg in a small preterm infant, ranges for  $SaO_2$  must be developed that maintain the  $PaO_2$  within this range.

### Skin Surface Oxygen Monitoring

The first noninvasive technique to gain widespread clinical acceptance was the skin surface oxygen ( $PsO_2$ ) electrode (Huch et al, 1976; Landers and Hansen, 1994) (Fig. 45–2). The  $PsO_2$  electrode does not measure  $PaO_2$  directly; it simply measures the  $PO_2$  on the surface of the skin. If certain conditions are met—an appropriate electrode temperature for a given skin thickness (Fig. 45–3) and normal circulation—the two measurements are highly correlated, and the  $PsO_2$  provides a reasonable estimate of the  $PaO_2$  for values between 15 and 150 mm Hg.

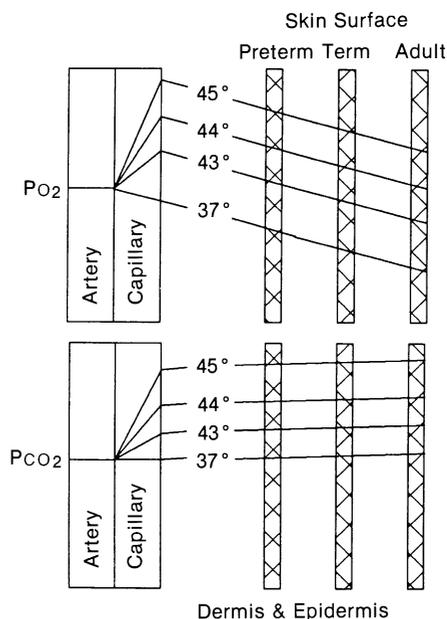

**FIGURE 45-2.** The  $\text{PsO}_2$  electrode consists of a servo-controlled heater, a platinum cathode, and a silver-silver chloride anode that is immersed in an electrolyte solution and covered with semipermeable membrane. An external voltage maintains the cathode negative with respect to the anode. Oxygen diffuses across the membrane to the negatively charged cathode, and because it is extremely electrophilic, it readily accepts electrons from the cathode. The reduced oxygen species react with KCl in the electrolyte to form KOH, and liberated chloride ions are deposited on the anode. As electrons are removed from the cathode, electrons flow from the anode and generate an electrical current that can be measured in the external circuit. This current is proportional to the rate of diffusion of oxygen molecules across the membrane into the electrode. The rate of diffusion, in turn, is proportional to the  $\text{PsO}_2$  and the permeability of the membrane to oxygen. Oxygen electrodes must be *zeroed* to compensate for the current produced by the external voltage, and a gain must be set to adjust the output for a given membrane permeability.

Problems arise when the  $\text{PsO}_2$  differs from the  $\text{PaO}_2$  (Table 45-1). Skin thickness, skin blood flow, oxygen consumption, and electrode temperature all affect the correlation (see Fig. 45-3). The  $\text{PsO}_2$  electrode itself also may interfere with the correlation between  $\text{PsO}_2$  and  $\text{PaO}_2$ . The electrode consumes oxygen at a rate limited by the membrane permeability. If membrane permeability increases, oxygen consumption by the electrode can lower the  $\text{PsO}_2$ . Because an infinite supply of oxygen exists at the time of calibration, the electrode calibrates normally.

### Skin Surface Carbon Dioxide Monitoring

The skin surface carbon dioxide ( $\text{PsCO}_2$ ) electrode is a glass pH electrode modified so that it can be heated and mounted on the skin (Brunstler et al, 1982; Hansen and Tooley, 1979).  $\text{CO}_2$  diffuses into the electrode, producing a change in pH. The  $\text{PsCO}_2$  electrode measures the concentration of  $\text{CO}_2$  on the surface of the skin and is little affected by skin thickness or membrane permeability. It is affected by blood flow to the skin and must be heated to 42° to 44° C to produce vasodilation. Heating increases

**FIGURE 45-3. Top,** In unheated skin, as oxygen diffuses from the capillary bed across the dermis and epidermis,  $\text{PO}_2$  decreases relative to  $\text{PaO}_2$  because of skin consumption of oxygen. As skin thickness increases (preterm infant versus term infant versus adult), this discrepancy increases. To counteract this effect,  $\text{PsO}_2$  electrodes are heated. Heating increases capillary and tissue  $\text{PO}_2$  by producing vasodilation, thereby increasing oxygen delivery to the skin, and by shifting the oxygen-hemoglobin dissociation curve to the right. The subsequent fall in  $\text{PO}_2$  as oxygen diffuses to the skin surface counterbalances the effect of heating and lowers  $\text{PO}_2$  at the skin surface to a value approaching  $\text{PaO}_2$ . Optimal correlation between  $\text{PaO}_2$  and  $\text{PsO}_2$  requires that electrode temperature be appropriate for skin thickness. **Bottom,** Because of local carbon dioxide production, the  $\text{PsCO}_2$  of even unheated skin is greater than  $\text{PaCO}_2$ . Heating the electrode increases  $\text{PsCO}_2$  further. The effect of electrode temperature on  $\text{PsCO}_2$  is constant and predictable, so that correction factors can be built into the calibration procedure.

$\text{PsCO}_2$  relative to  $\text{PaCO}_2$ , and correction factors must be incorporated into the calibration procedure so that the digital or graphic readout of  $\text{PsCO}_2$  equals  $\text{PaCO}_2$  (see Fig. 45-3).

**TABLE 45-1**

### Factors Affecting Skin Surface $\text{O}_2$ and $\text{CO}_2$ Tensions

Increase $\text{PsO}_2$	Increase $\text{PsCO}_2$
Increased $\text{PaO}_2$	Increased $\text{PaCO}_2$
Decrease $\text{PsO}_2$	Increased temperature
Decreased $\text{PaO}_2$	Increased skin $\text{CO}_2$ production
Decreased skin perfusion	Decreased perfusion
Increased skin thickness (age-related)	Decrease $\text{PsCO}_2$
Edema	Decreased $\text{PaCO}_2$
Damaged membrane	Decreased temperature

## MECHANICAL VENTILATION

### Continuous Positive Airway Pressure

#### Treatment of Respiratory Distress Syndrome

Continuous positive airway pressure (CPAP) was developed as a technique to improve oxygenation in spontaneously breathing premature infants with hyaline membrane disease (Gregory et al, 1971). Positive pressure was applied through an endotracheal tube, endopharyngeal tube, nasal prongs, face mask, or head box, or by creating continuous negative pressure around the chest with the airway at atmospheric pressure.

The primary role of CPAP is to support small airways and prevent the generalized atelectasis of the surfactant-deficient lung. At the same time, CPAP improves oxygenation in infants with hyaline membrane disease by improving ventilation to open poorly ventilated air spaces, relieving local vasoconstriction and decreasing the right-to-left shunt and the alveolar-arterial oxygen tension difference (Aa.DO<sub>2</sub>) (Corbet et al, 1975; Hansen et al, 1979). CPAP decreases tidal volume (VT), minute ventilation, and the arterial-alveolar carbon dioxide tension difference (aA.DCO<sub>2</sub>), suggesting that it improves alveolar ventilation (Bancalari et al, 1973; Hansen et al, 1979; Landers et al, 1986).

The infant flow driver is a relatively new device for delivering nasal CPAP that generates positive pressure at the airway, keeps the level of distending pressure constant throughout inspiration, and probably assists with inspiration (Moa and Nilsson, 1993). When compared with conventional modes for delivery of nasal CPAP, this device increases lung volume more for any change in distending pressure (Courtney et al, 2001) while increasing compliance and decreasing work of breathing (Pandit et al, 2001).

Between 1973 and 1976, four randomized controlled trials of CPAP to treat respiratory distress syndrome (RDS) were conducted (Belenky et al, 1976; Durbin et al, 1976; Fanaroff et al, 1973; Rhodes and Hall, 1973). A meta-analysis of the results of these trials (Bancalari and Sinclair, 1992) showed that CPAP reduced mortality from hyaline membrane disease, reduced the need for subsequent mechanical ventilation, and increased the risk of air leak. There was no detectable effect on the risk of bronchopulmonary dysplasia. Bancalari and Sinclair (1992) then analyzed results of five trials comparing early with late CPAP for the treatment of hyaline membrane disease (Allen et al, 1977; Gerard et al, 1975; Hegyi and Hiatt, 1981; Krouskop et al, 1975; Mockrin and Bancalari, 1975) and found that early application of CPAP reduced the need for subsequent mechanical ventilation without affecting mortality or the risk of air leak.

#### Early Nasal Continuous Positive Airway Pressure

Many clinicians believe that endotracheal CPAP alone is not likely to be successful in smaller infants (birth weight of less than 1500 g) and proceed directly to mechanical ventilation (Drew, 1982). This approach has come into question in recent years, however (Poets and Sens, 1996). A study comparing outcomes in different academic medical centers (Avery et al, 1987) noted that the institution

reporting the best survival without chronic lung disease was also the one that used nasal CPAP early and extensively for stabilization of very low-birth-weight (VLBW) infants (Wung et al, 1975). Since that report, there has been a renewed interest in the use of very early nasal CPAP for the initial stabilization and management of VLBW infants. Several reports from Denmark suggested that more than half of infants weighing less than 1500 g could be managed exclusively with nasal CPAP and oxygen if high values for PaCO<sub>2</sub> were tolerated (Kamper and Ringsted, 1990; Kamper et al, 1993; Lundstrom and Greisen, 1993). Two trials compared outcomes in infants weighing less than 1500 g who were managed with early nasal CPAP with outcomes in historic controls. Early nasal CPAP was found to reduce the need for subsequent intubation and mechanical ventilation by roughly 50% without affecting overall mortality or the incidence of chronic lung disease (Gittermann et al, 1997; Jacobsen et al, 1993). Lindner and colleagues (1999) found that in infants weighing less than 1000 g, early nasal CPAP reduced the rate of intubation in the delivery room by 50% and that 25% of these infants could be managed by nasal CPAP alone. The infants who could be managed on nasal CPAP alone had a lower mortality rate and a reduced incidence of chronic lung disease and severe intracranial hemorrhage. DeKlerk and DeKlerk (2001) used historic controls to show that for infants weighing between 1000 and 1500 g, early nasal CPAP reduced the need for subsequent mechanical ventilation as well as a number of other problems including chronic lung disease, need for pressor support, and necrotizing enterocolitis. All of these studies suffer from the lack of a randomized group of control infants, and many of the outcomes may reflect other changes in practice or differences in underlying disease severity. However, their results are intriguing and call for randomized controlled trials to determine the safety and utility of early nasal CPAP.

Verder and colleagues (1994) studied the effects of routine surfactant administration in combination with early nasal CPAP in infants between 25 and 35 weeks of gestational age. They intubated the infants for surfactant administration, mechanically ventilated them briefly to allow the surfactant to distribute, and then extubated them and continued nasal CPAP. They found that surfactant administration significantly reduced the need for subsequent mechanical ventilation and, in a later study in infants born at less than 30 weeks of gestational age, found that this effect was magnified if surfactant was administered early (Verder et al, 1999).

#### Techniques for Administration of Continuous Positive Airway Pressure for the Treatment of Respiratory Distress

Traditionally, endotracheal CPAP is used in larger infants (birth weight greater than 1500 g) with respiratory distress in the hope that mechanical ventilation will not be necessary; it should be started when the oxygen requirement reaches 50%. In these infants, the initial level of endotracheal CPAP used is 5 cm H<sub>2</sub>O at an oxygen requirement of 50%, and the pressure is increased in 1-cm H<sub>2</sub>O steps for

each 10% increase in the oxygen requirement; the incidence of pulmonary air leak with this regimen is no higher than the spontaneous rate for RDS (Corbet and Adams, 1978). Infants who require an oxygen concentration of more than 80% with endotracheal CPAP of 8 to 10 cm H<sub>2</sub>O will usually need mechanical ventilation. However, with the advent of surfactant therapy, it is now common to omit the initial CPAP step, to start surfactant administration and mechanical ventilation when the oxygen requirement is 40% to 50%, or less, and to use CPAP only later when the infant is near clinical recovery and extubation. Another possible strategy in larger infants is the use of intubation and mechanical ventilation for surfactant administration and then endotracheal CPAP (Mandy et al, 1999).

In the past, nasal CPAP has usually been administered by a positive pressure ventilator set in the CPAP mode (ventilator CPAP), or by placing the expiratory limb of a constant-flow circuit into water at a depth sufficient to generate the required positive end-expiratory pressure (bubble CPAP) (Wung et al, 1975). In more recent years, nasal CPAP has been administered using the infant flow driver. When compared with ventilator CPAP, the infant flow driver produces a greater change in lung volume for any given change in pressure (Courtney et al, 2001), increases lung compliance, and decreases work of breathing (Pandit et al, 2001). The infant flow driver delivers slightly more oxygen than is provided by the other nasal CPAP devices (0.5% to 3%) (Ahluwalia et al, 1998; Kavvadia et al, 2000; Mazzella et al, 2001). A single controlled trial compared the infant flow driver with bubble CPAP in infants of less than 36 weeks of gestation eligible for CPAP and found that in infants managed with the infant flow driver, work of breathing was less, with lower respiratory rates and lower oxygen requirements. These studies all suggest that the infant flow driver probably assists with inspiration, improving overall gas exchange. Another controlled trial found that infants managed with bubble CPAP had lower minute ventilation and respiratory rates than in infants managed with ventilator CPAP, despite no differences in SaO<sub>2</sub> or P<sub>s</sub>CO<sub>2</sub> (Lee et al, 1998). This improvement in gas exchange may be the result of vibrations transmitted from the bubble chamber to the chest.

Typically, nasal CPAP is delivered using binasal prongs or an endotracheal tube shortened to fit 2 to 3 cm into the nose (mononasal prong) or left longer and placed in the pharynx (nasopharyngeal tube). Courtney and colleagues (2001) found that respiratory rate, thoracoabdominal asymmetry (a measure of inspiratory loading), and FIO<sub>2</sub> all were higher in infants receiving nasal CPAP through a mononasal prong than in infants receiving CPAP via binasal prongs. Davis and colleagues (2001) found that with ventilator CPAP, binasal prongs were more effective than mononasal prongs in preventing failure of extubation in infants weighing less than 1000 g. When binasal and mononasal prongs were compared using the infant flow driver, however, no differences in pressure transmitted to the nasopharynx were found (Pederson and Nielsen, 1994).

Of interest, two studies (Locke et al, 1993; Sreenan et al, 2001) have shown that the use of nasal cannulas to deliver oxygen may result in positive end-expiratory pressure. This seemed to occur only when the cannulas were 0.3 cm in

outer diameter. Because the amount of end pressure delivered is difficult to assess in this instance, the use of nasal cannulas to deliver nasal CPAP should be discouraged.

Most authors suggest starting nasal CPAP at a pressure of 5 to 6 cm H<sub>2</sub>O and then increasing to a maximum of 8 to 10 cm H<sub>2</sub>O based on the clinical response and the oxygen requirement. Indications for subsequent intubation and mechanical ventilation include intractable apnea and persistent hypoxemia in 80% to 100% oxygen. Because CPAP may overdistend the lung, impairing the pulmonary circulation, attempts have been made to identify optimal levels. As CPAP is increased and approaches optimum, the aA.DCO<sub>2</sub> falls significantly; but as the optimal level is exceeded, both the aA.DCO<sub>2</sub> and the arterial PCO<sub>2</sub> rise significantly (Landers et al, 1986). Under clinical conditions, hypercarbia may indicate excessive CPAP, which should be recognized and corrected before oxygenation deteriorates.

### Intermittent Positive Pressure Ventilation

Advances in techniques for intermittent positive pressure ventilation have dramatically altered outcomes in infants with a variety of lung diseases. To use these techniques effectively, the clinician must have a thorough understanding of how the various components of intermittent positive-pressure ventilation affect the lung of the newborn.

#### Positive Pressure Inflation of the Lung

During a positive pressure breath, gas flows into the lung because airway pressure is greater than alveolar pressure. The volume of gas entering the lung over time is a function of the peak inflation pressure (PIP), duration of inspiration (Ti), and respiratory system compliance (Cr<sub>s</sub>) and resistance (R<sub>r</sub>s) (Figs. 45-4 and 45-5). For purposes of this discussion, exhalation is considered to be passive.

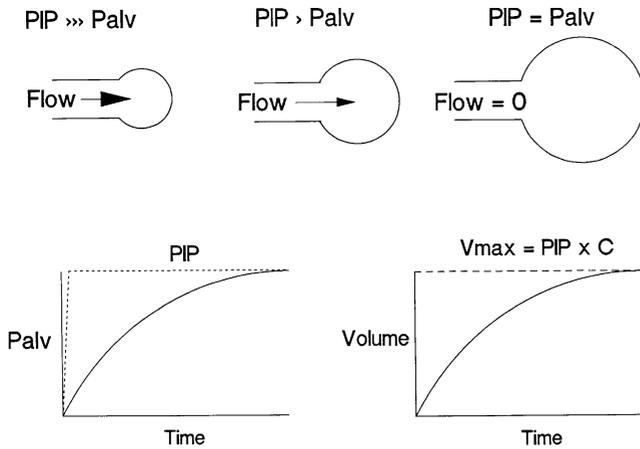

Most ventilators that are currently in use in neonatal intensive care units (NICUs) are time cycled and pressure limited (Fig. 45-6). PIP, positive end-expiratory pressure (PEEP), Ti, and expiratory time (Te) are adjusted independently or linked by the Ti/Te ratio. The rate is altered by changing Ti or Te or both. Mean airway pressure (MAP) is the average pressure at the proximal airway over time. If the inspiratory pressure waveform resembles a square wave (see Fig. 45-6), then

$$\text{MAP} = (\text{PIP} - \text{PEEP}) \times (\text{Ti}/[\text{Ti} + \text{Te}]) + \text{PEEP}$$

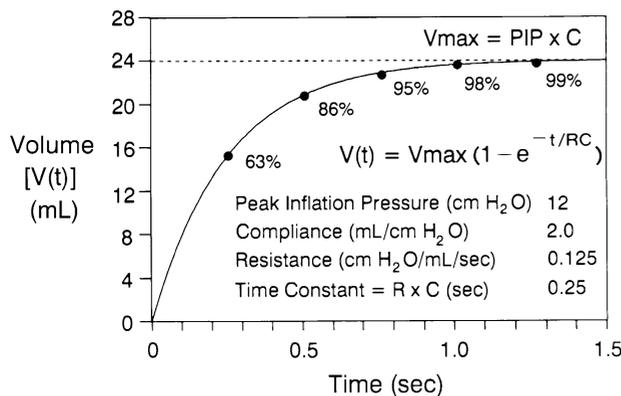

#### Effects of Positive Pressure Ventilation on Gas Exchange

##### Determinants of Oxygenation

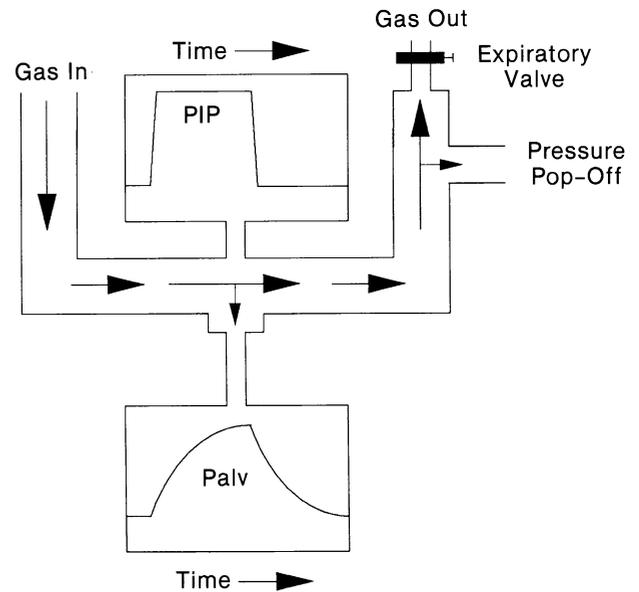

In infants with parenchymal lung disease, hypoxemia is related to the presence of open but severely underventilated lung units (see Chapter 44). In these units, alveolar ventilation is not sufficient to maintain the alveolar oxygen tension (PAO<sub>2</sub>) much above mixed venous PO<sub>2</sub>. These lung units can cause arterial hypoxemia by two different mechanisms: (1) ventilation-perfusion mismatch and (2) right-to-left shunt.

**FIGURE 45-4.** Positive pressure inflation of the lung. In this example, airway pressure increases rapidly to a plateau (peak inflation pressure [PIP]) (dashed line). Initially, alveolar pressure (Palv) is equal to atmospheric pressure and is much less than airway pressure ( $PIP \gg \gg Palv$ ). As a result of this large driving pressure, gas flows into the lung, and the volume of gas in the lung increases as a function of time. Obviously, because Palv is directly related to lung volume ( $Palv = \text{volume}/\text{compliance}$ ), it also increases as a function of time. Therefore, the driving pressure for gas flow ( $PIP - Palv$ ) and the rate of gas flow into the lung both decrease over time. Ultimately, Palv becomes equal to PIP, and flow ceases. Therefore, the maximal volume of gas that can enter the lung ( $V_{max}$ ) during any positive pressure breath is ultimately determined by PIP and compliance (C):  $V_{max} = PIP \times C$ .

**FIGURE 45-5.** Lung inflation over time. As in Figure 45-4, airway pressure is rapidly increased to 25 cm H<sub>2</sub>O and then maintained at a plateau. The volume of gas in the lung,  $V(t)$ , increases over time according to the relationship:  $V(t) = V_{max} \times (1 - e^{-t/RC})$ , where R is the resistance of the respiratory system and C is the compliance. The maximal volume of gas that can flow into the lung ( $V_{max}$ ) is limited by the peak airway pressure (PIP) and C (i.e.,  $V_{max} = PIP \times C$ ). The rate of lung inflation, similar to the rate of deflation, is described by an exponential equation involving the respiratory time constant ( $Trs$ ). As described in Chapter 44,  $Trs = R \times C$ . For an inspiratory time equal to 1 time constant ( $Ti = 1 \times Trs$ ), the lung inflates to 63% of its maximal volume ( $V_{max}$ ). For  $Ti = 2 \times Trs$ , it reaches 86% of  $V_{max}$ ; for  $3 \times Trs$ , 95%; for  $4 \times Trs$ , 98%; and for  $5 \times Trs$ , 99%. Therefore, the volume of gas entering the lung during a positive pressure breath is determined by the peak inflation pressure (PIP), the duration of inspiration ( $Ti$ ), and respiratory system compliance ( $Crs$ ) and resistance ( $Rrs$ ).

**FIGURE 45-6.** Time-cycled, pressure-limited ventilator. Gas flows continuously through the ventilator circuit while a flow resistor on the exhalation limb of the circuit provides positive end-expiratory pressure. During inspiration, the expiratory valve is closed, and pressure builds up in the circuit for a preset time ( $Ti$ ). The rate of the pressure buildup is determined to a large extent by the system flow. In this example, flow is high, and the pressure waveform is a square wave. PIP is limited by venting excessive pressure to the atmosphere. Airway pressure increases rapidly and is held at a plateau. Alveolar pressure increases gradually as gas flows into the lung from the ventilator. The rate of gas flow to the patient is determined primarily by the driving pressure ( $PIP - Palv$ ) and the resistance (R), so flow =  $(PIP - Palv)/R$ , not by the rate of gas flow through the ventilator circuit.

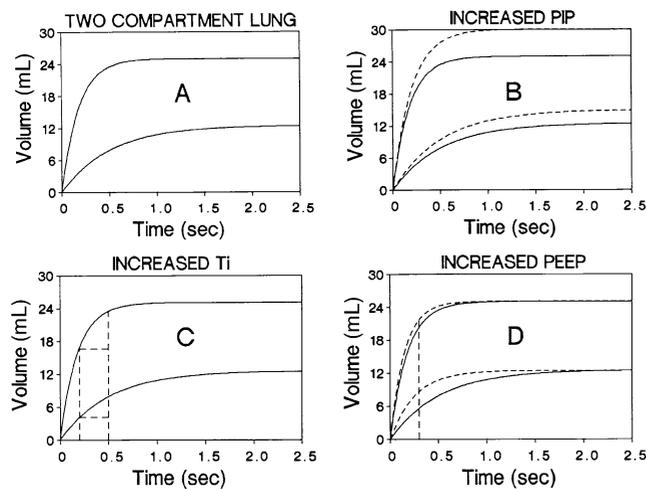

**Ventilation-Perfusion Mismatch**

In term infants with meconium aspiration pneumonia or older infants with bronchopulmonary dysplasia, blood continues to flow past the poorly ventilated lung units and remains poorly oxygenated. When it mixes with the remainder of the pulmonary venous return, it decreases overall systemic oxygen saturation. The severity of the resultant hypoxemia is directly related to the severity of the hypoxia in the poorly ventilated lung units and to the quantity of blood flowing past them.

**Right-to-Left Shunt**

In infants with RDS, the cause of hypoxemia is right-to-left shunt. In these infants, intense vasoconstriction occurs in blood vessels supplying severely underventilated lung units, causing blood to be directed away from these lung units through intrapulmonary and extrapulmonary shunts (Hansen et al, 1979). The magnitude of the right-to-left shunt—as well as, correspondingly, the severity of the arterial hypoxemia—is related to the severity of the hypoxia in the open, underventilated lung units and to the number of these units present in the lung. Therefore, regardless of the underlying parenchymal disease, the degree of arterial hypoxemia is determined by the  $PAO_2$  in open but severely underventilated units of the lung; the only way to increase arterial  $PO_2$  is to increase the  $PAO_2$  in these lung units.

Several studies have shown that increasing the MAP increases PaO<sub>2</sub> in infants with lung disease, suggesting that increases in MAP must somehow increase the PAO<sub>2</sub> in poorly ventilated units of the lung (Herman and Reynolds, 1973; Stewart et al, 1981). As discussed previously, MAP is really a function of PIP, PEEP, and Ti. Increasing MAP by increasing PIP increases the driving pressure for gas flow into poorly ventilated lung units (Fig. 45-7). Increasing MAP by increasing Ti allows more time for gas to distribute to these units. Finally, increasing MAP by increasing PEEP splints small airways open, decreases airway resistance, decreases the time constant for inspiration, and allows more gas to enter the lung unit for any given PIP or Ti. All three techniques improve ventilation to the poorly ventilated lung units and increase their PAO<sub>2</sub>. For a given increase in MAP, increasing PEEP or PIP results in a greater increase in

**FIGURE 45-7.** Effects of ventilatory manipulations on each compartment of a two-compartment lung. **A**, Plot of lung volume over time during a positive pressure inflation of the lung (PIP = 25 cm H<sub>2</sub>O). The top curve represents normal lung units (compliance = 1 mL/cm H<sub>2</sub>O, resistance = 0.150 cm H<sub>2</sub>O/mL/second, and time constant = 0.15 second). These lung units inflate to a greater maximal volume ( $V_{max} = PIP \times C = 25$  mL) and reach  $V_{max}$  quickly (5 time constants = 0.75 second). The lower curve represents poorly ventilated lung units (compliance = 0.5 mL/cm H<sub>2</sub>O, resistance = 1.0 cm H<sub>2</sub>O/mL/second, and time constant = 0.5 second). Obviously, these units have a lower  $V_{max}$  (12.5 mL) and take longer to reach  $V_{max}$  (5 time constants = 2.5 seconds). As stated previously, the only ventilatory means of increasing the patient's PaO<sub>2</sub> is to increase the volume of gas entering poorly ventilated lung units. **B**, Increasing peak inflation pressure (dashed curves) increases the volume of gas entering each group of lung units. The increase is greater in normal lung units than in poorly ventilated lung units for any inspiratory time value (Ti). The net result is overdistention of normal parts of the lung incurred in an attempt to ventilate the poorly ventilated lung units. **C**, Increasing Ti from 0.2 to 0.5 seconds increases the volume of gas entering each group of lung units. As in **B**, the increase, as well as corresponding tendency for overdistention, is much more pronounced in the normal parts of the lung. **D**, Increasing positive end-expiratory pressure (PEEP) decreases the time constant in each group of lung units. The net effect is to allow more gas to enter each part of the lung for any given PIP or Ti. In this case, the effect is more pronounced in the poorly ventilated lung units. As a result, the likelihood of overdistention of normal lung units is less.

PaO<sub>2</sub> than can be obtained by increasing Ti (Stewart et al, 1981). The reason for this discrepancy lies in the effects of mechanical ventilation on the normal parts of the lung.

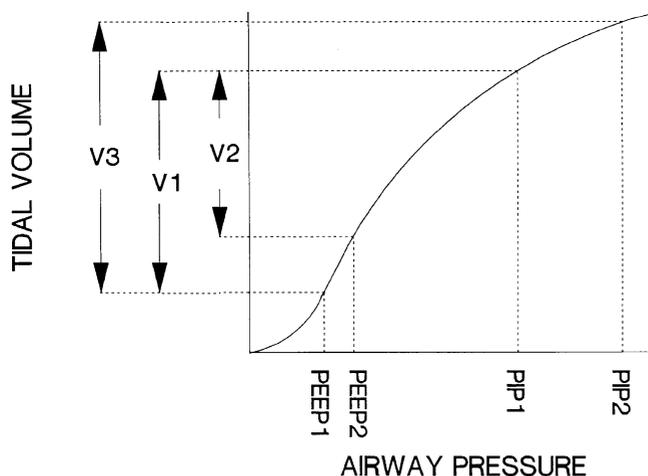

None of the parenchymal lung diseases, including RDS, is homogeneous (Richardson et al, 1992). Relatively normal lung units coexist with severely underventilated lung units. Because all are connected, however, all are exposed to the same airway pressures during mechanical ventilation. Relatively normal units may have a low airway resistance and high compliance and may be subject to overdistention with increases in MAP. The risk of overdistention is greatest when MAP is increased by increasing Ti, less with increases in PIP, and least with increases in PEEP (see Fig. 45-7). As discussed in Chapter 44, overdistended lung units compress intra-alveolar vessels and redirect blood flow past poorly ventilated lung units or through shunt pathways (Landers et al, 1986). This increase in ventilation-perfusion mismatching tends to offset any increase in PaO<sub>2</sub> that occurs because of increased oxygenation in poorly ventilated lung units. This phenomenon probably explains why PaO<sub>2</sub> increases less when MAP is increased by increasing Ti than when it is increased by increasing PEEP or PIP.

Besides its effects on oxygenation, alveolar overdistention carries the risk of alveolar rupture and pulmonary interstitial emphysema (PIE). The propensity for increases in Ti to result in alveolar overdistention is supported by its high correlation with pulmonary air leaks in one study that explored the antecedents of alveolar rupture (Primhak, 1983). It is also supported by the results of two controlled trials showing a higher incidence of pneumothorax in infants ventilated with a long Ti than in those ventilated with a short Ti (Heicher et al, 1981; Oxford Region Controlled Trial, 1991).

### Determinants of Ventilation

The other important function of mechanical ventilation is to ventilate adequately, to control PaCO<sub>2</sub>. PaCO<sub>2</sub> is equal to the rate of CO<sub>2</sub> production divided by the alveolar ventilation ( $\dot{V}_A$ ). The latter is represented by the equation  $\dot{V}_A = (V_t - V_d) \times RR$ , where  $V_t$  is tidal volume,  $V_d$  is dead space volume, and RR is respiratory rate. If  $V_d$  and CO<sub>2</sub> production are relatively constant, PaCO<sub>2</sub> is proportional to  $1/(RR \times V_t)$ . PaCO<sub>2</sub> decreases if either RR or  $V_t$  is increased, and PaCO<sub>2</sub> increases if RR or  $V_t$  is decreased. On a pressure-limited respirator, at a constant inspiratory time, the  $V_t$  is determined by the lung compliance and by PIP and PEEP (Fig. 45-8). If Ti is less than 3 time constants, increasing Ti will also increase  $V_t$  but at the expense of overdistention of more normal lung units. PaCO<sub>2</sub> can be decreased by increasing RR, by increasing PIP, or by decreasing PEEP. Conversely, PaCO<sub>2</sub> can be increased by decreasing RR, by decreasing PIP, or by increasing PEEP.

Although it is attractive to try to lower the PaCO<sub>2</sub> by increasing the respirator rate, rather than by adjusting ventilatory pressures, data suggest that this approach may not be entirely without risk. As the respirator rate increases, the absolute time allotted for expiration decreases. If expiratory time decreases to less than 3 time constants for expiration, gas trapping (Simbruner, 1986) and alveolar overdistention may occur (Kano et al, 1993).

**FIGURE 45-8.** Determinants of tidal volume. Lung volume is plotted as a function of inflation pressure. As the ventilator cycles between positive end-expiratory pressure (PEEP1) and peak inflation pressure (PIP1), the lung volume changes, generating tidal volume (V1). Increasing PEEP to PEEP2 forces the ventilator to cycle between PEEP2 and PIP1 and results in a lower tidal volume (V2). Leaving PEEP at PEEP1 while increasing peak inflation pressure to PIP2 increases the tidal volume to V3.

### Implementation

Because tiny premature infants characteristically have structurally immature lungs and weak chest walls, many centers have a standard practice of providing some form of respiratory support (i.e., nasal CPAP or mechanical ventilation) for all infants who weigh between 1000 and 1250 g. For infants who weigh between 1250 and 1500 g and have RDS, respiratory support also may be necessary. The use of early nasal CPAP in these circumstances has been discussed in detail previously.

### Intubation and Mechanical Ventilation

Intubation and mechanical ventilation at birth still constitute routine practice in many centers for infants weighing between 1000 and 1250 g. In addition, infants in whom nasal CPAP is unsuccessful because of apnea or persistent hypoxemia will require intubation and mechanical ventilation. Infants usually are intubated orally with an endotracheal tube that allows an audible air leak to ensure that the tube is not too tight against the walls of the trachea. A 2.5-mm-internal-diameter (ID) tube is appropriate for infants weighing less than 1 kg, 3.0 mm for those weighing between 1 and 2 kg, and 3.5 mm for those weighing more than 2 kg. For standard use, orotracheal intubation is preferred over nasotracheal because nasotracheal intubation has been found to cause nasal deformities (McMillan et al, 1986).

During intubation, infants often require a fraction of inspired oxygen ( $FIO_2$ ) that is 10% greater than they were receiving before the initiation of mechanical ventilation. It is always valuable to hand-ventilate an infant initially to determine the minimal PIP necessary to achieve good chest wall excursion and good bilateral breath sounds. A rate of 60 breaths/minute (which approximates the normal

rate for a premature infant) and PEEP of 5 cm  $H_2O$  are often used. In general, oxygenation can be improved by increasing MAP by increasing PEEP or PIP.  $Ti$  should rarely be prolonged, because of the risk of alveolar overdistention. An infant with poor pulmonary blood flow due to hypotension, hypovolemia, cardiac failure, or high pulmonary vascular resistance also may have a low  $PaO_2$ , and treatment should be directed to improving blood pressure and cardiac output.

Hypercapnia is treated by increasing PIP or respirator rate. To allow sufficient time for exhalation, the respirator rate should not ordinarily exceed 80 breaths/minute. The overall cardiopulmonary status of the infant must be kept in mind. Data have suggested that attempts to control  $PaCO_2$  rigorously may result in worsened lung injury (Garland et al, 1995; Kraybill et al, 1989). Ventilation with large tidal volumes has been shown to damage the lung of immature animals (Carlton et al, 1990; Hernandez et al, 1989). Hypocapnia exacerbates lung injury following ischemia-reperfusion (Laffey et al, 2000) and may be a risk factor for periventricular leukomalacia (PVL) (Okumura et al, 2001) and cerebral palsy in preterm infants (Collins et al, 2001). Hypercapnia has been shown to protect the lungs of rabbits from ventilator-induced lung injury (Sinclair et al, 2002) and to protect the brains of neonatal rats from hypoxic-ischemic damage (Vannucci et al, 1995). Two published studies have compared *permissive hypercapnia* ( $PaCO_2$  typically between 45 and 55 mm Hg) with normocapnia ( $PaCO_2$  typically between 35 and 45 mm Hg) and have found no reduction in death or bronchopulmonary dysplasia (Carlo et al, 2002; Mariani et al, 1999). Comorbid conditions such as intraventricular hemorrhage (IVH) and PVL also were similar in frequency in both groups. Therefore, the data are not sufficient to recommend ventilator strategies that routinely target high arterial  $CO_2$  tensions. However, many centers allow the  $PaCO_2$  to increase to 50 to 60 mm Hg or above in infants with severe respiratory distress, in whom the risk of lung injury or air block is great.

If the infant's breathing is asynchronous, especially if the blood pressure is low, then it is common to find that the blood pressure wave fluctuates (Perlman and Thach, 1988). Asynchrony also is associated with an increased incidence of pneumothorax. Sometimes, an increase in the rate to 70 or 80 beats/minute may promote adequate synchrony (Greenough et al, 1987), or breathing can be suppressed with narcotics (Goldstein and Brazzy, 1991). If narcotics are given, expiratory braking may be impaired, so it is again important to use generous levels of PEEP to promote the maintenance of lung volume (Miller et al, 1994).

The use of neuromuscular blockade to facilitate mechanical ventilation in the newborn remains controversial. Paralysis may result in decreased dynamic lung compliance and increased airway resistance and removes any contribution of the infant's own respiratory effort from tidal breathing (Bhutani et al, 1988). Therefore, it is often necessary to increase ventilator pressures after initiation of neuromuscular blockade. Venous return also is impaired by lack of movement and decreased muscle tone, and generalized edema may develop with this treatment.

Ventilator gas should be warmed to 34° to 36° C, and relative humidity should be greater than 90% to prevent excessive water loss from the respiratory tract and injury

to the lung from exposure to cold dry air (Chatburn, 1989; Gomez and Hansen, 1999; Hanssler et al, 1992; Tarnow-Mordi et al, 1989). This warming is most easily accomplished by using a heated nebulizer with heated ventilator circuits to prevent condensation of water in the ventilator tubing. Tracheal suctioning and chest physiotherapy should be minimized in the infant with RDS in the first few days after birth because their secretions are scant, and there is little evidence that suctioning and chest physiotherapy are of benefit. Concern has been expressed that these interventions might increase the risk of intracranial hemorrhage (Greisen et al, 1985; Perlman and Volpe, 1983). Infants with secretions (e.g., meconium aspiration or pneumonia) and older infants with RDS may require suctioning of the trachea as often as every 2 to 4 hours. Even then, suctioning often is associated with acute side effects of hypoxia, hypertension, and bradycardia (Simbruner et al, 1981) and, with deep suctioning, the risk of airway injury (Miller et al, 1981). If hand ventilation accompanies suctioning, a manometer must be attached to the bag to prevent delivery of excessive PIP.

### **Weaning from Mechanical Ventilation**

#### **Nasal CPAP to Facilitate Weaning from Mechanical Ventilation**

For infants weighing less than 1500 g, when PIP is less than 20 cm H<sub>2</sub>O and FIO<sub>2</sub> is less than 0.30, it is possible to decrease gradually the respiratory rate to 15 to 20 breaths/minute and then to wean directly to nasal CPAP (Wung et al, 1975). For this group of infants, the resistance of the endotracheal tube is such that periods of endotracheal CPAP or ventilatory rates less than 15 breaths/minute cannot be tolerated (Lesouef et al, 1984). A more recent study has shown, in fact, that chest-abdomen asynchrony (a measure of inspiratory loading) is much less for infants breathing through nasal prongs than for those breathing through an endotracheal tube (Kiciman et al, 1998).

Seven randomized clinical trials comparing postextubation nasal CPAP with extubation to an oxygen hood (Annibale et al, 1994; Chan and Greenough, 1993b; Davis et al, 1998; Engelke et al, 1982; Higgins et al, 1991; So et al, 1995; Tapia et al, 1995) were recently summarized in a meta-analysis (Davis and Henderson-Smart, 1999). Nasal CPAP reduced extubation failure rates by roughly 62% but did not decrease the number of infants requiring oxygen support at 28 days. A subgroup analysis suggested that nasal CPAP greater than 5 cm H<sub>2</sub>O was necessary for efficacy. These findings were confirmed by a subsequent controlled trial and meta-analysis by Dimitriou and coworkers in 2000. Overall, these studies and the meta-analyses provide support for the use of nasal CPAP as a tool for weaning small premature infants from mechanical ventilation.

#### **Nasal Ventilation to Facilitate Weaning from Mechanical Ventilation**

Lin and colleagues (1998) compared nasal intermittent positive pressure ventilation (IPPV) with conventional nasal CPAP in a group of 34 infants between 590 and 1880 g and

found that nasal IPPV was more effective in reducing apnea. More recently, Kiciman and colleagues (1998) noted that nasal synchronized intermittent ventilation (SIMV) (see later) was more effective in reducing chest-abdomen asynchrony than was endotracheal CPAP or nasal CPAP delivered by an infant flow driver, suggesting that nasal SIMV was particularly useful in unloading the respiratory system of the preterm infant. Three subsequent clinical trials (Barrington et al, 2001; Friedlich et al, 1999; Khalaf et al, 2001) all showed that nasal SIMV was more effective than nasal CPAP in weaning infants from mechanical ventilation. The single study that reported gastrointestinal outcomes noted no increase in distention, feeding intolerance, or perforation (Barrington et al, 2001). These trials are interesting and suggest that nasal SIMV requires additional study as a weaning tool from mechanical ventilation. However, nasal CPAP delivered by the infant flow driver was also effective in reducing chest-abdomen asynchrony when compared with conventional nasal CPAP (Kiciman et al, 1998) but slightly less than nasal SIMV. Additional trials should compare nasal SIMV and nasal CPAP delivered by the infant flow driver.

### **Patient-Triggered Ventilation**

The use of patient-triggered ventilation (PTV) is now relatively common in the NICU to achieve a greater degree of synchrony between the infant's breathing and the ventilator. Asynchronous breathing may impair oxygenation, increase ventilator requirements, necessitate heavy sedation or paralysis, or, more important, may result in blood pressure and cerebral blood flow fluctuations (Rennie et al, 1987), which have been linked to IVH (Perlman and Thach, 1988; Perlman et al, 1983).

PTV is used in four modes:

1. In *synchronized intermittent mandatory ventilation* (SIMV), a single triggered breath is given in equal windows of time, with the other patient-initiated breaths in each window not assisted; this means that the rate of supported breaths can be slowly reduced, with all assisted breaths well synchronized.
2. In *assist/control mode* (A/CV), all breaths are triggered, so the patient controls the ventilator rate, and weaning is accomplished by reducing the PIP; during apnea, controlled breaths are delivered at the preset rate.
3. In *pressure support ventilation* (PSV), a constant pressure is applied during inspiration and terminated when a decrease in air flow is sensed.
4. In *proportional assist ventilation* (PAV), the applied airway pressure is servo-controlled throughout each spontaneous breath. Pressure increases in proportion to the instantaneous tidal volume and inspiratory air flow generated by the patient.

These ventilators detect inspiratory activity (Bernstein, 1993) by measuring one of the following:

- flow of gas through the endotracheal tube using a hot-wire anemometer (Hird and Greenough, 1991a) or a variable-orifice pneumotachometer
- changes in airway pressure (Greenough et al, 1991) measured near the orifice of the endotracheal tube

- changes in chest wall impedance (Visveshwara et al, 1991) using a cardiorespiratory monitor
- diaphragm movements using a balloon-like pressure capsule (Graseby capsule) taped to the abdomen (Mehta et al, 1986)

The delay of a triggered breath from the beginning of a spontaneous respiration is the response time (in milliseconds) and includes both the “trigger” and “system” delay. In general, response times are less than 100 msec. As the response time increases, less of the spontaneous inspiratory effort is supported, and the likelihood increases that positive pressure support will interfere with expiration. Triggering mechanisms that are too sensitive or that are prone to artifacts can result in autocycling (inappropriate triggering of the ventilator due to artifact), and those that are not sensitive enough will cause the ventilator to miss spontaneous breaths. Several studies have investigated the performance of various trigger mechanisms. Although the results are somewhat inconsistent between the different trials, it appears that triggers that rely on measurements of air flow, pressure change, and diaphragm movement are roughly comparable and are faster and more reliable than those based on changes in impedance of the thorax (Bernstein et al, 1993; Dimitriou et al, 2001; Hummler et al, 1996; John et al, 1994). Of interest, differences in processing of the signal by the ventilator may contribute to greater differences than choice of triggering mechanism (Bernstein et al, 1993; Sanders et al, 2001). Finally, one study suggested that in infants with severe lung disease, changes in air flow and pressure at the airway may be damped, and measurements of diaphragm movement with the Graseby capsule may be superior (John et al, 1994).

Early trials comparing PTV (SIMV or A/CV) with conventional ventilation (CV) suggested that PTV resulted in greater synchrony between the ventilator and patient, improved oxygenation, improved weaning from mechanical ventilation (Bernstein et al, 1994; Cleary et al, 1995; Mizuno et al, 1994; Visveshwara et al, 1991), and reduced fluctuations in blood pressure (Hummler et al, 1996). Greenough and colleagues (2001) recently reported a meta-analysis of six trials comparing PTV (SIMV or A/CV) with CV (Baumer, 2000; Beresford et al, 2000; Bernstein et al 1996; Chan and Greenough, 1993c; Chen et al, 1997; Donn et al, 1994). They found that infants receiving PTV had a shorter duration of ventilation (roughly 32 hours) than that in infants receiving CV. There were no differences in the incidence of extubation failure, air leak, chronic lung disease, or severe IVH between the two groups. In this review, the authors also performed a meta-analysis of two studies comparing SIMV with A/CV (Chan and Greenough, 1994a; Dimitriou et al, 1995) and found no statistically significant difference in duration of weaning or frequency of weaning failure, extubation failure, or air leaks between the two techniques.

Although PSV would help overcome the resistance of the endotracheal tube and could facilitate weaning from mechanical ventilation in premature infants, no neonatal trials have been reported. Two trials have reported the use of PAV to reduce respiratory load in low-birth-weight infants. In one trial, PAV was compared with A/CV and CV in premature infants with acute respiratory distress.

Arterial oxygenation was similar in all three groups, but the infants on PAV had lower airway and transpulmonary pressures and a lower oxygen index (Schulze et al, 1999). In another trial comparing PAV with CPAP in infants recovering from respiratory distress, PAV resulted in less chest wall distortion and thoracoabdominal asynchrony (Musante et al, 2001). There have been no controlled trials of the use of PAV for prolonged periods of time during acute respiratory distress or during weaning from respiratory support.

A more recent approach to PTV allows the user to set the volume to be delivered by the ventilator. Tidal volume is measured using the same hot-wire anemometer (HWA) that the ventilator uses to trigger breaths. In this mode, a maximum pressure can be set, but if the preset volume is reached before the ventilator reaches the maximum pressure, the breath is terminated. Volume guarantee (VG) can be used with SIMV or AC/V. Short clinical trials carried out in infants with acute respiratory distress or recovering from respiratory distress have found that PTV with VG results in less breath-to-breath variability in tidal volume and similar gas exchange at lower airway pressures when compared with standard PTV (Abubakar and Kesler, 2001; Cheema and Ahluwalia, 2001; Herrera et al, 2002; Mrozek et al, 2000). One trial in infants with acute respiratory distress found that when compared with PSV, PSV with VG resulted in a higher minute ventilation and mean airway pressure (Olsen et al, 2002). There are no randomized controlled trials of PTV with VG that have examined the effects on outcomes such as air leak or chronic lung disease. In addition, there is some concern about measurements of tidal volume in premature infants in the presence of leaks around the endotracheal tube.

## High-Frequency Ventilation

Respiratory rates on the ventilator between 60 and 80 breaths/minute represent conventional ventilation; high-frequency ventilation (HFV) refers to respirator rates between 150 and 3000 breaths/minute. Three modes of HFV have been used in the newborn (Slutsky, 1988): high-frequency jet ventilation (HFJV), high-frequency oscillatory ventilation (HFOV), and high-frequency flow-interrupted ventilation (HFIV) (Clark, 1994).

In HFJV, the ventilator delivers a high-pressure puff of gas through a small-bore cannula usually positioned in the airway at the proximal end of the endotracheal tube. The actual volume of gas delivered cannot be known because the volume delivered by the jet may be augmented by gas from the auxiliary circuit that is dragged along with the high-pressure puff. Exhalation is passive.

In HFOV, the ventilator uses a piston or moving diaphragm to pump gas into and out of the lung, making both inspiration and expiration active. The oscillator uses small tidal volumes (usually less than VD) and relies on a bias flow of gas to flush CO<sub>2</sub> out of the system and to maintain a supply of fresh gas at the proximal end of the endotracheal tube.

In HFIV, the ventilator uses a circuit similar to that of a conventional ventilator. Gas flow through the circuit is interrupted by a motorized rotating ball. Constant end-expiratory

pressure is adjusted by a valve on the expiratory limb of the circuit. As for HFJV, exhalation is passive. A newer ventilator interrupts flow by a set of metered pneumatic valves. This ventilator also creates an active exhalation using a Venturi system and functions more like an HFOV ventilator than a classic flow interrupter.

### Mechanisms of Gas Exchange

The mechanism responsible for oxygenation with HFV is the same as for CV—it depends on increasing the  $PAO_2$  in the poorly ventilated part of the lung (Froese and Bryan, 1987; Slutsky, 1988). As with CV, HFV accomplishes this by increasing MAP. Whether or not HFV results in comparable levels of oxygenation with lower MAPs is still controversial.

The difference between HFV and CV lies in the methods of removing  $CO_2$ . HFV seemingly defies conventional pulmonary physiology by removing  $CO_2$  by rapid ventilation of the lung with tidal volumes less than the anatomic dead space. With HFV, removal of  $CO_2$  may be accomplished by five mechanisms:

1. Some alveoli are located near enough to central airways that bulk convection of gas can play a role in  $CO_2$  exchange.
2. Similar to CV, HFV relies on molecular diffusion for gas exchange within the terminal lung units.
3. At the high frequencies employed with HFV, gas exchange between lung units with uneven time constants (pendelluft) can set up circulating currents that enhance gas mixing in the lung and  $CO_2$  exchange.
4. The velocity profile of gas in the airways is asymmetrical (i.e., in the center of the parabolic gas stream, forward transport is slightly greater than backward transport of gas, and at the edge of the stream, backward transport is greater than forward). At high frequencies, this results in a net forward flow of fresh gas down the center of the airway and a net backward flow of alveolar-airway gas up the airway.
5. At high frequencies, a form of facilitated diffusion occurs secondary to enhanced dispersion of both turbulent and laminar streams of gas flow (Taylor dispersion).

During HFV, these mechanisms combine so that the rate of  $CO_2$  elimination is proportional to the respiratory frequency multiplied by the square of the tidal volume.

### Potential Problems

One of the major problems associated with HFV is related to humidification of inspired gas. This is a particular problem with HFJV, in which inadequate humidification combined with the high-pressure pulses of gas has resulted in cases of necrotizing tracheitis (Gomez and Hansen, 1999). It is much less of a problem with HFIV and HFOV, in which the bias flow can be adequately humidified. The other concern with the use of HFV is that of gas trapping. At high frequencies, expiration may be shortened to the point at which expiratory time is less than 3 time constants, and gas trapping may occur. This may be a particular problem when the inspiratory time-to-expiratory time ratio is increased from 1:2 to 1:1 (Gerstmann et al, 1990).

## Clinical Experience

### High-Frequency Jet Ventilation

Early studies in infants with hyaline membrane disease showed that HFJV could provide adequate oxygenation with low MAP and PIP over limited period of times (Carlo et al, 1984; Pagani et al, 1985). Three randomized controlled trials have compared HFJV with CV in premature infants with respiratory distress (Carlo et al, 1990; Keszler et al, 1997; Wiswell et al, 1996). Two of these studies (Carlo et al, 1990; Wiswell et al, 1996) used lower mean airway pressures (*low-volume strategy*) when switching from CV to HFJV, whereas the third (Keszler et al, 1997) used higher mean airway pressures (*high-volume strategy*). Surfactant was administered to infants in the two most recent trials (Keszler et al, 1997; Wiswell et al, 1996). There were no differences in mortality, pulmonary air leak, or IVH between the HFJV and CV groups in any of the studies. The study using the high-volume strategy (Keszler et al, 1997) noted a reduction in the incidence of chronic lung disease at 36 weeks of postmenstrual age in the HFJV group, as well as a reduction in the requirement for home oxygen. The other trials found no effect on chronic lung disease. The other more recent trial (Wiswell et al, 1996) found that the infants ventilated with HFJV were more likely to develop cystic PVL. Because a number of infants in the high-volume-strategy study (Keszler et al, 1997) was in fact ventilated using a low-volume strategy, the investigators were able to compare the two strategies within their trial. They noted that the incidence of PVL was increased only in those infants receiving HFJV with a low-volume strategy. A recent meta-analysis of these trials (Bhuta and Henderson-Smart, 2000) confirmed that HFJV was associated with a reduction in chronic lung disease in survivors at 36 weeks of postmenstrual age but cautioned against routine use of HFJV for premature infants with respiratory distress until issues regarding ideal strategies are resolved.

Descriptive reports suggest that HFJV may be useful in the management of newborn infants with severe respiratory failure who are on maximal ventilatory support and are being considered for treatment with extracorporeal membrane oxygenation (Baumgart et al, 1992; Davis et al, 1992) (see also Chapter 48). Trials in infants with persistent pulmonary hypertension of the neonate (PPHN) have shown that HFJV improves ventilation (Carlo et al, 1989) and oxygenation (Engle et al, 1997) at lower ventilatory pressures but has no effect on ultimate outcome. One study comparing HFJV with CV in an experimental model of meconium aspiration pneumonia found HFJV to be superior (Trindade et al, 1985), whereas another found CV to be superior (Mammel et al, 1983). (See Chapter 48, Respiratory Failure in the Term Infant.)

### High-Frequency Flow-Interrupted Ventilation

HFIV was used in a controlled trial in preterm infants with RDS; the results were not different from those with conventional mechanical ventilation (Pardou et al, 1993). In one nonrandomized trial, HFIV improved oxygenation in infants with PPHN without hypocarbia or alkalosis and

appeared to reduce the duration of mechanical ventilation and the incidence of chronic lung disease (Jirapaet et al, 2001).

### **High-Frequency Oscillatory Ventilation for the Initial Management of Respiratory Distress Syndrome**

Nine randomized controlled trials compared HFOV with CV for primary management of premature infants with RDS (Clark et al, 1992; Gerstmann et al, 1996; HIFI Study Group, 1989; Johnson et al, 2002; Moriette et al, 2001; Ogawa et al, 1993; Plavka et al, 1999; Rettwitz-Volk et al, 1998; Thome et al, 1999). A recent review and meta-analysis have summarized the findings of the first eight of these trials (Henderson-Smart et al, 2001).

**Mortality.** There was no difference in mortality at 28 to 30 days or at 36 to 37 weeks of postmenstrual age in any of the individual trials or in the overall meta-analysis.

**Chronic Lung Disease.** In the four trials (Moriette et al, 2001; Ogawa et al, 1993; Plavka et al 1999; Thome et al, 1999) reporting need for oxygen at 28 days, there was no difference between the HFOV and CV groups in any of the individual trials or in the overall analysis. In another subgroup analysis, four trials defined chronic lung disease as the use of oxygen or mechanical ventilation plus an abnormal chest radiograph at 28 to 30 days (Clark et al, 1992; Gerstmann et al, 1996; HIFI Study Group, 1989; Ogawa et al, 1993). Two of these trials (Clark et al, 1992; Gerstmann et al, 1996) showed that HFOV reduced the incidence of chronic lung disease but the difference was not significant when all four trials were analyzed. However, if the meta-analysis was confined to three trials using a high-volume strategy, the incidence of chronic lung disease decreased significantly (Clark et al, 1992; Gerstmann et al, 1996; Ogawa et al, 1993). Chronic lung disease at 36 to 37 weeks of postmenstrual age was reported in six trials (Clark et al, 1992; Gerstmann et al, 1996; Johnson et al, 2002; Moriette et al, 2001; Plavka et al 1999; Rettwitz-Volk et al, 1998; Thome et al, 1999) and was decreased significantly in the HFOV group. Of interest, five of these six studies used a high-volume strategy.

**Air Leak.** The risk of air leak was increased by HFOV in the trial by Thome and coworkers (1999) and was increased in the overall analysis of six trials by meta-analysis (Henderson-Smart et al, 2001).

**Intraventricular Hemorrhage.** There was no difference in the rate of IVH between the two groups in the individual trials or in the overall analysis. Severe IVH (grade 3 or 4) was increased in the HFOV group in two individual trials (HIFI Study Group, 1989; Moriette et al, 2001) and in the meta-analysis of all eight trials.

**Periventricular Leukomalacia.** There was no significant increase in PVL in the seven studies reporting this outcome (Gerstmann et al, 1996; HIFI Study Group, 1989; Moriette

et al, 2001; Ogawa et al, 1993; Plavka et al, 1999; Rettwitz-Volk et al, 1998; Thome et al, 1999). In a subgroup analysis of the two studies not using a high volume strategy (HIFI Study Group, 1989; Rettwitz-Volk et al, 1998), the incidence of PVL was increased significantly.

**Neurodevelopmental Outcome.** Follow-up evaluation at 16 to 24 months of age revealed more neurologic deficits in the HFOV group (HIFI Study Group, 1990), probably related to the increased incidence of severe IVH in this group. In the study by Gerstmann and colleagues (2001), neurodevelopmental outcome at age 6 years was normal and not different between the two groups. Frequency of significant retinopathy of prematurity was actually reduced in the HFOV group in a meta-analysis of two trials using a high-volume strategy (Gerstmann et al, 1996; Thome et al, 1999).

### **Clinical Considerations**

The concern about high-frequency ventilation and severe IVH and PVL was addressed in a meta-analysis (Clark et al, 1996) that included four trials using HFOV for initial treatment of premature infants with respiratory distress (Clark et al, 1992; Gerstmann et al, 1996; HIFI Study Group, 1989; Ogawa et al, 1993), one trial of rescue therapy (HIFO Study Group, 1993), three trials of HFJV for the treatment of respiratory distress (Carlo et al, 1987, 1990; Wiswell et al, 1996), and one trial using HFJV for treatment of premature infants with PIE (Keszler et al, 1991). The investigators found no difference in the incidence of severe IVH between the HFV group and the CV group. However, they did find an increase in the rate of PVL in the HFV group. This difference disappeared if the HIFI study was excluded.

Two trials in 2002 compared HFOV with CV. Johnson and colleagues (2002) studied 797 patients. They found no differences between the two groups in mortality, survival with chronic lung disease, air leak, IVH, PVL, or retinopathy of prematurity. Courtney and colleagues (2002) compared HFOV with SIMV in 500 premature infants with respiratory distress. They found that the incidence of chronic lung disease was reduced in the HFOV group, and infants in this group were extubated 1 week earlier. The risk of pulmonary air leak was increased in the HFOV group. There were no differences in mortality, IVH, or PVL between the two groups.

Although it is possible that the use of HFOV for the initial therapy of premature infants with respiratory distress may reduce the incidence of bronchopulmonary dysplasia, the same studies suggest that it may increase the risk of pulmonary air leak and PVL. In addition, outcomes appear to be *very* dependent on the ventilator strategy employed. Until these issues are resolved, HFOV cannot be recommended as the routine method of providing mechanical ventilation to premature infants with respiratory distress. Should CV and surfactant therapy fail, however, HFOV is a reasonable form of rescue therapy.

The usual recommendation for HFOV in the management of severe respiratory failure is to start at an MAP 2 to 3 cm H<sub>2</sub>O above the MAP being used for CV, at a rate of 10 Hz, at an inspiratory-expiratory ratio (I:E) of 1:2, and at a pressure difference that moves the chest visibly. Chan and

Greenough (1993a) recommended a rate of 10 Hz and an MAP of 5 cm H<sub>2</sub>O above the MAP used for CV. In general, oxygenation is controlled with MAP, and ventilation is controlled with amplitude and rate. Few changes are made in the rate, but if hypercarbia dictates a larger VT at the same  $\Delta$  pressure, this can be accomplished by a reduction of the rate to 9 or 8 Hz. The reduction in rate allows a larger volume to be transmitted. If PIE dictates a smaller VT at the same  $\Delta$  pressure, this can be accomplished by an increase in the rate as high as 15 Hz. The MAP may be increased to 25 cm H<sub>2</sub>O or higher, but depression of the circulation becomes an important factor, and volume support may be needed. When oxygenation is improved, it is usual to begin weaning from oxygen first and favor the continued use of high MAP. When the MAP has been decreased to 9 to 12 cm H<sub>2</sub>O, it is usual to change the patient back to CV at a level of MAP 2 to 3 cm H<sub>2</sub>O lower.

### High-Frequency Ventilation in the Management of Air Leak Problems

In uncontrolled trials, HFIV (Frantz et al, 1983; Gaylord et al, 1987) and HFJV (Boros et al, 1985; Pokora et al, 1983) both appear to provide some benefit in the management of low-birth-weight infants with pulmonary interstitial emphysema (PIE). Keszler and colleagues (1991) reported the results of a large multicenter controlled trial in the management of premature infants with PIE, comparing HFJV with CV at rapid rates; the success criteria were prospectively defined, and provision was made for crossover as necessary. Overall, 61% of infants who started on HFJV and only 31% of those who started on CV were successfully managed—a significantly improved result with HFJV. More patients starting on CV had to be crossed over to HFJV. When patients were crossed over to HFJV, the success rate was much higher (45%) than when patients were crossed over to CV (9%). Radiographic improvement was clearly more rapid with HFJV. After excluding crossover, the mortality rate among infants who started on HFJV was 35%, compared with 53% among those who started on conventional ventilation. In this study of PIE, a low-volume strategy was pursued, with encouragement of the lung to derecruit; such a strategy can be followed with other forms of HFV in the management of PIE.

### Liquid Ventilation

For the past 30 years or so, investigations have been pursuing the possibility of treating ventilatory failure with liquid rather than gaseous ventilation (Shaffer et al, 1984; Wolfson et al, 1996). The discovery of a class of compounds known as fluorocarbons has led to significant advances because they are chemically and physiologically inert. Perfluorocarbon (PFC), the compound being used in both animal experimentation and human clinical studies, has a greater solubility for respiratory gases than the solubility of blood. It also has some of the properties of surfactant, with a low surface tension. When instilled into the lung, this radiopaque compound gradually recruits

alveoli without barotrauma and, because of its low vapor pressure, is rapidly eliminated by vaporization.

The first human trials of liquid ventilation were conducted in “near-death” infants in 1989. The lungs were filled with the PFC liquid, and tidal volumes of liquid were cycled into and out of the lung using a gravity-assisted approach. The infants tolerated the procedure, and gas exchange and lung compliance improved. All three infants died after discontinuation of liquid ventilation (Greenspan et al, 1997). In 1996, Leach and colleagues reported on 10 preterm infants who received partial liquid ventilation (PLV) for up to 24 to 76 hours. For PLV, the lungs are filled with PFC to functional residual capacity (20 mL/kg) while gas ventilation is continued. They also noted dramatic improvements in gas exchange and lung compliance. Eight of the 10 infants in their study survived to 36 weeks of corrected gestational age. Although these findings are encouraging and suggest that PLV may be a feasible treatment for some infants with respiratory failure, animal studies have not been encouraging, and clearly, randomized controlled trials must be performed before more widespread use of this technology can be recommended.

### Complications of Respiratory Support

#### Air Block

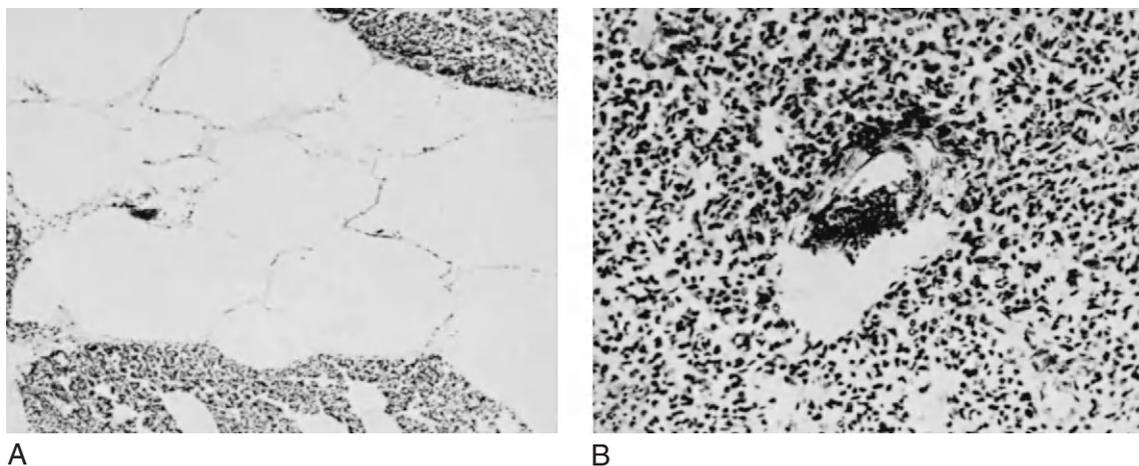

The most serious complication of mechanical ventilation is air block. PIE, pneumomediastinum, subcutaneous emphysema, pneumothorax, pneumopericardium, pneumoperitoneum, and intravascular air all are manifestations of the air block syndrome, and all begin with some degree of PIE (Kirkpatrick et al, 1974; Macklin and Macklin, 1944).

#### Pulmonary Interstitial Emphysema

##### Pathophysiology

PIE is the result of alveolar rupture from overdistention of alveoli abutting nonalveolar structures and marginal alveoli (Caldwell et al, 1970; Hansen and Gest, 1984) (Figs. 45–9 and 45–10). It occurs most commonly in preterm or term infants undergoing mechanical ventilation for some form of parenchymal lung disease. In these infants, distribution of inspired gas is nonuniform, with the bulk of each breath being distributed to the more normal lung units. As a result, these lung units may become overdistended and rupture. Gas trapping from an insufficient expiratory time also can result in alveolar overdistention and rupture. Once alveolar rupture occurs, air is forced from the alveoli into the loose connective tissue sheaths surrounding airways and pulmonary arterioles and into the interlobular septa containing pulmonary veins. The air follows a track along these sheaths to the hilum of the lung, producing the characteristic radiographic appearance of PIE (Fig. 45–11).

PIE increases the volume of gas within the lung parenchyma and splints the lung in full inflation, thereby decreasing lung compliance. Air trapped within the interstitial cuffs compresses airways and increases airway resistance. In addition, air in the interstitial space impairs lymphatic function, allowing fluid to accumulate in the interstitial cuffs and in alveoli (Leonidas et al, 1979). PaCO<sub>2</sub>

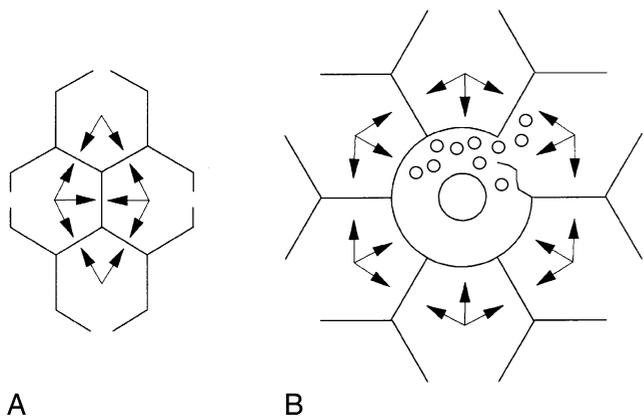

**FIGURE 45-9.** **A**, Photomicrograph of the lung of an infant who died of emphysema and bilateral pneumothorax. The alveoli in the center show much distention, their septa thinned. Some of the septa have ruptured. In the periphery, the lung is atelectatic. **B**, Higher-power view showing a blood vessel in cross section. The vessel is compressed by a surrounding collar of air that has filled and ballooned the perivascular space.

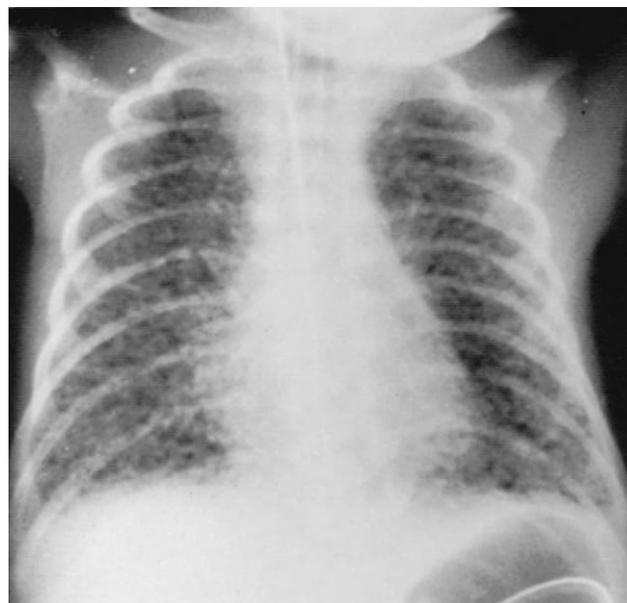

increases and  $\text{PaO}_2$  decreases. The increase in  $\text{PaCO}_2$  occurs early and is the result of increased respiratory dead space and reduced minute ventilation. The decrease in  $\text{PaO}_2$  results in part from reduction in alveolar ventilation and in part from ventilation-perfusion mismatch secondary to mechanical obstruction of airways by interstitial air and edema fluid. It also results from compression of pulmonary

arterioles by air in the perivascular cuffs with increased pulmonary vascular resistance (Brazy and Blackmon, 1977) and right-to-left shunting of blood.

Once interstitial air reaches the hilum of the lung, it coalesces to form large hilar blebs, or it tracks beneath the visceral pleura to form large subpleural pockets of air. In both instances, these accumulations of air can be large enough to compress normal lung and impair ventilation, or to cause circulatory embarrassment by encroaching on mediastinal structures (Plenat et al, 1978).

**FIGURE 45-10.** Mechanism of alveolar rupture. Partitioned alveoli (**A**) have their bases lying against other alveoli, whereas marginal alveoli (**B**) abut bronchi, blood vessels, or pleura. During lung inflation, these two different types of alveoli behave quite differently. Partitioned alveoli are free to expand equally in all directions, as they abut the equally distensible walls of adjacent alveoli. In addition, the pressure within each alveolus is balanced by an equal pressure inside surrounding alveoli, so no unbalanced forces occur across the alveolar wall. Marginal alveoli, especially those surrounding blood vessels, are tethered at the base to a less distensible structure and are not as free to expand in all directions. During lung inflation, the connective tissue sheaths surrounding pulmonary blood vessels attempt to expand with the alveoli, while the vessels themselves increase in size only slightly. As a result, unbalanced forces develop across the wall at the base of the alveolus, and air ruptures into the adjacent connective tissue sheath.

**FIGURE 45-11.** Pulmonary interstitial emphysema. The lung is grossly hyperinflated, with coarse radiolucencies extending from the pleura to the hilum. These radiolucencies represent bubbles of air in the perivascular and peribronchial interstitial cuffs.

### Prevention

The cause of PIE is alveolar overdistention and rupture. Therefore, ventilatory techniques that minimize alveolar overdistention would be expected to reduce the risk of PIE. Previous data have shown that increases in inspiratory time are associated with pulmonary air leaks (Primhak, 1983), and two controlled trials done prior to routine surfactant replacement showed that techniques for ventilation that rely on shorter inspiratory times decrease the incidence of PIE (Heicher et al, 1981; Oxford Region Controlled Trial, 1991).

### Treatment

Because the site of the air leak behaves like a check valve, gas trapping occurs, resulting in further alveolar overdistention and rupture. Therefore, the first step in treatment must be to interrupt this cycle by putting to rest the more severely involved areas in the lung. If PIE is unilateral, this can be done by positioning the infant with the involved side down (Swingle et al, 1984) or by selectively intubating the main bronchus on the uninvolved side (Brooks et al, 1977). If PIE is bilateral, the involved areas can be put to rest by taking advantage of regional differences in time constants in the lung. Areas with PIE have airway compression and long time constants for inspiration and expiration. Mechanical ventilation using short inspiratory times (0.1 second), low inflation pressures, and small tidal volumes is ineffective in inflating these areas of the lung and should not contribute to further gas trapping (Meadow and Cheromcha, 1985). Over time, these areas deflate and collapse. Unfortunately, it may be difficult to maintain oxygenation and ventilation while selectively underventilating the areas of the lung with PIE. If this happens, it may be necessary to increase the respirator rate to 80 to 100 breaths/minute. The advantage of rapid-rate ventilation is that it makes maximal use of the less severely involved lung units and may compensate for the respiratory deterioration associated with selective underventilation of areas with extensive PIE. A multicenter controlled trial in 1991 (Keszler et al, 1991) found that HFJV allowed the use of lower peak and mean airway pressures in the treatment of infants with PIE than did rapid-rate CV. Furthermore, HFJV led to more frequent and rapid improvement in PIE than did rapid-rate CV (see earlier section, "High-Frequency Ventilation").

### Prognosis

PIE is a serious complication of mechanical ventilation. Infants in whom PIE develops have a significantly increased risk of developing chronic lung disease, as well as higher mortality rates (Gaylord et al, 1985; Powers and Clemens, 1993). In fact, for infants in whom PIE develops on day 0 or 1 after birth, the gestational age-adjusted odds ratio for risk of dying is nearly 10 to 1 and for developing chronic lung disease is 3 to 1 (Powers and Clemens, 1993).

## ***Pneumomediastinum and Pneumothorax***

### Epidemiology

The incidence of spontaneous pneumomediastinum and pneumothorax in term infants is 1% to 2%, presumably because high transpulmonary pressures exerted at birth,

when coupled with some degree of ventilation inhomogeneity, result in alveolar overdistention and rupture (Chernick and Avery, 1963; Lubchenco, 1959). In the presence of underlying lung disease, the incidence of pneumothorax increases dramatically. Pneumothorax develops in 10% of infants with retained fetal lung fluid and in 5% to 10% of spontaneously breathing infants with hyaline membrane disease. CPAP increases the incidence of pneumothorax in infants with hyaline membrane disease only slightly, whereas positive pressure ventilation increases the risk dramatically. Treatment with surfactant, however, markedly lowers this risk.

### Natural History

Pneumomediastinum occurs when air that has tracked through the perivascular and peribronchial cuffs to the hilum ruptures into the mediastinum. From there, air can rupture through the mediastinum into the pleural space, producing tension pneumothorax. Available evidence suggests that air in the mediastinum seldom achieves enough tension to cause circulatory embarrassment, because as the tension increases, air can dissect into the soft tissues of the neck to produce subcutaneous emphysema or rupture into the intrapleural space. On the other hand, tension pneumothorax can result in very high pressures within the pleural space, collapsing the lung on the involved side and resulting in immediate hypoxia and hypercapnia. In addition, by compressing mediastinal structures and impeding venous return, pneumothorax may result in circulatory collapse.

### Diagnosis

Pneumomediastinum usually is asymptomatic or associated with mild tachypnea. In the spontaneously breathing infant, however, pneumothorax usually results in clinically significant tachypnea, grunting, irritability, pallor, and cyanosis. The cardiac point of maximum impulse may be shifted away from the pneumothorax, and often the affected hemithorax appears to bulge. Differential breath sounds are unreliable markers of pneumothorax in the infant. Arterial pressure tracings may reveal a reduction in pulse pressure. In the infant on a mechanical ventilator, signs may be more dramatic, with sudden onset of hypoxemia and cardiovascular collapse (Ogata et al, 1976). Transillumination of the chest is increased over the affected side. Pneumothorax should be confirmed by chest radiograph (Fig. 45-12), if at all possible. Needle aspiration of the chest to diagnose pneumothorax relieves acute distress but should be discouraged. If needle aspiration is necessary, it should ordinarily be followed by tube thoracostomy.

### Treatment

Asymptomatic or mildly symptomatic spontaneously breathing infants may simply be observed closely until spontaneous resolution occurs. Although having infants breathe 100% oxygen hastens reabsorption of intrapleural air (Chernick and Avery, 1963), the risk associated with prolonged hyperoxia limits usefulness of this therapy in preterm infants. Infants with moderate to severe symptoms and all infants receiving positive pressure ventilation

**FIGURE 45-12.** Tension pneumothorax. The lung on the involved side is collapsed, and the mediastinum is shifted to the opposite side. Pleura can be seen bulging into the intercostal spaces.

require tube thoracostomy. The tube may be inserted at the midaxillary line and directed anteriorly or placed in the second intercostal space in the midclavicular line and directed toward the diaphragm so that the tip lies between the lung and the anterior chest wall (Allen et al, 1981). When placing the tube, the operator must take care to avoid impaling the lung, especially if a trocar, rather than curved hemostats, is used to direct the tube. Care also must be taken to avoid placing the tube too far into the chest, compressing mediastinal structures (Gooding et al, 1981). It also is possible to drain pneumothoraces using pigtail catheters that are placed percutaneously into the pleural space. This technique involves less trauma but may not be effective in addressing large air leaks (Wood and Dubik, 1995). The thoracostomy tube or catheter usually is connected to a water seal with 10 to 20 cm H<sub>2</sub>O negative pressure and is left in place until it ceases to drain. The negative pressure should be discontinued, and the tube should be left under the water seal for 12 to 24 hours before removal. Infant chest tubes should never be clamped.

### ***Pneumopericardium***

Pneumopericardium results from direct tracking of interstitial air along the great vessels into the pericardial sac (Varano and Maisels, 1974). Gas under tension in the pericardium impairs atrial and ventricular filling, decreases stroke volume, and ultimately decreases cardiac output and systemic blood pressure. Infants present with increasing cyanosis, muffled heart sounds, and decreased systemic blood pressure. The chest radiograph is diagnostic (Fig. 45-13). Needle aspiration alleviates the acute symptoms, but because recurrence rate is high (53%), continuous tube drainage is frequently necessary (Reppert et al, 1977). The mortality rate associated with pneumopericardium has been reported to be as high as 75%.

**FIGURE 45-13.** Pneumopericardium. A thin rim of pericardium is visible and clearly separated from the heart by air within the pericardial sac.

### ***Pneumoperitoneum***

Pneumoperitoneum results from dissection of air from the mediastinum along the sheaths of the aorta and vena cava, with subsequent rupture into the peritoneal cavity. Infants with this condition present with abdominal distention of sudden onset and a typical abdominal radiograph. Occasionally, the pneumoperitoneum may be large enough to cause respiratory embarrassment by compromising descent of the diaphragm and may require drainage. A more common problem, however, is the difficulty in distinguishing this cause of peritoneal air from a primary gastrointestinal catastrophe, such as a perforated ulcer or necrotizing enterocolitis (Knight and Abdenour, 1981). Obtaining more than 0.5 mL of green or brown fluid on paracentesis is suggestive of primary bowel disease, especially if bacteria are present on Gram stain. Measurement of the PO<sub>2</sub> of the gas aspirated from the abdomen also may be of some help, because it is likely to be very high if the gas is of pulmonary origin. Finally, a careful upper gastrointestinal series performed with water-soluble contrast may be of use in distinguishing the cause of intraperitoneal air (Cohen et al, 1982).

### ***Intravascular Air***

The classic belief was that intravascular air resulted from pumping air directly into the pulmonary venous system when airway pressure was extremely high (70 cm H<sub>2</sub>O). More recently, studies have found that the air is more commonly found in the systemic venous circulation, and it has been suggested that the air actually is pumped under high pressure through the pulmonary lymphatics into the systemic venous circulation (Booth et al, 1995). This theory is compatible with the observation of interstitial air in the loose connective tissue cuffs containing the pulmonary lymphatics. Intravascular air results in immediate cardiovascular collapse and is often diagnosed when air is seen in

vessels on chest radiographs taken to determine the cause of cardiovascular collapse. Although intravascular air usually is fatal, placing the infant head down on the left side may favor displacement of cerebral emboli.

### Airway Complications

Prolonged orotracheal intubation may cause palatal grooving, potentially interfering with dentition (Duke et al, 1976; Moylan et al, 1980), whereas nasotracheal intubation may result in cosmetic deformities of the nose (Jung and Thomas, 1974) and even nasal obstruction. Subglottic stenosis, although rare, can be a disastrous complication of intubation. A too snug-fitting endotracheal tube, prolonged duration of intubation, and multiple reintubations all correlate with subsequent subglottic stenosis (Fan et al, 1983; Sherman et al, 1986). Some infants have required tracheostomy.

Necrotizing tracheobronchitis (Pietsch et al, 1985) is a necrotic inflammatory process involving the trachea and main bronchi that has been described in newborns requiring mechanical ventilation. Sloughing of the tracheal epithelium results in occlusion of the distal trachea. Infants present with acute respiratory deterioration with symptoms of airway obstruction, hyperexpansion on chest radiograph, and poor chest movement. Emergency bronchoscopy may be necessary to relieve airway obstruction. The lesion is thought to result from drying of the tracheal mucosa secondary to inadequate humidification in the presence of high rates of gas flow and high concentrations of oxygen.

Atelectasis occasionally occurs after extubation from mechanical ventilation, with the right upper lobe most commonly affected. In some instances, atelectasis may reflect injury to the bronchi from suction catheters. In small preterm infants, postextubation atelectasis may result from chest wall instability and may be prevented by weaning to nasal CPAP.

## Surfactant Treatment of Respiratory Disorders

H. William Taeusch, Daniela Ramirez-Schrempp, and Ian A. Laing

### HISTORIC OVERVIEW

The infant mortality rate in the United States has halved in the last 20 years or so, a drop explained largely by the use of replacement surfactant for premature babies and positioning infants on their backs for sleeping to reduce the occurrence of sudden infant death syndrome (SIDS). The increased survival due to the treatment of newborn infants with surfactant amounts to 3 lives per 10,000 births. If 10 million infants are born in developed countries each year, then an estimated 30,000 lives have been saved in the past 10 years with surfactant therapy. Morbidity is also reduced. Pneumothoraces and other forms of air leak have become a rarity for infants with respiratory distress syndrome (RDS) (Malloy and Freeman, 2000).

All current exogenous surfactants reduce the severity of RDS. Most also reduce the mortality rates associated with RDS by 40% to 60%, and they significantly reduce overall mortality among premature infants at risk for RDS.

The story of the development of surfactant therapy is now a well-told tale (Avery, 2000; Clements and Avery, 1998). In 1929, by comparing pressures after inflating lungs with air and with fluid, von Neergard first inferred that surface forces contribute in a major way to mechanical properties of the lung. Several investigators (e.g., Gruenwald, Macklin) suggested that the lung contains substances that result in low surface tension. Comparing foam from lungs with foams from other detergents, Pattle estimated that surface tension in the lung is near zero, a startling conclusion. Clements discovered that material in the aqueous layer lining alveolar spaces has the unique ability to change surface tension according to surface area (alveolar volume). Clements, among others, identified the major constituents of pulmonary surfactant as lipids and proteins. In 1959, Mary Ellen Avery working with Jere Mead established that insufficiency of surfactant was associated with RDS (Avery and Mead, 1959).

The 1960s and 1970s were marked by *successful* trials of surfactant in animals with surfactant deficiency and *unsuccessful* clinical studies of use of surfactant in human infants. In retrospect, lack of success in the early clinical trials was due to the use of inadequate formulations and delivery methods. Then Fujiwara and colleagues (1980) published a paper describing a series of 10 infants with severe RDS who were markedly improved after treatment with bovine surfactant compared with historic controls. Their success

where others had failed was due to three essential factors: use of an animal-derived surfactant that was extensively tested *in vitro*; delivery as a liquid via the endotracheal tube; and the use of positive end-expiratory pressure, without which the effectiveness of surfactant therapy is limited. The work of these investigators was followed by a decade of clinical trials matched with basic science discoveries that led to the widespread use of surfactant throughout the developed world by around 1990. The review by Comroe (1977) illustrates the benefit of interactions among scientists and clinicians involved in surfactant research, and some of their contributions are listed in Table 46–1.

### COMPOSITION OF SURFACTANT

Human pulmonary surfactant consists of 90% lipids and 10% proteins. Phosphatidylcholines (lecithins), such as 1,2-dipalmitoyl-*sn*-phosphatidylcholine (DPPC) (36%), unsaturated phosphatidylcholine (32%), and phosphatidylglycerol (PG) (10%), constitute the bulk of the lipids (Fig. 46–1). In truth, because surfactant has multiple functions and is a mixture of several compounds, and because some of its constituents may be secreted into the alveoli from at least two cell types, it is impossible to say with exactitude what surfactant is. Operationally, surfactant is defined by its functions, by co-isolation of lipids and associated proteins from bronchoalveolar lavage fluid from normal humans and animals, and by measuring the secretions of alveolar type II cells. As the lung of the fetus matures in utero, lung fluid containing surfactant lipids and proteins enters the amniotic fluid, where it may be sampled, allowing estimation of lung maturity in cases of threatened premature delivery. In Table 46–2, the lipid constituents of human surfactant are compared with those of four exogenous surfactants used to treat surfactant deficiency in humans. Fig. 46–2 indicates the synthetic pathways by which the lipids are made. (see also relevant discussion in Chapter 42, Lung Development: Embryology, Growth, Maturation, and Developmental Biology.)

Four proteins are known to be associated with surfactant lipids (Table 46–3). They are known as surfactant proteins A to D: SP-A, SP-B, SP-C, and SP-D. SP-A is a hydrophilic, calcium-binding glycoprotein of 28 to 36 kDa synthesized by the alveolar type II cell and secreted as a large complex constructed from 18 polypeptide chains. SP-A consists of an N-terminal alpha-helical segment, a triple-helix coiled structure, an alpha helix, and a carbohydrate recognition domain. SP-B is a hydrophobic polypeptide of approximately 18 kDa with two identical polypeptide chains linked by a disulfide bridge. SP-C is very hydrophobic, and its main form is a 35-residue peptide chain containing two thioester-linked palmitoyl groups. SP-D is a hydrophilic glycoprotein. Like SP-A, SP-D has a collagen-like domain, a short linking region, and a C-lectin-like C-terminal domain. It is assembled as a multimer of 43-kDa subunits. SP-A and SP-D are members of a family of immunoprotective proteins termed collectins (collagen-lectins). SP-B and SP-C are stored in the lamellar bodies of the alveolar type II cell, whereas SP-A and SP-D are secreted separately both from alveolar

TABLE 46-1

## Historic Contributions to the Development of Surfactant Therapy

1806	Laplace describes the relationship $\text{inflating pressure} = 2 \times \text{surface tension}/\text{bubble radius}$ .
1929	Von Neergaard infers the importance of surface tension in the lungs.
1950s	Macklin and Gruenwald suggest again the importance of surface forces; Pattle suggests that the lungs contain a surfactant that lowers surface tension.
1957	Clements infers that lung surfactant changes surface tension with changes in lung volume.
1959	Avery and Mead describe surfactant inadequacy in lungs of infants who died of RDS.
1965	Chu and others were unsuccessful in treating infants with aerosolized surfactant lipids.
1973	King and Clements characterize surfactant lipids and identify a surfactant-specific protein.
1970s	Gluck, Clements, and coworkers find that amniotic fluid surfactant lipids predict RDS; Enhorning, Robertson, and coworkers show benefits of surfactant treatment of immature animals.
1971	Gregory demonstrates success of CPAP treatment for infants with RDS.
1980	Fujiwara successfully treats infants with a liquid preparation of bovine surfactant.
1980s	Characterization of surfactant lipids and their synthesis and metabolism.
1988	TA surfactant approved for clinical use in Japan. Extensive clinical trials in Europe and the United States of a variety of surfactants.
1990s	Approval of Exosurf and Survanta in the United States and Curosurf in Europe, leading to widespread use of surfactants. Cloning and regulation of surfactant proteins. Extensive clinical trials. Approval in the United States of Curosurf and Infasurf.

CPAP, continuous positive airway pressure; RDS, respiratory distress syndrome; TA, tracheal aspirate.

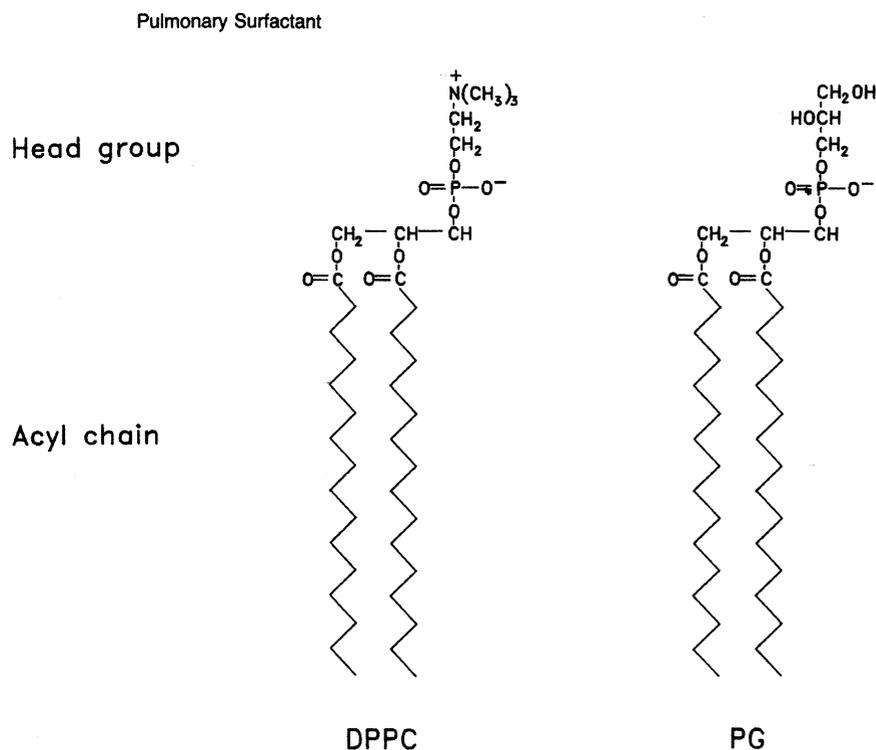

type II cells and from other cells lining the entrance to the alveoli (McCormack and Whitsett, 2002) (see relevant discussion in Chapter 42). The proteins in natural mammalian surfactant are compared with the proteins contained in the modified surfactants that are available for therapy in Table 46-4. Fig. 46-3 shows current molecular models of the four surfactant-associated proteins.

Note that Exosurf contains no proteins. Due to extraction with organic solvents during the purification process, the other surfactants used clinically contain the

hydrophobic proteins, SP-B and SP-C, but lack the more hydrophilic SP-A and SP-D.

## SURFACTANT PHENOMENA AND SURFACTANT FUNCTION

Surface tension results from intermolecular attractive forces of molecules (e.g., hydrogen bonds, electrostatic and van der Waals forces). Among fluids, the surface tension of water and

**FIGURE 46-1.** Molecular structures of dipalmitoyl phosphatidylcholine (DPPC) and phosphatidylglycerol (PG). Phospholipid molecules pack densely, forming membrane monolayers, bilayers, and vesicles and other aggregate forms. Strong molecular interactions occur between polar head groups. Distinct interactions occur between atoms composing the more hydrophobic acyl chains. (From Polin RA, Fox WW: *Fetal and Neonatal Physiology*, 3rd ed. Philadelphia, Elsevier, 2003, p 944.)

salt solutions is relatively high, approximately 72 mN/m. The force of surface tension is measured in a number of ways— for example, by the size of a fluid drop in air hanging from a pipette, the downward pull on a plate hanging in a fluid surface, the pressure needed to inflate a bubble in fluid, the deformation characteristics of a bubble under increasing pressure in a fluid, or the lateral force needed to compress a surface film on an aqueous buffer (Fig. 46-4).

If the air spaces of the lung were lined with extracellular fluid alone (conferring a high surface tension), then the pressure needed to inflate the lungs would be high, lung compliance would be low, the work of breathing would be great, and the air spaces would tend to collapse at end-expiration, leaving a low functional residual capacity and limiting excretion of carbon dioxide and saturation of pulmonary venous blood with oxygen. In addition, the

TABLE 46-3

**Characteristics of Surfactant Proteins****SP-A**

Most abundant surfactant-related protein  
 Enhances phospholipid aggregation and order  
 Immunoprotective  
 Reduces surfactant inactivation  
 Two genes located on chromosome 10  
 Hydrophilic  
 35-kDa monomer; mature form is an octadecamer of 630 kDa

**SP-B**

Essential for surfactant activity  
 Enhances rate of surface film creation  
 Creates “surfactant reservoirs”  
 Prevents surfactant inactivation  
 Anti-inflammatory  
 Affects intracellular processing of SP-C  
 Necessary for tubular myelin formation  
 Enhances phospholipid adsorption  
 Gene located on chromosome 2  
 Hydrophobic  
 79-amino-acid monomer; mature form is a homodimer of 18 kDa

**SP-C**

Decreases order and packing density in phospholipid bilayers  
 Enhances phospholipid adsorption  
 Increases respreading and contributes to film refining during cycling  
 Gene located on chromosome 8  
 Hydrophobic  
 35 aminoacids; mature form is a homodimer

**SP-D**

Immunoprotective  
 May have a role in controlling release of surfactant into alveoli  
 Gene located on chromosome 10  
 Hydrophilic  
 43-kDa monomer; four triplet monomers in cross-like form

in infants with RDS (and in children and adults with lung injuries and acute RDS).

Clements had the first insight that the unusual mixture of substances lining mammalian lungs—pulmonary surfactant—has the capability of changing its surface tension with changes in lung volume (i.e., in lung surface area). This feature stabilizes the lungs at low lung volumes (it allows partially inflated alveoli of unequal sizes to coexist) and allows increased recoil at higher lung volumes. If surface tension remains unequally distributed according to alveolar size, then the inflating pressure on the whole lung can maintain patency of large and small airways in parallel. This theory was directly proved by Schürch and colleagues (1976), who described the surface tension in the walls of air spaces of variable sizes by evaluating the spreading characteristics of microdroplets of fluorocarbons. How does pulmonary surfactant change surface tension with changing lung volume? Below the surface (air-liquid interface), a water molecule is attracted equally in all directions by neighboring molecules. Molecules beneath the surface attract molecules on the surface to a degree much greater than is true for molecules above the surface (in the gas phase). These forces make liquids with a high surface tension (mercury, water) bead on a solid surface.

A *surfactant*, or surface-active agent, is any molecule that localizes on aqueous surfaces. Surface tension reduces according to the number of surface-active molecules in a given surface area. An increase of surfactant molecules lowers surface tension, as the net attractive forces among surfactant molecules is less than those for water molecules. At very low surface tensions, an aqueous surface containing a surfactant can be viewed as a two-dimensional solid, excluding water, with surfactant molecules compacted contiguously.

Soaps and detergents are soluble surfactants and lower surface tension of water, but these compounds for the most part do not change surface tension as surface area changes. For that to occur, a relatively insoluble surfactant is necessary. An amphipathic molecule is one with both hydrophobic and hydrophilic regions, so that it concentrates at the surface, where the hydrophilic portion is in the water phase, while the hydrophobic part of the molecule extrudes in the air. Pulmonary surfactant contains (see Table 46-2) a specific amphipathic compound called dipalmitoyl phosphatidylcholine (DPPC) (formerly called dipalmitoyl lecithin). DPPC consists of a three-carbon glycerol backbone, with palmitate on the first and second carbons and with a phosphate linkage to choline on the third carbon.

law of Laplace ( $P = 2ST/r$ ), if applied to air spaces that are in contiguity and are lined with liquid with invariant surface tension ( $ST$ ), dictates that small alveoli (small radius,  $r$ ) would tend to collapse into larger ones, driven by the tendency of their internal pressure ( $P$ ) to increase. All of these phenomena are present to a variable degree

Karger AG, Basel.)

### Surface Tension and Work

**FIGURE 46-4.** Surface tension is related to the work necessary to expand a surface. Surface tension has units of force per length or work or energy per area. Work must be done against surface tension in order to increase the surface area of a system. Surface tension is defined thermodynamically as a change in free energy per unit surface area. (From Notter R: *Lung Surfactants: Basic Science and Clinical Applications*. New York, Marcel Dekker, 2000, p 11.)

When DPPC is compressed on an aqueous surface, not only are attractive forces minimal among DPPC molecules, but net intermolecular forces become repulsive, leading to the concept of surface pressure—the tendency of such molecules to fly apart on the surface (Surface pressure is equal to the surface tension of clean water minus the surface tension of the surfactant film; therefore, the lower the surface tension, the higher the surface pressure.)

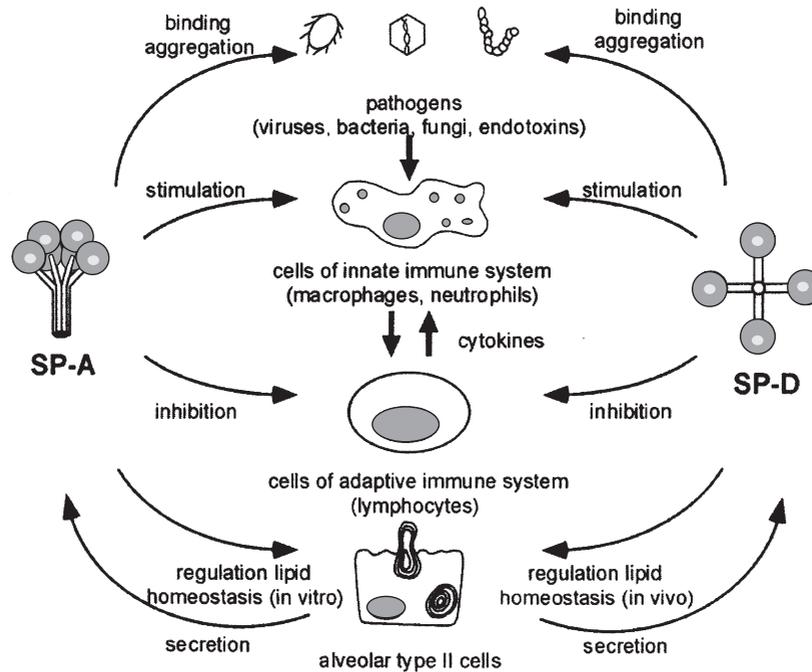

As the lung expands and contracts, the surfactant lining layer expands and contracts in an inhomogeneous manner. As lung volume reduces, the dispersed molecules of surfactant at the air-water interface coalesce into islands of enriched DPPC surrounded by more fluid areas of other lipids and proteins. The DPPC islands join, and the surface becomes solid and homogeneous as lung volume reduces further. At lowest lung volumes, the surface is compacted, distorted, and pleated into multilayers. On reexpansion, the multilayers are reincorporated into the surface, and the process repeats. During lung injury, serum proteins and other substances that have leaked into alveoli can absorb into the expanded surface layer, preventing the reincorporation of the extruded surfactant back into the surface, an explanation for one mechanism of inactivation of surfactant (Warriner et al, 2002).

No clinical conditions have been described with genetic abnormalities specifically for surfactant lipids. Knockout mice with absent SP-A or SP-D have relatively normal surfactant activity and pulmonary mechanics in the newborn period. No humans with absence of either of these proteins have been described, although SP-A polymorphisms have been described that correlate with both increased and decreased risks of respiratory distress, for reasons that remain unclear (Hallman et al, 2001). Surfactant deficient in SP-A is more susceptible to inactivation *in vitro* and *in vivo*. In the presence of calcium, surfactant proteins act to aggregate lipids to form a specific protein-lipid structure in the alveoli called tubular myelin that represents a transition form of surfactant between the osmiophilic bodies secreted from alveolar type II cells and the surfactant surface film. The structure of tubular myelin may protect secreted surfactant from inactivating materials and may promote the rate of adsorption of surfactant lipids into a surface film.

About  $20^8$  bacteria, in addition to particulate matter, viruses, fungi, and gaseous pollutants, are inhaled by adults breathing 12,000 liters of air per day. With a moist surface the size of a badminton court within the lungs, protective measures are necessary, and a major role for SP-A and SP-D is defense against infection (Fig. 46-5).

SP-A and SP-D are large-molecular-weight, complement-like proteins that both have a collagen-like tail with a globular sugar-binding (lectin) head. Both help opsonize bacteria and prepare various particles for engulfment and destruction by alveolar macrophages. SP-A has been shown to bind and enhance the uptake of a number of microorganisms (McCormack and Whitsett, 2002). Mice in which the SP-A gene has been knocked out have increased susceptibility to infection with group B beta-hemolytic streptococci and *Pseudomonas aeruginosa*. SP-A similarly protects the lungs against *Escherichia coli*, *Klebsiella*, fungi, and respiratory syncytial virus (RSV). SP-D also has been shown to have a similar potential role in protection against *E. coli*, *Klebsiella*, and RSV.

Disruption of the gene encoding SP-B is lethal for newborn (knockout) mice, which die of RDS, and a similar rare lethal RDS has been described for human newborns (reviewed in Cole et al, 2001). Babies with SP-B deficiency present with severe respiratory distress in the neonatal period. Because the condition in some respects mimics severe RDS in premature infants, the deficiency is recognized most clearly in term infants. SP-B deficiency is not relieved by the administration of exogenous surfactant, and the condition is fatal (without lung transplantation). Therefore, SP-B is a single-gene product essential for life.

**FIGURE 46-5.** Mechanisms of SP-A- and SP-D-mediated host defenses in the lung. SP-A and SP-D are secreted by alveolar type II cells and Clara cells (not shown). SP-A and SP-D are large multimeric proteins and belong to a family of collagenous C-type lectins designated collectins. Besides a role in the homeostasis of lung surfactant (in the case of SP-A based on *in vitro* and in the case of SP-D based on *in vivo* studies), both lung collectins are believed to play a role in the innate immunity of the lung. SP-A and SP-D can bind to a broad spectrum of pathogens, including bacteria, viruses, fungi, and yeasts, but also lipopolysaccharides (LPSs, endotoxin) and allergens. Furthermore, SP-A and SP-D enhance the clearing of various pathogens by neutrophils and macrophages by aggregation of the pathogens or by direct interaction of the collectins with receptors on the phagocytic cells. Finally, the lung collectins are suggested to dampen an excessive inflammatory response by inhibiting the secretion of cytokines and the proliferation of lymphocytes. (From Vaandrager A, Van Golde L: Lung surfactant proteins A and D in innate immune defense. *Biol Neonate* 77[suppl 1]:9-13, 2000. © S. Karger AG, Basel.)

Absence of SP-C also has been described (Amin et al, 2001). This condition appears to cause interstitial lung disease manifesting in later childhood or even adulthood but does not cause neonatal RDS.

SP-B and SP-C facilitate the initial adsorption and the reincorporation of surfactant lipids into surface films and help prevent inactivation of surfactant, presumably by their ability to both order and disorder lipid membranes (Johansson and Curstedt, 1997; Kruger et al, 2002; Perez-Gil, 2002; Wang et al, 2002). Lung injuries of different causes can down-regulate surfactant proteins. A recent study, for example, finds that SP-A and SP-D are diminished in the lungs of children with gastroesophageal reflux (Griese et al, 2002).

An excellent and extensive review of pulmonary surfactant has recently been published (Notter, 2000).

## PHYSIOLOGY AND PATHOPHYSIOLOGY

In the term infant, after clearance of alveolar fluid present during fetal life, with mature amounts of alveolar surfactant, the opening pressures (pressure at which air first enters the lung) are relatively low. Pulmonary compliance is normal, and the work of breathing is minimal. During expiration, a sizable functional residual capacity allows a reservoir of air between breaths. Low surface tension in alveoli helps increase egress of fluid from air spaces and keeps lungs edema-free. All of these attributes are reversed in premature infants with RDS or in older children or adults with acute RDS from lung injuries.

Why does surfactant deficiency matter in the lung? If surface tension in the lung is high, then air spaces tend to contract, lowering lung compliance and increasing the work of breathing. If the work of breathing is increased, then more respiratory drive from the brain is required to maintain normal alveolar ventilation and gas exchange. In premature infants with RDS, the increased work of breathing is manifested by intercostal and subcostal retractions as the infant generates higher negative pleural pressure to maintain alveolar ventilation. Alveolar ventilation is reduced, and the increased work of breathing generates high oxygen needs. Apneic spells may occur as respiratory drive becomes insufficient to inflate stiff (non-compliant) lungs. Smaller alveoli collapse into larger ones, creating the “Swiss cheese” or “ground-glass” appearance on chest radiographs; atelectasis and overinflated alveoli coexist, leading to ventilation-perfusion mismatching and right-to-left intrapulmonary shunting, resulting in hypoxemia. Hypercarbia may coexist with the hypoxemia. (see Chapter 47, Respiratory Distress in the Preterm Infant.)

The effects of pulmonary surfactant on the lung are summarized in Table 46–5.

Before the use of surfactant therapy, infants with RDS were treated with oxygen sufficient to overcome intrapulmonary shunting; constant distending airway pressure, that is, continuous positive airway pressure (CPAP); and ventilator support. CPAP is a mechanical partial substitute for surfactant, holding air spaces open at end-expiration. CPAP reduces *atelectrauma*, the damage done to lungs by repeatedly reopening collapsed air spaces. High levels of oxygen were required to maintain

**TABLE 46–5**

### Effects of Pulmonary Surfactant on the Lung

Maintains a gas reservoir at the end of expiration (FRC)
Provides a protective yet gas-permeable barrier between air and tissue in the lungs; fosters clearance of foreign material from the lung
Maintains optimal compliance of the lung. (low at high lung volume and high at low lung volume)
Enhances liquid efflux from alveoli, thus reducing edema
Lowers work of breathing and hence oxygen consumption
Allows optimal ventilation-perfusion ratios (large and small alveoli coexist)
In part, self-regulates secretion and metabolism
FRC, forced residual capacity

Data from Soll and Morley, 2001.

adequate PaO<sub>2</sub> in the face of widespread atelectasis, and this use “burned” the lung after several days (*oxytrauma*). High tidal volumes and inspiratory pressures were used on the ventilator to overcome low lung compliance (*volutrauma* and *barotrauma*). These therapeutic practices may combine to evoke inflammatory processes that could affect distant organs (*biotrauma*). Lung damage from ventilation and high levels of inspired oxygen also damage capillaries, so plasma (and in worst cases whole blood) leaks into air spaces, resulting in surfactant inactivation. Therefore, surfactant inactivation rapidly joins with surfactant insufficiency in RDS. Surfactant inactivation occurs not only in the preterm infant but also in association with lung injury states including meconium aspiration syndrome and pneumonia. Surfactant inactivation is a hallmark of acute (adult) RDS. Surfactant treatment acts to prevent or partially reverse all of these processes if given early in the course of the disease.

## SURFACTANT DEVELOPMENT, TURNOVER, SYNTHESIS, AND SECRETION

Lung surfactant is synthesized, processed, packed, secreted, and recycled by alveolar type II cells, which comprise 10% to 15% of the cells in the mature distal lung and are stem cells for alveolar epithelial (type I) cells. Type II cells produce, along with other cells, cytokines and growth factors that mediate lung growth, maturation, and repair. In the smooth endoplasmic reticulum, surfactant phospholipids and proteins are synthesized and exported in the Golgi system as osmiophilic lamellar bodies, where surfactant is stored and some of the final processing occurs. Lamellar bodies, which are storage sites for surfactant, are first observed at 22 weeks of gestation. From the lamellar bodies, surfactant is secreted by exocytosis into the liquid lining of the alveoli. Other cells in the distal lung also secrete surfactant proteins, and some assembly of lipid-protein complexes may occur after secretion. Surfactant secretion is stimulated by hyperventilation and mechanical stretch, catecholamines, ATP, protein kinases A and C, cyclic adenosine monophosphate (cAMP), phorbol esters, prostaglandins, and leukotrienes. Surfactant secretion is

inhibited by SP-A and possibly by other surfactant lipids and proteins.

Pulmonary surfactant appears in the future air spaces at 23 to 24 weeks of gestation. Because of net efflux of pulmonary fluid from the fetal lung, surfactant lipids and proteins are seen in the amniotic fluid starting at about 24 weeks of gestation. These surfactant constituents can be sampled by amniocentesis, allowing assessment of biochemical maturity of the fetal lung by various methods including determination of lecithin-to-sphingomyelin (L/S) ratio, measurement of phosphatidylglycerol (PG), and tests of bubble stability. With the continuing development of thin-walled air spaces and sufficient production of surfactant, the incidence of RDS falls in linear fashion from 24 to 34 weeks of gestation. Mature levels of pulmonary surfactant usually are present after week 35 of gestation. (see Chapters 6 and 42).

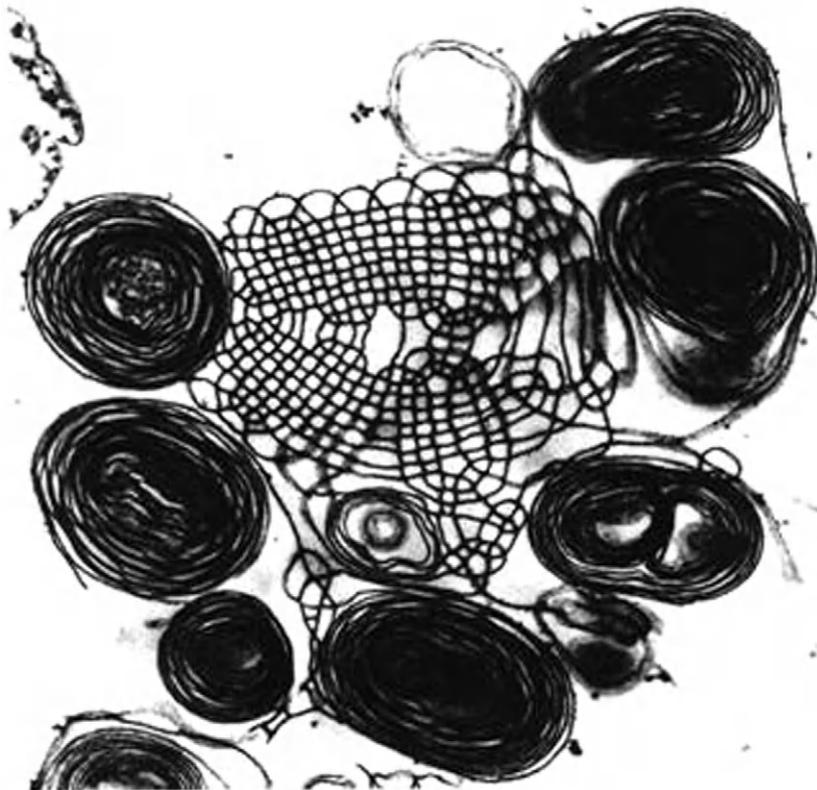

The ontogeny, synthesis, and secretion of the constituents of pulmonary surfactant are elaborately regulated (Copland and Post, 2002; McCormack and Whitsett, 2002; Whitsett and Weaver, 2002) (Fig. 46-6 and Fig. 46-7). The clinical corollary is that some maternal diseases, conditions, and treatments may perturb the endocrine milieu of the fetus, thereby affecting rates of development of both the lung structure and pulmonary surfactant. To prevent RDS in the premature infant, prenatal glucocorticoids are now universally recommended for mothers at risk of giving birth before the infant's lungs are mature (see Chapters 6 and 42). Maternal diseases that stress the fetus and cause endogenous fetal secretion of catecholamines, hypothalamic hormones, thyroid hormones, and glucocorticoids may contribute to precocious surfactant production. Neverthe-

less, such diseases, including pregnancy-induced hypertension and chorioamnionitis, may involve poor placental function and may be associated with chronic and/or acute hypoxemia for the fetus, offsetting the benefit of the enhanced rate of appearance of surfactant. Maternal diabetes and male gender of the infant are associated with delay in lung maturation and in production of surfactant.

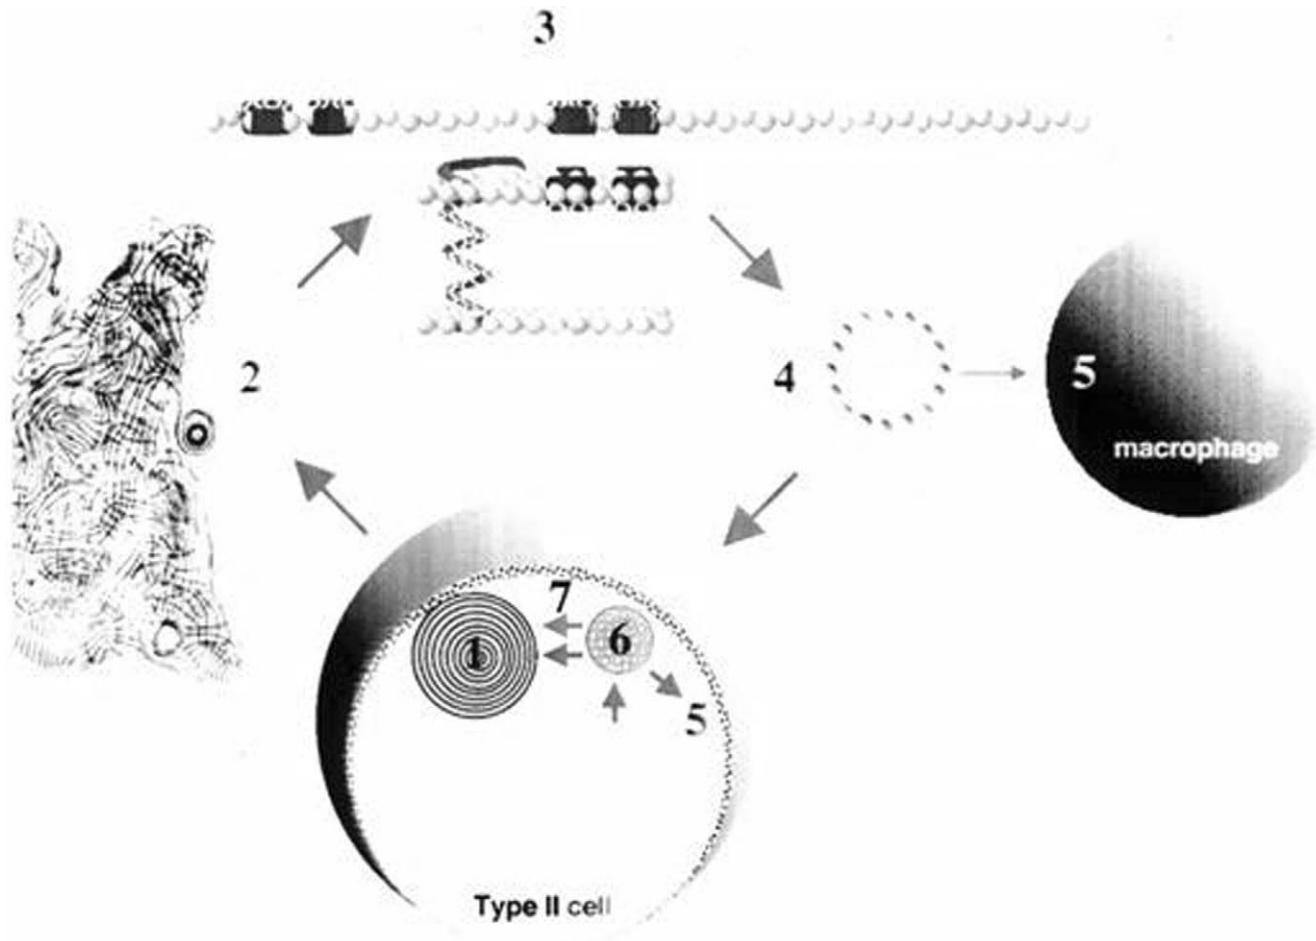

Catabolism of surfactant is slow. Most surfactant is taken up by endocytosis from the alveolar lumen. Approximately 5% of secreted surfactant is cleared from the lung every hour in newborn animals, compared with 25% to 50% every hour in adults. Approximately 95% of secreted phosphatidylcholine is recycled. Endogenous phosphatidylcholine has a turnover rate of 13 hours in preterm lambs, and phosphatidylglycerol's estimated half-life is 30 hours. Recycling pathways for both endogenous and replacement surfactants are active in preterm human lungs. The effete surfactant is returned to the alveolar type II cell to provide the raw materials for recycling.

Clinical studies have shown that the incidence or severity of RDS is affected by many factors. Table 46-6 lists factors that may increase or decrease the amount of available surfactant. Humoral factors are important for control of surfactant synthesis, including glucocorticoids, catecholamines, thyroid hormones, and insulin. (see Chapters 6, 42, and 47).

Alveolar type II cells secrete osmiophilic bodies that contain most of the surfactant lipids and proteins. The catecholamine surge at birth serves two important lung functions: It stimulates the reversal of fluid production such that alveolar fluid is taken up rather than produced, and it stimulates the secretion of the stored intracellular osmiophilic bodies. In the extracellular fluid space in the

**FIGURE 46-6.** Transmission electron micrograph of lamellar bodies forming tubular myelin in the (fluid-filled) air space of a fetal rat. (From Polin RA, Fox WW: *Fetal and Neonatal Physiology*, 3rd ed. Philadelphia, Elsevier, 2003, p 968.)

**FIGURE 46-7.** Surfactant homeostasis. 1, Lamellar body. 2, Large aggregate surfactant in alveolar hypophase. 3, Surface film. 4, Small aggregate surfactant. 5, Surfactant catabolic pathway. 6, Multi-vesicular body. 7, Recycling/biosynthetic pathway. Arrows represent anabolic pathways and catabolic pathways. Peptides are SP-B and SP-C. alveoli, osmiophilic bodies transform into tubular myelin, which in turn form a monomolecular lipid surface film. In concert with the charged phospholipids, the three surfactant proteins—SP-A, SP-B, and SP-C—facilitate this process of adsorption of surfactant lipids to the surface.

From recurring expansion and contraction, the surface film desorbs into the alveolar liquid in the form of small vesicles that are not surface active. These vesicles are either engulfed by macrophages or pinocytosed into alveolar type II cells, where the lipid constituents are recycled. The uptake of used surfactant is under the control of granulocyte-macrophage colony-stimulating factor (GM-CSF), in the absence of which alveolar proteinosis occurs (Reed et al, 1999). The half-life for secreted surfactant in premature infants is over one day. Surfactant instilled in the trachea is thought to be catabolized by similar pathways.

**CLINICAL USES OF SURFACTANT**

Today, replacement surfactant is used predominantly in the prophylaxis and treatment of respiratory distress syndrome in preterm infants. It is increasingly recognized, however, that exogenous surfactant has a role in conditions of surfactant inactivation in infants of any gestational age.

Clinical trials demonstrate that administration of surfactant, natural or synthetic, for treatment or prophylaxis

is associated with decreased mortality rates and a decrease in the risk of pneumothorax. Suresh and Soll (2001) estimate from meta-analysis a reduction of 30% to 65% in the relative risk of pneumothorax, and up to 40% reduction in the relative risk of death. Surfactant administration reduces the severity of RDS but will not eliminate the mortality and morbidity associated with other complications of prematurity.

Before the use of therapeutic surfactants, RDS usually worsened for a few days after birth, followed by death or improvement. Now, if cost and availability are not problems, surfactant usually is administered in the delivery room to premature infants at significant risk for disease, thereby ameliorating the classic clinical and radiographic signs of RDS (Suresh and Soll, 2001).

### Indications and Timing of Treatment

If surfactant deficiency in the neonate could be confidently predicted antenatally, then early use of exogenous surfactant would be clearly beneficial. It is important to acknowledge, however, that gestational age is inversely related to the accuracy of the test results for fetal lung maturity. Screening tests such as the foam stability test, determination of optical density at 650 nm, and semi-quantitative measurement of phosphatidylglycerol have a low positive predictive value and high sensitivity. Quantitative tests such as determination of L/S ratio and saturated phosphatidylcholine assay, on the other hand, have a high predictive value that tends to be associated with low sensitivity.

Prophylactic surfactant administration (defined as giving surfactant in the first minutes of life before overt signs of classic RDS have developed) improves clinical outcome over that obtained with surfactant treatment given later. Studies in preterm animals showed that surfactant treatment given before they breathe or receive positive pressure ventilation is associated with less epithelial damage (Jobe et al, 1993). If surfactant is given at the time of birth, there is a reduction in transvascular protein permeation and reduction in pulmonary edema (Carlton et al, 1995). Surfactant given within 15 minutes of birth produces better clinical outcomes in infants born at less than 31 weeks of gestation who require intubation (Egberts et al, 1997; Soll and Morley, 2001). If 100 such infants were administered prophylactic surfactant, there would be two fewer cases of pneumothorax and five fewer deaths than would occur with later treatment. Surfactant administered in the first 15 minutes of life is just as effective as surfactant given at or before the first breaths (Kendig et al, 1998).

Most infants born at a gestation of less than 27 weeks will be deficient in surfactant. The use of prophylactic surfactant for infants born at greater than 32 weeks of gestation would result in unnecessary treatment in a large number of infants, particularly those whose mothers had received a full course of antenatal corticosteroids. It is not yet clear where the cutoff should be to provide maximum benefit to infants with true surfactant deficiency, while protecting those more mature infants against unnecessary, costly, and possibly harmful administration of exogenous surfactant.

### Surfactant Delivery

In the delivery room, when surfactant is administered in the first minutes of life, the experienced clinician will have ensured that the endotracheal tube tip is truly in the trachea and not in the esophagus. It is equally important that the tube tip is not situated in the right main bronchus. Many endotracheal tubes are designed with a black tip, which, if still partly visible, testifies to the tube tip being in the larynx. When time is not critical, a chest radiograph should be carried out to ascertain that the tube tip position is optimal.

The initial recommendations for positioning during administration of surfactant in order to optimize distribution of surfactant throughout the lung are now often ignored. Survanta, Curosurf, or Infasurf are administered into the endotracheal tube as a liquid in aliquots. An endotracheal tube adaptor with a side hole for instillation obviates the need for disconnecting the infant from the ventilator during surfactant treatment and, in our experience, minimizes the oxygen desaturation sometimes seen with surfactant administration. Surprisingly, bolus administration probably gives better distribution than intratracheal infusions. In animal studies, slow infusions resulted in a non-homogenous distribution pattern (Suresh and Soll, 2001). Walther has found that cerebral blood flow may be altered during surfactant administration probably due to the desaturation episodes with reflex changes in blood pressure (van de Bor, 1991). The goal during administration should be to maintain homeostasis of the infant.

The dosage of surfactant is not well worked out, nor is it known what the dose-response relationships are for infants with RDS of varying degrees of severity. Particularly when surfactant is being instilled in the delivery room, the clinician may not yet know the weight of the infant. Dosages range from 2.5 to 5 mL/kg of body weight and from 50 to 200 mg/kg. Even with use of the smaller volumes, unknown quantities of surfactant may well up through or around the endotracheal tube. These effects can be minimized by two methods: First, while the bolus of surfactant is being instilled, gentle pressure on the cricoid will reduce the amount of surfactant returning around the endotracheal tube. Also, for some of the smallest infants who are unstable, we may give a half-dose, followed by another half-dose 30 minutes later.

Some authorities have suggested the use of surfactant given in the delivery room with immediate extubation, followed by continuous distending airway pressure (i.e., CPAP) administered by nasal prongs in an effort to reduce ventilator damage to the lungs. The decision must be made clinically. For an infant with good respiratory drive and an  $\text{FIO}_2$  of less than 0.30 extubation after surfactant administration is likely to be successful. The early use of nasal CPAP is safe under these circumstances, but it is not yet known whether the combination of prophylactic surfactant and nasal CPAP will reduce the incidence of chronic lung disease (Thomson, 2002).

### Choice of Surfactant: Natural Versus Synthetic Surfactants

Although both synthetic, protein-free surfactants and natural (animal-derived) surfactants have both been shown to

improve outcome, they vary in effectiveness. Natural surfactant has rapid action, and most natural surfactants contain both SP-B and SP-C. Meta-analysis of comparisons in clinical trials shows that natural surfactants are associated with fewer air leaks and improved survival compared with synthetic surfactants (Soll and Blanco, 2001). One study comparing the synthetic surfactant Pumactant with porcine surfactant Curosurf was stopped early because of the lower mortality rate for the infants receiving natural surfactant (Ainsworth et al, 2000). Despite the theoretical advantages of protein-free synthetic surfactants and their relative ease of manufacture with lesser costs, the improved clinical results with natural surfactants have resulted in their largely supplanting the protein-free synthetic surfactants.

### *Comparisons of Natural Surfactants*

Only a few large, well-controlled trials have compared modified natural surfactants. Bloom and colleagues (1997) carried out a prospective, randomized, double-blind, multicenter clinical trial that compared the relative safety and efficacy of Infasurf with Survanta. Thirteen neonatal intensive care units (NICUs) participated. A total of 608 infants with RDS were randomly assigned to receive Infasurf or Survanta in a dose of 100 mg/kg, with an initial dose of 4 mL/kg. Twenty-two percent of the infants who received Infasurf and 33% of those who received Survanta required a fourth dose. The interval between doses was significantly longer for Infasurf. The average fraction of inspired oxygen (FIO<sub>2</sub>) was lower in the infants who received Infasurf during the first 24 hours, by about 5% to 10%. Differences were not apparent after 24 hours. These investigators also evaluated prophylaxis with Survanta versus Infasurf in 374 infants born at 29 weeks of gestation at birth weights of less than 1250 g. In this group of infants, those receiving Infasurf had longer interdose intervals after the second dose compared with those receiving Survanta, but equal numbers of doses of surfactant were administered to both groups of infants. No differences in inspired oxygen concentration or mean airway pressure were noted in the prevention group. The survival rate was higher in the Survanta treatment group by 6%, and the mortality rate for infants with weights of less than 600 g was extremely low (26%) in the Survanta treatment group, compared with 63% in the Infasurf treatment group. The investigators attributed the extremely low mortality rate to chance in the very low-birth-weight group of infants who received Survanta. Infants who received Survanta required more days of ventilation and oxygen support, primarily because of increased survival of those weighing only 600 g at birth. In both the treatment and prophylaxis groups, no significant differences were found for air leaks, complications associated with dosing, complications of prematurity, overall mortality, or survival without chronic lung disease.

A more recent retrospective review of 5169 records of neonates who received either Survanta or Infasurf concluded that there is no difference in mortality rates for infants receiving these two exogenous surfactants, in contrast with the study described before. There also was no difference found in the incidence of necrotizing enterocolitis or intraventricular hemorrhage or in length of hospital stay (Clark et al, 2001).

Speer and colleagues (1995) compared Survanta with Curosurf regimens in a randomized clinical trial. Seventy-five infants (birth weights 700 to 1500 g) with established RDS received an initial dose of Curosurf (200 mg/kg) or Survanta (100 mg/kg). Patients who remained ventilator dependent with an FIO<sub>2</sub> greater than 0.3 received up to two additional doses of Curosurf (each 100 mg/kg) or up to three additional doses of Survanta (each 100 mg/kg). Infants who received Curosurf had increased oxygenation and reduced ventilatory requirements compared with such requirements in infants who received Survanta, for up to 24 hours after initial treatment. The average total dose was 273 mg/kg in the Curosurf treatment group and 218 mg/kg in the Survanta treatment group. Differences in total duration of ventilation and total time of exposure to supplemental oxygen between the two groups were not significant. Although comparing Curosurf at twice the dose of Survanta, this study shows few differences that could be considered clinically significant; however, important differences could be masked by small numbers of enrolled infants.

A recently reported study comparing Curosurf with Survanta showed significantly less oxygen use over 6 days when Curosurf was administered (Ramanathan et al, 2002).

In summary, whereas large clinical differences were found in comparisons of natural with synthetic protein-free surfactants, relatively small differences are found in clinical trials that compare different natural surfactants. Whatever differences are evident may be due either to differences in the infants under study or the surfactants being compared or to the differing dosages. It remains unclear what the optimal concentrations and volumes for surfactant treatment should be. Based on animal experiments, it is probable that higher doses of surfactant will be necessary for lung injuries in which surfactant inactivation plays a role.

Although surfactant may be beneficial for lung diseases other than RDS (see later on), no comparative studies on the use of surfactants for these different diseases have been conducted.

### **Interactions with Steroids**

Corticosteroids given before preterm birth are effective in preventing RDS and neonatal mortality (see also Chapters 42 and 47). The efficacy of neonatal surfactant therapy is enhanced by antenatal exposure to corticosteroids (Jobe et al, 1993).

### **Dosage of Exogenous Surfactant**

Dosages between 50 and 200 mg/kg have been used successfully in animal and human studies, with retreatment occurring up to four times in the first 24 hours. These dosages form the basis for the manufacturers' recommendations for dosage and retreatment. (Repeated doses of surfactant are thought to be useful because they overcome inactivation that may result from soluble proteins and other factors present in the alveoli.) The meta-analysis of studies that compare single with multiple doses shows that repeated doses decrease the risk for pneumothoraces and death. No complications were reported with multiple doses (Suresh and Soll, 2001).

There is reason to follow the manufacturers' recommendations (maximum of four doses of Survanta, given every 6 hours; two of Curosurf, given every 12 hours; and three doses of Infasurf, also given every 12 hours). This phenomenon may be due to alveolar damage and inactivation occurring during the natural course of the disease. If an infant has responded to the first dose and has subsequently deteriorated, a second dose should be seriously considered, even if the recommended time gap has not yet elapsed, and even if the chest radiograph indicates relatively well-expanded lung fields. Usually the most remarkable responses are seen after the first dose. Rarely have we seen dramatic responses after a third or fourth dose.

### Clinical Responses

If extubation of the infant after instillation of exogenous surfactant is not clinically indicated, pediatricians should nevertheless be aware of the rapid improvements in pulmonary compliance that follow a dose of natural surfactant. Within minutes, the requirement for positive pressure and enriched oxygen are much diminished. To avoid damage to the alveoli from barotrauma, positive inspiratory pressures must be rapidly reduced, along with  $\text{FIO}_2$ . A not unusual scenario is the use of 80%  $\text{FIO}_2$  and positive inspiratory pressure (PIP) of 22 cm  $\text{H}_2\text{O}$  for respiratory support of the infant; then, after instillation of a dose of natural surfactant, the improved pulmonary compliance dictates reduction of PIP to 16 cm  $\text{H}_2\text{O}$  and of  $\text{FIO}_2$  to 25%. The data of Fujiwara (1990) and Charon (1989) and their colleagues indicate that about 65% of infants with RDS have a sustained improvement with exogenous surfactant; about 20% have a transient improvement, followed by a relapse requiring further surfactant treatment; and about 15% do not have a significant response (Fig. 46–8). Response to surfactant constitutes an indicator of survival (Hamvas et al, 1993; Kuint et al, 1994). In the case of Survanta, a poor response and the need for a fourth dose have been associated with the development of bronchopulmonary dysplasia.

Possible reasons for a poor response include:

- The patient may not have RDS, and particularly in the near-term infant, SP-B deficiency should be considered (see also Chapter 42).
- The patient may have RDS, but a severe complication in another organ may cause clinical deterioration—in particular, intraventricular hemorrhage.
- The patient may have RDS, but there may be an additional problem in the lung, such as pneumonia, interstitial edema, or pulmonary edema due to patent ductus arteriosus or excessive fluid intake (Hallman et al, 1991). Poor responders, before treatment, may have a higher airway resistance than that in good responders (Wallenbrock et al, 1992). This may reflect the general level of injury and lung edema.
- The RDS may be so severe that the dose is insufficient.
- The ventilation settings may not be optimal.
- The surfactant preparation may not be optimal.
- Surfactant activity may have been inhibited by plasma proteins and other serum or airway (meconium) substances.

Among infants with a clinical diagnosis of RDS, some may be found to have high levels of static respiratory compliance incompatible with a diagnosis of surfactant

deficiency. A majority of such infants will respond poorly to treatment with exogenous surfactant (Stenson et al, 1994). Nevertheless, static respiratory compliance measurement has not lent itself to routine use in NICUs.

### Monitoring

During administration of the exogenous surfactant, heart rate, color, chest expansion, oximeter and endotracheal tube patency have to be monitored. If surfactant is being administered by infusion and the heart rate slows down or oxygen saturation falls more than 15%, dosing should be slowed down or stopped. The child should be carefully evaluated clinically to establish the cause of the deterioration. Pulmonary hemorrhage is a rare complication of surfactant administration. If chest expansion improves substantially after dosing, peak ventilator inspiratory pressures should be reduced immediately. Failure or delay to reduce pressures can result in lung overdistention and pulmonary air leak. The clinician must be in constant attendance of the child during the first 30 minutes, to compensate for the acute changes in compliance.

Although the incidence of patent ductus arteriosus may not increase after surfactant treatment, we have the strong clinical impression that the time of onset of left-to-right shunting may be affected—that is, the onset of manifestations of a clinically significant PDA may occur within 36 hours of birth, as pulmonary vascular resistance decreases sooner. In our experience, some infants have evidence of large left-to-right shunts at 12 to 18 hours of age after surfactant treatment, which may be a factor predisposing to intraventricular hemorrhage.

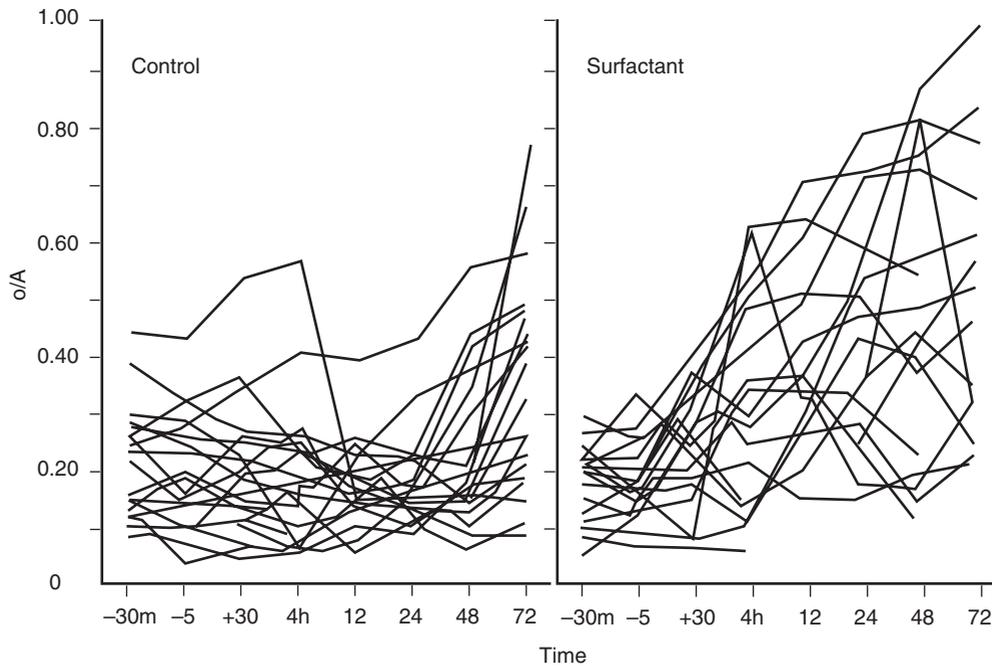

The most commonly experienced adverse effects of surfactant administration are cardiorespiratory or mechanical. In some infants, acute bradycardia or even cardiac arrest develops. Sometimes the endotracheal tube will become blocked with surfactant, and occasionally it is necessary to clear such a blockage urgently, or even to change the endotracheal tube. Intubation of the right main bronchus can result in delivery of the surfactant to the right side only, and this can cause overexpansion of the right lung and atelectasis of the left lung.

Surfactant instillation can cause transient suppression of the electroencephalogram (Lundstrom and Greisen, 1996). The cause of this suppression is not known, nor has it been linked to a long-term detrimental outcome.

No other significant toxicity has been documented. Concern has existed whether sensitivity to bovine surfactant and serum proteins would occur. No problems in this regard have been reported, and Chida and colleagues (1988) have indicated that surfactant treatment may actually suppress formation of autoantibody to surfactant proteins by reducing the alveolar-capillary leaks associated with lung damage incurred by the disease process and its treatment (e.g., barotrauma).

### Long-Term Outcome

Although surfactant has reduced significantly the mortality rate for preterm infants, there is no good evidence that the incidence of chronic lung disease has diminished significantly. The explanation for this lack of improvement in

**FIGURE 46-8.** Sequential arterial-to-alveolar ratios are plotted against time for control infants or infants treated with surfactant. Variability is marked for both groups, but improvement from 4 to 48 hours after treatment is apparent in the group receiving surfactant. Arterial-alveolar ratios of more than 0.8 are expected for infants with normal lung function. The scale on the abscissa is non-linear (-30 m, -5, +30 indicate minutes before and after treatment). (Redrawn from Chida S, Phelps DS, et al: *Surfactant-associated proteins in tracheal aspirates of infants with respiratory distress syndrome after exogenous surfactant therapy.* *Am Rev Resp Dis* 137:943, 1988.)

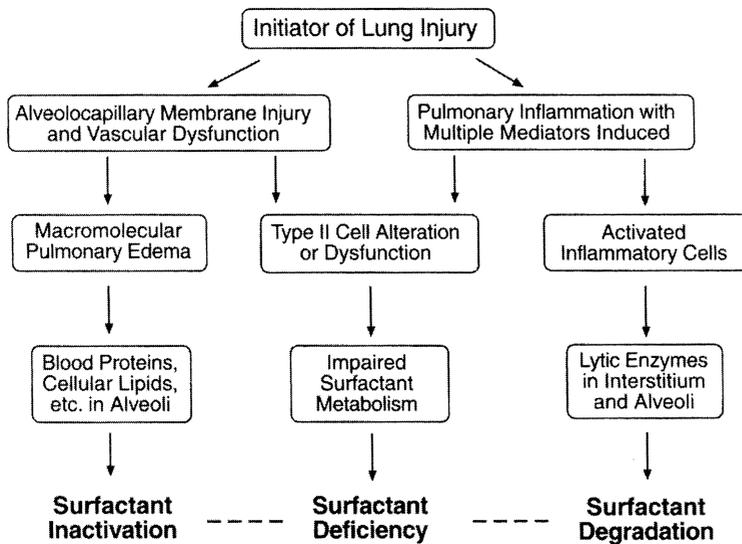

outcomes in these children may be due to the effect of surfactant itself. With exogenous surfactant therapy and prenatal steroids, smaller infants survive, and the pathogenesis of bronchopulmonary dysplasia may have changed from barotrauma and toxicity lesions to an inflammatory response due to prolonged ventilation and infection. However, the more severe cases have become less common (Bancalari and del Moral, 2001).

#### Surfactant Use in Diseases Other than Respiratory Distress Syndrome

Many neonatal pulmonary conditions including RDS have an element of surfactant inactivation from leakage of plasma across damaged endothelial and epithelial membranes into alveoli (Landmann et al, 2002). The rationale for the use of surfactant for conditions other than RDS is that inactivation (usually by leakage of serum constituents into alveoli) may be reversed to some degree by surfactant treatment. Obviously, surfactant inactivation and surfactant insufficiency may be superimposed in some infants with RDS, such as those with severe birth asphyxia. Some clinical data suggest that surfactant is useful in infants with pneumonia, diaphragmatic hernia with lung hypoplasia, meconium aspiration, and ARDS and in some infants who require extracorporeal membrane oxygenation (ECMO) (Fig. 46-9). Infants and children with acute lung injuries, pulmonary hemorrhage, bronchiolitis, chronic bronchitis, asthma, and lung transplantation may eventually be candidates for therapy with newer surfactants.

If meconium constituents reach alveoli, surfactant can be inactivated. Meconium has a dose-dependent effect on surfactant that can be overcome by high doses of surfactant. Several reports have now shown that replacement surfactant has a role in the treatment of meconium aspiration syndrome, limiting disease severity and reducing the need for extracorporeal membrane oxygenation (Findlay et al, 1996; Halliday et al, 1996; Soll and Dargaville, 2002). It is not yet clear whether surfactant lavage provides any clinical benefit over surfactant instillation, although in preliminary work, Wiswell and colleagues (2002) found that lung lavage with fluid containing surfactant improves outcomes. Herting and colleagues (2000) conducted a study to evaluate surfactant effectiveness in neonates with respiratory failure and group B streptococcal (GBS) infection. They concluded that surfactant therapy improves gas exchange in a majority of patients with GBS pneumonia. The response is slower than in the treated patients with RDS, and repeated doses are often required. Surfactant therapy has a place in the management of respiratory failure in term infants even in the absence of known meconium aspiration syndrome or pneumonia (Lotze et al, 1998).

Other conditions suggested as indications for surfactant use include congenital diaphragmatic hernia, respiratory syncytial virus pneumonia, pulmonary hemorrhage, bronchopulmonary dysplasia, bronchiolitis, asthma, and adult (acute) RDS (Curley and Halliday, 2001; Wiswell, 2001).

**FIGURE 46-9.** Schematic representation of surfactant-related events in acute respiratory distress syndrome (ARDS)-related lung injury. As part of the pathophysiology of acute lung injury (ALI) and ARDS, surfactant can be inactivated by biophysical interactions with inhibitory compounds present in the lungs through edema and inflammation. Active surfactant components also can be degraded or altered chemically, and surfactant can become deficient due to type II cell injury or alteration. Surfactant dysfunction/deficiency can also result from depletion or alteration of active large surfactant aggregate subtypes. Not shown are the multiple aspects of inflammatory lung injury unrelated to lung surfactant that also contribute to ARDS. (From Notter R: *Lung Surfactants: Basic Science and Clinical Applications*. New York, Marcel Dekker, 2000, p 246.)

### NEW APPROACHES

After all the clinical and laboratory-based evidence in favor of the use of surfactant, a reasonable question is whether this therapy is good enough. Because the most commonly used surfactants are derived from lung lavage or minced lung of animals, we remain in an era not dissimilar from the times when ground thyroid or animal-derived insulins were used for replacement therapy. Batch-to-batch variation, requirement for intratracheal administration, possible inclusion of unknown impurities, the remote possibility of transmission of infectious agents, the theoretical possibility of immunologic consequences, the susceptibility to inactivation, and, finally, cost per dose (about \$400/vial, with 1 or 2 vials required per newborn) all are reasons to seek to improve what is already extraordinarily beneficial.

Theoretically, administration of surfactant by aerosolization should be less of a physical challenge to the infant. Unfortunately, only small amounts of aerosolized surfactant are successfully delivered to the lung, and its use in combination with CPAP has shown no clear clinical benefits to surfactant administration via the trachea (Berggren et al, 2000).

Much current work is aimed at developing synthetic or partially synthetic surfactants using modified lipids or surfactant proteins that are synthesized or made by recombinant DNA technology—or by including organic polymers that mimic some of the activities of the surfactant proteins (Taeusch and Keough, 2001). Surfactants containing analogues of SP-C or SP-B show promise (Hafner et al, 1999; Palmblad et al, 2001; Walther, 2000).

## Respiratory Distress in the Preterm Infant

Stephen Welty, Thomas N. Hansen, and Anthony Corbet

### RESPIRATORY DISTRESS SYNDROME

Respiratory distress syndrome (RDS), previously referred to as *hyaline membrane disease* (HMD), occurs after the onset of breathing in infants with insufficiency of the pulmonary surfactant system.

#### Epidemiology

An estimated 40,000 cases of RDS occur annually in the United States (Farrell and Wood, 1976), affecting about 14% of all low-birth-weight infants (Farrell and Avery, 1975). The incidence is 60% at 29 weeks of gestation but declines with maturation to near zero by 39 weeks (Usher et al, 1971). The condition is more common in male than in female infants (Miller and Futrakul, 1968) and is more common in white than in nonwhite infants (Richardson and Torday, 1994); at each level of gestational age, RDS is less common in black infants, and this phenomenon is not explained by other factors that may influence lung maturity (Hulsey et al, 1993). At any given gestational age, the incidence is higher for infants born by cesarean section without labor than for those born by vaginal delivery (Fedrick and Butler, 1972); there is a significantly increased risk if elective cesarean section is performed before completion of 39 weeks of gestation (Morrison et al, 1995).

When the occurrence of RDS is corrected for the important effect of gestational age, the occurrence of RDS is significantly increased in gestational diabetes and in insulin-dependent mothers without vascular disease (Robert et al, 1976). Most such infants of diabetic mothers are large for gestational age, and similar overnourished infants in the absence of maternal diabetes also are at increased risk (Naeye et al, 1974). Evidence suggests that the incidence of RDS in infants of diabetic mothers is now much less, almost certainly because of improved medical control of diabetes (Kjos et al, 1990).

Early reports in comparatively large infants suggested that the risk is decreased in infants who are small for gestational age (Gluck and Kulovich, 1973). In the much less mature infants seen more recently, however, comparisons of appropriate (weight)-for-gestational-age (AGA) and small-for-gestational-age (SGA) infants, both weight-matched and gestation-matched, suggest that immature

SGA infants do not have this advantage (Pena et al, 1988). In fact, there is some evidence that the risk of RDS at constant gestational age may be increased in SGA infants, that the mortality rate may be higher (Lemons et al, 2001; Thompson et al, 1992; Tyson et al, 1995), and that the development of bronchopulmonary dysplasia (BPD) is more likely. Maternal conditions that compromise fetal growth also may be associated with decreased risk, including pregnancy-induced hypertension (Yoon et al, 1980), chronic hypertension, subacute placental abruption, narcotic addiction (Glass et al, 1971), and maternal smoking. More recently, Tubman and colleagues (1991) found an increased risk for RDS in infants of hypertensive mothers; this was because of the high incidence of cesarean section delivery without benefit of labor. There is some evidence that the incidence of RDS may be reduced in infants of cocaine-addicted mothers (Zuckerman et al, 1991).

There has been controversy about whether prolonged rupture of membranes may protect against RDS (Jones et al, 1975). A more recent stepwise discriminant analysis suggested that when gestational age is carefully controlled, pulmonary maturation continues but is not accelerated after premature rupture of the membranes (PROM). In fact, there is a strong suggestion that PROM actually increases the risk of RDS at a given gestational age (Hallak and Bottoms, 1993). Suggestions that birth asphyxia predisposes infants to RDS (Table 47-1) are based on lower Apgar scores in human infants with RDS (James, 1975) and some experimental evidence in lambs (Orzalezi et al, 1965). In an examination of umbilical artery blood at birth, however, it was found that infants with RDS are not more acidemic at birth (Kenny et al, 1976), and that lower Apgar scores associated with RDS are better explained by relative immaturity and defective lung function. Other studies have confirmed that infants with RDS are not more acidemic at birth (Hibbard et al, 1991; Tejani and Verma, 1989). Furthermore, in a study of premature twins, although second-born twins had a higher incidence of RDS than first-born twins, as reported previously, and had much lower Apgar scores, there was no evidence for increased acidemia in cord blood samples of either all second-born twins or all second-born twins with RDS (Kenny et al, 1977).

#### Pathology

The gross findings at autopsy include diffuse lung atelectasis, congestion, and edema; if the lungs are inflated at postmortem examination, distensibility is found to be greatly reduced, and the lungs collapse more readily with deflation (Gribetz et al, 1959). On histologic examination, the peripheral air spaces are collapsed, but more proximal respiratory bronchioles, lined with necrotic epithelium and hyaline membranes, have an overdistended appearance (Finlay-Jones et al, 1974) (Figs. 47-1 and 47-2). There is obvious pulmonary edema with congested capillaries, and the lymphatic and interstitial spaces are distended with fluid. The epithelial damage appears within 30 minutes of the onset of breathing; the hyaline membranes, composed of plasma exudation products and associated with damaged

TABLE 47-1

**Respiratory Distress Syndrome****Epidemiology**

Worldwide  
 Prematurity predisposes  
 Cesarean section without labor predisposes  
 Perinatal asphyxia predisposes  
 Male > female  
 White > black  
 Second-born twin at greater risk  
 PROM spares  
 IUGR spares  
 Maternal stress spares  
 Maternal diabetes predisposes if < 37 weeks  
 Maternal hemorrhage predisposes

**Clinical Signs**

Onset near the time of birth  
 Retractions and tachypnea  
 Expiratory grunt  
 Cyanosis  
 Systemic hypotension  
 Characteristic chest film  
 Course to death or improvement in 3 to 5 days  
 Fine inspiratory rales  
 Hypothermia  
 Peripheral edema  
 Pulmonary edema

**Pathophysiology**

Reduced lung compliance  
 Reduced FRC  
 Poor lung distensibility  
 Poor alveolar stability  
 Right-to-left shunts  
 Reduced effective pulmonary blood flow  
 If hypotensive and hypoxic, poor peripheral perfusion, poor renal perfusion, myocardial malfunction  
 Patent ductus arteriosus contributes

**Pathobiochemistry**

Respiratory acidosis  
 Decreased saturated phospholipids  
 Low AF L/S ratio  
 Low surfactant-associated proteins  
 Decreased total serum proteins  
 Decreased fibrinolysis  
 Low thyroxine levels

**Pathology**

Atelectasis  
 Injury to epithelial cells, edema  
 Membrane contains fibrin and cellular products  
 No tubular myelin  
 Osmiophilic lamellar bodies decreased early, increased later

**Etiology**

Surfactant deficiency during disease  
 Probable inadequate hormonal (corticoid) stimulus in utero  
 DPL synthesis impaired and/or destruction increased  
 Autonomic dysfunction

**Prevention**

Prenatal glucocorticoids for >24 hours  
 Surfactant replacement before 1–2 hours

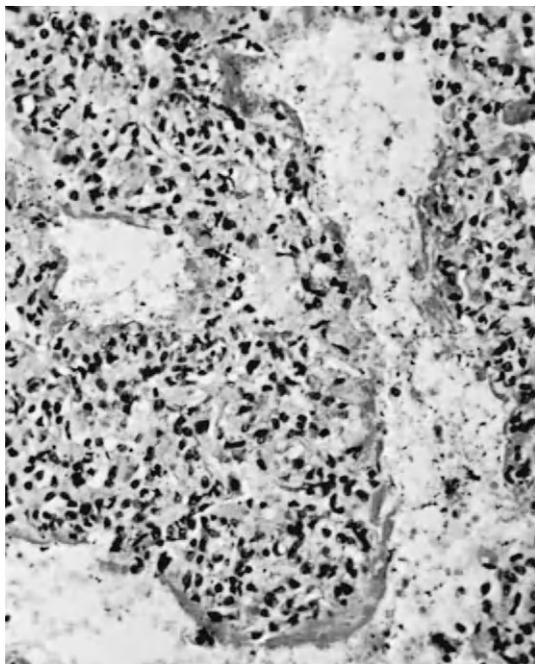

AF, amniotic fluid; DPL, dipalmitoyl lecithin; FRC, functional residual capacity; IUGR, intrauterine growth retardation/restriction; L/S, lecithin/sphingomyelin; PROM, prolonged rupture of membranes (>16 hours).

capillaries, appear within 3 hours of birth (Gandy et al, 1970). In experimental animals, the bronchiolar lesions may be completely prevented (Nilsson et al, 1978), and the leakage of protein may be considerably reduced (Ikegami et al, 1992), by the administration of exogenous surfactant at birth. This finding indicates that the bronchiolar lesions are secondary to atelectasis in terminal air spaces and to disruptive overdistention of more proximal airways. Pulmonary edema is a common finding in infants with RDS and probably represents an acute inflammatory process. Studies in premature lambs demonstrate that there is a marked accumulation of neutrophils within the air spaces and capillaries within 2 hours of delivery and stabilization, which is associated with permeability pulmonary edema (Bland et al, 2000), and that neutrophil depletion totally abrogates the development of pulmonary edema. There is indirect evidence that neutrophils play a role in lung injury in infants with RDS. Circulating neu-

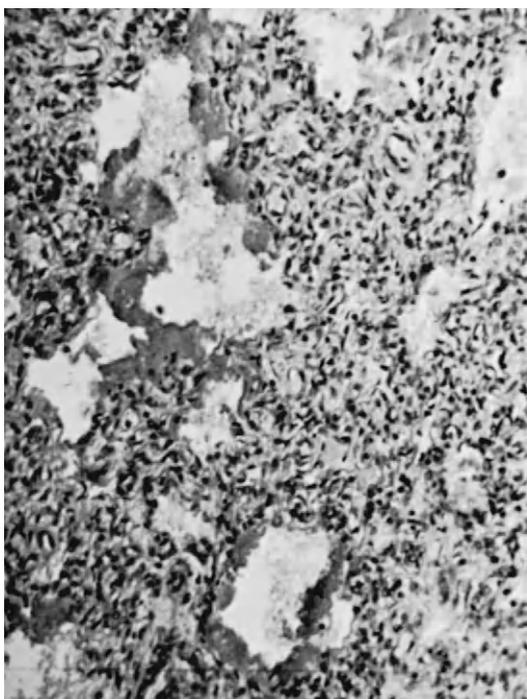

trophil counts are lower in infants with RDS than in infants without RDS, and the neutrophil count is inversely correlated with the severity of RDS (Brus et al, 1997). Circulating neutrophils from infants with RDS have more activation markers on their surface than are seen in neutrophils from infants without RDS (Nupponen et al, 2002), and neutrophil oxidation products are much higher in tracheal aspirates from infants with RDS than in those from infants without RDS (Buss et al, 2003). These findings indicate that neutrophil activation is a prominent feature in RDS, which then leads to vascular injury and subsequent pulmonary edema observed histologically.

**Pathophysiology**

In RDS the respiratory rate is elevated, so despite a reduction in each tidal volume, the minute ventilation initially is increased. The functional residual capacity (FRC), analyzed by nitrogen washout, is reduced: the greater the

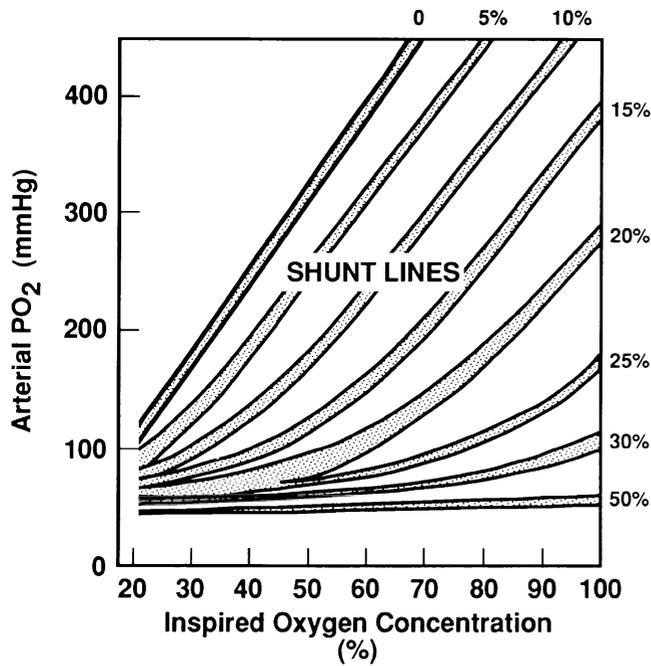

**FIGURE 47-1.** Photomicrograph of a section of lung of an infant born at 32 weeks of gestation and weighing 1640 g. He seemed well for 1 hour; then dyspnea appeared and gradually increased with deepening sternal and costal retractions. He died at 22 hours of age. Unexpanded lung, with dilated air spaces lined with thick, homogeneously staining membrane, can be seen.

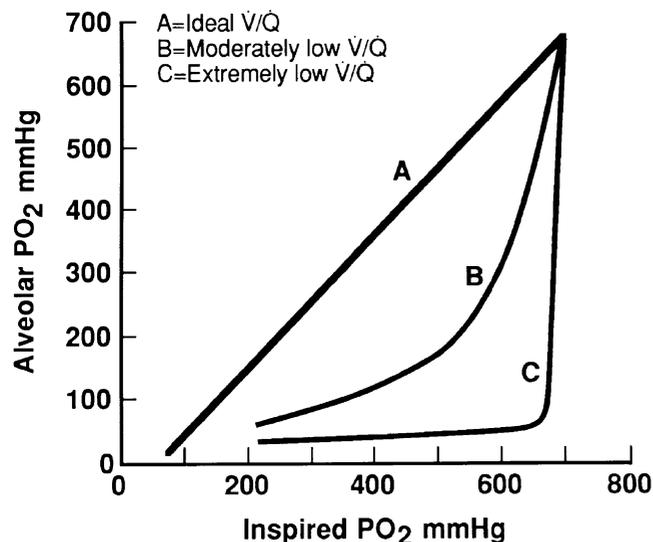

**FIGURE 47-2.** Photomicrograph of a section of lung of a premature infant weighing 2270 g at birth whose dyspnea was first noticed at 8 hours and who died after steadily increasing respiratory difficulty at 27 hours of age. The appearance of the section of lung is in all respects similar to that in Figure 47-1. The pattern of aeration and atelectasis has been described as Swiss cheese-like, in contrast with lace-like aeration.

need for oxygen, the smaller the measured value for FRC (Richardson et al, 1986). In keeping with the reduced static lung compliance found at autopsy (Gribetz et al, 1959), the static lung compliance measured by multiple airway occlusions during exhalation also is markedly reduced, the average value being only 0.5 mL/cm H<sub>2</sub>O/kg (Dreizen et al, 1988). As a result, the work of breathing is greatly increased. Measurements of airway resistance suggest values in the normal range, but there is a tendency toward an increase. In one study, the average value was 69 cm H<sub>2</sub>O/L/second, compared with a reference value of 42 cm H<sub>2</sub>O/L/second (Hjalmarson and Olsson, 1974). More recently, Edberg (1991) found decreased compliance, increased resistance, decreased lung volume, and reduced gas mixing efficiency in very low-birth-weight (VLBW) infants with RDS. From these data, it can be approximated that the overall time constant in RDS would be less than 0.05 seconds (see Chapter 44 on pulmonary physiology). Because the patency of small peripheral airways depends on proximal spread of surfactant (Macklem et al, 1970), in some regions of lung the local time constants may be more prolonged. The curvature of nitrogen washout traces is better represented by a two-space mathematical model than by a one-space assumption (Richardson and Jung, 1978). The postulated “slow” space may represent those parts of the lung with more prolonged time constants. Passive-exhalation flow-volume plots obtained in preterm lambs with HMD also exhibit curvature, suggesting the presence of both fast and slow spaces in the lung (Richardson et al, 1989). Mathematical modeling of these plots suggests that airway resistance in the slow space is significantly increased. Finally, clamping and unclamping of the airway of these lambs during passive exhalation reveal the presence of pendelluft, further suggesting that measurements of lung mechanics are time dependent and that a significant slow space exists (Richardson et al, 1992).

The alveolar-arterial oxygen tension difference (Aa.DO<sub>2</sub>) and right-to-left shunt during breathing of 100% oxygen are greatly increased, many infants having values for shunt in the range of 50% to 90% of cardiac output (Strang and MacLeish, 1961). As there is no evidence for a diffusion limitation (Krauss et al, 1976), it is commonly stated that large shunts at the foramen ovale and ductus arteriosus and in atelectatic lung constitute the only cause of severe hypoxemia in HMD. If this were true and the shunt was 50%, it can be seen from Figure 47-3 that changing inspired oxygen would have little effect on arterial oxygen pressure, and oxygen therapy would be relatively ineffective. In fact, precipitous changes in arterial oxygen tension and calculated venous admixture occur if inspired oxygen is reduced. This effect indicates the presence of an open, poorly ventilated lung compartment with extremely low ventilation-perfusion ratio ( $\dot{V}/\dot{Q}$ ), representing a significant proportion of the lung and producing variable hypoxic vasoconstriction and alterations in right-to-left shunt as the inspired oxygen changes (Corbet et al, 1974). Therefore, in infants with RDS the severity of arterial hypoxemia is directly related to the size of the open, poorly ventilated compartment. The relationship among  $\dot{V}/\dot{Q}$ , alveolar oxygen tension, and changing inspired oxygen (Fig. 47-4) indicates how oxygen concentration as high as 90% is required before the oxygen pressure in very low

**FIGURE 47-3.** The relationship between inspired oxygen concentration and arterial oxygen tension as it is affected by true right to left shunting. The assumptions are a hemoglobin of 10 to 14 g/dL; arterial  $PCO_2$  of 25 to 40 mm Hg; and arterial-mixed venous oxygen tension difference ( $\bar{a}\bar{v}.DO_2$ ) of 5 mL/100 cc. (From Benatar SR, Hewlett AM, Nunn JF: *The use of iso-shunt lines for control of oxygen therapy. Br J Anaesthesiol* 45:711, 1973.)

**FIGURE 47-4.** The relationship between inspired  $PO_2$  and alveolar  $PO_2$ . In an open lung compartment with extremely low ventilation-perfusion ratio ( $\dot{V}/\dot{Q}$ ), the alveolar  $PO_2$  rises very slowly until greater than 90% oxygen is reached, when it rises rapidly. This phenomenon accounts for the often dramatic changes in arterial  $PO_2$  with small changes in inspired  $O_2$ , especially reductions of inspired  $O_2$ , seen in patients with respiratory distress syndrome. (From West JB: *Ventilation-perfusion inequality and overall gas exchange in computer models of the lung. Respir Physiol* 7:88, 1969.)

$\dot{V}/\dot{Q}$  units will rise significantly (West, 1969). (See also Chapter 44.) Because perfusion of the open, extremely low  $\dot{V}/\dot{Q}$  compartment is greatly reduced by hypoxic vasoconstriction, it makes only a small contribution to cardiac output, and measurements of arterial-alveolar partial pressure difference for nitrogen ( $aA.DN_2$ ) are not greatly increased in HMD (Corbet et al, 1974). It should not be overlooked that this lung compartment makes a significant contribution to the oxygenation defect in HMD.

Measurements of the arterial-alveolar tension difference for carbon dioxide ( $aA.DCO_2$ ) and alveolar dead space ( $VD$ ) are markedly increased in HMD (Nelson et al, 1962). Although minute ventilation is increased, the alveolar ventilation is actually decreased, as reflected by the elevated values for arterial  $CO_2$  tension. Because a large part of the lung is collapsed or poorly ventilated, most alveolar ventilation is diverted to a relatively small part of the lung, represented by the reduced FRC. Because this compartment is small, it is relatively overventilated, so the  $\dot{V}/\dot{Q}$  and the measured  $aA.DCO_2$  are high (Hansen et al, 1979). Measurements of pulmonary blood flow, utilizing the disappearance of gases that enter ventilated parts of the lung, confirm that perfusion of ventilated lung is very low (Chu et al, 1967). Based on the foregoing considerations, an idealized model of the lung in RDS is shown in Figure 47-5, representing the three lung compartments: shunt, open low  $\dot{V}/\dot{Q}$ , and high  $\dot{V}/\dot{Q}$ . Under conditions of changed inspired oxygen and and changed levels of CPAP, there is a close correspondence between predicted and measured values for  $aA.DCO_2$ , suggesting the validity of this model (Hansen et al, 1979; Landers et al, 1986).

In infants with RDS undergoing treatment in a neonatal intensive care unit (NICU), the pulmonary artery pressure declines more slowly after birth than in preterm infants without RDS (Seppanen et al, 1994). The systemic arterial pressure is maintained similar to that in controls and tends to rise slowly with time; by 24 hours the systemic

	$\dot{V}/\dot{Q} > 1$	$\dot{V}/\dot{Q} < < 1$	$\dot{V}/\dot{Q} = 0$
Ventilation	0.999	0.001	0.000
Perfusion	0.330	0.030	0.640
	$V/Q=3$	$Q_o/Q_t$	$Q_s/Q_t$

**FIGURE 47-5.** Three-compartment model of hyaline membrane disease (high  $\dot{V}/\dot{Q}$ , open low  $\dot{V}/\dot{Q}$ , and shunt; the shunt includes shunt at the ductus, at the foramen, and at collapsed air spaces). The high  $\dot{V}/\dot{Q}$  compartment receives nearly all the ventilation. From the measured value for arterial  $PO_2$ , the calculated venous admixture is 0.67 of cardiac output. Thus, perfusion of the high  $\dot{V}/\dot{Q}$  compartment is 0.33 of cardiac output, and the value for  $V/Q$  is 3. From the latter value, a predicted value for the arterial-alveolar carbon dioxide tension difference ( $aA.DCO_2$ ) can be calculated and compared with the measured value. If a value of 0.03 is assumed for the fraction of blood flowing past "open" but very poorly ventilated lung units ( $Q_o/Q_t$ ), then the calculated value for the shunt fraction ( $Q_s/Q_t$ ) is 0.64. (From Hansen TN, Corbet AJS, Kenny JD, et al: *Effects of oxygen and constant positive pressure breathing on  $aA.DCO_2$  in hyaline membrane disease. Pediatr Res* 13:1167, 1979.)

arterial pressure is well above the pulmonary artery pressure. Extrapulmonary right-to-left shunting at the foramen ovale or the ductus arteriosus disappears by 24 hours (Seppanen et al, 1994), and left-to-right shunting at the ductus arteriosus is very common by age 24 hours (Dudell and Gersony, 1984). In experimental animals, it is not thought that this early left-to-right ductal shunt makes an important contribution to the overall lung dysfunction of RDS (Morrow et al, 1995), but as the pulmonary artery pressure continues to fall with time, the ductal shunt assumes a much greater importance. In preterm infants without RDS, the ductus arteriosus tends to close within 4 days of birth (Reller et al, 1988), whereas in those with RDS, the ductus tends to remain open (Reller et al, 1993), which may become a significant problem by 3 to 4 days of age (Corbet, 1996).

## Diagnosis

### Clinical Diagnosis

The infant with RDS untreated with surfactant replacement or end-expiratory pressure is almost always premature and is cyanotic in room air. Beginning at or immediately after birth, breathing is rapid or labored. Infants usually have a characteristic grunt during expiration, caused by closure of the glottis, the effect of which is to maintain lung volume and gas exchange during exhalation. Frequently, the unventilated infant requires 40% to 50% oxygen after birth for relief of central cyanosis but then develops an increasing oxygen requirement over 24 to 48 hours; this may reach as high as 100%. In other infants, the oxygen requirement transiently decreases as acidosis or hypothermia is corrected or fetal lung fluid is cleared; the oxygen requirement begins to increase only after 3 to 6 hours. More severely affected infants have an immediate high oxygen requirement that increases rapidly to 100%; without surfactant and mechanical ventilation, they may die within 24 hours. Another group of larger infants needs less oxygen initially and manifests a slowly progressive course of generalized atelectasis over 48 to 72 hours. The urine output is low for the first 24 to 48 hours, but soon thereafter, a diuresis ensues. If RDS is uncomplicated, recovery starts after 48 hours. The decline in oxygen requirement is relatively rapid after 72 hours, and usually oxygen can be discontinued after 1 week. The VLBW infant (less than 1500 g) usually will require mechanical ventilation and have a more prolonged course. A few infants with RDS also appear to have a contribution from pulmonary hypertension; they are easy to ventilate, especially after exogenous surfactant, but are difficult to oxygenate, and they have severe pulmonary hypertension as evaluated by echocardiographic criteria (Abman et al, 1993; Golan et al, 1995; Walther et al, 1985). Administration of exogenous surfactant has dramatically reduced the incidence and severity of RDS.

### Laboratory Diagnosis

Based on arterial blood gas values, infants with untreated RDS have a moderate to severe oxygenation defect, significant hypercarbia, and a mild metabolic acidosis with elevation of blood lactate (Sinclair, 1973). The lecithin-sphingomyelin (L/S) ratio and phosphatidylglycerol (PG) level remain low in serial tracheal aspirate samples for

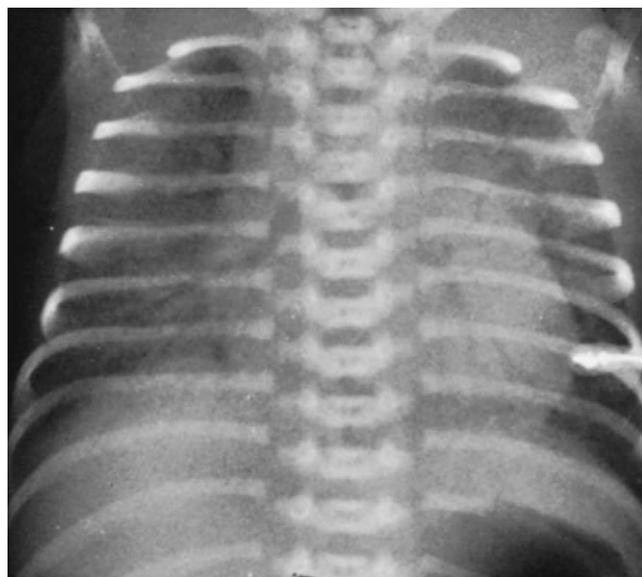

48 hours and then increase with recovery; the saturated phosphatidylcholine (SP-C) levels remain low in RDS and reach normal levels after 4 to 7 days; the surfactant protein A (SP-A)-to-SP-C ratio is low in RDS. (See Chapter 42 on lung development and Chapter 46 on surfactant.)

### Radiographic Diagnosis

Diffuse, fine granular densities that develop during the first 6 hours of life are seen on the chest radiograph (Fig. 47-6); occurrence of these densities is influenced by size of the infant, severity of disease, treatment with surfactant, and degree of ventilatory support. The densities may be more pronounced at the lung bases than at the apices. The lung volume may appear normal early, especially if the infant is strong enough to overdistend less affected regions, but ultimately the lung volume is decreased. Positive airway pressure frequently obliterates these diagnostic findings. Other conditions such as pneumonia or pulmonary edema may have very similar radiographic features.

### Etiology

RDS is primarily a developmental deficiency in the amount of surface-active material at the air-liquid interface of the lung, as demonstrated by pressure-volume curves with air and saline in infants who died from RDS (Avery and Fletcher, 1974). Saline extracts of minced lung from infants who died from RDS have higher surface tensions than those in lungs of controls (Avery and Mead, 1959); this finding is associated with lower levels of total tissue phospholipid (Brumley et al, 1967) and SP-C (Adams et al, 1970). Although on the basis of theoretical considerations of the amount required, a more than adequate amount of phospholipid evidently is present in total lung (Clements and Tooley, 1977), only a small proportion of lung phospholipid is surface-active material (Rieutort et al, 1986).

**FIGURE 47-6.** Typical chest radiograph of an infant with hyaline membrane disease.

Infants with RDS may synthesize adequate amounts of SP-C but cannot package and export it to the alveolar surface in a way that makes it function as surfactant. In infants who die, deMello and colleagues (1987) have demonstrated the complete absence of tubular myelin and a modest deficiency of lamellar bodies in type II cells, in comparison with controls. For further discussion of the role of surfactant proteins in RDS, see Chapter 42 on lung development and Chapter 46 on surfactant.

It has been suggested that surfactant function in infants with RDS is inhibited by plasma proteins (Ikegami et al, 1986), which leak into the respiratory bronchioles at the sites of overdistention and epithelial damage. In particular, a plasma protein of relative molecular weight 110,000 has been implicated. Fibrinogen, hemoglobin, and albumin are potent inhibitors of surfactant (Seeger et al, 1993). It is of critical importance for the lungs to have adequate surfactant at the gas-liquid interface from the earliest possible moment after birth; otherwise, acute lung injury and surfactant inhibition will supervene rapidly, contributing to a cycle of worsening disease (Nilsson et al, 1978). Thus, RDS is due to a developmental deficiency of surfactant at birth, but associated lung injury results in surfactant dysfunction as well.

Based on the results of animal experiments, it is estimated that the air spaces of the newborn infant at term contain about 75 mg/kg of SP-C; this compares with only 10 to 15 mg/kg in adults and only 1 to 10 mg/kg in premature infants with RDS (Ikegami et al, 1993). Aside from lower surfactant content, the surfactant from premature infants has decreased biophysical function and is more susceptible to inactivation than surfactant from adults, presumably because it contains lower amounts of surfactant proteins (Ueda et al, 1994). The pool size of alveolar surfactant in recovering premature infants has not been determined but has been measured in preterm monkeys recovering from RDS, in which the pool size increased to 100 mg/kg within 3 to 4 days of birth (Jackson et al, 1986). Dipalmitoyl phosphatidylcholine (DPPC) concentrations in tracheal aspirate samples increase in premature infants recovering from RDS (Hallman et al, 1976). These findings indicate that as premature infants recover from RDS, the alveolar pool size approaches that in the term infant. The evidence suggests that newborn infants need more surfactant than that required in adults for adequate function, which may mean that in the neonatal lung, more surfactant is present in an inactive or catabolic form and that more surfactant is inhibited by excessive fluid and protein. (See also Chapter 46 on surfactant.)

### Prevention

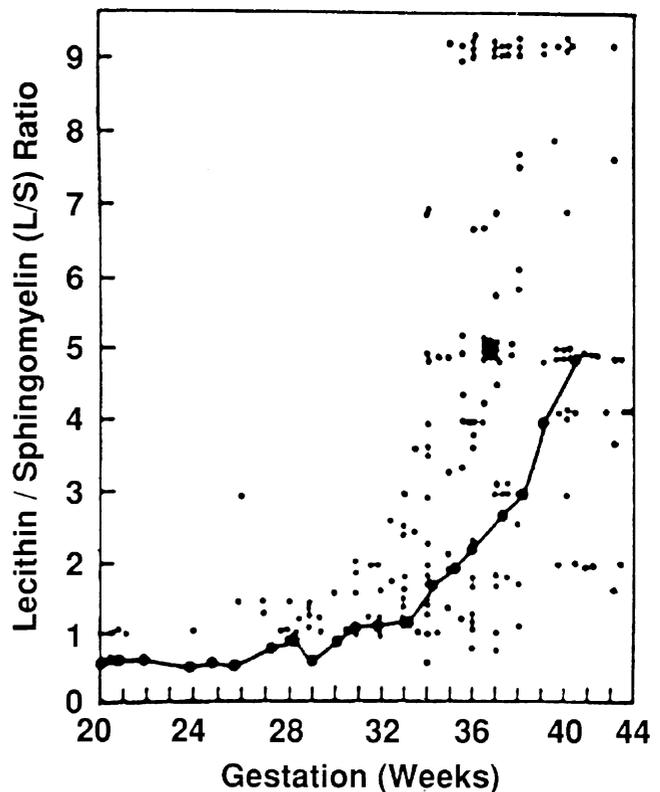

Because RDS is a problem of insufficient lung maturity, the best way to prevent it would be to prevent premature birth; for this purpose, the effective strategies are thought to be cervical cerclage, discovery and treatment of bacterial infections, and the liberal use of tocolytics (Joint Working Party, 1992). At present, however, the two major approaches to the problem are (1) prediction of the risk for RDS by antenatal testing of amniotic fluid samples and (2) antenatal treatment of women in preterm labor with glucocorticoid hormones to accelerate fetal lung maturation. In addition, the prophylactic administration of exogenous surfactant at

birth is designed to prevent RDS, and this strategy has been successful, especially with the use of mammalian surfactants (see Chapter 46.)

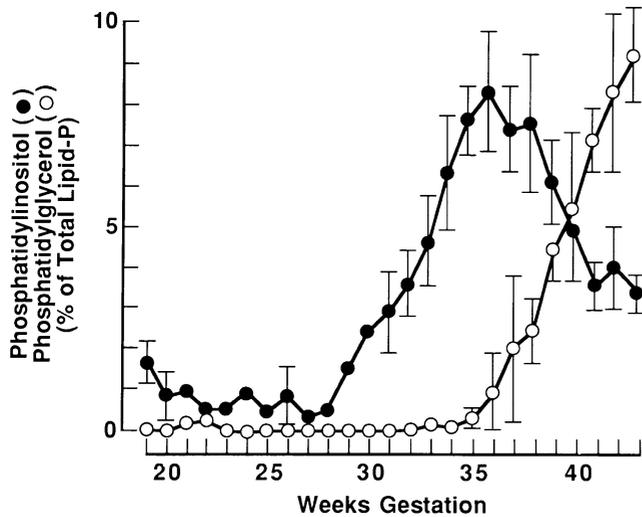

### Prenatal Prediction

In normal pregnancy, the L/S ratio displays a remarkably stable pattern, increasing slowly to a value of 1 at 32 weeks, rising more rapidly to 2 at 35 weeks, and accelerating very rapidly thereafter (Gluck and Kulovich, 1973) (Fig. 47-7). In an abnormal pregnancy, there is a much wider scatter of values, reflecting conditions that accelerate or decelerate lung maturation. The ratio may reach 2 as early as 28 weeks or remain at 1 until close to term. The incidence of RDS is only 0.5% for an L/S ratio of 2 or more but 100% for an L/S ratio below 1; between 1 and 2, the risk of RDS decreases progressively. The L/S ratio reflects the secretory activity of the lung, which is greatly accelerated at 35 weeks. Elective cesarean section delivery of infants who have an unrecognized low L/S ratio carries an unnecessary risk of RDS (Hack et al, 1976).

Phosphatidylinositol (PI) in amniotic fluid progressively increases until 36 weeks and then decreases (Hallman et al, 1976). At about this time, PG appears and increases until term (Fig. 47-8). The appearance time of PG may be accelerated or delayed in the same way as noted for the L/S ratio. Thin-layer chromatography is very sensitive, so values for PG of less than 1% of total phospholipid, by reflective

**FIGURE 47-7.** The lecithin-sphingomyelin (L/S) ratio in normal and abnormal pregnancies, indicating wide biologic scatter. (From Gluck L, Kulovich MV: *The evaluation of functional maturity in the human fetus*. In Gluck L [ed]: *Modern Perinatal Medicine*. Chicago, Year Book Medical Publishers, 1974.)

**FIGURE 47-8.** Phosphatidylglycerol and phosphatidylinositol content of amniotic fluid plotted against gestational age. (From Hallman M, Kulovich MV, Kirkpatrick E, et al: *Phosphatidylinositol and phosphatidylglycerol in amniotic fluid: Indices of lung maturity.* *Am J Obstet Gynecol* 125:613, 1976.)

densitometry on the chromatographic plate, should be considered negative; this correlates with the less sensitive but much faster immunologic detection methods for PG, such as the AmnioStat-FLM (Irvine Scientific, Santa Ana, CA) which has detection limits of 0.05  $\mu\text{g}/\text{mL}$  (Towers and Garite, 1989). The presence of PG at 1% of total phospholipid indicates a remarkably low risk for RDS, less than 0.5%. If a patient has both an L/S ratio of less than 2 and a PG of less than 1%, the risk for RDS is greater than 80% (Hallman and Teramo, 1981). Besides an L/S ratio below 1, this combination is the best predictor of RDS available to the clinician. In certain pregnancies characterized by diabetes and Rh isoimmunization, the L/S ratio has proved less reliable, the risk of RDS at a value between 2 and 3 still being approximately 13% (Hallman and Teramo, 1981). However, in infants with both an L/S ratio above 2 and PG of 1% or more, the risk has been reduced to zero. Other factors must be considered in the interpretation of the L/S ratio: A low L/S ratio carries a much smaller risk at a more advanced gestation, and in black mothers, the risk of RDS in the infant is extremely low with an L/S ratio of more than 1.2 (Richardson and Torday, 1994).

The measurements of SP-A and SP-B by ELISA have been made in amniotic fluid samples for the purpose of predicting the occurrence of RDS (Dilger et al, 1994). Although SP-A and SP-B increased with advancing gestation, the excellent predictive values of L/S and PG were not improved by the additional measurement of surfactant proteins (Pryhuber et al, 1991).

A rapid test for the evaluation of amniotic fluid samples is the foam stability test, in which samples of variable dilution are shaken with 95% alcohol and the tubes examined for stable foam (Clements et al, 1972); it has not been found entirely satisfactory but may be used in conjunction with other tests. A modification of this "shake test" is the stable microbubble test, in which stable bubbles are

counted under the microscope; fewer than 5 stable microbubbles/ $\text{mm}^2$  are considered positive for RDS (Chida and Fujiwara, 1993; Chida et al, 1993). This test has been found to have a positive result predictive value of 95% to 100% and a negative result predictive value of 85% to 90%. This test is rapid and inexpensive and may be adapted for use with tracheal aspirate samples after birth.

Recently, amniotic fluid lamellar body counts have been studied to determine the predictive value of this method for the development of HMD and for comparison with traditional measurements of phospholipids in amniotic fluid samples (Dalence et al, 1995). In this method, amniotic fluid samples are analyzed by Coulter counter, and the lamellar bodies are read as platelets. Values of greater than 30,000/ $\mu\text{L}$  have a negative predictive value of 100%, and values less than 10,000/ $\mu\text{L}$  have a positive predictive value of 67%. This assessment is quick, cheap, and available and has advantages over many of the other tests of phospholipid concentrations.

#### Early Postnatal Prediction

The L/S ratio may be used in tracheal aspirate samples to predict RDS, but the threshold level of 2.0 must be raised to 3.0 (Harker et al, 1992); the measurement of PG on tracheal aspirate samples also is very useful, and the combination of low L/S ratio and absent PG on tracheal aspirate samples gives a positive result predictive value of 89%. Skelton and Jeffery (1994) have obtained good results with the "click test," another modification of the shake test, in tracheal aspirate samples from preterm infants. After shaking a 0.2-mL sample of tracheal aspirate with an equal volume of 95% ethanol, the bubbles, suspended in airless water, are examined under the microscope; if the bubbles increase and decrease in size, this means an active surfactant and therefore a negative result. The positive result predictive accuracy was 100% and the negative result predictive accuracy was 93% for tracheal aspirate samples from preterm infants. Either this test or the stable microbubble test as described may be used in tracheal aspirate samples of small premature infants at birth for predicting the presence of RDS; in turn, the result may be used in deciding on the use of early surfactant therapy. The measurement of static lung compliance also is very useful for this purpose; with a value of less than 1.8 mL/cm  $\text{H}_2\text{O}/\text{m}$  of body length, the positive result predictive value is 100%; with a value of more than 1.8, the negative result predictive value is 92% (Wilkie et al, 1994). This test is complex and expensive, however.

#### Prophylaxis with Antenatal Glucocorticoid Hormones

A vast literature on the effect of corticosteroid hormones on lung and surfactant maturation in animal and tissue culture models has accumulated (Ballard, 1986). Since 1972, when Liggins and Howie described decreased mortality, decreased incidence of RDS, and less severe RDS in a prospective blinded study done in New Zealand, more than 30 studies have been published worldwide. Unfortunately, not all of these studies have been of appropriate size, and not all have been of sufficient quality to exclude the problems of bias and error; these shortcomings have resulted in widespread misinterpretation of the results and

a regrettable underutilization of glucocorticoid therapy (Ryan and Finer, 1995).

The National Perinatal Epidemiology Unit at Oxford University published the results of a meta-analysis of 12 randomized controlled trials (Crowley et al, 1990); to be included, the trials had to meet rigorous standards. The authors concluded that maternal steroid therapy significantly reduced the incidence of RDS, intraventricular hemorrhage (IVH), necrotizing enterocolitis (NEC), and neonatal death; in addition, they concluded that the duration and costs of hospital care for the newborn infant were greatly decreased. The benefits applied to all infants born at a gestational age of 24 to 34 weeks and were not affected by race or gender or by the presence of prelabor rupture of amniotic membranes (Crowley, 1992).

Recently, the National Institutes of Health reported the conclusions of a panel of experts; they commissioned an updated meta-analysis, a neonatal registry review, and a cost-benefit analysis and evaluated the scientific literature according to the rigorous standards of the U.S. Preventive Services Task Force (NIH Consensus Development Panel, 1995; NIH Consensus Development Conference Statement, 1995). The investigators concluded that the incidences of RDS, IVH, and neonatal death were significantly reduced (odds ratios of 0.5, 0.5, and 0.6, respectively), and they regarded the evidence as compelling. The benefits were not affected by race or gender or by the presence of PROM, and, most important, the benefits were still apparent in infants in whom exposure was less than 24 hours. In infants of 24 to 28 weeks, the evidence for a reduced incidence of RDS was less certain, but the severity of RDS and the incidence of severe IVH were significantly decreased.

There is no reasonable evidence that the incidence of infection is increased in either the mother or the infant. The results of long-term follow-up studies have shown no problems with general health or neurodevelopment that could be attributed to the use of hormone therapy (Ballard, 1986). The NIH panel estimated that if the use of prenatal steroids could be increased from the level of 15% in preterm infants at 24 to 34 weeks of gestation to a level of 60%, then the cost savings for initial hospital care alone would be \$157 million each year in the United States.

The recommendations of the NIH panel are as follows: (1) all fetuses between 24 and 34 weeks of gestation are candidates for this therapy; (2) the decision should not be influenced by race, gender, PROM, or anticipated surfactant therapy; (3) all obstetric patients eligible for tocolytic therapy should receive steroids; (4) because therapy for less than 24 hours is effective, all patients should be treated unless immediate delivery is anticipated; (5) patients whose pregnancies have not reached 30 weeks of gestation should be treated because of the reduction in IVH; (6) treatment may be withheld in the presence of overt amnionitis; and (7) treatment consists of betamethasone, 12 mg every 24 hours for two doses, or dexamethasone, 6 mg every 12 hours for four doses. Liggins and Howie (1972) reported a high incidence of RDS in infants delivered more than 7 days after maternal steroid treatment, suggesting that the beneficial effect could be reversible. However, routine retreatment after 7 days is not recommended. Subsequent to the recommendations of the NIH consensus conference, use of repeat courses of antenatal steroids

to mothers with threatened preterm labor became widespread. Animal studies of repeat antenatal steroid administrations were concerning because of evidence of deleterious effects on lung and somatic growth as well as on cerebral myelination and development (Jobe et al, 1998; Okajima et al, 2001; Uno et al, 1990). Data in humans are not well established, but possible decreases in somatic and brain growth, as well as increases in the incidence of chronic lung disease and neonatal sepsis and in the mortality rate, have been suggested (Banks et al, 1999; French et al, 1999). The revised recommendations reiterated those from the previous consensus conference and added: "Because of insufficient scientific data from randomized clinical trials regarding efficacy and safety, repeat courses of corticosteroids should not be used routinely. In general, repeat courses should be reserved for patients enrolled in randomized controlled trials. Several randomized trials are in progress" (National Institutes of Health Consensus Development Panel, 2001). Specific recommendations also were made directing clinical and basic scientific research efforts to characterize optimal treatment.

A number of recent studies has examined the use of antenatal steroids in mothers at risk for delivery of a very immature infant, a problem that has been of great concern to many obstetricians. To examine the question of treatment before 30 weeks of gestation, Kattner and colleagues (1992) carried out a meta-analysis with over 250 infants and found a significant reduction in the incidence of RDS with maternal steroid treatment. Then, in a prospective study, they enrolled 135 mothers in a trial of prenatal steroids and found a significant increase in survival in the infants whose mothers had received treatment. Garite and colleagues (1992) performed a small randomized controlled trial of prenatal corticosteroids in mothers without PROM at gestational age 24 to 28 weeks; they found no reduction in the incidence of RDS, but they found dramatic reductions in the incidences of severe IVH and the severity of RDS. The data obtained for the March of Dimes-sponsored Prematurity Prevention Program were analyzed for the effect of prenatal steroids; major reductions in the incidence of RDS, IVH, and death were found in infants between 26 and 31 weeks of gestation who had received prenatal steroids (Maher et al, 1994). The data for a controlled trial of indomethacin were examined for the effect of antenatal steroids; in infants between 600 and 1250 g birth weight, a large decrease in the incidence of IVH was found with antenatal steroid treatment (Ment et al, 1995).

Prenatal glucocorticoids appear to have several other beneficial effects in the small preterm infant (Ballard, 1986). Clyman and colleagues (1981) demonstrated a significant reduction in the incidence of clinically significant patent ductus arteriosus (PDA) with prenatal betamethasone therapy. Van Marter and associates (1990) reported data indicating that the incidence of BPD is reduced in preterm infants exposed to prenatal corticosteroids; this appears logical in view of the evidence relating RDS, especially severe RDS, to the occurrence of BPD. Other effects observed in animal models include decreased pulmonary protein leaks (Rider et al, 1989), induction of antioxidant enzymes in rat lung (Frank et al, 1985), and acceleration of renal function in the fetal lamb (Scholle and Braunlich, 1989; Stonestreet et al, 1983).

The results for prenatal steroid therapy can be further improved; the effects of prenatal steroid and exogenous surfactant therapy proved to be additive in several initial small trials (Jobe, 1993). The effect of prenatal steroids has been retrospectively analyzed in the large number of infants enrolled in the many large controlled trials of exogenous surfactant performed in the last 10 years or so. The beneficial effects of steroids are still clearly apparent (Wright et al, 1995), even in populations that also have benefited from the use of exogenous surfactant therapy.

Several other hormones, particularly thyroid hormone, are known to have a positive effect on lung development in tissue culture and animal models; because thyroid hormone does not cross the placenta, thyrotropin-releasing hormone (TRH) has been used instead. Early randomized controlled trials of prenatal TRH given in addition to corticosteroids have demonstrated further improvements in outcome, compared with controls treated with steroids alone; Ballard and colleagues (1992) noted a significant reduction in death and BPD at a postconceptional age of 36 weeks, and Knight and associates (1994) reported a New Zealand trial in which significant reductions in RDS incidence, RDS severity, frequency of BPD, and mortality rate were found. However, an Australian controlled trial of TRH, which used a smaller dose and a longer dosage interval, found an increased risk for severe RDS (ACTOBAT Study Group, 1995), and Pierce and colleagues (1992) found decreased survival rates in oxygen-exposed newborn rats given TRH prenatally. In a more recent large clinical trial, nearly 1000 mothers were randomized to either TRH or placebo antenatally in addition to steroids at less than 30 weeks of gestation. Of the 1134 infants delivered, 769 were born at less than 32 weeks of gestation. In these infants, at increased risk of RDS and chronic lung disease, there were no differences in the rate of RDS (66% for TRH versus 65% for placebo), death (11% versus 11%), or chronic lung disease (32% versus 34%) (Ballard et al, 1998). On the basis of the most recent studies, the addition of prenatal TRH to antenatal steroids given to mothers at risk for very preterm delivery cannot be recommended for clinical practice.

## Treatment

### *Resuscitation*

The mortality rate among all infants, including those with HMD, is increased by asphyxia. Therefore, the presence of a skilled resuscitation team at the delivery of high-risk infants can reduce the morbidity and mortality rates of the disease (see Chapter 28 on resuscitation).

### *Lung Expansion*

Because secretion of surfactant is impaired by inadequate expansion of the lungs at birth (Lawson et al, 1979), many experts believe that it is appropriate to intubate all infants weighing less than 1000 g at birth and to initiate mechanical ventilation with positive end-expiratory pressure (PEEP) in the delivery room. Another approach to obtaining lung expansion in this weight group is early utilization of nasal CPAP, without automatic intubation. These two approaches in this weight group have not been compared in a randomized study, but centers using the delivery room management approach of nasal CPAP have a low incidence of

BPD, and these centers do not report differences in mortality rate or occurrence of IVH or other important morbidity (Van Marter et al, 2000). Intubation and mechanical ventilation may be used for larger premature infants if they have respiratory distress or are not vigorous in the delivery room. For infants with birth weights of less than 1000 g in whom intubation combined with mechanical ventilation is chosen, the administration of artificial replacement surfactant within the first 15 minutes of life is associated with lower mortality and less BPD than in infants who are given surfactant later in the course of RDS (see Chapter 46 on surfactant).

### *Thermal Neutrality*

Infants should be nursed in a warm environment so that oxygen consumption is maintained at minimal levels. This usually means servo-controlling the anterior abdominal skin temperature at 36.5° C, but in small premature infants, the skin temperature may need to be servo-controlled at 36.9° C in order to maintain the rectal temperature at 37° C. The measured energy expenditure is 55 calories/kg/day during the first 4 days (Samiec et al, 1994); unfortunately, the caloric intake is usually only 25 calories/kg/day, so it is very important to minimize overall caloric expenditure.

### *Blood Gas Monitoring*

Infants with RDS require monitoring of blood pressure, blood gases, electrolytes, calcium, and glucose. Blood samples may be obtained from an umbilical artery catheter.

### *Oxygen*

Oxygen therapy is beneficial despite the presence of large right-to-left shunts. Increased inspired oxygen produces (1) a rise of alveolar oxygen pressure in open low  $\dot{V}/\dot{Q}$  units (see Fig. 47-4); (2) relief of regional hypoxic vasoconstriction in this compartment; (3) a reduction in true right-to-left shunt; and (4) an increase in arterial oxygen saturation (Hansen et al, 1979).

### *Fluid Restriction and Attention to Serum Electrolytes*

Because RDS is characterized by high-surface-tension pulmonary edema (Boughton et al, 1970), high-permeability pulmonary edema (Jefferies et al, 1984), and marked fluid retention, fluid restriction to 50 mL/kg/day is indicated for many infants with RDS for the first 48 hours or until the onset of diuresis. The complex hormonal responses to RDS result in high levels of arginine vasopressin and low concentrations of atrial natriuretic peptide, favoring a low urine output and fluid retention (Ronconi et al, 1995); subsequently, an increase in atrial natriuretic peptide concentration occurs with the onset of the diuretic phase observed in the course of RDS. A controlled trial of fluid restriction, compared with a modest increase in fluid intake, showed a significant reduction in the incidence of BPD at the age of 1 month and at a postconceptional age near term (Tammela et al, 1992). In addition, a meta-analysis in which fluid restriction was compared with a modest increase in daily fluid intakes found a reduction in the incidence of PDA, NEC, and death in the infants in whom fluid restriction was applied (Bell and Acarregui, 2001). Close attention should

be paid to fluid intake, urine output, urine concentration, and serum electrolytes. Premature infants have an excess of extracellular fluid and are expected to lose at least 10% of body weight by the end of the first week of life. It is not necessary or beneficial to administer sodium in the first few days of life (Costarino et al, 1992), and potassium also should be restricted, as hyperkalemia may be troublesome (Stefano et al, 1993). In the infant who develops hyponatremia in the first few days of life in association with RDS, without an appropriate loss in weight, the hyponatremia does not represent a depletion in total body sodium but indicates excessive total body water, and consideration should be given to decreasing the rate of fluid administration further. In the very immature infant (24 to 26 weeks of gestation) with very permeable skin, evaporative losses may be excessive, and much higher amounts of fluid may be required. If the serum sodium rises sharply, especially if it approaches 150 mEq/L, it can be assumed that insensible water losses through the skin are excessive, and the fluid intake should be liberalized accordingly. To minimize insensible water losses, it is useful to manage the infant in a humidified incubator; or if the infant is on an open warmer, a transparent plastic cover can be placed across the infant and across the sides of the bassinet and then a gentle flow of heated mist directed into the infant's microenvironment. It should be noted that antenatal corticosteroid administration decreases permeability of the very preterm infant's skin. If fluids must be liberalized, the development of hyperglycemia is not uncommon; in this situation, a continuous enteric infusion of water may be useful to control the serum sodium (Gaylord et al, 1995).

### *Minimal Stimulation*

Manipulations such as heel sticks, tracheal suctioning, diaper changes, and even weighing should be kept to a minimum, as these procedures have been shown to reduce arterial oxygen tension (Lucey, 1981); they probably also increase oxygen consumption and may contribute to the genesis of cerebral hemorrhage by rapidly raising arterial blood pressure to excessive levels. It is not appropriate to give enteral feedings to infants with RDS, because this condition usually is accompanied by poor intestinal motility. Many centers now insert both an umbilical vein catheter and an umbilical artery catheter and use the venous catheter to infuse glucose and the arterial catheter to infuse saline. The major reason for use of the two catheters is that a source of glucose-free blood is needed to monitor glucose tolerance adequately without the use of heel sticks, which are painful to the infant and very disturbing.

### *Blood Pressure Support*

Premature infants with RDS frequently have a low arterial blood pressure in the first 12 hours of life, as defined by normative data (Versmold et al, 1981). Many extremely low-birth-weight (ELBW) infants with RDS probably have low blood pressure for many days after birth, which may predispose them to brain injury (Kopelman, 1990). A working party of the Royal College of Physicians has defined hypotension in small premature infants as a mean blood pressure of less than the gestational age in completed weeks (Joint Working Party, 1992). However, there

is a tendency for the blood pressure to rise spontaneously in the first 12 hours of life (Moscoso et al, 1983).

Adequate oxygenation may be difficult in the presence of hypotension and reduced pulmonary blood flow. In infants with a low hematocrit, poor peripheral perfusion, and metabolic acidosis, the hypotension often is due to hypovolemia and will respond to a cautious infusion of 10 to 20 mL/kg of saline. Only a few infants have obvious signs of hypovolemia, however, and echocardiographic studies in small premature infants have shown that many have decreased cardiac contractility, which is reflected in a poor cardiac output and significant hypotension (Gill and Weindling, 1993a). If there are no signs of hypovolemia, the infusion of dopamine at 5 to 10  $\mu\text{g}/\text{kg}/\text{minute}$  usually is effective at increasing the mean blood pressure. A randomized controlled trial of Plasmanate versus dopamine in hypotensive preterm infants showed that only 45% responded to Plasmanate, but 89% responded to dopamine (Gill and Weindling, 1993b). Some investigators have suggested that dopamine is superior to dobutamine for the correction of hypotension in small premature infants (Christophe Roze et al, 1993), and this was confirmed in a controlled trial (Klarr et al, 1994) in which dopamine was successful in elevating the mean blood pressure in 97% of infants and dobutamine was successful in 67% of infants. Serial echocardiographic data have shown dopamine dose-dependent increases in cardiac output and stroke volume, without significant changes in heart rate or systemic vascular resistance (Padbury et al, 1986).

Helbeck and colleagues (1993) presented evidence that some small preterm infants with RDS have low cortisol levels and that their hypotension is corrected with hydrocortisone. Others have found that small premature infants with RDS needing inotrope support have lower cortisol levels than small premature infants with RDS not needing inotrope support (Scott and Watterberg, 1995). Other centers have found that dexamethasone often corrects the low blood pressure in these infants after an interval of 6 to 12 hours (Fauser et al, 1993). These investigators suggest that the mechanism involves protein induction of adrenergic receptors. Glucocorticoids given in the first 96 hours of life in premature infants, however, have been associated with an increased incidence of intestinal perforation and abnormal developmental outcomes, including cerebral palsy. The Committee on the Fetus and Newborn of the American Academy of Pediatrics (2002) has recommended that postnatal steroids not be given to premature infants unless the infant is on maximal support. (See also Chapter 49 on BPD.) One of the many benefits of prenatal corticosteroid therapy is that the mean blood pressure is higher in treated infants (Moise et al, 1995). In a study in which a single dose of dexamethasone was given within 2 hours of birth to infants born at less than 28 weeks of gestation, blood pressures were higher and ventilator pressures lower than in the infants receiving placebo (Kopelman et al, 1999); however, it is not clear that even this amount of exposure to dexamethasone is safe. Evans and Iyer (1993) found that the mean blood pressure increased after successful closure of the ductus arteriosus with indomethacin, but the effect was small. Adequate attention to the blood pressure is very important in the management of RDS.

### **Alkali Therapy**

Severe metabolic acidosis may increase pulmonary vascular resistance, impair surfactant synthesis, reduce cardiac output, and ultimately reduce ventilation. An early trial showed that continuous infusion of glucose-bicarbonate solutions reduced the mortality rate for RDS (Usher, 1963). With the introduction of better methods for oxygenating infants however, bicarbonate therapy no longer appears to have much benefit (Corbet et al, 1977), and it may be harmful in infants who are not being ventilated adequately and have a high arterial PCO<sub>2</sub>.

### **Closure of the Patent Ductus Arteriosus**

Especially in infants weighing less than 1000 g at birth, a PDA may contribute significantly to the overall problem during recovery from RDS and may predispose the infant to the development of BPD. If the ductus is demonstrated to be patent at the age of 3 to 4 days by two-dimensional echocardiography and pulsed Doppler ultrasonography, the evidence suggests that it is unlikely to close spontaneously within a reasonable time (Dudell and Gersony, 1984); therefore, it should be closed, either with indomethacin therapy or with surgery (see Chapter 56 on PDA).

### **Surfactant Replacement**

Infants with birth weights of less than 1000 g should receive prophylactic exogenous surfactant within 15 to 30 minutes of birth, but only after adequate stabilization; in larger infants, surfactant treatment should begin as early as possible, preferably before the age of 2 hours, and certainly before the age of 6 hours. A mammalian surfactant is currently preferred; the dose should be 100 mg/kg, the interval between doses should be between 6 and 12 hours, and two or three doses should be given. The drug should be given as rapidly as possible with a catheter passed into the endotracheal tube, followed by bag-tube ventilation to ensure even distribution, but it should not be given so rapidly as to obstruct the airways and promote hypercarbia. The number of aliquots for each dose does not matter, two aliquots being as good as four aliquots. After surfactant instillation, it is customary to maintain the patient on continuous mechanical ventilation (CMV), but Verder and colleagues (1994) have demonstrated that larger infants may be extubated to nasal CPAP and that the need for endotracheal intubation and CMV may be reduced. Trials of this approach in lower-birth-weight infants are underway.

### **Corticosteroids**

See Chapter 49 for a discussion of the potential role of glucocorticoids in the prevention and treatment of BPD.

### **Prognosis**

The chances of survival in RDS are directly related to birth weight and gestational age and are affected by prenatal treatment with glucocorticoids, by surfactant replacement therapy, and by the severity and complications of the disease.

## **TRANSIENT TACHYPNEA OF THE NEWBORN**

Transient tachypnea of the newborn (TTN) also is known as *delayed clearance of fetal lung fluid*. In 1966, Avery and coworkers reported on eight near-term infants with early onset of respiratory distress whose chest radiographs showed hyperaeration of the lungs, prominent pulmonary vascular markings, and mild cardiomegaly (Fig. 47–9). The respiratory symptoms were transient and relatively mild, and most infants improved within 2 to 5 days. The investigators named the disorder “transient tachypnea of the newborn” and speculated that it was the result of delayed clearance of fetal lung liquid.

### **Pathophysiology**

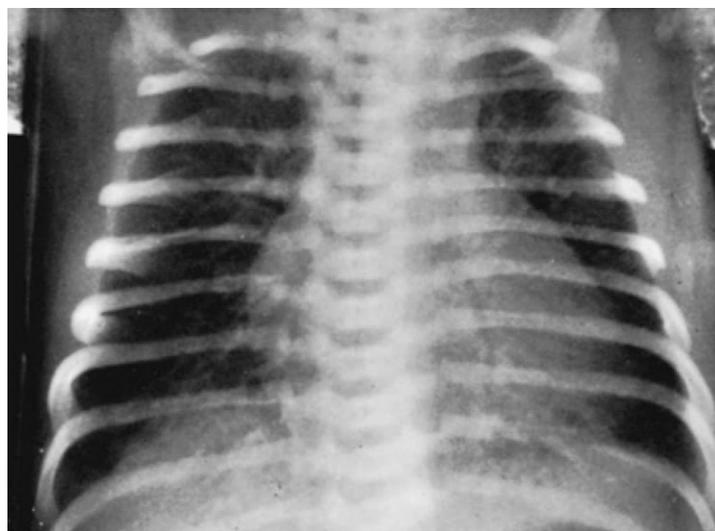

#### **Fetal Lung Fluid**

Most authors agree with Avery and her coworkers that TTN represents a transient pulmonary edema resulting from delayed clearance of fetal lung liquid. The lung liquid that fills the potential air spaces of the lung (20 to 30 mL/kg of body weight) is quite distinct from amniotic fluid or plasma (Adams et al, 1963; Adamson et al, 1969; Humphreys et al, 1967) (Table 47–2). The possibility that the lung could contribute to amniotic fluid was first proposed by Jost and Policard (1948), when they demonstrated an increase in lung volume in the rabbit fetus after ligation of the trachea. Evidence for active secretion of lung liquid was provided by Strang (1967), who measured the ratios of cations and anions between lung liquid and plasma. Olver and Strang (1974) later demonstrated that lung liquid required active transport of chloride ions from plasma in excess of the bicarbonate movement in the opposite direction. This liquid contains large amounts of chloride, relatively small amounts of bicarbonate, and almost no protein. Its potassium concentration is similar to that of plasma until near term, when it increases in response to surfactant secretion. Fetal lung liquid is secreted by the lung at approximately 4 to 6 mL/kg/hour along an electrochemical gradient that is produced by the active pumping of chloride from the interstitium into the air space. Although the site of the chloride pump is unknown, it can be inhibited by a variety of mediators that include beta agonists, arginine vasopressin, and prostaglandin E<sub>2</sub> (Bland, 1988; Walters and Olver, 1978).

The potential airways of the fetus are in contact with amniotic fluid when the glottis is open. Rarely does amniotic fluid itself enter the developing lung, except in circumstances of fetal distress. When the fetus is stimulated to gasp, sufficient pressure is applied across the lung to allow entry of amniotic fluid and sometimes squamous debris and even meconium. The rapid, irregular respiratory movements described as fetal breathing do not, in effect, move much fluid, as fluid is approximately 100 times as viscous as air, and the rapid, small respiratory movements of the fetus are not associated with high transpulmonary pressures.

#### **Clearance of the Fetal Lung Fluid**

In order for the fetus to complete the transition from intrauterine to extrauterine life, the lung must clear this liquid soon after birth. The process of clearing liquid from the lung actually begins 2 to 3 days prior to birth with a decrease in the rate of secretion of fetal lung liquid.

**FIGURE 47-9.** The large cardiovascular silhouette, air bronchogram, and streaky lung fields were seen at 2 hours of age (**A**) but had cleared by 24 hours of age (**B**), typical of transient tachypnea of the newborn or delayed clearance of lung liquid.

**B**

However, lung liquid begins to clear in earnest with the onset of labor. Data obtained from experiments using fetal lambs show that nearly two thirds of the total clearance of liquid that occurs during the transition from intrauterine to extrauterine life occurs during labor (Bland, 1983, 1988; Bland et al, 1982). With the onset of labor, the pulmonary epithelium changes from a chloride-secreting membrane to a sodium-absorbing membrane, with reversal of the

direction of flow of lung liquid. This change is an active metabolic process involving increased  $\text{Na}^+$ ,  $\text{K}^+$ -ATPase activity in the epithelial cells and serves to drive liquid from the lung lumen into the interstitium. In addition, because lung liquid contains very little protein, oncotic pressure also favors the movement of water from the air space back into the interstitium, and from there into the vascular compartment (Berthiaume et al, 1987; Bland, 1988; Bland

**TABLE 47-2**

**Interstitial Fluid Estimated from Measurements in Lung Lymph**

Component	Lung Liquid	Interstitial Fluid	Plasma	Amniotic Fluid
Sodium (mEq/L)	150	147	150	113
Potassium (mEq/L)	6.3	4.8	4.8	7.6
Chloride (mEq/L)	157	107	107	87
Bicarbonate (mEq/L)	3	25	24	19
pH	6.27	7.31	7.34	7.02
Protein (g/dL)	0.03	3.27	4.09	0.10

Data from Adams et al, 1963; Adamson et al, 1969; Bland, 1983; and Humphreys et al, 1967.

and Nielson, 1992). In the past, physicians believed that some of the reduction in lung water at birth was caused by vaginal compression of the chest, which expelled liquid from the lung. However, although lung water content in fetal rabbits delivered vaginally with labor is less than the lung water of rabbits delivered by cesarean section without labor, the lung water content in fetal rabbits delivered by cesarean section during labor is not different (Bland et al, 1979). These data suggest that any mechanical effects on the clearance of fetal lung liquid are minimal.

### *Delayed Clearance of the Fetal Lung Fluid*

Infants born without labor do not have the opportunity for early lung liquid clearance and begin their extrauterine life with excess water in their lungs. In addition, the increase in Na<sup>+</sup>, K<sup>+</sup>-ATPase activity around the time of labor appears to be developmentally regulated, suggesting that preterm infants would not be able to use this pathway effectively to help clear fetal lung fluid. Infants with TTN often are hypoproteinemic, and decreased plasma oncotic pressure may delay the direct absorption of water into the blood vessels (Cummings et al, 1993). Finally, these infants can have elevated pulmonary vascular pressures and ventricular dysfunction (Halliday et al, 1981), which will increase central venous pressure and impair thoracic duct function and the removal of interstitial water by the lymphatics. This is especially true in infants who receive large transfusions of blood from the placenta as a result of delayed cord clamping or milking of the cord (Saigal et al, 1977).

### *Transient Pulmonary Edema*

The symptoms of TTN result from compression of the compliant airways by water that has accumulated in the perivascular cuffs of the extra-alveolar interstitium. This compression results in airway obstruction and hyperaeration of the lungs secondary to gas trapping. Hypoxia results from the continued perfusion of poorly ventilated lung units; hypercarbia results from mechanical interference with alveolar ventilation and from central nervous system depression. Lung function measurements in infants with TTN are compatible with airway obstruction and gas trapping. The FRC measured by gas dilution is normal or reduced, whereas measurements of thoracic gas volume by plethysmography are increased, suggesting that some of the gas in the lungs is not in communication with the airways (Krauss and Auld, 1971).

### *Clinical Signs*

It initially was thought that TTN was limited to term or larger preterm infants, but it is now clear that very small infants also may present with pulmonary edema from retained fetal lung liquid; this may complicate their surfactant deficiency, accounting for some of their need for supplemental oxygen and ventilation. There is often a history of heavy maternal sedation, maternal diabetes, or delivery by elective cesarean section. Affected infants may be mildly depressed at birth, which may mask many of their early symptoms. They are often very tachypneic, with respiratory rates ranging from 60 to 120 breaths/minute, and may have hyperinflation with grunting, chest wall retractions, and nasal flaring.

Arterial blood gas values often reveal a respiratory acidosis, which resolves within 8 to 24 hours, and mild to moderate hypoxemia. These infants seldom require more than 40% oxygen to maintain an adequate PaO<sub>2</sub> and usually are in room air by 24 hours of age. They have no evidence to indicate right-to-left shunting of blood at the ductus arteriosus or foramen ovale. They respond rapidly and well to nasal CPAP therapy.

Chest radiographs reveal hyperaeration, which often is accompanied by mild cardiomegaly (see Fig. 47–9). Water contained in the perivascular cuffs produces prominent vascular markings in a “sunburst pattern” emanating from the hilum. The interlobar fissures are widened, and pleural effusions may be present. Occasionally, coarse fluffy densities may be seen, indicating alveolar edema. The radiographic abnormalities resolve over the first 2 to 3 days after birth, or more rapidly with treatment with nasal CPAP.

### *Clinical Course and Treatment*

As its name implies, TTN is a benign, self-limited disease. The infant's need for supplemental oxygen usually is highest at the onset of the disease and then progressively decreases. Infants with uncomplicated disease usually recover rapidly, without any residual pulmonary disability. Although the symptoms of TTN relate to pulmonary edema, one controlled trial that assessed therapy with diuretics found no evidence for their efficacy (Wiswell et al, 1985). (See Chapter 46 for treatment with surfactant and Chapter 45 for a complete discussion of the principles of respiratory monitoring and therapy.)

## Respiratory Failure in the Term Infant

Roberta A. Ballard, Thomas N. Hansen, and Anthony Corbet

The pathophysiology of respiratory failure in the term or near-term infant, although sharing some of the same developmental physiologic issues that affect the preterm infant, includes a number of etiologic disorders not commonly seen in the more immature infant. In particular, persistent pulmonary hypertension of the newborn (PPHN) and meconium aspiration syndrome tend to be seen most commonly in term or post-term infants. In addition, other entities such as perinatal-neonatal asphyxia or pneumonia, particularly those due to group B streptococcal infection, may cause profound respiratory failure in infants with otherwise normal mature lungs. Finally, a small but significant number of infants may have severe respiratory distress secondary to abnormalities or maldevelopment of the surfactant system or abnormal development of the alveoli or the pulmonary vascular system. Management of intractable pulmonary failure in these infants also includes therapies not available or established for the preterm infant, including use of inhaled nitric oxide (iNO) and extracorporeal membrane oxygenation (ECMO).

In the approach to the term infant with respiratory failure presented in this chapter, it is assumed that appropriate studies have ruled out the presence of anatomic anomalies of the airway (see Chapters 50 and 51). In the absence of such abnormalities, the evaluation should now be directed at (1) ruling out cyanotic congenital heart disease and (2) attempting to determine whether the primary underlying disorder is due to intrinsic parenchymal lung disease, such as meconium aspiration or pneumonia, or to entities causing inadequate pulmonary blood flow, such as shock, asphyxia, cardiomyopathy, or PPHN.

This chapter addresses the etiology, pathobiology, and therapy of disorders that commonly lead to respiratory failure in term infants, with the assumption that both airway anomalies and congenital heart disease have been ruled out.

### PERSISTENT PULMONARY HYPERTENSION OF THE NEWBORN

Gersony and coworkers (1969) described a group of term infants without structural heart disease who became cyanotic shortly after birth and had only mild respiratory distress. These infants all had suprasystemic pulmonary arterial pressures and evidence of right-to-left shunting of

blood across persistent fetal pathways (the foramen ovale and ductus arteriosus). The nature of these shunts initially led to the name “persistence of the fetal circulation.” Subsequently, the name was changed to *persistent pulmonary hypertension of the newborn* to describe the pathophysiology of the disorder more accurately.

### Pathogenesis

Successful transition from intrauterine to extrauterine life requires that the pulmonary vascular resistance decrease precipitously at birth. In infants with PPHN, this decrease either does not occur or the vascular resistance does not remain low. Pulmonary arterial pressure is elevated, and blood is shunted right to left across the ductus arteriosus and foramen ovale. In addition, the persistently high pulmonary vascular resistance increases right ventricular afterload and oxygen demand and impairs oxygen delivery to the right ventricle, the posterior wall of the left ventricle, and the subendocardial regions of the right ventricle. Increased right ventricular afterload often results in displacement of the septum into the left ventricle, impairing left ventricular filling and reducing cardiac output.

In some instances, pulmonary vascular resistance remains only transiently elevated at birth (Table 48–1) and decreases rapidly once the underlying condition is corrected. In a number of other conditions, however, the pulmonary vascular resistance remains persistently elevated, either because of active constriction of pulmonary vessels or because of some anatomic abnormality.

Active constriction of pulmonary vessels can complicate the course of bacterial sepsis or pneumonia in the newborn (Shankaran et al, 1982). Experiments in animals show that this increase in pulmonary vascular resistance is temporally related to increased plasma thromboxane concentrations (Hammerman et al, 1988) and can be blocked by the administration of inhibitors of prostaglandin synthesis (Rojas et al, 1983). Active constriction of pulmonary vessels can also complicate the course of meconium aspiration pneumonia. Some studies suggest that vasoactive substances present in meconium or amniotic fluid diffuse through the lung and either constrict pulmonary vessels directly or induce platelet aggregation in the microcirculation, with the subsequent release of thromboxane. Clinical data support this hypothesis and show an association among perinatal aspiration syndromes, transient thrombocytopenia, and PPHN. Moreover, pathologic data demonstrate platelet plugging in the microcirculation of the lung of infants dying of PPHN associated with meconium aspiration pneumonia (Levin et al, 1983). Alternatively, in utero hypoxia may lead both to changes in the pulmonary vessels and to passage of meconium, and some infants born through meconium *without* aspiration have PPHN (see later on).

Anatomic abnormalities of the pulmonary vascular bed fall into two general categories: those associated with underdevelopment of the lung and those that result from maldevelopment of the vessels. In the case of pulmonary hypoplasia, lung mass is reduced, yet cardiac output is appropriate for body size. As a result, the volume of blood

TABLE 48-1

**Causes of Persistent Pulmonary Hypertension****Transient Pulmonary Hypertension**

Hypoxia with or without acidosis  
 Hypothermia  
 Hypoglycemia  
 Polycythemia

**Persistent Pulmonary Hypertension**

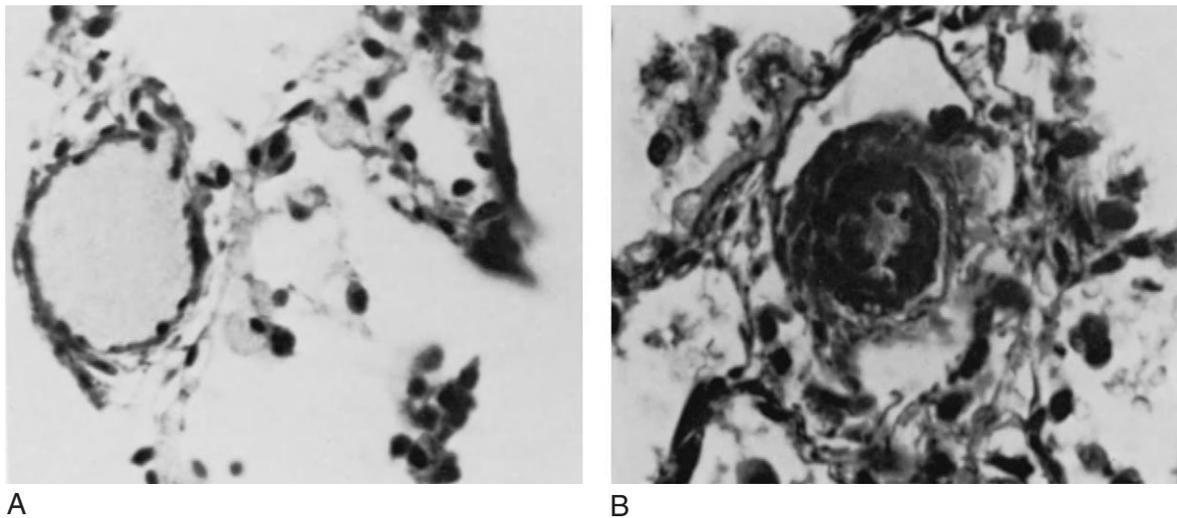

Active vasoconstriction  
 Bacterial sepsis and/or pneumonia  
 Perinatal aspiration syndromes  
 Underdevelopment of the lung  
 Diaphragmatic hernia  
 Potter syndrome  
 Other causes of pulmonary hypoplasia  
 Maldevelopment of pulmonary vessels  
 Idiopathic  
 Chronic intrauterine asphyxia  
 Meconium aspiration pneumonitis  
 Premature closure of the fetal ductus arteriosus

flowing through the existing pulmonary vessels is relatively high, pulmonary arterial pressures are high, and relative pulmonary vascular resistance is increased. In addition to this anatomic impediment to flow, infants with pulmonary hypoplasia are likely to have maldevelopment of the pulmonary vessels and an increased pulmonary vascular resistance from anatomic obstruction of existing vessels (Geggel et al, 1986; Naeye et al, 1976).

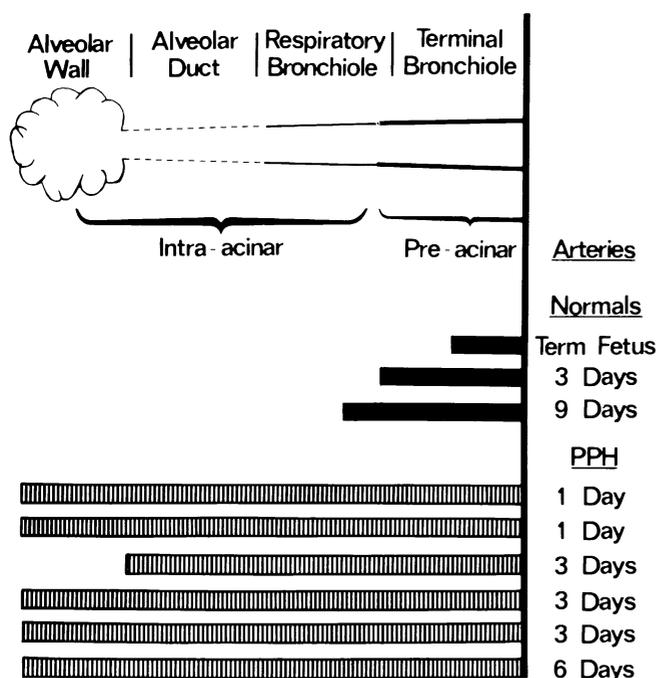

Maldevelopment of pulmonary vessels refers predominantly to abnormalities of vascular smooth muscle found

in lungs of infants dying from PPHN (Murphy et al, 1981) (Fig. 48-1). In these infants, pulmonary arterial smooth muscle hypertrophies and extends from preacinar arteries into normally nonmuscular intra-acinar arteries, even to the level of the alveolus (Fig. 48-2). This thickened muscle encroaches on the vessel lumen, resulting in mechanical obstruction to blood flow. In extreme cases, vascular maldevelopment can cause a reduction in the number of arteries per unit of cross-sectional area of the lung. A review of the associated clinical entities and the available data from experiments in animals suggest that this vascular maldevelopment is the result of sustained pulmonary hypertension in utero. PPHN is strongly associated with low-grade chronic intrauterine hypoxia. In fact, it is likely that unrecognized asphyxia or ductal closure may account for a large proportion of cases labeled as "idiopathic." In chronically asphyxiated fetuses, pulmonary arterial pressure can be increased by active constriction of pulmonary arterioles secondary to hypoxia. Because the pulmonary circulation is parallel to the systemic circulation, it also can be increased secondary to asphyxia-induced increases in systemic arterial pressure. Experimental data from fetal rats and lambs support both of these hypotheses (Soifer et al, 1987); however, although systemic hypertension (even by itself) consistently results in vascular maldevelopment (Levin et al, 1978b), intrauterine hypoxia does not consistently result in vascular maldevelopment (Geggel et al, 1986).

Premature closure of the ductus arteriosus secondary to maternal ingestion of inhibitors of prostaglandin synthesis has been associated with PPHN. Experiments in animals show that premature closure of the ductus (Morin, 1989; Wild et al, 1989) results in maldevelopment of pulmonary vessels, presumably by forcing a greater portion of the combined ventricular output

**FIGURE 48-1.** Photomicrographs of alveolar wall arteries distended with the barium gelatin suspension from a 3-day-old infant with normal lungs (**A**) and from a 3-day-old infant with persistent hypertension (**B**). The normal artery, seen in **A**, is nonmuscular, with a single-endothelial-cell lining surrounded by a thin layer of connective tissue. In **B**, the artery wall is composed of smooth muscle (darkly stained), two cell layers thick, surrounded by a thick connective tissue sheath enclosing a dilated lymphatic (located superiorly). (Elastin-van Gieson stain,  $\times 250$ .) (Courtesy of Dr. John Murphy.)

**FIGURE 48-2.** Vascular maldevelopment in persistent pulmonary hypertension of the newborn. In normal infants, no muscular arteries are found within the acinus. All patients with pulmonary hypertension had extension of muscle into intra-acinar arteries. (From Murphy JD, Rabinovitch M, Goldstein JD, Reid LM: *The structural basis of persistent pulmonary hypertension of the newborn infant.* *J Pediatr* 98:962, 1981.)

through the lungs at a significantly higher pressure (Levin et al, 1978a). The association between meconium aspiration pneumonia and vascular maldevelopment is interesting. Of 11 infants dying of meconium aspiration pneumonia, 10 were found to have significant vascular smooth muscle hypertrophy with extension of muscle into intra-acinar arteries (Murphy et al, 1984). This maldevelopment could be secondary to chronic intrauterine asphyxia, and recent work by Stenmark and Mecham (1997) suggests a complex interaction of epithelial and mesenchymal cells with growth factors in the developing lung and extracellular matrix protein changes that may be influenced by chronic hypoxia. Finally, because disorders associated with underdevelopment of the lung also result in intrauterine pulmonary hypertension, it is not too surprising that they also frequently are associated with maldevelopment of existing vessels. This is particularly true in infants with congenital diaphragmatic hernia, accounting for much of the respiratory instability of these infants (see Chapter 51).

It has become apparent that these anatomically abnormal vessels also exhibit certain functional abnormalities (Morin and Stenmark, 1995). One of the more important functions of the vascular endothelium is to produce the vasodilator NO. NO is produced in endothelial cells from L-arginine by the enzyme NO synthase. It diffuses rapidly into smooth muscle cells, where it stimulates production of cyclic guanosine monophos-

phate (cGMP) and smooth muscle relaxation. NO production by endothelial cells is responsible for the vasodilation that occurs in response to substances such as acetylcholine and bradykinin. Accordingly, these mediators are called *endothelial cell-dependent vasodilators*. Because NO is such a potent pulmonary vasodilator, it is tempting to speculate that impaired NO synthesis contributes to PPHN. In support of this speculation, investigators have shown that infants with PPHN have lower urinary nitrite and nitrate concentrations than those in infants without pulmonary disease, suggesting that their ability to produce NO may be impaired (Dollberg et al, 1995). Adults with pulmonary hypertension have reduced expression of NO synthase in their lungs (Giaid and Saleh, 1995), and chronic inhibition of NO production in the fetal lamb results in PPHN (Fineman et al, 1995). Data show that endothelial cell-dependent vasodilation is impaired in fetal lambs with pulmonary hypertension secondary to early closure of the ductus arteriosus (McQueston et al, 1995). How much of this impairment is at the level of NO synthase versus guanylate cyclase remains to be determined (Steinhorn et al, 1995).

In addition to production of the vasodilator NO, endothelial cells also produce many other factors including endothelin-1, which may act as a pulmonary vasoconstrictor in the newborn. Infants with PPHN have increased concentrations of endothelin-1 in arterial blood. These concentrations correlate with the severity of the pulmonary hypertension (Rosenberg et al, 1993). Many other factors including presence of oxygen free radicals (Sanderud, 1991) are associated with increased pulmonary vascular resistance. Table 48-2 (Kinsella and Abman, 1995) lists factors associated with either an increase or a decrease in pulmonary vascular resistance.

In their review of the cellular and molecular mechanisms of pulmonary vascular remodeling, Stenmark and Mecham (1997) discuss the vascular development in the lung and the cellular responses that occur in pulmonary hypertension. They review the evidence for endothelial cell replication in control of vasculogenesis with an interaction of epithelial cells and mesenchymal cells as well as the specific growth factors known to play a role in the developing lung. Smooth muscle cell replication in the pulmonary vasculature, which occurs at a very high rate in the embryo, decreases when the embryo becomes a fetus and decreases more than 2000-fold from embryonic to adult life. In addition, major changes in extracellular matrix protein occur during development that have an effect on the migration and differentiation of smooth muscle cells. These components include collagen, elastin, fibronectin, and tenascin-C (Cowan et al, 2000b). Cowan and colleagues provided further evidence that endothelial alterations may allow extravasation of a serum factor capable of stimulating smooth muscle cell production of a vascular serine-elastase. They found that tenascin-C amplifies the response of smooth muscle cells to growth factors that are liberated through matrix proteolysis. Reversal of fatal pulmonary hypertension in an animal model by a serine-elastase inhibitor also has been demonstrated (Cowan et al, 2000a).

TABLE 48-2

## Factors Known to Decrease or Increase Pulmonary Vascular Resistance

Decreases	Increases
<b>Mechanical Factors</b>	
Normal lung inflation	Overinflation or underinflation
Vascular cell structural changes	Excessive muscularization, vascular remodeling
Interstitial fluid and pressure changes	Altered mechanical properties of smooth muscle
Shear stress	Pulmonary hypoplasia
	Alveolar capillary dysplasia
	Pulmonary thromboemboli
	Main pulmonary artery distention
	Ventricular dysfunction, venous hypertension
<b>Endogenous Mediators and Mechanisms</b>	
Oxygen (but not hyperoxia)	Hypoxia
Nitric oxide	Oxygen-derived free radicals
Prostacyclin	Acidosis
Adenosine, ATP, magnesium	Endothelin-1
Bradykinin	Leukotrienes
Atrial natriuretic factor	Thromboxanes
Alkalosis	Platelet-activating factor
K <sup>+</sup> channel activation	Ca <sup>2+</sup> channel activation
Histamine	α-adrenergic stimulation
Acetylcholine	Prostaglandin F <sub>2α</sub>
β-adrenergic stimulation	

Adapted from Kinsella and Abman, 1995.

### Clinical Manifestations

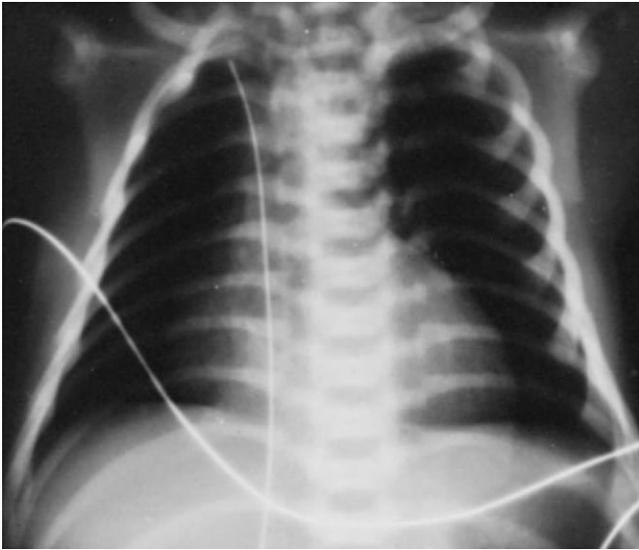

Affected infants usually are delivered at term or post-term and frequently are born through meconium-stained fluid. They often are thought to be normal after brief distress at birth. Then within the first 12 hours after birth, they are recognized as having cyanosis and tachypnea, without apnea and retractions or grunting. They frequently have a cardiac murmur that is compatible with tricuspid insufficiency, but systemic blood pressure is normal. Hypoglycemia frequently complicates many of the associated conditions, such as sepsis and meconium aspiration; hypocalcemia also frequently occurs. Arterial blood gas analysis reveals severe arterial oxygen desaturation, but CO<sub>2</sub> tensions may be relatively normal. In infants with significant ductal level right-to-left shunting, the oxygen saturation measured from the right brachial or radial artery is greater than that obtained from the umbilical artery. Chest radiographs may reveal cardiomegaly. For infants with idiopathic PPHN without parenchymal lung disease, the lung fields are clear and appear undervascularized (Fig. 48-3). For the remainder of the associated entities, chest radiographs reflect the underlying parenchymal disease. Electrocardiograms reveal ventricular hypertrophy appropriate for age; in more severe cases, they also reveal ST segment depression in the precordial leads, suggestive of ischemia. All infants suspected of having PPHN should undergo ultrasound examination of the heart to rule out cyanotic congenital heart disease, to document right-to-left shunting of blood at the foramen ovale and ductus arteriosus, and to measure systolic time intervals. Prolonged systolic time intervals support a diagnosis of pulmonary hypertension, but such findings are not

definitive because the intervals also can be prolonged by right ventricular dysfunction. Please see Chapter 54 for further discussion of the evaluation of PPHN by echocardiography. At some point in the course of the disease, most infants with PPHN increase their PaO<sub>2</sub> above 100 mm Hg, at least transiently, in response to some therapeutic intervention. Infants who can never be oxygenated should be considered for additional echocardiographic studies or cardiac catheterization.

### Management

It is essential at each stage in the management of these infants to determine whether or not parenchymal lung disease is contributing to their respiratory failure. Initially, the most common contributing parenchymal diseases are aspiration of particulate meconium, severe overwhelming pneumonia, and cardiogenic pulmonary edema secondary to asphyxia. However, if the infant has no evidence of parenchymal lung disease, it is essential to avoid either excessive oxygen exposure or overventilation of the lungs. Oxygen toxicity as well as lung damage from stretch, along with decreased cardiac output secondary to decreased venous return due to excessive pressure applied to the respiratory system, contributes to worsening of the disease (Table 48-2) (Kinsella and Abman, 1995).

If adequate ventilation of the infant is possible (to achieve PaCO<sub>2</sub> in the normal range and good chest wall movement and good breath sounds), it is more likely that the hypoxic failure is secondary to decreased pulmonary blood flow and may be due to PPHN. Attention should

**FIGURE 48-3.** Chest radiograph from an infant with idiopathic persistent pulmonary hypertension of the newborn. Lung fields appear hyperlucent, with decreased vascularity.

first be paid to making sure that the infant is ventilated adequately, that blood pressure and cardiac output are supported, and that additional environmental stresses such as hypothermia, hyperthermia, excessive noise, or discomfort causing agitation in the infant have been minimized. All of these infants should be nursed in a neutral thermal environment. Cold stress raises the metabolic rate, increases oxygen consumption, and causes the infant to release norepinephrine, which is a pulmonary vasoconstrictor. Fluids should be restricted and hypoglycemia and hypocalcemia corrected. Systemic hypotension and acidosis should be corrected by judicious use of blood and alkali. Calcium, blood products, and hyperosmolar solutions are potentially vasoactive and should be infused with caution in this group of infants. Infusion of dopamine or, under some circumstances, dobutamine or epinephrine may increase cardiac output without affecting systemic or pulmonary vascular resistance. If the central hematocrit is greater than 60% to 65%, a partial exchange transfusion should be performed to lower the hematocrit and to reduce the effects of hyperviscosity on the pulmonary artery pressure.

Based on results from several centers suggesting that conservative medical management of infants with PPHN may reduce the need for extracorporeal membrane oxygenation and improve outcome (Dworetz et al, 1989; Wung et al, 1985), we have adopted an approach to therapy that seeks to reduce oxygen demand while maximizing oxygen delivery. A review by Walsh-Sukys and colleagues (1994) found, however, that use of gentler ventilation was slow to permeate standard management of PPHN. Subsequently, reporting for the NICHD Neonatal Network, Walsh-Sukys with other associates (2000) further noted that a wide range in clinical practice continued in the absence of controlled clinical trials.

In infants with PPHN, the pulmonary circulation seems to be exceptionally sensitive to changes in oxygen

tension. Therefore, it is advisable to try to maintain the  $\text{PaO}_2$  between 70 and 100 mm Hg if possible. There is no evidence to suggest that maintaining  $\text{PaO}_2$  in excess of 100 mm Hg improves the outcome for the infant with PPHN, and prolonged exposure to excessively high  $\text{PaO}_2$  can injure other organs, such as the brain and the eye (Hansen and Gest, 1984). However, in patients with very severe PPHN, attempts to maintain  $\text{PaO}_2$  between 70 and 100 mm Hg may result in unacceptable complications of therapy. Therefore, many centers now tolerate much lower values for  $\text{PaO}_2$  (as low as 40 mm Hg) in infants with severe PPHN (Wung et al, 1985).

Oxygen should be given by nasal cannula or hood, in concentrations of up to 100% if necessary. If oxygen alone does not lower the pulmonary vascular resistance and improve arterial oxygen saturation, the next step is to induce alkalosis. Although several studies in animals have shown that both respiratory and metabolic alkalosis effectively lower pulmonary vascular resistance (Fike and Hansen, 1989; Schreiber et al, 1986), only respiratory alkalosis has been studied in infants (Drummond et al, 1981). Clearly, however, metabolic alkalization benefits these infants and many clinicians prefer metabolic alkalization over hyperventilation as the initial approach, as low  $\text{PaCO}_2$  levels are associated with poor neurodevelopmental outcome. The use of neuromuscular blockers such as pancuronium bromide in these infants is controversial and probably should be reserved for infants with parenchymal disease requiring extremely high inspiratory pressures. Because these infants are extremely sensitive to external stimuli, they should be sedated and handled as little as possible. To avoid alveolar overdistention, the inspiratory time is kept short (0.15 to 0.30 seconds). The lungs of infants with PPHN frequently have normal to prolonged expiratory time constants, so expiratory time must be kept relatively long to prevent gas trapping. Inspiratory pressure is adjusted to control the  $\text{PaCO}_2$ . Positive end-expiratory pressure (PEEP) is useful only in patients with parenchymal lung disease. If the pulmonary hypertension is severe, however, the infant frequently develops surfactant deficiency and pulmonary edema over time and consequently may respond to end-expiratory pressure and/or surfactant replacement later in the course of the disease.

### *High-Frequency Ventilation*

For those infants with parenchymal lung disease underlying their PPHN, both high-frequency jet ventilation (HFJV) and high-frequency oscillatory ventilation (HFOV) are highly effective in controlling  $\text{PaCO}_2$ . As a result, several groups have postulated that these ventilatory modalities may be effective in improving oxygenation in infants with PPHN associated with parenchymal disease. HFJV results in reductions in both  $\text{PaCO}_2$  and ventilator pressures in infants with PPHN but has no effect on ultimate outcome (Carlo et al, 1989).

Descriptive reports suggest that HFOV may be useful in the management of newborn infants with severe respiratory failure who are on maximal ventilatory support and are being considered for treatment with ECMO (Carter et al, 1990; Cornish et al, 1987). Clark and colleagues (1994) compared HFOV with conventional ventilation in

79 patients with PPHN in a randomized trial that allowed cross-over for treatment failures. There were no differences in mortality, treatment failures, or pulmonary outcomes between the two groups. Of interest, of the 24 patients in whom conventional ventilation failed, 15 (63%) responded to HFO, whereas only 4 (23%) of the 17 in whom HFO failed responded to conventional ventilation ( $P = .03$ ). A more recent trial (Kinsella et al, 1997) compared HFOV with conventional ventilation with iNO using a cross-over design that allocated patients in whom both therapies failed to a group for treatment with the combination of HFOV and iNO. Response to HFOV or iNO alone was similar between the two groups (23% and 28%, respectively), as was the response to the cross-over treatment (21% and 14%, respectively). Roughly one third of infants in whom both treatments failed, however, responded to the combination of HFOV and iNO. The response rates were best for infants with meconium aspiration syndrome or respiratory distress syndrome (RDS). Their results support the use of HFOV in combination with iNO, especially in infants in whom iNO alone fails. Both trials support the premise that HFOV for PPHN should be used only in hospitals that can also provide ECMO, because patients in whom HFOV therapy fails must be managed with conventional ventilation for the purpose of transportation.

### *Surfactant Replacement*

Data suggest that surfactant deficiency may play a role in several of the diseases associated with PPHN. Meconium aspiration pneumonia (Sun et al, 1993a, 1993b) and bacterial pneumonia both are associated with surfactant inactivation, and surfactant replacement therapy appears to improve gas exchange in infants with these conditions (Al-Mateen et al, 1994; Auten et al, 1991; Herting, 2000; Khammash et al, 1993). Although results with use of surfactant to treat severe respiratory failure in the term infant (Lotze et al, 1998) are promising, surfactant replacement therapy for infants with PPHN must still be considered experimental. For the infant in whom adequate ventilation with oxygen and appropriate cardiovascular support does not result in an acceptable PaO<sub>2</sub>, the remaining alternative is to try to lower the pulmonary vascular resistance by pharmacologic means.

### *Inhaled Nitric Oxide Therapy*

It has long been postulated that vascular tone is an intrinsic property of the blood vessels. The observation that this was true only when the endothelium remained intact (Furchgott and Zawadzki, 1980) led to the suggestion that an endothelial cell-derived relaxing factor existed. In experiments done by Ignarro and colleagues (1987), it was shown that the endothelial cell-derived relaxing factor was identical with NO, a gas that could be delivered to the lung by inhalation. NO is produced in the endothelial cell by NO synthase, which catalyzes the conversion of arginine and oxygen to citrulline and NO (Palmer et al, 1988); the NO diffuses to the smooth muscle cell and activates guanyl cyclase, which converts guanosine triphosphate (GTP) into cGMP, producing smooth muscle relaxation.

Inhaled NO (iNO) initially was used in laboratory animal models to produce a specific decrease in pulmonary artery pressure (Frostell et al, 1991). No similar effect on the systemic circulation occurs because on entering the pulmonary bloodstream, NO is rapidly inactivated by combination with hemoglobin, forming first nitrosohemoglobin and then methemoglobin. Studies in the lamb and piglet models of PPHN (Etches et al, 1994; Kinsella et al, 1994; Roberts et al, 1993a; Zayek et al, 1993) demonstrate that iNO can reduce frequency of deaths and pulmonary artery pressure in a dose-related fashion from 0 to 80 parts per million (ppm).

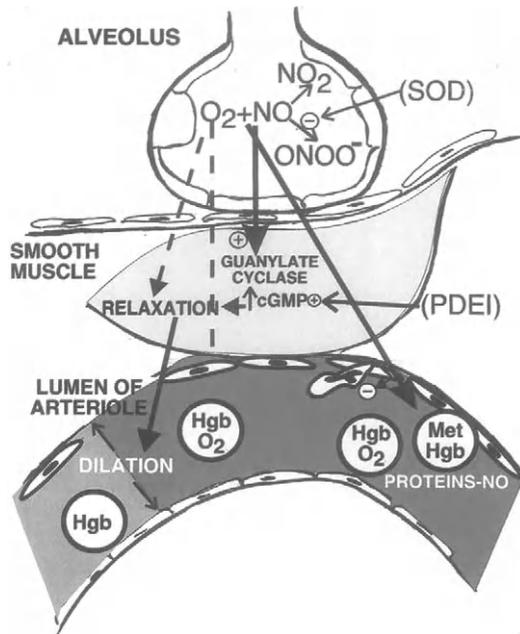

### CLINICAL EXPERIENCE

These animal studies led to simultaneous reports by Roberts and colleagues (1992) and Kinsella and associates (1992b) showing that low-dose iNO (between 5 and 80 ppm) could produce a fall in pulmonary artery pressure, with improved systemic oxygenation, in newborn infants with severe respiratory failure due to PPHN. NO did this without decreasing systemic blood pressure or producing other toxic side effects.

This targeted delivery of dilator therapy by inhalation to the pulmonary vasculature with improved oxygenation had tremendous clinical appeal. Reports of improved oxygenation in PPHN (Kinsella et al, 1993), in congenital heart disease (Roberts et al, 1993b), in acquired RDS in children (Abman et al, 1994) and in adults (Zapol and Hurfor, 1993) rapidly followed the animal studies. Finer and coworkers (1994) found that most responding patients had a satisfactory response at NO levels of less than 20 ppm and that higher doses did not produce any improvement in the response. It is essential to remember that even though NO may improve pulmonary vascular resistance, it may have little effect if the lungs are not adequately recruited, if myocardial function is severely impaired, or if systemic circulatory insufficiency is present. On the other hand, infants with pure PPHN may respond to NO without much additional therapy. Gupta and colleagues (2002) reported their 5-year single-center experience with iNO combined with gentle ventilation (described in Wung et al, 1985): Their patients had 72% survival, and the need for ECMO was reduced compared with that in historical controls) from 23.9% to 12.8%.

### CLINICAL TRIALS

Several large multicenter, multinational trials of iNO therapy have been conducted. Although there was considerable variation in the design of the trials with regard to entry criteria, prior treatments, randomization, blinding, placebo, dose ranges, and therapeutic outcomes, on the whole these trials represent a determined attempt to delineate the role of iNO therapy in the treatment of neonatal respiratory failure (Abman and Kinsella, 1995). Several controlled trials of iNO therapy have demonstrated clinically important outcome improvement. In the Neonatal Inhaled Nitric Oxide Study (NINOS) trial (1997), the mortality rates among 121 controls and 114 treated infants were the same, but the need for ECMO was reduced from 64% in control subjects to 46% in those

**FIGURE 48-4.** Nitric oxide (NO) synthesis. cGMP, cyclic guanosine monophosphate; Hgb, hemoglobin; Met Hgb, methemoglobin; PDEI, phosphodiesterase inhibitors; SOD, superoxide dismutase. (From Davidson D: *iNO for PPHN. Current evidence for safe and effective guidelines. Tufts University School of Medicine Reports in Neonatal Respiratory Disease 10[2], 2000.*)

given iNO treatment. Similarly, in a trial reported by Roberts and associates (1997), although mortality rate was unchanged, the need for ECMO was reduced from 71% in control subjects to 40% in treated infants. In three additional controlled trials, the need for ECMO was reduced (Clark et al, 2000; Cornfield et al, 1999; Davidson et al, 1998). It seems reasonable to conclude that iNO reduces the need for ECMO by about one third.

Promising new research into the biochemistry of iNO is ongoing that may lead over time to the use of lower doses of NO. It is possible that the vasodilatory effect of iNO may be enhanced by cGMP-specific phosphodiesterase inhibitors and that superoxide dismutase may enhance the response to iNO (see Fig. 48-4) (Davidson, 2000).

#### TOXICITY OF NITRIC OXIDE

With the exception of anesthesia, the use of inhaled gas therapy in medicine is rare. There continue to be concerns about the possible toxicity of NO. When exposed to oxygen, NO is slowly converted to NO<sub>2</sub>. The Centers for Disease Control and Prevention recommendation is that NO<sub>2</sub> levels not exceed 5 ppm. The higher the oxygen concentration, the higher the rate of conversion of NO to NO<sub>2</sub>; an NO concentration of 20 ppm exposed to 95% oxygen achieves an NO<sub>2</sub> level of 5 ppm after 5 minutes. In addition, when exposed to superoxide radicals in the lung lining liquid, NO is converted to peroxynitrite, which generates hydroxyl radicals, potentially producing significant injury to surfactant lipids and proteins (Haddad et al,

1993). There is no evidence, however, that NO treatment is associated with an increased incidence of BPD, and in fact, trials using iNO to prevent BPD are under way (see Chapter 49). Another concern has been that NO may inhibit platelet function or prolong bleeding time, promoting the occurrence of hemorrhagic complications (Edwards, 1995); however, bleeding has not been a problem in clinical trials.

#### CLINICAL SAFETY

The inherent reactivity of NO and oxygen meant that new techniques needed to be developed to ensure safety. NO is fed into the inspiration line of the ventilator distal to the humidifier, so its exposure to oxygen is as short as possible before inhalation. Exhaled gas is collected at the PEEP valve and exhausted into the wall suction system of the hospital. The concentrations of NO and NO<sub>2</sub>, sampled at the patient manifold, are measured constantly by electrochemical sensors. The level of methemoglobin in blood usually does not exceed 2%, and the level of NO<sub>2</sub> in the inspired gas usually does not exceed 2 ppm, but they both must be monitored. Because of the low inspired concentrations of NO, new delivery systems and new detection devices have been developed to provide safe, accurate methods of gas delivery. The inspired iNO concentration should be weaned to the minimal effective level once the oxygen concentration has been weaned (usually to less than 80%) and the infant is stable. The patient should be weaned from iNO over a period of 12 to 48 hours, as tolerated.

As a result of these trials, the Food and Drug Administration (FDA) has approved the use of iNO for treatment of pulmonary hypertension in the term and near-term newborn infant (Centers for Disease Control and Prevention recommendations, 1998). This is currently the only approved use of iNO, although a number of clinical trials are ongoing to examine use of iNO in the preterm infant to prevent BPD (see Chapter 49), as well as in the adult or older child with acute RDS.

#### Outcome in Patients with Persistent Pulmonary Hypertension of the Newborn

In the past, mortality rates for infants with PPHN ranged from 20% to 40%, and the incidence of subsequent neurologic handicap ranged from 12% to 25% (Ballard and Leonard, 1984). Sell and coworkers (1985), however, found that only 40% of 40 infants with PPHN in their institution were developmentally normal at 1 to 4 years: 32% had abnormal or suspect findings on neurologic examination, and 20% had neurosensory hearing loss.

It should be noted, however, that most of the infants described before 1992 were managed with hyperventilation with significant hypocarbia (often with a PaCO<sub>2</sub> of less than 20 to 25 mm Hg for hours to days), and the exposure to hypocarbia correlates with poor outcome. Marron and colleagues (1992) reported on 34 infants managed conservatively without induced alkalosis. All 34 survived. Of the 27 who returned for follow-up, 4 had severe neurologic deficits, 5 had minor abnormalities, and none had any evidence of sensorineural hearing loss. The outcome for

infants with PPHN has been further improved with the careful use of iNO and of ECMO when appropriate (see later on).

### Outcome after Inhaled Nitric Oxide Therapy

Four reports have described the neurodevelopmental outcome for a group of newborns who received iNO for PPHN (Clark et al, 2003; Lipkin et al, 2002; Neonatal Inhaled Nitric Oxide Study Group, 2000; Rosenberg, 2002). Although all of these reports are follow-up studies showing an initial improved pulmonary outcome and decreased requirement for ECMO, this improvement has not translated into a reduced need for outpatient treatment of lung disease or reduced rehospitalization rates. On the other hand, there is no evidence that being treated with iNO and avoiding ECMO is associated with any increase in adverse pulmonary or neurologic effects. These follow-up studies, however, all are relatively short-term (including infants up to 1 year of age), and much longer follow-up will be necessary to determine that use of iNO has improved intact survival of critically ill term infants.

## MECONIUM ASPIRATION PNEUMONIA

Meconium, an odorless, thick, blackish green material, is first demonstrable in the fetal intestine during the third month of gestation. It is an accumulation of debris that consists of desquamated cells from the alimentary tract and skin, lanugo hairs, fatty material from the vernix caseosa, amniotic fluid, and various intestinal secretions. Meconium is biochemically composed of a mucopolysaccharide of high blood group specificity, a small amount of lipid, and a small amount of protein, which decreases throughout gestation. Its blackish green color is the result of bile pigments.

### Pathogenesis

Meconium staining of amniotic fluid (MSAF) occurs in roughly 10% to 26% of all deliveries (Nathan et al, 1994). The risk of MSAF is strongly correlated with gestational age. Before 37 weeks of gestation, the risk of MSAF is less than 2%, whereas the risk after 42 weeks of gestation is nearly 44%.

The cause of MSAF is controversial. At one time, the passage of meconium in utero was thought to be synonymous with ongoing fetal asphyxia. At present, however, the relationship between MSAF and fetal asphyxia is unclear. A number of studies have failed to show any consistent effects of MSAF on Apgar scores, fetal scalp pH, or incidence of fetal heart rate abnormalities (Abramovici et al, 1974; Baker et al, 1992; Miller et al, 1975). These studies led to speculation that asphyxial episodes too brief to decrease pH or Apgar scores may cause the passage of meconium in utero. These conclusions were supported by a study showing that there was no correlation between the consistency of meconium and markers of fetal asphyxia (Trimmer and Gilstrap, 1991). Several studies have suggested that the presence of meconium (Nathan et al, 1994), especially thick meconium (Berkus et al, 1994), increases the risk of fetal acidosis and an adverse neonatal

outcome. Moreover, one study found that although MSAF correlated poorly with markers of acute intrauterine asphyxia (pH, lactate, and hypoxanthine concentrations), it correlated well with blood erythropoietin concentration (a marker of chronic intrauterine asphyxia). The strong correlation between MSAF and gestational age supports two additional theories: (1) It is possible that the passage of meconium in utero is the result of transient parasympathetic stimulation from cord compression in a neurologically mature fetus. (2) Passage of meconium in utero is a natural phenomenon that reflects the maturity of the gastrointestinal tract. Despite these theories, most authorities agree that MSAF in connection with fetal heart rate abnormalities is a marker for fetal distress and is associated with an increased perinatal morbidity.

Meconium may enter the trachea and airways in utero. In one study, meconium was recovered from the tracheas of 56% of meconium-stained infants in the delivery room (Gregory et al, 1970). Another study (Davis et al, 1985) described 12 infants who died with meconium aspiration pneumonia, even though their tracheas were suctioned vigorously in the delivery room. These findings suggest that in some instances, particularly with distressed fetuses who are gasping, considerable peripheral migration of meconium can occur before birth. Autopsy findings of meconium in the terminal airways of stillborn fetuses support this theory (Brown and Gleicher, 1981). It is highly unlikely, however, that significant intrauterine aspiration of meconium is the result of normal fetal breathing, because the rate of production of fetal lung fluid is such that the net movement of fluid is out of the lung. It is more likely that meconium is aspirated into the tracheobronchial tree when the fetus begins to gasp deeply in response to hypoxia and acidosis. Data showing that cord arterial pH is lower in meconium-stained infants with meconium in their tracheas at delivery support this hypothesis (Yeomans et al, 1989). It is unknown whether the reduced rate of production of fetal lung fluid that accompanies labor contributes to the movement of meconium into the trachea or to its migration peripherally.

If meconium is not removed from the trachea after delivery, with the onset of respiration it migrates from the central airways to the periphery of the lung. Initially, particles of meconium produce mechanical obstruction of the small airways that results in hyperinflation with patchy atelectasis. Later, small airway obstruction is the result of chemical pneumonitis and interstitial edema. During this later stage, hyperinflation persists, and areas of atelectasis become more extensive. In addition, there is infiltration of the alveolar septa by neutrophils, necrosis of alveolar and airway epithelia, and accumulation of proteinaceous debris within the alveolus.

Infants who die of meconium aspiration pneumonia complicated by pulmonary hypertension frequently have evidence of injury to the vascular bed of the lung. In these infants, vascular smooth muscle extends into the walls of normally nonmuscular intra-acinar arterioles, reducing their luminal diameter, which subsequently interferes with the normal postnatal drop in pulmonary vascular resistance. In addition, these infants may demonstrate plugs of platelets in their small vessels that reduce the

overall cross-sectional area of the pulmonary vascular bed (Levin et al, 1983).

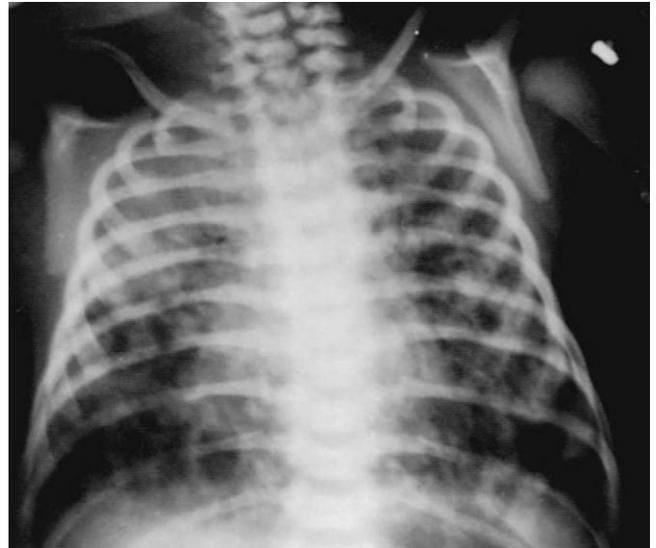

Airway resistance is increased in newborn infants and experimental animals with meconium aspiration pneumonia (Tran et al, 1980; Yeh et al, 1982). In addition, dynamic lung compliance is reduced while static lung compliance is unchanged, suggesting that airway obstruction is patchy and located in peripheral airways. Functional residual capacity is increased in animals with meconium aspiration pneumonia but not in humans. The effects of meconium on surfactant function have been studied in a number of animal models of meconium aspiration. Data suggest that meconium does inactivate surfactant (Davey et al, 1993; Moses et al, 1991; Sun et al, 1993a). Furthermore, several investigators have shown that surfactant replacement may improve gas exchange in animals with meconium aspiration pneumonia (Ohama et al, 1994; Paranka et al, 1992; Sun et al, 1993b). Gas exchange is inevitably altered in meconium aspiration pneumonia. In the absence of persistent pulmonary hypertension, hypoxia is the result of continued perfusion of poorly ventilated lung units, whereas hypercarbia is the result of a decrease in minute ventilation and increase in respiratory dead space. Some infants with meconium aspiration pneumonia have elevated pulmonary arterial pressures with shunting of blood right to left across the foramen ovale and ductus arteriosus (see discussion of pulmonary hypertension).

#### Clinical Manifestations

Infants with meconium aspiration pneumonia are often postmature and have visible meconium staining of the nails, the skin, and the umbilical cord. Asphyxia is a finding in many cases, and much of the early distress may relate more to asphyxia and retained fetal lung fluid complicated by elevated pulmonary vascular resistance than to the presence of meconium in the airways. Infants with meconium aspiration pneumonia have clinical evidence of lung overinflation, with a barrel chest. Auscultation of the chest reveals diffuse rales and rhonchi. The chest radiograph shows patchy areas of atelectasis and areas of overinflation (Fig. 48–5). Pneumothorax and pneumomediastinum are common. The clinical symptoms progress over 12 to 24 hours as meconium migrates to the periphery of the lung. Because meconium must ultimately be removed by phagocytes, respiratory distress and requirements for supplemental oxygen may persist for days or even weeks after birth. Infants who present with a shorter course and with rapid resolution of symptoms are more likely to have had retained fetal lung fluid with some PPHN than meconium aspiration pneumonia.

#### Therapy

Symptomatic infants with meconium suctioned from their tracheas should be given chest physiotherapy and warmed humidified oxygen to breathe. Lung lavage may result in deterioration of lung function. Because of the high incidence of air leaks, positive-pressure ventilation should be avoided, if possible. Judicious use of nasal or endotracheal continuous positive airway pressure (CPAP) (4 to 7 cm

**FIGURE 48–5.** Chest radiograph from an infant with meconium aspiration pneumonia.

H<sub>2</sub>O) may improve oxygenation in the patient who is unresponsive to oxygen administration alone. This improvement in oxygenation is achieved presumably by stabilizing the small airways and improving the ventilation of poorly ventilated lung units. However, many of these infants may also have some degree of delayed clearance of lung water as a result of perinatal asphyxia. High airway pressures may impair oxygenation by impeding blood flow to well-ventilated lung units. Mechanical ventilation should be reserved for infants with apnea from birth asphyxia or for those who cannot maintain their PaO<sub>2</sub> greater than 50 mm Hg in 100% oxygen, because infants with meconium aspiration pneumonia often are large and vigorous and tend to fight mechanical ventilation, and agitation increases the chances of air leak. If this occurs, the patient may require neuromuscular blockade. Because meconium aspiration pneumonia is an obstructive lung disease, the time constant for expiration is prolonged in severely involved areas of the lung. Careful attention must be paid to expiratory time (ventilatory rate) to prevent inadvertent PEEP, further gas trapping, and alveolar rupture.

The role of antibiotics in the treatment of meconium aspiration pneumonia is controversial. Meconium enhances bacterial growth by reducing host resistance, and the risk of intra-amniotic infection is increased in the presence of MSAF (Romero et al, 1991; Wen et al, 1995). However, no studies have shown that infection plays a role in the pathogenesis of meconium aspiration pneumonia. Because of the difficulty in distinguishing this disorder from bacterial pneumonia, we routinely institute antibiotic therapy in infants with presumed meconium aspiration pneumonia, pending negative cultures.

The use of corticosteroids for treatment of meconium aspiration pneumonia is not recommended. The time to weaning to room air is prolonged by corticosteroids in infants with meconium aspiration pneumonia (Yeh et al, 1977), and the mortality rate for rabbits with experimental

meconium aspiration pneumonia is increased by treatment with corticosteroids (Frantz et al, 1975).

As discussed earlier, there is some evidence that infants with meconium aspiration pneumonia have surfactant inactivation. A recent controlled trial studied the effects of surfactant replacement (up to 4 doses of 150 mg/kg of beractant every 6 hours) on infants who were being mechanically ventilated for meconium aspiration pneumonia (Findlay et al, 1996). The investigators found that surfactant replacement therapy, if started within 6 hours after birth, improved oxygenation and reduced the incidence of air leaks, severity of pulmonary morbidity, and duration of hospitalization. Other therapies for the infant with meconium aspiration pneumonia and PPHN, including the use of high-frequency ventilation, iNO, and ECMO, are covered elsewhere in this chapter.

### Prevention of Meconium Aspiration Pneumonia

Several older studies have shown that by clearing the airway of meconium at the time of birth, meconium aspiration pneumonia can be virtually eliminated (Carson et al, 1976; Gregory et al, 1970; Ting and Brady, 1975). Based on these results, the American Heart Association and the American Academy of Pediatrics have recommended a combined obstetric and pediatric approach to the infant with MSAF (Bloom and Cropley, 2000). For infants born through thin watery meconium, no special management is necessary. For infants born through thick particulate or *pea soup* meconium, they recommend the following steps:

1. When the infant's head is delivered, the mouth, pharynx, and nose should be thoroughly suctioned by the obstetrician using a 10 F or larger suction catheter.
2. If the baby is vigorous, the mouth and nose are cleared of secretions, and oxygen is given as needed.
3. If the infant is not vigorous, the hypopharynx should be visualized and residual meconium removed by suctioning. Then the trachea should be intubated and meconium suctioned from the lower airway.

Tracheal suctioning should be performed using an appropriately sized endotracheal tube and a large-bore meconium aspirator. In the presence of severe asphyxia, it may not be possible to clear the trachea of all meconium, and clinical judgment must be used to determine the amount of suctioning. Studies have found that 7% to 10% of meconium-stained infants had meconium in their tracheas even when there was not any meconium visible at the vocal cords. A free flow of oxygen should be provided via oxygen tubing to minimize hypoxia during suctioning. After tracheal suctioning, the stomach should be emptied to prevent aspiration of swallowed meconium.

A number of investigators have tried to prevent meconium aspiration by infusing saline into the amniotic cavity of mothers with heavy meconium staining of the amniotic fluid. Several randomized trials have shown that amnioinfusion decreases the risk of meconium below the vocal cords, and a meta-analysis of five controlled trials found that amnioinfusion decreased the risk of meconium below the vocal cords and the risk of meconium aspira-

tion pneumonia (Dye et al, 1994). One large retrospective study (Usta et al, 1995) and a randomized, controlled trial (Spong et al, 1994) found no benefit to a policy of routine amnioinfusion. Furthermore, in the controlled trial, the risk of endometritis-chorioamnionitis was increased in the amnioinfusion group. As a result, the role of amnioinfusion in the prevention of MAP is still controversial.

### Outcome

The outcome for infants with meconium aspiration pneumonia has improved dramatically. In the past, meconium aspiration pneumonia carried a risk of pneumothorax and pneumomediastinum of between 10% and 20%. This risk increased to as high as 50% if the infant required mechanical ventilation. Now with improved approaches to the management of PPHN and the availability of extracorporeal membrane oxygenation, the mortality for meconium-stained infants is roughly 0.15% in the total population (Nathan et al, 1994). The mortality for severely affected infants with meconium aspiration pneumonia requiring extracorporeal membrane oxygenation is less than 7% in most centers and approaches zero in some units.

## OTHER CAUSES OF RESPIRATORY FAILURE IN THE TERM INFANT

### Postasphyxial Pulmonary Edema

Pulmonary edema in newborn lambs following asphyxia from umbilical cord occlusion was described by Adamson and colleagues (1970). The lambs showed transudation of fluid from the circulation into the lungs in the presence of elevated lung capillary pressures. Infants with this condition are often depressed in the delivery room and require mechanical ventilation immediately or soon after birth (Corbet, 1990). In other infants breathing unassisted, there may be severe respiratory distress because of pulmonary edema, transient cardiomegaly, and cerebral irritation; Strang (1977) called this condition *postasphyxial lung edema*. The radiologic appearance of the lungs is that of pulmonary congestion or pulmonary edema with diffuse coarse densities, and in some reports this may be called pneumonia. The heart may be enlarged on the chest radiograph with evidence of mitral or tricuspid valve insufficiency, hypotension, hepatomegaly, poor perfusion, and reduced urine output. On the echocardiogram, there may be evidence of poor myocardial contractility and low cardiac output. Some infants have ischemic changes on the electrocardiogram, and they may have elevated creatine kinase and liver transaminase levels in the blood.

Infants with postasphyxial pulmonary edema do not usually have physical evidence for prematurity as in the case of RDS, or tracheal evidence for meconium aspiration, or bacterial evidence for neonatal pneumonia; instead, they have evidence of asphyxia, heart failure, ventricular dysfunction, pulmonary edema, and often pulmonary hypertension. Some of these infants develop clinical pulmonary hemorrhage, which is now known to be hemorrhagic pulmonary edema, the most severe form of

postasphyxial pulmonary edema. Treatment consists of oxygen supported with PEEP, mechanical ventilation, and circulation support, until spontaneous recovery occurs in a few days.

### Surfactant Protein Deficiencies

Several families have been described in which full-term infants developed prolonged and eventually fatal RDS; detailed tissue analysis suggested that they had what was originally called “congenital alveolar proteinosis” and is now known to be surfactant protein-B (SP-B) deficiency (deMello et al, 1994a). Other families have since been described. The condition is due to mutations in the SP-B gene; the most commonly described mutation (121 ins 2) involves a two-base-pair insertion at position 375 in codon 121 of the complementary DNA (Nogee et al, 1994); the additional two bases produce a frameshift signal for termination of translation after codon 214. There is no detectable messenger RNA (mRNA) for SP-B.

The chest radiograph shows the granular pattern characteristic of hyaline membrane disease (HMD) in preterm infants; hence, these infants initially may resemble other term infants with RDS. There is frequently evidence for severe pulmonary hypertension. The alveolar spaces are packed with a proteinaceous material rich in SP-A and SP-C but poor in SP-B or phospholipids, and surfactant function assessed by pulsating surfactometer is abnormal. The lamellar bodies in granular pneumocytes are poorly formed, and there may be basal rather than apical secretion, indicating defective transport protein signaling within the alveolar type II epithelial cells (deMello et al, 1994b).

Oxygen, mechanical ventilation, repeated administration of bovine surfactant containing relatively high levels of SP-B, and eventually ECMO have not been successful in changing the outcome. A few infants have survived for several months on mechanical ventilation (Ballard et al, 1995). More recently, several infants have undergone lung transplantation, with apparent success.

Prenatal amniotic fluid profiles have shown an L/S ratio of less than 2 and the absence of phosphatidylglycerol (PG) and SP-B at full-term gestation (Hamvas et al, 1994). To establish the diagnosis in newborn infants, tracheal aspirates or lung lavage aspirates should be examined for SP-B by either the enzyme-linked immunosorbent assay or by the Western blot procedure; the presence of even low levels of SP-B makes the diagnosis unlikely (Nogee, 1995). It may be possible to test the infant or the parents for the gene mutation in a DNA diagnostic laboratory. Biopsy or autopsy samples of the affected infant's lung may be examined for surfactant proteins by immunostaining.

Ballard and colleagues (1995) have described a term newborn infant with partial SP-B deficiency who needed ECMO and remained on mechanical ventilation until death at 9 months of age. The mother had the previously described point mutation in exon 4, and the father had a new point mutation at codon 236 in exon 7, which resulted in a single amino acid substitution. The infant's

surfactant contained low levels of SP-B, more precursor than mature protein, and near-normal levels of mRNA for SP-B; these findings suggested a defect in translation or in post-translational processing. Other mutations have been reported, frequently occurring in conjunction with the 121 ins 2 mutation (Cole et al, 2001). Recently, infants with abnormalities of SPC also have been found to have significant respiratory distress (Amin et al, 2001; Nogee et al, 2001). (See also Chapter 42 on lung development and Chapter 46 on surfactant.)

### ALVEOLAR CAPILLARY DYSPLASIA

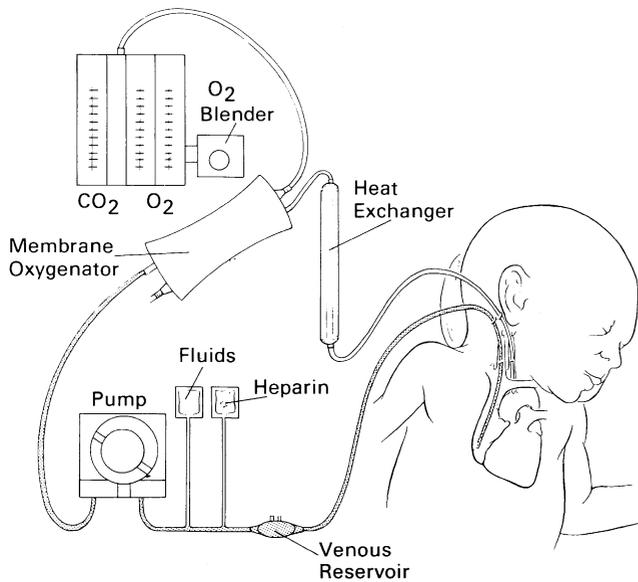

Alveolar capillary dysplasia is a rare cause of persistent pulmonary hypertension. This disorder is characterized by failure of formation and ingrowth of alveolar capillaries, medial muscle hypertrophy of pulmonary arteries, and anomalously located pulmonary veins running along with pulmonary arteries, instead of in their normal position in the interlobular septa. The patients sometimes present with symptoms similar to those of idiopathic PPHN and may be impossible to wean from ECMO. However, the early presentation may be mild (some cases have been discharged) (Boggs et al, 1994; Vassal et al, 1998). A familial occurrence has been reported. There is no gender predilection, but 50% of the patients have other anomalies (genitourinary, gastrointestinal, cardiovascular).

### EXTRACORPOREAL MEMBRANE OXYGENATION

In a group of infants with severe lung disease, progressive respiratory failure, and life-threatening hypoxemia who do not respond to maximal ventilatory support or iNO, ECMO may be considered as a treatment of last resort. This is a highly invasive procedure and should not be started without good reason. Physicians using ECMO should review their own experiences and determine appropriate criteria for selecting infants with at least an 80% risk of death from their condition. Most centers report that about 80% of such infants survive when treated with ECMO.

#### Conduct of Extracorporeal Membrane Oxygenation

For venoarterial ECMO, the system consists of a venous pressure control module, a roller pump, a countercurrent membrane oxygenator, and a heat exchanger, connected in series and primed with heparinized buffered blood (Short and Pearson, 1986) (Fig. 48–6). A catheter (14 F) is inserted in the right internal jugular vein with its tip in the right atrium, and another catheter (8 to 12 F) is inserted in the right common carotid artery with its tip in the arch of the aorta. The infant is given a bolus dose of heparin and connected to the system, with venous blood drained by gravity from the right atrium and fully oxygenated blood infused at the aorta. The heart and lungs, to a variable extent, are bypassed. The venous control module regulates the operation of the pump, ensuring that the venous drainage from the patient and the pump output to the patient are balanced.

**FIGURE 48-6.** Extracorporeal membrane oxygenation (ECMO) system. (From Short BL, Miller MK, Anderson KD: *Extracorporeal membrane oxygenation in the management of respiratory failure in the newborn. Clin Perinatol* 14:737, 1987.)

Over 30 minutes, the flow is slowly increased to about 120 to 150 mL/kg/minute, after which the mechanical ventilator can be reduced to benign settings, 25% to 30% oxygen, 15 to 20 cm H<sub>2</sub>O peak pressure, 5 cm H<sub>2</sub>O PEEP, and a rate of 10 breaths/minute. The arterial oxygen pressure can be maintained between 50 and 70 mm Hg by adjusting the ECMO flow. The venous oxygen saturation may be used to assess the overall level of oxygenation; values below 70% suggest that the cardiac output may not be sufficient. Heparinization is continued by an adjustable infusion, to maintain the activated clotting time at 180 to 220 seconds, up to two times longer than normal. In addition, packed red blood cells are transfused to maintain the hematocrit above 40%, platelets are transfused to maintain the platelet count above 100,000/mm<sup>3</sup>, and fresh frozen plasma is transfused to maintain the fibrinogen level above 200 mg/dL.

The ECMO flow can usually be decreased gradually to about 90 to 100 mL/kg/minute after the first day. An improvement in lung function may be recognized by increased lung compliance with the use of periodic bag-tube ventilation and increased pulse oximeter saturation. After 4 to 5 days, the ECMO flow is further reduced, and the ventilator settings are again increased to assume responsibility for gas exchange. Ideally, the settings should be comparatively benign, such as oxygen concentration 40% to 50%, rate 40 to 60 breaths/minute, PEEP 8 to 10 cm H<sub>2</sub>O, and peak inflation pressure 20 to 25 cm H<sub>2</sub>O. After a brief period at a low ECMO flow (30 mL/kg/minute), to ensure adequate pulmonary function, the infant can be decannulated and the vessels ligated; it is usual to place a Broviac central venous line in the right external jugular

vein at this time for the purpose of continued parenteral nutrition.

### Patient Selection

Patients with meconium aspiration pneumonia, RDS, neonatal pneumonia, congenital diaphragmatic hernia, and PPHN are prime candidates for this therapy. Because of systemic heparinization, infants weighing less than 2000 g and less than 34 weeks of gestation at birth have a high incidence of cerebral hemorrhage (Cilley et al, 1986) and should be excluded, as should larger infants if they already have evidence for cerebral hemorrhage or cerebral infarction. All patients should undergo head ultrasound examination before initiation of ECMO. Those who are older than 7 to 14 days and have been exposed to prolonged mechanical ventilation with oxygen are not good candidates because their lung disease may not be reversible. Infants with severe malformations should be excluded. A thorough search for congenital heart disease should be made with echocardiography before ECMO (Palmisano et al, 1992), and occasionally an emergency chromosome analysis is necessary in patients with dysmorphic features.

The definition of life-threatening hypoxemia, sufficient to justify ECMO, is still somewhat controversial among neonatal centers. Many centers prefer to use the oxygenation index, the product of three factors: (1) the percent oxygen, (2) the mean airway pressure, and (3) the reciprocal of arterial PO<sub>2</sub> (Keszler et al, 1992). Failure to respond to iNO at 40 ppm for 2 to 3 hours is considered a reliable indication for ECMO. In our current practice, most patients who are placed on ECMO have an arterial PO<sub>2</sub> of less than 50 mm Hg. When the arterial oxygen tension is this low, despite intensive medical therapy, there is an increased risk that anaerobic metabolism may result in severe metabolic acidosis, which increases the likelihood of either death or significant morbidity. Patients with an arterial PO<sub>2</sub> of more than 50 mm Hg and a normal acid-base status, with no evidence of anaerobic metabolism, may survive without ECMO.

### Efficacy of Extracorporeal Membrane Oxygenation

The efficacy of ECMO was assessed in a randomized, controlled trial in adult patients and was found not to be superior to conventional therapy (Zapol et al, 1979). There have been two North American attempts to conduct a randomized, controlled trial of ECMO in newborn infants. In the first (Bartlett et al, 1985), an unusual trial design resulted in a small control group (only one patient), so the results in favor of ECMO were widely discounted. In the second controlled trial (O'Rourke et al, 1989), more appropriately randomized, 6 of 10 infants survived with conventional mechanical ventilation, and 9 of 9 infants survived with ECMO. Although this difference was not significant, further enrollment into the ECMO group suggested superior results with ECMO. Both of these trials reflected the bias of investigators in favor of ECMO. In the second trial, the mortality rate in controls was much lower than the 80% expected. It then became impossible to conduct a good randomized, controlled trial in North America, where ECMO has become universally accepted. A con-

trolled trial in Great Britain demonstrated improved survival in infants with intractable respiratory failure with the use of ECMO (UK Collaborative ECMO Trial Group, 1996). Of 93 patients allocated randomly to ECMO, 3 improved and did not need ECMO, 5 were excluded (most for congenital heart disease), 7 died before ECMO could be started, and 78 were treated with ECMO. There were 30 deaths in these 93 patients (32% mortality rate), compared with 54 deaths among 92 control subjects who were not allocated to ECMO (59% mortality rate), a significantly better result. The improvement was most noticeable among those with idiopathic persistent pulmonary hypertension, but it was significant among those with meconium aspiration pneumonia, and even among those with congenital diaphragmatic hernia.

### Outcome with Extracorporeal Membrane Oxygenation

There has been much concern about the long-term outcome of infants who have received ECMO. Schumacher and colleagues (1988) reviewed multiple reports and found that at follow-up assessment, 81% of 643 patients were considered to be normal, 7% had borderline abnormalities, and 12% had serious disabilities. These results are considered to be as good as, and possibly better than, the results in infants with the same conditions treated without ECMO (Klein and Whittlesey, 1994). An evaluation of the effect of neonatal risk factors and treatment strategy on long-term outcome for ECMO survivors (Vaucher, 1996) found that compared with 52 infants who met criteria for use of ECMO but were successfully treated with conventional or high-frequency ventilation, the 138 ECMO survivors were more mature in spite of having earlier, more severe pulmonary disease. The ECMO survivors were also more likely to have had meconium aspiration. They had significantly fewer ventilator days (9 versus 11), hospital days (23 versus 29), and less chronic lung disease (12% versus 25%). At 12 to 30 months, the mean developmental scores of the ECMO survivors were similar to those of infants who survived without ECMO. Those infants who had chronic lung disease had significantly lower motor scores and were more likely to have cerebral palsy than were those without chronic lung disease (27% versus 6%). The investigators concluded that neonatal ECMO candidates who were treated with ECMO did as well as or better than neonates whose conditions were managed with alternate treatment strategies. It should be noted that these infants all were treated prior to the FDA approval of iNO as therapy for respiratory failure in term or near-term infants. The only follow-up from a randomized trial of neonatal ECMO is that reported by Bennett and colleagues (2001) for the UK Collaborative Trial. The 4-year follow-up demonstrated improved, intact survival in critically term neonates who received ECMO, compared with that in the control group.

### Problems with Extracorporeal Membrane Oxygenation

Because ECMO is an invasive procedure and because contact of blood with a plastic surface sets off a massive release of potent mediators, there are a large number of associated problems, for example:

1. The circuit must be constantly observed for large air bubbles and clots, which, if present on the arterial side of the circuit, may embolize into the patient's systemic circulation, with potentially disastrous results. Some centers use a trap on the patient's side of the circuit. In addition, an unnoticed disconnection anywhere in the circuit may rapidly cause hemorrhagic shock, so constant vigilance is necessary.
2. If the patient receives too much heparin, there may be hemorrhagic complications, such as bleeding at the operative site, bleeding into the brain, bleeding into the peritoneal or pleural space, or gastrointestinal bleeding. The use of cautery and fibrin glue at the surgical site or the use of systemic aminocaproic acid (Amicar) may help lessen the incidence of hemorrhage. In some cases, a consumptive coagulopathy (excessive consumption of coagulation factors) may develop, as the plastic surface of the circuit becomes coated with multiple fibrin thrombus layers; this condition may become so serious that decannulation or a change of the circuit may be necessary. The level of fibrin split products should remain less than 10  $\mu\text{g}/\text{mL}$  during routine ECMO.
3. The patient may develop a low cardiac output, which does not increase when ECMO flow is reduced and which may prolong the length of time on ECMO; this condition is known as the *cardiac stun syndrome* (Hirschl et al, 1992). The reason for this problem may be twofold: that coronary perfusion is dependent on poorly oxygenated left ventricular blood (Kinsella et al, 1992a) and that retrograde flow from the aortic catheter may increase the afterload resistance to left ventricular ejection. This condition should not be confused with the universal reduction in cardiac output and myocardial contractility that occurs because the heart is unloaded in venoarterial ECMO (Kimball et al, 1991).
4. Within a few hours of initiation of ECMO, the lungs frequently develop a diffuse, dense opacification and further loss of compliance; this is thought to be caused by high-permeability pulmonary edema, possibly secondary to activated complement fragments and increased leukotriene production. This pulmonary edema lessens within a few days, especially if high PEEP levels (10 to 12 cm  $\text{H}_2\text{O}$ ) are maintained (Keszler et al, 1992). Because surfactant may be inactivated by pulmonary edema fluid, exogenous surfactant therapy may be helpful (Lotze et al, 1993).
5. The urine output often decreases dramatically on ECMO, and the patient may become edematous. As in the case of the lungs, the edema is probably caused by capillary injury from activated complement fragments and increased leukotriene production. This injury cascade leads to hypotension, with the need for frequent infusions of colloid to raise the blood pressure; these infusions are in addition to those given to maintain the hematocrit, platelet, and fibrinogen levels. As the capillary injury resolves after a few days, the edema may be treated with loop diuretics, but sometimes hemofiltration becomes necessary, especially if pulmonary edema fails to resolve.

6. The use of the carotid artery for cannulation and its ligation at the time of decannulation have raised much concern about the circulation to the brain and the possibility of brain injury. Schumacher and colleagues (1988) reported an increased incidence of right-sided ischemic lesions of the brain. In some centers, the carotid artery is reconstructed at the time of decannulation (Taylor et al, 1992). Baumgart and colleagues (1994) found, using color-coded Doppler imaging, that the brain blood flow profile was improved with this procedure, but head computed tomography scans before discharge and neurodevelopmental status at age 1 year did not suggest any improvement in the outcome. Some centers use a second catheter placed in the cephalic segment of the internal jugular vein to improve the venous drainage of the brain; this measure improves the total ECMO flow but has not been shown to change the outcome.
7. Some patients develop systemic hypertension on ECMO; this effect may be related to circulation overload and may respond to diuresis or hemofiltration. Because the heart and lungs are bypassed, there may be a deficiency of epinephrine degradation; because renal blood flow is nonpulsatile, there may be high levels of plasma renin; and because the right atrium is decompressed, there may be high levels of arginine vasopressin. Hypertension may predispose the patient to cerebral hemorrhage, so treatment with hydralazine or enalapril may be necessary.
8. A few patients develop excessive hemolysis, related to high pressures in the circuit (greater than 300 mm Hg); this problem may be monitored by measurements of plasma free hemoglobin, which should remain below 40 mg/100 mL.
9. After ECMO, many patients have problems with feeding; the reason for this is not understood, but because the vascular catheters lie near the vagus nerve, there may be temporary injury causing esophageal dysfunction and gastroesophageal reflux. Some of these patients also may develop a superior vena cava syndrome (Zreik et al, 1995) or a chylothorax, and some may have transient vocal cord paralysis, again related to the catheters.

### Venovenous Extracorporeal Membrane Oxygenation

The initial development of ECMO was venoarterial, but there has been increasing use of venovenous ECMO, especially when a single dual-lumen catheter can be placed in the right atrium. The catheter must be carefully placed so that well-oxygenated blood is directed toward the tricuspid valve, to minimize recirculation into the venous drainage.

The major advantage of this technique is that the carotid artery does not have to be sacrificed. In addition, because the pulmonary and coronary circulations receive well-oxygenated blood, there may be significant improvements in pulmonary artery pressures and myocardial function. Because of the recirculation problem, the capacity to deliver oxygen is less than in venoarterial ECMO;

the ECMO flow must usually be higher, frequently in the range of 120 to 140 mL/kg/minute, and lower levels of arterial PO<sub>2</sub>, in the range of 40 to 60 mm Hg, must often be accepted. If the circulation and hemoglobin levels are well maintained and if the patient's acid-base status and blood lactate levels remain normal, it is unlikely that a state of oxygen deficiency exists. Also, because of the recirculation problem, the central venous oxygen saturation cannot be used as an assessment of overall oxygenation. Commonly a cephalic venous catheter is used to monitor cerebral venous oxygen saturation; values of less than 60% are considered evidence for oxygen deficiency.

Despite the use of pressors to maintain the circulation, venovenous ECMO must be changed to venoarterial ECMO in up to 10% of patients. Nevertheless, Cornish and associates (1993) found that most patients referred to an ECMO center could be managed effectively with venovenous ECMO; myocardial function usually improved, and pressors could be gradually withdrawn. The neurodevelopmental outcome of patients after venovenous ECMO is similar to that after venoarterial ECMO (van Meurs et al, 1994).

### LIQUID VENTILATION

During the past 25 years or so, investigators have been pursuing the possibility of treating ventilatory failure with liquid rather than gaseous ventilation (Shaffer et al, 1984; Wolfson et al, 1996). The discovery of a class of compounds known as fluorocarbons has led to significant advances because they are chemically and physiologically inert. Perfluorocarbon, the compound that has been used in both animal experimentation and human clinical studies, has a greater solubility for respiratory gases than that of blood. It has some of the properties of surfactant, with a low surface tension. When instilled into the lung, this radiopaque compound gradually recruits alveoli without barotrauma and, because of its low vapor pressure, is rapidly eliminated by vaporization. Although animal studies initially were encouraging, there are no successful controlled trials in humans at this time (Greenspan, 1990; Leach et al, 1993, 1995, 1996).

# Bronchopulmonary Dysplasia

Beverly A. Banks-Randall  
and Roberta A. Ballard

## HISTORICAL OVERVIEW

Bronchopulmonary dysplasia (BPD), which is referred to also as *chronic lung disease of prematurity*, is the most common chronic lung disease of childhood. BPD was first described by Northway and colleagues, in 1967, as a severe chronic lung injury in premature infants who survived hyaline membrane disease after treatment with mechanical ventilation and oxygen. Four distinct clinical and pathologic stages were described, progressing from typical respiratory distress syndrome (RDS), with alveolar interstitial edema as well as atelectasis, to massive fibrosis and consolidation of the lung with areas of cystic emphysema and overinflation.

BPD as originally described occurred predominantly in larger preterm infants born at 30 to 34 weeks of gestation with a history of severe respiratory distress necessitating high levels of ventilatory support and oxygen exposure for a prolonged period of time. These infants were born before the introduction of antenatal corticosteroids or postnatal surfactant replacement and at a time when ventilators were first being adapted for use in the newborn.

Since that time, much has been learned about BPD, and the disorder as originally described has virtually disappeared. The infants who are more commonly affected with BPD today are those of extremely low birth weight and born at less than 26 weeks of gestation. Following treatment with antenatal corticosteroids, combined with postnatal surfactant, these infants initially frequently do remarkably well, requiring only low concentrations of oxygen for treatment of RDS, which usually responds favorably to exogenous surfactant. They often then have several days during which there is minimal or no requirement for supplemental oxygen or ventilatory support. Although the initial definition of BPD was a requirement for oxygen at more than 28 days after birth, at present the definition has been revised to include oxygen *or* ventilatory support at 36 weeks of post-menstrual age. The definition of BPD was reviewed at a recent National Institutes of Health-sponsored workshop on BPD (Jobe and Bancalari, 2001). The new definition specifies diagnostic criteria including the need for oxygen, positive pressure ventilation, and/or continuous positive airway pressure (CPAP), along with postnatal age, to better characterize the severity of BPD

(Table 49-1). The form of BPD seen in the tiny preterm infant who has had minimal initial respiratory distress is now being called the “new” BPD (Bancalari, 2001; Jobe, 1999).

## BRONCHOPULMONARY DYSPLASIA

### Epidemiology

BPD is now relatively rare in infants born beyond 32 to 34 weeks of gestation but may be increasing in infants born at less than 26 weeks of gestation at a weight of less than 1000 g. In the National Institute of Child Health and Development (NICHD) Neonate Network, the incidence of BPD at 36 weeks in all infants weighing 501 to 1500 g increased from 19% in 1990 to 23% in 1996 and remained at 22% in 2000. In addition, for those very low-birth-weight infants who require prolonged mechanical ventilation, approximately 60% are oxygen dependent at 28 days, and 30% are still oxygen dependent at 36 weeks post-menstrual age. For those weighing less than 1000 g, the incidence of BPD was 40% in the NICHD Neonatal Network; if the infant required mechanical ventilation, the incidence of BPD was as high as 77%, with an overall incidence for mild cases of 31%; for moderate cases, 28%; and for severe cases, 18% (Ehrenkranz et al, 2001).

Although there has been a marked decrease in BPD in larger infants, recent data from the NICHD Network as well as from the Vermont Oxford Database indicate that in the years since 1996, there has been no further decrease in the incidence of BPD (see Chapter 1). The odds of developing BPD increase by approximately two-to threefold for each lower week of gestational age (Palta et al, 1998).

### Pathobiology

BPD is fundamentally the result of abnormal reparative processes in response to injury and inflammation occurring in an immature lung of a genetically susceptible infant (Fig. 49-1). Thus, it is very clear that the pathogenesis of BPD begins with a very immature lung complicated by iatrogenic damage from therapy with oxygen and volume ventilation with superimposed infection and inflammation as well as pulmonary edema complicated by poor nutrition.

### Pathologic Stages of Disease

The original description of BPD pathology by Northway divided the disease into four distinct clinicopathologic stages (Fig. 49-2). Stage 1 pathologic findings were consistent with hyaline membrane disease (now called “respiratory distress syndrome”). In stage 2 (age 4 to 10 days), atelectasis was more extensive, alternating with areas of emphysema, and the chest film again showed opaque lung fields with air bronchograms. It is worth noting that at the time of this description in the late 1960s, the usefulness of CPAP or positive end-expiratory pressure (PEEP) as we know it today had not yet been described. The ventilation of these infants was with zero PEEP, contributing to severe atelectasis. During stage 3, at 11 to 30 days of age, prominent features included extensive bronchial and

TABLE 49-1

**Diagnostic Criteria for Bronchopulmonary Dysplasia**

Treatment with  $\text{FIO}_2$  greater than 0.21 for at least 28 days  
PLUS

Failure of room air challenge test at 36 weeks of  
post-menstrual age

**Classification of Severity**

Mild	Requires up to 0.30 effective $\text{FIO}_2^*$
Moderate	Requires greater than 0.30 effective $\text{FIO}_2^*$
Severe	Requires ventilatory support, usually with oxygen

\*Effective  $\text{FIO}_2$  is based on infant's weight and the concentration and flow of oxygen through a nasal cannula or in a hood.

$\text{FIO}_2$ , fraction of inspired oxygen.

Data from Jobe and Bancalari, 2001.

bronchiolar metaplasia and hyperplasia. On the chest film, the lung now began to show cystic areas. During stage 4, after 30 days of age, there was massive fibrosis of the lung with destruction of alveoli and airways. The radiographs revealed fibrosis and edema with areas of consolidation as well as areas of overinflation.

**Pathologic Findings in the “New” Form of the Disease**

In the “new” BPD, the lungs are more uniformly inflated and actually have minimal airway injury or fibrosis. The major abnormality is a decrease in alveolar number, referred to as *alveolar hypoplasia* (Burri, 1997; Coalson et al, 1999; Husain et al, 1998). In the very preterm infants in whom

this “new” BPD is seen, the lung is just finishing the canalicular stage of development at the time of birth; consequently, a number of factors that interfere with the progress of alveolar development may contribute to the development of the “new” BPD.

**Etiologic Factors**

Our current understanding of BPD indicates a multifactorial etiology incorporating many contributing factors.

**Host Susceptibility and Genetic Predisposition**

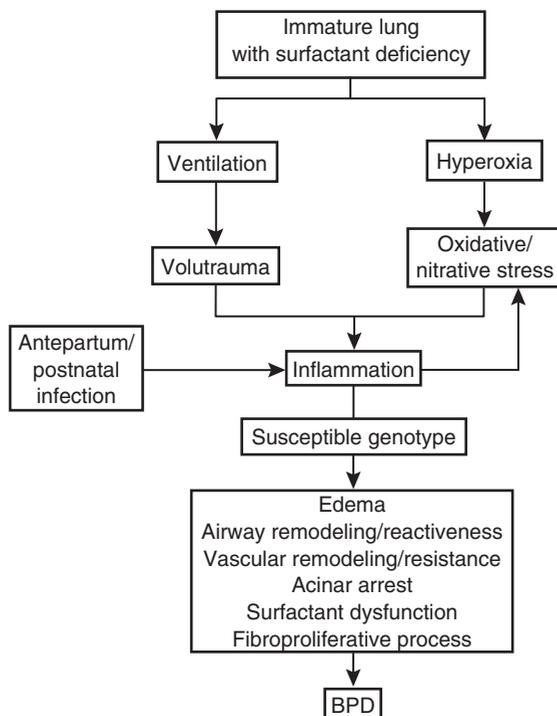

By far the most important factor in the pathogenesis of BPD is prematurity. Intrauterine growth retardation/restriction also contributes to increased risk (Lal et al, 2003).

It has been known for some time that infants born to certain families are more likely to have RDS at any given gestational age than those in other families. In addition, it has been clear that a family history of asthma and reactive airway disease also puts an infant at additional disadvantage (Bertrand et al, 1985; Evans et al, 1998; Nickerson and Taussig, 1980). Little is known about the genetic contribution to the occurrence of BPD among premature infants. One small study demonstrated an association between BPD and human leukocyte antigen-A2 (HLA-A2). Infants with a family history of asthma are at greater risk for BPD. The availability of the human genome sequence, continuing characterization of single nucleotide polymorphisms (SNPs), and advances in genetic epidemiology give us the tools to identify polymorphisms that affect susceptibility to BPD.

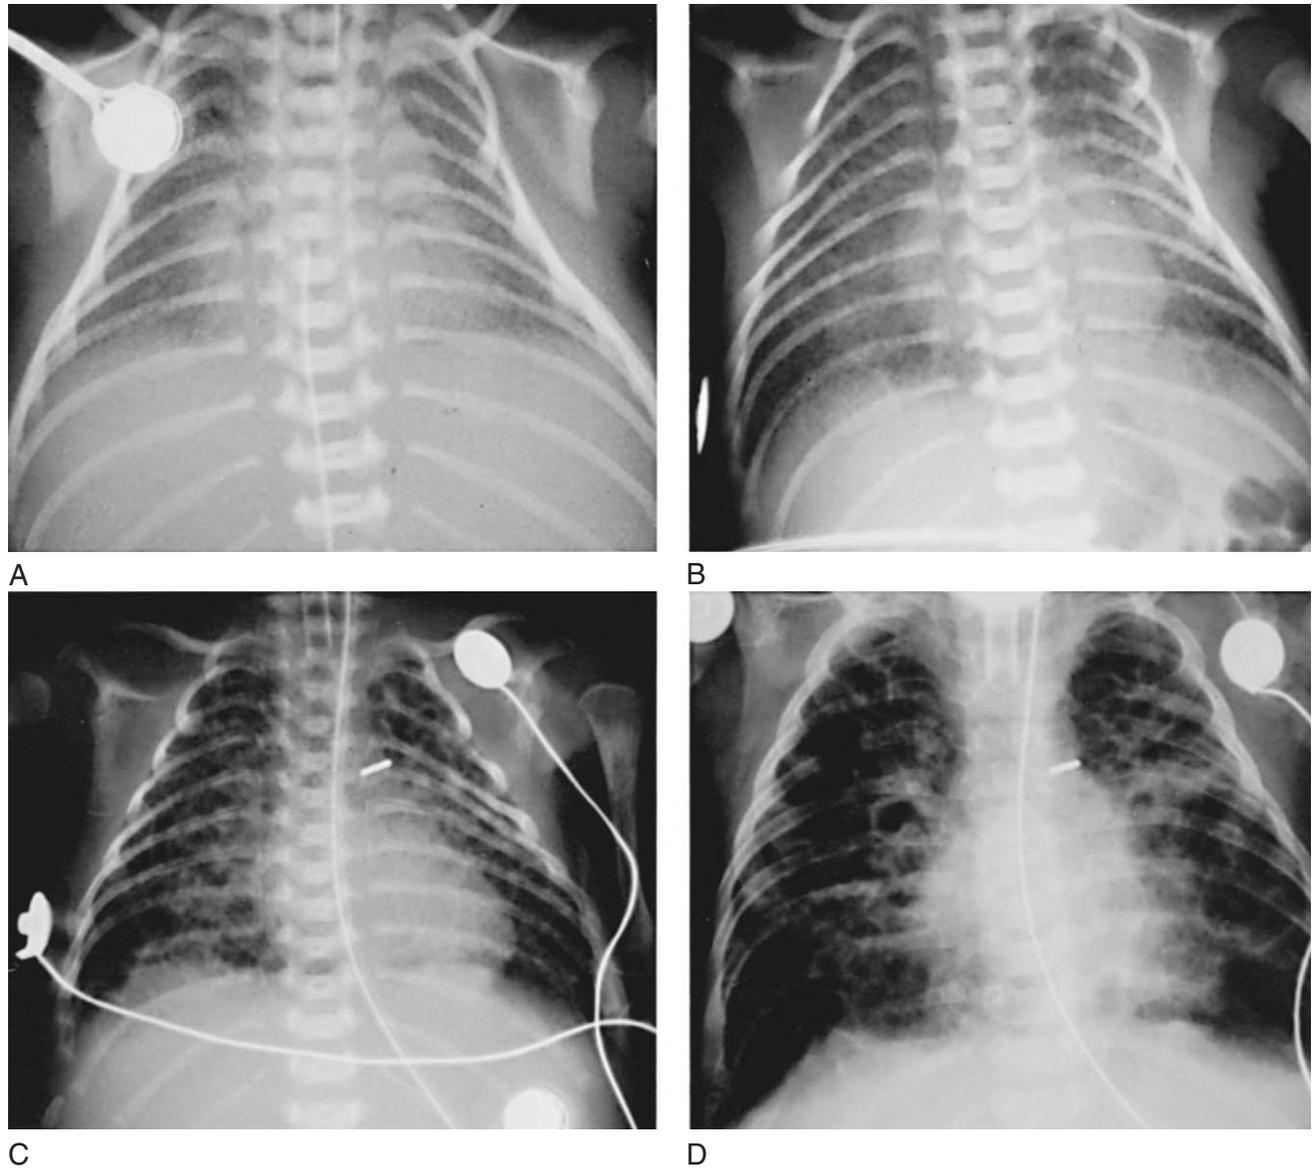

Genetic polymorphisms may contribute to an infant's risk of developing BPD by influencing (1) degree of lung maturity, in particular the content or function of surfactant and the abundance of alveoli at the time of birth; (2) the intensity of the inflammatory response and the propensity to fibrosis; (3) the ability of antioxidant enzymes to protect the lung from free radical damage; and (4) the ability of the neonatal lung and vascular tissue to mature and form alveoli. Ideal candidate genes for genetic analysis would include those with clear biologic significance in pathogenesis of BPD, those with polymorphisms that affect protein level or function, and those with polymorphisms that are amenable to high throughput screening assays. The genes encoding surfactant proteins (SPs), transforming growth factor- $\beta_1$  (TGF- $\beta_1$ ), and vascular endothelial growth factor (VEGF) meet these criteria as ideal candidate genes. Nevertheless, it remains clear that immaturity of the lung is the single most important etiologic factor in BPD.

**Inflammation**

A complex inflammatory response clearly plays a major role in the development of BPD (Yoon, 1999). This response may be triggered by a number of other factors thought to be a part of the pathobiology of BPD. These triggers include oxygen toxicity with oxidant damage, ventilation with volutrauma due to use of excessive tidal volumes, and infection prior to delivery, with increased concentrations of inflammatory cytokines in amniotic fluid, as well as cytokines produced as a result of neonatal infection.

**FIGURE 49-1.** Immature lung with surfactant deficiency. BPD, bronchopulmonary dysplasia.

**FIGURE 49-2.** A–D, Radiographs illustrating the four stages of bronchopulmonary dysplasia.

The inflammatory response is reflected in increased numbers of neutrophils in tracheal aspirate samples as early as the second day of life (Arnon et al, 1993). Although alveolar macrophages are essential for recognition, ingestion, and elimination of lung pathogens, they also produce fibroblast, epithelial, and endothelial cell growth factors, leading to lung tissue repair. In addition, they can have deleterious effects through release of oxygen radicals and can release fibronectin, a large glycoprotein that is a growth factor for fibroblasts, as well as releasing the growth factor TGF- $\beta$ , which stimulates the growth of mesenchymal cells and inhibits proliferation of epithelial cells. Among the markers of inflammation that have been found in high concentrations in tracheal aspirates of infants in whom BPD develops are interleukins IL-6, IL-8, IL-11; TNF- $\alpha$  and TGF- $\beta$ ; and elastase, type IV collagen, endothelin-1 (Groneck et al, 1996; Kotecha et al, 1995, 1996; Jonsson et al, 1997; Ohki et al, 2001; Niu et al, 1998; Ramsay et al,

1998), and soluble E-selectin and intercellular adhesion molecule-1 (ICAM-1). Table 49-2 lists the factors that have been found in tracheal aspirates and are associated with the development of BPD in the preterm infant.

#### Neonatal Infection

Postnatal bacterial sepsis clearly increases the risk of BPD (Gonzalez et al, 1996; Romagnoli, 1998). Airway microbial colonization even without frank sepsis also may increase the risk of BPD. A study of tracheal aspirate samples from ventilated preterm infants revealed that those with positive bacterial, including *Ureaplasma urealyticum*, cultures in the first day of life had an increased airway inflammatory response (Groneck et al, 1996). Continued tracheal colonization with certain bacterial agents, including *Ureaplasma*, has also been associated with increased risk of BPD. If the concept of the new BPD in the tiny preterm infant is regarded

TABLE 49-2

as a syndrome of arrested lung development, then it may be that either infection or inflammatory cytokines may contribute to the arrest of normal alveolarization and development.

#### Oxygen Toxicity

In the initial cases of BPD reported by Northway and colleagues (1967), it was clear that exposure to high oxygen concentration was a factor in development of the disease. Subsequent reports have continued to show an association between high levels of supplemental oxygen or prolonged oxygen exposure and lung damage in ventilated preterm infants. Recent evidence (STOP-ROP, 2000) suggests that even a slight increase in inhaled oxygen concentration over a prolonged time contributes to pulmonary pathology. In experimental animals, oxygen toxicity follows a course similar to that of BPD, and postmortem findings are similar (Chang et al, 2003; Coalson et al, 1995). The damage to the lung caused by oxygen toxicity appears to be mediated by reactive oxygen species that are produced during univalent reduction of molecular oxygen. These species include superoxide anion ( $O_2^-$ ), hydrogen peroxide ( $H_2O_2$ ), and hydroxyl radical ( $OH^-$ ). Evidence suggests the presence of an oxidant-antioxidant imbalance in lungs that are at risk for BPD, and the higher concentrations of lipid peroxidation metabolites such as the  $F_2$  isoprostanes found in preterm infants support this concept (Saugstad, 1996, 2001). The concept of oxidant-antioxidant imbalance is further supported by observations that preterm infants have lower levels of retinoic acid (Shenai et al, 2000), which has been shown to suppress both superoxide and hydrogen peroxide formation in stimulated neutrophils and macrophages. It is clear that reactive oxygen and nitrogen species, which are generated during pulmonary oxygen toxicity, are responsible for many of the pathologic features observed in the premature baboon model of BPD. There is some evidence (Chang et al, 2003) that treatment of the animals with a catalytic antioxidant metalloporphyrin can protect against some of the oxygen toxicity. The change in pattern in these animals, however, is similar to the original description of BPD in older preterm infants. It will be essential to observe whether or not blockage of oxidant damage with antioxidant therapy will have an effect on the known arrest of alveologenesis seen in the "new" BPD.

#### Ventilation with Volutrauma

As is the case with exposure to high oxygen, the association between overdistention of the preterm lung and the development of BPD is well established. It is clear that overinflation produces stress fractures of the capillary endothelium, epithelium, and basement membrane. This mechanical injury causes leakage of fluid into the alveolar spaces, with additional inflammatory response and the release of additional proinflammatory cytokines. The relative contribution of high peak inspiratory pressures (*barotrauma*) versus overdistention of the lung (*volutrauma*) to lung injury previously was a source of some controversy. Hernandez and colleagues (1989) compared the respective roles of high tidal volume with high peak inspiratory pressure (PIP) in immature New Zealand white rabbits to look at the effect on microvascular permeability in animals that were treated with chest wall restriction with a full-body plaster cast. Preventing overdistention also prevented any significant increase in microvascular permeability, even when the manometer indicated pressures up to 45 cm  $H_2O$ . In contrast, when isolated excised lungs were ventilated with peak inspiratory pressures of only 15 cm  $H_2O$  for 1 hour (with overdistention), there was an 850% increase in microvascular permeability. This finding suggests that preterm infants with relatively healthy lungs and highly compliant chest walls may experience significant lung injury even at apparently low ventilator pressures. In addition, in the preterm lamb model, manual ventilation with as few as 6 very large breaths at birth may compromise the therapeutic effect of subsequent surfactant administration, leading to significant lung damage (Bjorklund et al, 1997; Dreyfuss et al, 1998). Evidence that exposure to high tidal volumes in preterm human infants contributes to BPD comes from several sources. In particular, there is an association between hypocarbia and an increased incidence of BPD (Garland et al, 1995; Kraybill et al, 1989) as well as a known strong association between the occurrence of pneumothorax and pulmonary interstitial emphysema with lung overdistention.

Multiple attempts have been made to improve ventilatory strategies for the preterm infant that would result in a marked decrease in incidence of BPD. One such strategy is the use of high-frequency oscillatory ventilation (HFOV) (Courtney et al, 2002; Gerstmann et al, 1996; Johnson et al, 2002; Moriette et al, 2001). (See also Chapter 45 on the principles of respiratory care.) Although a statistically significant decrease in the incidence of BPD has been described, none of the studies using HFOV achieved large clinically relevant differences in outcome. On the other hand, attempts have been made to use a minimal ventilation strategy to prevent BPD (Carlo et al, 2002). Although the need for ventilatory support at 36 weeks of postmenstrual age was only 1% in the minimal ventilation group versus 16% in the routine conventional ventilation treatment group ( $P < .01$ ), the major morbidities and long-term outcomes were comparable in the two treatment groups. Thus, this approach also requires additional study.

In 1987, Avery and associates published a descriptive review of treatment center differences in the incidence of BPD. At one neonatal center, use of nasal CPAP immediately after delivery was associated with a much lower incidence of BPD than that reported by the other centers.

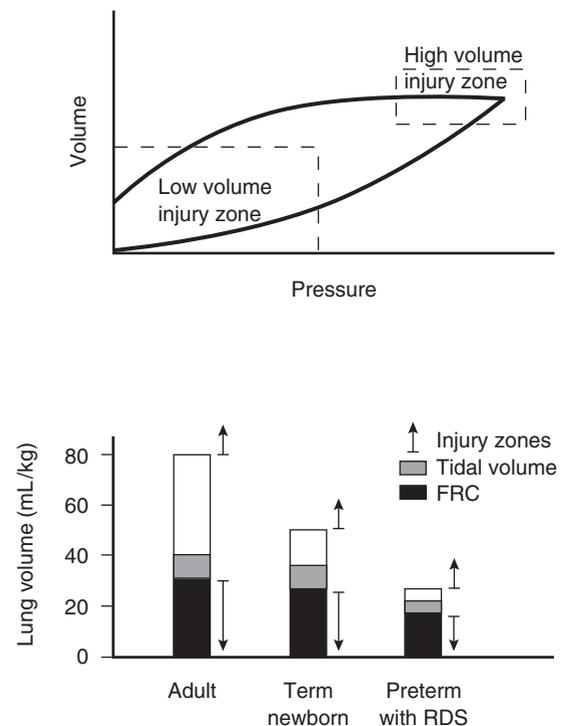

Van Marter and colleagues (2000) compared the practices and outcomes for neonatal units in Boston and at Columbia University and again found that the incidence of BPD at Columbia overall was much lower, as were other care practices including use of mechanical ventilation, surfactant, indomethacin, and sedation. The use of nasal CPAP was higher and infants at Columbia were intubated less frequently than at the other centers. These investigators found that the best predictor of subsequent BPD was requirement for ventilation on the day of birth (odds ratio 13.4, with a 95% confidence interval [CI] of 5.9 to 30.7).

It must be remembered, however, that infants requiring initial ventilation are often the sickest infants, and even at Columbia, these infants usually die without intervention. Much work is now in progress to improve the delivery systems for nasal CPAP. Use of the recently developed variable-flow nasal CPAP systems, including those employing a nasal mask, appears to significantly decrease work of breathing associated with the use of other systems for applying nasal CPAP (DeKlerk and DeKlerk, 2001; Pandit et al, 2001). Unfortunately, to date, no large randomized trial of this technique has been done. However, multiple attempts are ongoing to study early application of nasal CPAP, thus avoiding intubation and mechanical ventilation. On the other hand, it is clear from review of the literature that nasal CPAP is effective in preventing failure of extubation in preterm infants following a period of endotracheal intubation and intermittent positive pressure ventilation (IPPV) (Ho et al, 2002).

It is clear that loss of functional residual capacity (FRC) with onset of generalized atelectasis also can be a major contributor to the development of BPD. In infants who are being ventilated below a normal FRC, repetitive opening and closing of lung units occur in the presence of maldistribution. This then leads to areas of significant overdistention. There is accumulating evidence from both animal and human newborns that the optimal use of PEEP is associated with a lower risk for BPD. Figure 49-3 demonstrates the appearance of static pressure-volume curves for infants with either normal lungs or with RDS and also depicts the potential areas of lung injury from either high-volume ventilation or low-volume ventilation with atelectasis. There is general agreement that the least injurious approach to supporting ventilation in the preterm infant would be to avoid intubation and stabilize FRC with CPAP. However, many preterm infants are too small or too sick to tolerate the use of nasal CPAP alone and therefore will require intubation and mechanical ventilation. At this time, the approach that would seem most likely to contribute to prevention of BPD is the use of an optimal PEEP to support a normal FRC combined with low-tidal-volume ventilation. Large trials are under way to examine this hypothesis.

#### *Pulmonary Edema and Patent Ductus Arteriosus*

It is clear from animal studies (Bland et al, 2000) that abnormalities of lung fluid balance contribute to BPD. In the human, several studies done before routine administration of antenatal steroids or postnatal surfactant became available suggested that pulmonary edema and patent ductus arteriosus (PDA) contributed to the pathogenesis

**FIGURE 49-3.** Upper panel, Static pressure-volume curve indicating areas of lung injury from either high-volume ventilation or low-volume ventilation with atelectasis. Lower panel, Lung volumes for a normal adult, a term newborn, and a preterm with RDS. The low and high volume injury zones are indicated by arrows. The preterm lung is susceptible to injury with ventilation because of the small volume/kg between the two injury zones. FRC, functional residual capacity; RDS, respiratory distress syndrome.

of BPD (Brown et al, 1978; Van Marter et al, 1990a). Several investigators have also demonstrated that patency of the ductus arteriosus has a significant association with the incidence of BPD (Gonzalez et al, 1996). However, it is clear that excess flow through the ductus arteriosus can be controlled with appropriate levels of end-expiratory pressure and that the ductus itself can be closed pharmacologically with indomethacin. In addition, the more generalized use of antenatal steroids since the Consensus Conference in 1994 has reduced the incidence of PDA in the preterm infant.

#### *Poor Nutrition*

All of the aforementioned etiologic factors are intensified by the inadequate nutritional status that is virtually always present in sick preterm infants. These infants have delayed feeding as well as difficulty receiving adequate parenteral nutrition because of the need to restrict fluid. Because of the increased work of breathing, they also are generally in a catabolic state. In addition, they have vitamin deficiencies, particularly of vitamin A; the latter condition that has been associated with disruption of epithelial cell integrity in the animal model. They also have diminished amounts of antioxidant agents including vitamin E, which probably leads to potentiation of oxygen free radical injury. Each of these factors leads to increased susceptibility to infection,

which leads in turn to a further cycle of impaired defense against injury.

### Adrenal Insufficiency

It has been suggested (Watterberg and Scott, 1995; Watterberg et al, 1996) that preterm infants may have developmental immaturity of the hypothalamic-pituitary-adrenal axis and that the risk of BPD is increased secondary to inadequate response to inflammatory lung injury. Banks and colleagues (2001), reported, however, in a study of cortisol levels in 314 preterm infants, that even the earliest gestation infants (24 to 25 weeks) have an increase in cortisol after delivery and that levels were not associated with gestational age (Fig. 49-4). More important, there was only a weak association with severity of illness. Using the CRIB (Clinical Risk Index for Babies) score (International Neonatal Network, 1993) to adjust for clinical risk factors, low cortisol at 3 to 7 days of life contributed only very minimally to increasing the risk for BPD and there was no correlation at 14 to 28 days. It is possible that a high-risk subpopulation of preterm infants who have low cortisol levels or an inappropriate response to ACTH stimulation might benefit from low-dose hydrocortisone therapy; however, there is no evidence that adrenal insufficiency is a major contributor to BPD.

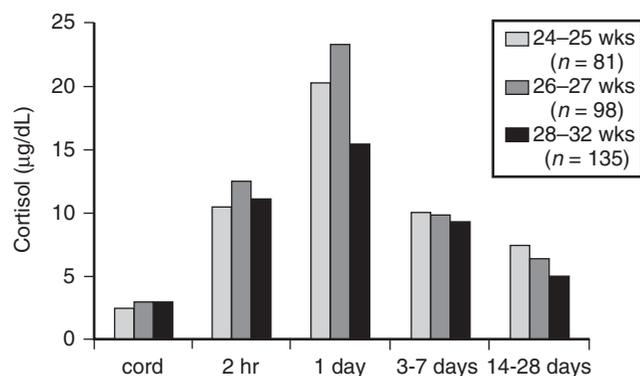

### Inhibition of Normal Lung Development

The insults contributing to BPD as described are occurring at a gestational age when alveolarization should be occurring. Development of alveoli can be delayed in a number of animal models by hypoxia, hyperoxia, glucocorticoids, and poor nutrition. In addition, cytokine overexpression also can interfere with normal septation (Albertine et al, 1999; Jobe, 1999; Massaro and Massaro, 2000).

Increasing evidence indicates that abnormal pulmonary vascular development is associated with all of these insults (Abman, 2001). Thus, with the arrest of alveolarization occurring in these infants, arrest of pulmonary vascular development also occurs (Bhatt et al, 2001).

### Preventive Factors

Jobe and Ikegami (2001) recently reviewed approaches to prevention of BPD. Among the practices they evalu-

**FIGURE 49-4.** Plasma cortisol concentrations in premature infants during the first 4 weeks of life. Data are mean levels stratified by gestational age: 24 to 25 weeks ( $n = 81$ ), 26 to 27 weeks ( $n = 98$ ), and 28 to 32 weeks ( $n = 135$ ).

ated were antenatal maternal steroid administration, use of surfactant, nasal CPAP, and postnatal corticosteroids (PNCS).

### Antenatal Steroids

Numerous clinical studies and several large meta-analyses have demonstrated that a single course of antenatal glucocorticoids administered to women at high risk for premature delivery results in a significant decrease in the mortality rate and in the morbidity associated with prematurity, including RDS, intraventricular hemorrhage (IVH), PDA, and necrotizing enterocolitis (NEC). However, the effect on the incidence of BPD among the survivors does not appear to be of substantial clinical importance (Van Marter et al, 1990b). This lack of clinical significance may be due to increased survival of more and smaller preterm infants (see also Chapter 47 on RDS).

### Surfactant

Although surfactant replacement therapy is clearly associated with decreased severity of RDS and with a lower associated mortality rate, there is no evidence overall that the survivors have a significantly decreased incidence of BPD. Again, this lack of correlation may be due to the improved survival of smaller, sicker infants.

### Gentle Ventilation

As described previously, there is evidence that volutrauma as well as atelectasis contribute directly to lung damage as well as releasing cytokines, which further the cycle of damage. Therefore, numerous trials of ventilatory modes including patient-triggered ventilation, high-frequency ventilation, and minimal ventilation (with the goal of keeping the  $\text{PaCO}_2$  above 55 mm Hg), as well as trials with some newer modes of ventilation, have been attempted (Carlo et al, 2002; Stark, 2002). (See also Chapter 45 on the principles of respiratory care.) Thus far, none of these trials has resulted in a substantial clinical benefit supporting a given mode of ventilation for general use in care of the newborn.

### Nasal Continuous Positive Airway Pressure

Current attempts to accomplish randomized clinical trials of the “Columbia approach” are under way (Aly, 2001). This approach involves immediate administration of “bubble” CPAP in the delivery room to high-risk preterm infants and also involves an initial tolerance of quite high  $\text{PaCO}_2$  values (in the range of 65 to 70 mm Hg) and subsequent tolerance of higher  $\text{PaCO}_2$  (55 to 68 mm Hg) as well. These trials have raised the question of what the optimal level of  $\text{PaCO}_2$  is in the preterm infant, as well as concern about the optimal oxygen saturation for these infants (Askie et al, 2003) (see later on).

### Fluid Restriction

Good evidence suggests that fluid overload contributes to an increased risk for BPD (Van Marter et al, 1990a), and some clinical trial data suggest that excessive fluid administration increases the risk of PDA, NEC, and death (Tammela, 1995). However, too-vigorous limitation of fluid administration contributes to the problem of undernutrition, thereby contributing to failure of development of alveoli.

### Vitamin A

Vitamin A is an essential nutrient for maintaining respiratory tract epithelial cells and also is stored in the septal cells of the alveoli involved in alveolar septation. Compelling animal data (Albertine et al, 1999) support the need for vitamin A as well (Fig. 49–5). Because vitamin A is accumulated predominantly in the third trimester, preterm infants have deficient liver stores of this vitamin (Zachman, 1989). These infants, who often are unable to tolerate enteral feedings, are at particular risk for vitamin A deficiency because vitamin A added to parenteral nutrition solutions is degraded by light and can adhere to the intravenous tubing, making it largely inaccessible. A number of clinical trials have investigated whether supplementation with vitamin A, typically by intramuscular injections, would result in a decrease in BPD. A large study by the NICHD Neonatal Network demonstrated a significant decrease in BPD (11%) with treatment with vitamin A (Tyson et al, 1999). A meta-analysis of clinical trials published in the Cochrane database in 1999 also revealed that vitamin A supplementation was associated with a reduction in BPD at 36 weeks (Darlow and Graham, 1999). Vitamin A is well tolerated, although it does involve intramuscular injections. It is also inexpensive and is to date the only intervention tested by randomized clinical trials demonstrated to produce a decrease in relative risk of death or BPD at 36 weeks of post-menstrual age. Although there has been a theoretical concern about potential skin or muscle complications from the injections, there was no evidence of damage at follow-up evaluation in the NICHD trial.

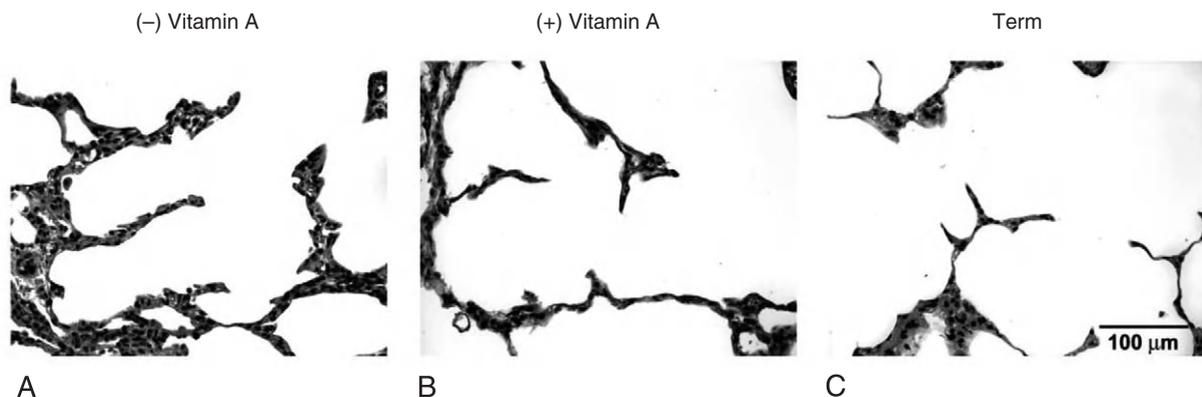

### Postnatal Corticosteroids

Preterm infants who were given PNCS demonstrate some decreased inflammatory markers and suppression of cytokine-mediated inflammatory reactions in their tracheal

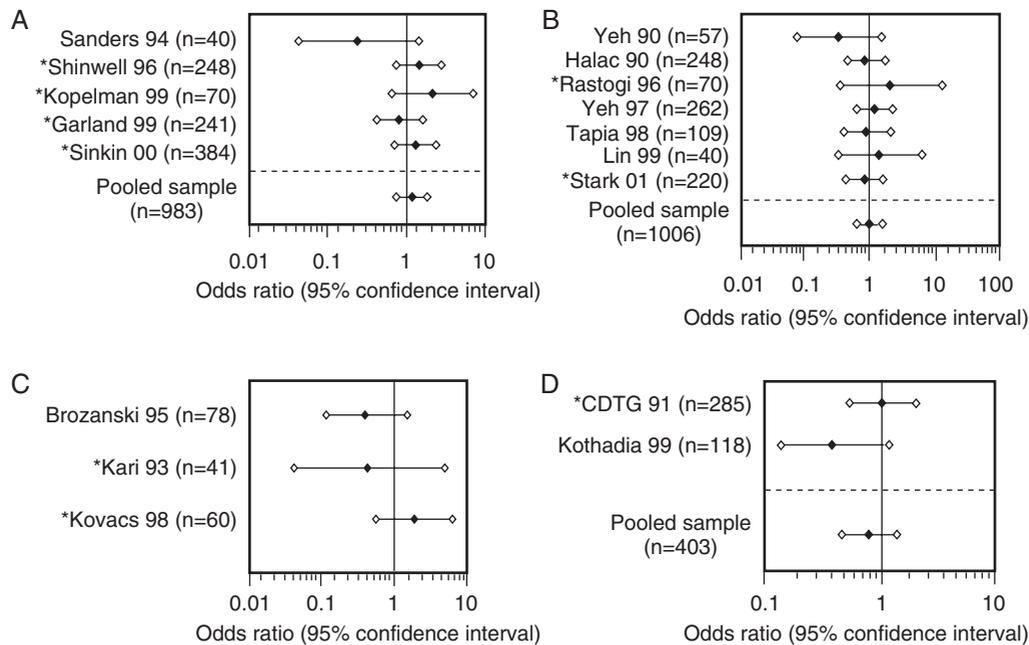

aspirates. Numerous theoretical reasons have been advanced regarding why postnatal administration of steroids might decrease the incidence of BPD, including the potential for increased surfactant synthesis, enhanced beta-adrenergic activity, increased antioxidant production, stabilization of cell and lysosomal membranes, and inhibition of prostaglandin and leukotriene synthesis (Watterberg et al, 1999). Although clinical trials have demonstrated increased dynamic compliance and decreased pulmonary resistance following treatment with PNCS, their overall impact on BPD and/or death are not compelling, and major concerns exist regarding both short- and long-term side effects.

A meta-analysis by Banks (2002) reviewed 40 clinical trials of dexamethasone and stratified outcome by time interval and duration of treatment, as shown in Figure 49–6. None of the regimens tried resulted in decreased mortality. Trials of 4-day or longer courses of dexamethasone in preterm infants less than 48 hours old, however, did demonstrate a decreased risk of death or BPD. Under these circumstances, one would need to treat approximately 9 infants with PNCS in order to prevent one adverse outcome of death or BPD.

On the other hand, significant adverse effects of dexamethasone are well known, including hypertension, hyperglycemia, adrenal suppression, and decreased growth. In addition, four large recently published trials (Garland et al, 1999, Sinkin et al, 2000; Stark et al, 2001; Vermont Oxford Network Steroid Study Group, 2001) have described an increased rate of early gastrointestinal perforation not associated with NEC in infants who received PNCS. Even more concerning, however, are results of follow-up in randomized trials involving large numbers of infants. It is now clear that administration of PNCS, particularly very early and/or prolonged administration, is associated with an increased incidence of cerebral palsy and adverse neurodevelopmental outcome (Finer et al,

**FIGURE 49–5.** Histopathology of evolving chronic lung disease (CLD) of prematurity in lambs that were mechanically ventilated for 3 weeks at 20 breaths/minute (~15 mL/kg tidal volume). **A**, Preterm lamb ventilated for 3 weeks, treated daily with saline (the vehicle for vitamin A) given intramuscularly. **B**, Preterm lamb ventilated for 3 weeks, treated daily with vitamin A (5,000 U/day) given intramuscularly. **C**, Term lamb ventilated for 3 weeks (control). The most simplified distal air spaces and most thickened alveolar walls are in the lung tissue of the preterm lamb that was not treated with vitamin A (seen in **A**). Secondary septa also are least evident in the preterm lamb that was not treated with vitamin A. All panels are of the same magnification (scale bar = 100  $\mu$ m).

**FIGURE 49-6.** Odds ratios and 95% confidence intervals for the effect of dexamethasone therapy on mortality. Figures are stratified by age at initiation of treatment and duration of therapy. Studies that allowed the use of open-label steroids are indicated with an asterisk. The estimated odds ratio for each trial is shown with the *black diamond*, and the 95% confidence interval for the odds ratio is shown with *open diamonds*. Pooled odds ratios determined by the Mantel-Hanszel technique are shown in the *bottom bar*. No odds ratio is significantly different from 1. **A**, Effect of dexamethasone on mortality when treatment is begun at less than 48 hours and continued for 1 to 3 days. **B**, Effect of dexamethasone on mortality when treatment is begun at less than 48 hours and continued for 4 or more days. **C**, Effect of dexamethasone on mortality when treatment is begun at 7 to 14 days. Because of significant variability in the study design of these three trials, a pooled odds ratio is not calculated. **D**, Effect of dexamethasone on mortality when treatment is begun at more than 14 days.

2000; O'Shea et al, 1999; Shinwell et al, 2000; Yeh et al, 1997). Figure 49-7 shows the risk-benefit balances for treating preterm infants with PNCS.

The high risk of poor neurodevelopmental outcome has led the American Academy of Pediatrics (AAP) and the Canadian Pediatric Society along with the European Pediatric Society to strongly recommend that (1) postnatal steroids be used only within randomized controlled trials that have neurodevelopmental outcome as a part of their protocol; (2) if steroids are to be used, they be used only under exceptional clinical circumstances; and (3) there be documented full, informed consent of the family regarding the potential short- and long-term risks of steroids. In addition, the goal should be to give the minimum dose for the shortest possible period of time. At present, the optimal course with the least side effects would appear to be limiting treatment to infants with severe disease (requiring fraction of inspired oxygen [FIO<sub>2</sub>] greater than 0.5 and mean airway pressure [MAP] greater than 12 to 14 cm of H<sub>2</sub>O) who are older than 7 days of age, and to use brief bursts of a 3-day course of steroids beginning at a dose of less than 0.25 mg/kg.

Although other routes of steroid administration, including inhalation (Cole, 2002), as well as the possibility of using other types of glucocorticoids such as hydrocortisone, have been suggested, no data at this point suggest clinical improvement with either inhaled steroids or use

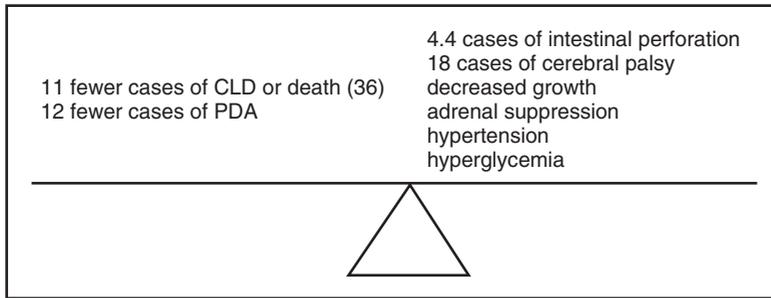

of hydrocortisone. A trial of early administration of low-dose hydrocortisone for prevention of BPD was recently stopped due to an increased incidence of intestinal perforation in treated infants.

#### Antioxidant Therapy

Some evidence in the baboon model of BPD indicates that a catalytic antioxidant metalloporphyrin can protect against hyperoxia-induced lung injury (Chan et al, 2003; Tanswell and Jankov, 2003). Superoxide dismutase is a naturally occurring enzyme that protects against oxygen free radical injury. Preliminary trials in the human infant have suggested that administration of exogenous superoxide dismutase might be of benefit (Davis, 2002; Davis et al, 2000, 2003). Some investigators have raised caution concerning use of antioxidants as therapy in the newborn (Jankov et al, 2001). Further trials of this intervention are needed before it can be recommended as useful in preventing BPD.

#### Inhaled Nitric Oxide

It has been hypothesized that inhaled nitric oxide (iNO) may potentially either prevent BPD or benefit infants with evolving BPD, as a result of several of its known effects. In fact, it may be that preterm infants with early BPD have a deficiency of endogenous NO, and that exogenous iNO, by causing pulmonary vasodilatation as

**FIGURE 49-7.** Balance of treatment of 100 ventilated preterm infants in the first 48 hours of life resulted in limited benefit and significant possibility for harm. CLD, chronic lung disease; PDA, patent ductus arteriosus.

well as bronchial dilatation (Martin et al, 2002), will reduce the need for oxygen and ventilatory support. Pilot data on iNO administration were obtained (Banks et al, 1999) in a group of preterm infants with severe BPD who were older than 28 days of age and still required mechanical ventilation with an MAP of greater than 10 cm H<sub>2</sub>O as well as inspired oxygen concentration of at least 45%, with a majority requiring greater than 75% oxygen. These infants were treated with iNO at 20 parts per million (ppm) and evaluated both within the first hour and after 72 hours. Approximately two thirds of the infants demonstrated marked improvement in oxygenation within 1 hour of beginning iNO therapy, and a similar number had significant decrease in oxygen requirement within 72 hours. Based on this pilot information as well as studies from Kinsella and colleagues (1999) confirming the safety of iNO, several randomized controlled trials of approaches preventing BPD with iNO are ongoing in North America. The hypothesis is that low-dose iNO administered to preterm infants with birth weights of 500 to 1250 g who require mechanical ventilation will increase survival without chronic lung disease at 36 weeks of post-menstrual age. In addition, it is hypothesized that the treatment will increase neither pulmonary inflammatory response nor level of oxidant stress and will have no adverse effect on either short- or long-term clinical outcome. Infants enrolled in these trials will be followed to at least 2 years of age to determine neurodevelopmental outcome as well.

### Clinical Course and Treatment

As mentioned earlier, the classic BPD described by Northway and colleagues is now extremely rare with the advent of antenatal steroids, postnatal surfactant, and ventilators and ventilator strategies better suited for newborn infants. Thus, here we address only the clinical course of the “new” BPD. As pointed out by Bancalari (2001) and others, a majority of infants who have BPD currently are extremely low-birth-weight (usually under 1000 g) infants who require prolonged ventilator support, often for management of apnea or poor respiratory effort. Following use of antenatal steroids and postnatal surfactant, these infants often initially require relatively low concentrations of oxygen and have fairly mild initial respiratory distress. They are extremely susceptible to infection, however, and often between 5 and 10 days of age they develop systemic sepsis and/or tracheitis and pneumonia. Infection contributes to the deterioration of respiratory status that occurs during this period in many of these infants.

Although certainly high-level oxygen and ventilator support contribute to the developing BPD, a number of other factors are involved as well.

Barrington and Finer (1998) reviewed the treatment of BPD. Management of these infants should be directed at (1) minimizing ventilatory support and overdistention while (2) supporting and maintaining adequate FRC with end-expiratory pressure. These goals can best be achieved with the use of nasal CPAP with a variable-flow delivery system (Courtney et al, 2001; Pandit et al, 2001). Successful use of nasal CPAP requires tolerance of permissive hypercapnia both immediately after birth (the recommendation of the group at Columbia is to tolerate levels as high as 70 mm Hg) as well as subsequent tolerance of PaCO<sub>2</sub> values well into the 60s, along with avoidance of PaCO<sub>2</sub> values under 40. This recommendation has led to the need for further investigation of the appropriate level of PCO<sub>2</sub> in these preterm infants. There has been concern that elevated levels might be associated with IVH or other adverse neurodevelopmental effects. However, recent studies in the human rather suggest that both hypocapnia (not hypercapnia) and hyperoxia place infants at increased risk for disabling cerebral palsy (Collins et al, 2001). In addition, there is some evidence that high PaCO<sub>2</sub> levels may actually be neuroprotective (Vanucci et al, 1995, 1997). In fact, some data (Laffey et al, 2000) indicate that PCO<sub>2</sub> values up to 100 mm Hg actually protect the lung from reperfusion injury and that buffering the low pH that results from high PCO<sub>2</sub> negates the protective effect of the high PCO<sub>2</sub>.

Another management issue that is crucial for maintaining infants on nasal CPAP is the expected level of oxygen saturation to be achieved. Again, there is enormous controversy regarding the appropriate oxygen status of these infants. It should be emphasized that in utero, the fetus is exposed to a PaO<sub>2</sub> of only 25 to 27 mm Hg and oxygen saturations below 80%. Yet, without any good data, keeping the preterm infant's oxygen saturation (SaO<sub>2</sub>) in a range of 90% to 95% is commonplace. In some institutions, levels have routinely been kept above 95%. The data from a recent large clinical trial (STOP-ROP, 2000) did not demonstrate any major value for protection against retinopathy of prematurity with exposure to SaO<sub>2</sub> ranges that were greater than 96%, compared with 89% to 94%. However, the pulmonary outcomes for the infants in this trial exposed to higher oxygen indicated more evidence of damage. On the other hand, in a randomized trial involving 358 infants born at less than 30 weeks of gestation who remained dependent on supplemental O<sub>2</sub> at 32 weeks, there was no evidence that targeting the

SaO<sub>2</sub> ranges in the 91% to 94% rather than 95% to 98% range had any effect on growth or development. However, maintaining the higher SaO<sub>2</sub> range resulted in longer exposure to oxygen, higher rates of O<sub>2</sub> dependence at a post-menstrual age of 36 weeks, and higher frequency of home-based oxygen therapy (Askie et al, 2003). Trials are ongoing to evaluate whether keeping oxygen saturation at lower levels (even allowing SaO<sub>2</sub> to fall to under 80%) might result in improvement in both pulmonary and neurodevelopmental outcomes.

### Ventilation

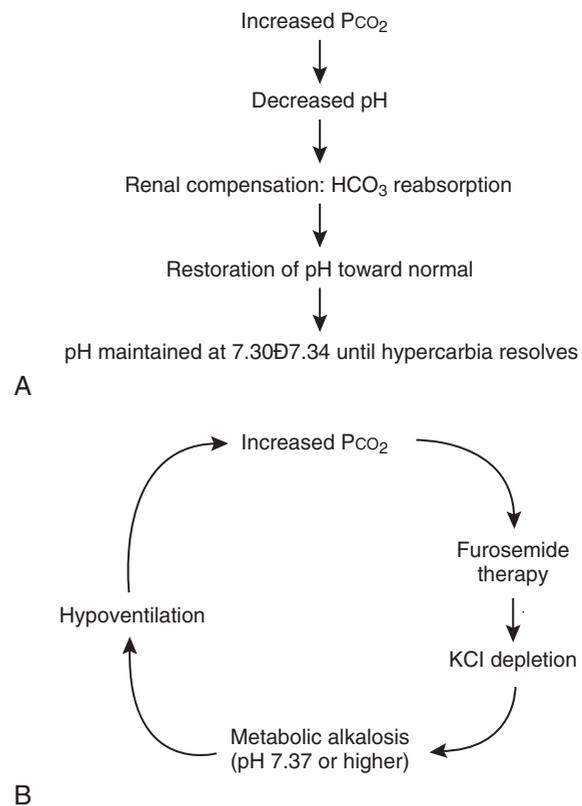

In spite of the development of numerous sophisticated ventilators for the newborn, there is still no clear advantage to any one approach to ventilating the preterm infant (see also Chapter 47). The general approach should be one of preventing atelectasis, sustaining FRC, using a minimal tidal volume (usually 4 to 6 cc/kg) and allowing the infant to trigger his or her own ventilation as much as possible (Carlo et al, 2002). It is also clear that infants can be extubated more successfully if they are extubated directly to nasal CPAP.

### Nutrition

It is clear that maximizing both enteral and parenteral nutrition is essential to growth and recovery of preterm infants with BPD. Beginning parenteral nutrition within the first 2 or 3 days after birth, as well as the use of aggressive feeding regimens, is crucial to success in these infants. In addition, it is appropriate to treat such infants with vitamin A, as it is the only agent shown to decrease the incidence of BPD in clinical trials.

### Diuretics

In infants with well-developed BPD, pulmonary edema is a major component of the illness. Diuretics, therefore, have been used for some time (Hazinski, 2000). There is clear evidence that either daily or alternate-day therapy with furosemide improves lung mechanics and gas exchange in infants with established BPD (Rush et al, 1990). Thiazide-type diuretics alone or in combination with spironolactone also have improved lung function in several studies. A major concern with diuretic usage, however, has been hypercalciuria along with metabolic alkalosis. There are no long-term trials of diuretic therapy; nevertheless, most centers use diuretics at some point in the management of infants with BPD. It is essential, if long-term diuretics are administered, that supplemental KCl also be administered to prevent the diuretic-induced metabolic alkalosis associated with hypochloremia as well as hypokalemia. The cycle that can be set up in these infants is demonstrated in Figure 49–8 (Hazinski, 2000). Diuretic-induced hypokalemia and alkalosis can be diagnosed by finding a blood pH (not the base deficit) that is inappropriate for the infant's clinical state. In chronic BPD, an infant who has become hypercarbic will, over time, have a compensated respiratory acidosis (pH of 7.3 to 7.35 in the presence of slightly elevated serum bicarbonate). However, if the infant is receiving diuretics and is not receiving adequate supplements of KCl, the infant's loss of potassium and chloride can lead to a primary meta-

**FIGURE 49–8.** **A**, Compensated respiratory acidosis in BPD. **B**, Diuretic-induced metabolic alkalosis in BPD. (Data from Hazinski TA: Drug treatment for established BPD. In Bland RD, Coalson JJ [eds]: *Chronic Lung Disease in Early Infancy*. New York, Marcel Dekker, 2000, pp 257-283.)

bolic alkalosis. The infant will hypoventilate to reduce blood pH, creating further inhibition of ventilation.

Another complication of concern for long-term diuretic therapy is hypercalciuria with potential calcium deposition in the renal interstitium with nephrocalcinosis.

### Bronchodilator Therapy

With established BPD, there is a significant increase in airway resistance, and there may also be persistent or intermittent wheezing. Several studies of either short-term, inhaled, or parenteral beta<sub>2</sub>-adrenergic agonist therapy have demonstrated some improvement in ventilation with such therapy. Inhaled albuterol has been the most widely used agent. Systemic use of bronchodilators has been more restricted because of a high incidence of side effects and a very narrow therapeutic index (DeBoeck et al, 1998). Hazinski (2000) points out that there are two pitfalls to the use of beta<sub>2</sub> agonist drugs: (1) there can be beta agonist-induced vasodilatation, which may lead to hypoxia; and (2) beta agonist-induced augmentation of airway instability in an infant with both BPD and tracheomalacia may occur. Both of these pitfalls may lead to complex ventilation-perfusion ( $\dot{V}/\dot{Q}$ ) relations. Discussions of these pitfalls as well as management are included in Hazinski's chapter in the textbook by Bland and Coalson (2000).

### Postnatal Corticosteroids

As discussed earlier, there has been a widespread effort to prevent chronic lung disease with the use of postnatal dexamethasone. Currently, recommendations of the American Academy of Pediatrics and the Canadian Pediatric Society are that use of postnatal steroids be restricted to randomized, controlled trials and, when these agents are given outside of such trials, that they be used only under exceptional circumstances of severity and after fully informing the parents of the potential problems with neurodevelopmental outcome.

### Outcome

The mortality rate among infants with the severest form of BPD with cor pulmonale can be as high as 40%. The mortality rate among infants who are discharged on therapy from the hospital is roughly 10%. In long-term follow-up assessments of preterm infants, BPD clearly is one of the major conditions associated with poor neurodevelopmental outcome (along with IVH and periventricular leukomalacia). Because there is a very powerful association of administration of postnatal steroids with increased cerebral palsy and poor outcome, however, it is unclear how much of the contribution to poor neurodevelopmental outcome in these infants is from the disease itself and how much is a result of treatment with postnatal steroids along with poor nutrition, impaired growth, and prolonged hospitalization. Long-term morbidity associated with BPD may include damage to supraglottic, glottic, subglottic, and tracheal tissues secondary to endotracheal intubation (Statement on the care of the child with chronic lung disease, 2003). Systemic hypertension has also been described in severe cases (Alagappan and Malloy, 1998).

### SUMMARY

BPD remains the most common form of chronic lung disease in children. It is estimated that there are between 10,000 and 12,000 infants with BPD at any one time in the United States. This disease remains very costly in terms of illness and long-term neurodevelopmental outcome, as well as the financial costs to families and society. The American Thoracic Society has recently published a well-referenced position paper on the care of the child with chronic lung disease of infancy and childhood that addresses many of the important ongoing issues in the care of these children (Statement on the care of the child with chronic lung disease, 2003).

It is hoped that combining treatment with vitamin A with new approaches to ventilation, including more vigorous use of nasal CPAP, along with the possibility of other interventions such as iNO, will lead to a significant decrease in the impact of this problem over the next 10 years.

## Anomalies of the Airways, Mediastinum, and Lung Parenchyma

Thomas N. Hansen and Anthony Corbet

### ANOMALIES OF THE AIRWAYS

#### Nasal Obstructive Disorders

Because newborns are preferential nasal breathers for the first 2 to 3 weeks of life, nasal obstruction may be associated with chest retractions and severe cyanosis, particularly during feedings, with airway obstruction relieved only when the mouth is open to cry. Respiratory distress due to nasal obstruction may manifest as a serious, life-threatening event shortly after birth.

#### Congenital Nasal Stenosis

With birth trauma, the nasal septum may become buckled or, less commonly, dislocated. Most cases respond to decongestant and steroid nasal drops, but dislocations require surgical manipulation (Presscott, 1995).

Nasal congestion may be associated with congenital syphilis, viral infection, maternal reserpine ingestion, and maternal fluphenazine ingestion.

Nasal pyriform aperture stenosis is characterized by excessive bone formation in the nasal processes of the maxillary bone; manifestations include severe obstruction and difficulty in passing a catheter. Because the newborn is a preferential nasal breather, an oral airway may be necessary to relieve the breathing difficulty. The obstruction is best demonstrated by computed tomography (CT) scan (Truong and Oudjhane, 1994). In most cases, the problem is resolved with nasal drops, but in more severe cases, surgery to remove excessive bone and nasal stenting are required. The condition may be associated with a solitary maxillary central incisor tooth; in other cases there may be more serious problems, including midline defects such as pituitary hypoplasia with endocrine insufficiency (Beregszaszi et al, 1996), diabetes insipidus (Godil et al, 2000), other manifestations of holoprosencephaly, and craniosynostosis (Van den Abbeele et al, 2001).

Nasal hypoplasia has been associated with warfarin embryopathy. In some newborns a nasolacrimal duct cyst may cause nasal obstruction.

### Congenital Choanal Atresia

#### Epidemiology

Congenital choanal atresia is caused by persistence of the bucconasal membrane, occurs in 1 per 10,000 births, and has a significant female preponderance. About half the cases are bilateral; these malformations necessarily constitute an immediate neonatal emergency at birth. Associated anomalies such as Treacher Collins syndrome are present in 50% of the cases (Hall, 1979). The most common collection of anomalies is called the *CHARGE association*, consisting of some combination of colobomas of the eyes, heart defects, atresia of the choanae, retardation of brain and body development, genital hypoplasia, and ear anomalies associated with deafness (Pagon et al, 1981).

#### Diagnosis

Because the newborn is a preferential nasal breather, there may be serious difficulties soon after birth. A catheter cannot be passed through the nose, and nasal instillation of radiopaque dye demonstrates obstruction. CT scan is the method of choice for making a definitive diagnosis (Crockett et al, 1987). Sometimes choanal stenosis rather than atresia may be present.

#### Treatment

Emergency prophylaxis consists of an oral anesthesia airway or even endotracheal intubation. Although 90% of cases involve bone rather than membrane, in some infants the bone is soft and easily penetrated. Surgery can be performed within a few days of birth. Correction can be accomplished using the transnasal approach with either Hegar dilators (Stahl and Jurkiewicz, 1985), or a carbon dioxide surgical laser (Healy et al, 1978). After the appropriate airway is created, polyvinyl tubes are sutured in place to prevent subsequent closure. The tubes are lavaged with saline and suctioned frequently, and after 6 weeks, they can be removed. The transnasal procedure with modern endoscopic biting and drilling instruments is often definitive (Josephson et al, 1998), or it can be followed by a transpalatal operation when the infant is much larger. If CT scan demonstrates a very thick bone component, transpalatal surgery during the newborn period is sometimes considered the best method of correction.

### Pharyngeal Deformities

#### Pierre Robin Syndrome

Pierre Robin syndrome has an incidence of 1 per 2000 births. The major feature is micrognathia with posterior displacement of the tongue into the pharynx, but 60% of the patients also have a cleft palate. Hereditary transmission may be through a dominant gene, with variable expressivity. Because the pharyngeal airway is narrowed by the tongue, obstructive respiratory distress and cyanosis are common during the newborn period; these episodes may progress to dangerous spells of apnea (Cozzi and Pierro, 1985). Obstruction is common when

the infant is in the supine position, during feeding, and in active sleep, when pharyngeal muscle tone is absent. Excessive air swallowing, followed by gastric distention, vomiting, and tracheal aspiration, are frequent problems. The pharyngeal obstruction is maintained by the generation of large negative pressures in the lower pharynx during inspiration and swallowing (Fletcher et al, 1969). Chronic obstruction leads to carbon dioxide retention, failure to thrive, and development of pulmonary hypertension with right ventricular failure (Johnson and Todd, 1980).

In an emergency, tracheal intubation should be performed. For a less invasive procedure, it is now customary to pass a 3.5-mm tube through the nose and into the hypopharynx (Heaf et al, 1982; Stern et al, 1972). This prevents the generation of negative pressure and greatly relieves the respiratory difficulty. The nasopharyngeal tube may be left in place for weeks or even months with adequate lavage and suctioning. The infant should be placed in the prone position to prevent the tongue from falling backward. If a nasopharyngeal tube does not adequately relieve the obstruction, tracheostomy is indicated to prevent progression to cor pulmonale. Nutrition can be maintained with a hypercaloric formula fed by nasogastric tube or gastrostomy. With the passage of time, the problem becomes less threatening, especially after a few months, when the infant gains better control of the tongue (Mallory and Paradise, 1979). Oral feedings can be introduced, usually with a long lamb's nipple to help hold the tongue forward. With adequate nutrition and growth of the mandible, the problem usually resolves by 6 to 12 months of age.

### **Glossoptosis-Apnea Syndrome**

Pierre Robin syndrome is not the only condition characterized by the tongue obstructing the airway. Infants with Beckwith-Wiedemann syndrome may have considerable breathing and apnea difficulties with an enlarged tongue. Infants with a normal-sized tongue who also have conditions such as unilateral choanal atresia, choanal stenosis, or swelling of the nasal mucosa may generate large negative pressures in the pharynx; in the absence of adequate muscular control over the tongue, they may develop pharyngeal obstruction, with respiratory distress, cyanosis, and severe episodes of apnea (Cozzi and Pierro, 1985).

### **Pharyngeal Incoordination**

Pharyngeal incoordination causes choking and cyanosis with feedings and may be complicated by aspiration pneumonia (Avery and Fletcher, 1974). Affected infants have difficulties in swallowing their own secretions. The condition may be seen in infants with severe hypoxic-ischemic encephalopathy and pseudobulbar palsy, in those with Arnold-Chiari malformation, and in those with Möbius syndrome. Some improvement may be obtained with the use of atropinergic drugs, which decrease secretions. Although some infants may gradually improve, the long-term management includes tube feedings or even gastrostomy.

## **Laryngeal Deformities**

### **Congenital Laryngeal Stridor (Laryngomalacia)**

A relatively common condition, congenital laryngeal stridor is due to the prolapse of poorly supported supraglottic structures—the arytenoids, the aryepiglottic folds, and the epiglottis—into the airway during inspiration. Despite loud inspiratory stridor and significant chest retractions, usually from birth or the first month of life, the infant seldom has cyanosis, hypercarbia, notable feeding difficulty or growth failure, or an abnormal cry (Richardson and Cotton, 1984). Congenital stridor is worse in the supine position with the neck flexed and subsides in the prone position with the neck extended (Cotton and Richardson, 1981). Obstruction is worse during episodes of agitation and lessens when the infant is calmed. Radiographic demonstration of prolapse of the aryepiglottic folds supports the diagnosis; ultrafast cine CT scan is effective at demonstrating the abnormalities without disturbance to the airway structures (Galvin et al, 1994). Confirmation may be obtained at laryngoscopy (Friedman et al, 1990), but care must be taken not to fixate the supraglottic tissues with the instrument. Some practitioners prefer to pass a flexible fiberoptic bronchoscope through the nose (Berkowitz, 1998), which does not disturb the supraglottic tissues. In some cases, gastroesophageal reflux or episodes of obstructive apnea may be associated with this condition (Belmont and Grundfast, 1984). About 18% of infants with a congenital lesion of the airway have a second lesion of some kind. Thus, the evaluation of stridor must include the examination of the entire upper airway and upper digestive tract (Friedman et al, 1984). The treatment is conservative and consists of placing the infant in the prone position, tracheostomy rarely being required; the condition spontaneously improves over about 18 months (Smith and Catlin, 1984). A very few patients may have severe obstructive apneas, cor pulmonale, and failure to thrive. In these cases unilateral supraglottoplasty with a carbon dioxide laser has been effective (Kelly and Gray, 1995); if necessary, the other side may be operated on later.

### **Vocal Cord Paralysis**

Unilateral cord paralysis is usually left-sided; stridor and retractions are not marked, and the voice is weak and hoarse. The infant may cough and choke during feedings, as laryngeal closure with swallowing is impaired. The condition is due to a lesion involving the recurrent laryngeal nerve, perhaps caused by excessive stretching of the neck during delivery. Another possible cause is trauma from ligation of a patent ductus arteriosus (Davis et al, 1988). Right-sided vocal cord paralysis has been reported as a complication of extracorporeal membrane oxygenation (ECMO) (Schumacher et al, 1989), presumably as a result of the surgical dissection for insertion of the catheters. Stridor may be less if the infant lies on the paralyzed side, when the affected cord can fall away from the midline (Cotton and Richardson, 1981). The condition often tends to improve over a period of several weeks or months.

Bilateral cord paralysis is a much more serious condition, accompanied by serious inspiratory stridor. Frequently,

however, the cry is normal. The diagnosis may be suspected at laryngoscopy and then confirmed with flexible fiberoptic bronchoscopy in the neonatal intensive care unit (NICU), rigid bronchoscopy in the operating room, or ultrafast cine CT scan in the radiology department. Associated problems may include pharyngeal incoordination with swallowing difficulty and esophageal dysfunction, recurrent apnea episodes, and tracheal aspiration of mucous secretions and formula. Usually, severe central nervous system problems also are present, such as hypoxic-ischemic encephalopathy, cerebral hemorrhage, Arnold-Chiari malformation, hydrocephalus, or brainstem dysgenesis. The stridor may resolve slowly if brain swelling subsides after birth. Tracheostomy frequently is required (Smith and Catlin, 1984), and the prognosis usually is poor because of the underlying problems.

### **Congenital Laryngeal Stenosis**

The larynx may be partially obstructed by a web or cyst that causes inspiratory stridor from birth and a hoarse cry. The diagnosis of congenital laryngeal stenosis is made by laryngoscopy. Treatment consists of endoscopic lysis with microlaryngeal surgery or a carbon dioxide laser (Smith and Catlin, 1984). Usually, one application is sufficient to correct this difficulty, and the prognosis is excellent.

### **Congenital Laryngeal Atresia**

In laryngeal atresia, the larynx may be completely obstructed by a web, seen in the delivery room during attempts to intubate the cyanotic infant. An endotracheal tube sometimes can be forced beyond the obstruction into the trachea. Otherwise, a large-bore needle should be inserted percutaneously into the trachea to maintain marginal gas exchange while preparations for emergency tracheostomy are made. Most infants with laryngeal atresia have other lethal malformations (Smith and Catlin, 1984).

This diagnosis has been made on fetal ultrasound scan, which shows enlarged lungs with inverted hemidiaphragms and a dilated trachea (Hedrick et al, 1994). The mother may be investigated for ascites or hydrops fetalis due to impaired venous return to the heart. The amniotic fluid lecithin may be very low in such cases. Bui and colleagues (2000) managed one case by uterine incision, delivery of the head, fetal laryngoscopy to confirm the diagnosis, fetal tracheostomy, and then delivery of the infant. Alternatively, in the absence of other lethal malformations, the characteristic ultrasound diagnosis may permit preparations for emergency tracheostomy after delivery of the infant.

### **Congenital Subglottic Stenosis**

Congenital subglottic stenosis is secondary to malformation of the cricoid cartilage. In severe cases, stridor is present from birth, and respiratory distress is obvious. In milder cases, excessive *croup* in an older infant may indicate the presence of this malformation (Healy et al, 1988; McGill, 1984).

### **Congenital Subglottic Hemangioma**

Subglottic hemangioma, often occurring in association with cutaneous hemangioma, may cause inspiratory stridor and expiratory wheezing, which progress with slow enlargement of the tumor (Cotton and Richardson, 1981). The presence of a cutaneous hemangioma in the facial beard distribution is often associated with a subglottic hemangioma (Orlow et al, 1997). Although some practitioners have advocated high-dose corticosteroid therapy (Brown et al, 1972) and others have tried intralesional injections of steroids, in many cases intubation or tracheostomy is eventually required. Results with removal by carbon dioxide laser have been encouraging (Healy and McGill, 1984), enabling treatment without tracheostomy in many cases (Hughes et al, 1999).

### **Acquired Subglottic Stenosis**

Extubation after prolonged endotracheal intubation sometimes is followed by inspiratory stridor and expiratory wheezing, produced by subglottic edema and fibrosis. The risk is greatest in infants who have had tightly fitting endotracheal tubes, frequent intubations, and prolonged intubation and mechanical ventilation (Downing and Kilbride, 1995; Sherman et al, 1986). Couser and associates (1992) reported the results of a controlled trial in which three doses of dexamethasone were given, starting 4 hours before extubation, to premature infants at high risk for subglottic edema; the incidence of stridor in the treatment group was greatly reduced. The initial evaluation of these patients may be performed with a flexible bronchoscope after extubation in the NICU.

For management of this condition, adequate humidification of inspired gas, nebulization of racemic epinephrine, and systemic, nebulized, or topical dexamethasone have proved useful. It may be helpful to use nasal continuous positive airway pressure (CPAP) to dilate the upper airway until improvement is obtained with steroid medication. In cases with no response to these measures, reintubation with a smaller endotracheal tube for a short period, while growth occurs, may be helpful.

Difficult cases should be evaluated by rigid bronchoscopy and in some instances by ultrafast cine CT scan. In some infants, an anterior cricoid split procedure may be successful (Seid and Canty, 1985). In this operation, a vertical incision is made in the cricoid and the first two tracheal cartilages, after which the airway is stented open with a larger endotracheal tube, which prevents the cut ends of the cartilage from abutting. The tube is maintained in place for 7 to 14 days, with the help of heavy sedation, and then removed under cover of steroid treatment (Tavin et al, 1994). More severely affected infants may require tracheostomy, followed by a formal surgical procedure with rib grafts to reconstruct the subglottic space later in life (Rowe et al, 1991).

### **Laryngotracheoesophageal Cleft (Congenital Laryngeal Cleft)**

In laryngotracheoesophageal cleft, a longitudinal communication is present between the airway and the esophagus, stretching from the larynx into the upper trachea or

sometimes as far as the carina. The condition is caused by failure of cephalic advancement of the tracheoesophageal septum. Affected infants have respiratory distress with inspiratory stridor and cyanosis, associated with tracheal aspiration of saliva and feedings. The chest radiograph may show evidence of aspiration pneumonia, and the cine esophagogram shows contrast material spilling into the trachea. The diagnosis can be established with direct laryngoscopy and bronchoscopy. Initially, the airway must be adequately secured with an endotracheal tube or tracheostomy (Richardson and Cotton, 1984). An esophagostomy can be fashioned to divert saliva from the trachea. These patients invariably have esophageal dysmotility and gastroesophageal reflux if fed with an orogastric tube; enteral feedings can be accomplished safely after gastric division and gastrostomy tube placement. Attempts at later operative repair through a lateral pharyngotomy with or without thoracotomy have been successful in a few infants (Burroughs and Leape, 1974; Cotton and Schreiber, 1981). Some practitioners prefer an anterior translaryngeal approach for laryngeal and esophageal repairs, with closure over an endotracheal tube (Evans et al, 1995).

## **Tracheal Deformities and Other Tracheal Disorders**

### **Tracheal Agenesis Syndrome**

In the rare condition of tracheal agenesis syndrome, the trachea is atretic just below the vocal cords, or it is absent all the way down to the carina (Altman et al, 1972). Clinical manifestations include severe distress, absence of vocal sounds, and severe cyanosis. Affected infants usually have a tracheoesophageal fistula as well as severe cardiac malformations, lung lobation defects, and sometimes renal and anal anomalies. Despite the presence of a larynx, intubation cannot be accomplished at delivery; however, if the tracheal tube is positioned in the esophagus and connected to a mechanical ventilator, reasonable gas exchange can be obtained through the tracheoesophageal fistula. When the tracheal atresia is high, a tracheostomy can be done. If survival seems possible, gastric division and a gastrostomy for feeding should be performed. Reconstructive surgery is not likely to be successful, however, and the prognosis is extremely poor, if not because of poor ventilation, then because of the underlying malformations.

### **Congenital Tracheal Stenosis**

In congenital tracheal stenosis, a segment of the trachea is narrowed, usually starting in the subglottic region. The affected segment may be short or long; occasionally, the entire trachea is hypoplastic, and the bronchi may be involved. The narrowing is caused by complete or nearly complete tracheal cartilage rings. The patient may have inspiratory stridor, expiratory wheezing, and often cyanotic episodes. Mild inflammation and small mucous plugs may cause life-threatening deterioration. In many cases, other congenital malformations are also present, such as vascular ring anomalies, congenital heart defects, tracheo-

esophageal fistula, especially the H type, and hemivertebrae (Benjamin et al, 1981); there also is an association with pulmonary agenesis (Volland et al, 1986). A series of cases without accompanying defects has been reported in premature infants, who presented with difficulties at tracheal intubation (Hauff et al, 1988).

Patients with this deformity usually can be intubated, but the endotracheal tube cannot be advanced and should not be forced; mechanical ventilation with generous levels of positive end-expiratory pressure (PEEP) may be helpful to stabilize the infant. Tracheostomy is not indicated and interferes with making the diagnosis (Nakayama et al, 1982). Sometimes the diagnosis can be made by chest radiographs, using air as the contrast medium, with inspiration and expiration films. Investigators have described a high-kilovoltage technique, the so-called lateral airways xeroradiogram (Benjamin, 1980). Fluoroscopy often is useful (Lobe et al, 1987). Either flexible fiberoptic bronchoscopy in the NICU or rigid bronchoscopy in the operating room is usually required. Because it is important to examine the lower limits of the stenosis, it may be necessary to proceed with tracheobronchography, but this may sometimes cause acute decompensation (Loeff et al, 1988). As an alternative, ultrafast cine CT scan has been developed as a useful diagnostic technique to define the lower limits of the stenosis (Galvin et al, 1994).

In most cases, the stenosis requires treatment of some kind in the operating room. Balloon dilation alone is not likely to be successful in the case of a complete tracheal cartilage ring, because cartilage cannot be stretched. For short-segment stenosis, the technique of balloon dilation with laser may be used; at rigid bronchoscopy the cartilage ring is split at the midline posterior aspect using the KTP laser, and the bronchoscope is advanced with the aid of serial balloon dilations (Otherson et al, 2000). For longer-segment stenosis Longaker and colleagues (1990) described segmental resection of the stenosis with end-to-end anastomosis, shortening the trachea, followed by serial balloon dilations through a rigid bronchoscope. Backer and colleagues (2000) described the successful use of free autografts of resected trachea for this type of tracheoplasty. However, for long-segment stenosis, a procedure called slide tracheoplasty is now commonly preferred (Lipshutz et al, 2000). The stenosis is transected in the middle; the upper segment is incised longitudinally along the anterior aspect; the lower segment is incised longitudinally at the posterior aspect; the incised segments are then slid over one another, shortening the trachea; and the edges are anastomosed.

The use of cardiopulmonary bypass has improved treatment, averting the need for complex anesthesiology techniques (Loeff et al, 1988). After midline sternotomy, tracheal resection, and tracheoplasty with shortening of the trachea, the patient may need fixation in a brace for at least 6 weeks to maintain neck flexion and prevent excessive stretching of the anastomosis (Nakayama et al, 1982).

For premature infants with congenital tracheal stenosis, patients who cannot undergo tracheal resection and tracheoplasty with cardiopulmonary bypass procedures, aggressive balloon dilations have been recommended, with splitting of the weaker posterior aspect of the tracheal rings (Messineo et al, 1992).

### Rupture of the Trachea

Tracheal rupture just below the cords is an uncommon lesion that may occur as a result of severe head traction with a difficult delivery; the infant presents with pneumomediastinum, pneumothorax, or subcutaneous emphysema, accompanied by other signs of birth trauma such as vocal cord or brachial or phrenic nerve palsy (Hogason et al, 1992). Tracheal intubation may be difficult because the trachea bends at the site of injury. At flexible fiberoptic bronchoscopy, the endotracheal tube can be positioned past the rupture and maintained in position using a total body brace for 10 to 14 days to ensure adequate healing. If tracheal stenosis occurs, this can later be resected with end-to-end anastomosis, making use of cardiopulmonary bypass if necessary.

### Acquired Tracheobronchial Stenosis

Lesions of the trachea and main bronchi are being increasingly recognized as acquired complications of prolonged intubation and mechanical ventilation of infants in the NICU. These lesions are thought to be inflammatory, related to movement of the endotracheal tube and suction catheter. To prevent these problems, the endotracheal tube should be adequately fixed in position, and it is recommended that in routine suctioning the catheter should not be pushed past the end of the endotracheal tube (Bailey et al, 1988). This lesion may be suspected in infants with recurrent lobar atelectasis, emphysema, or both, especially of the right lower lobe; with difficulties after extubation; or with a resistance noted during use of the suction catheter (Friedberg and Forte, 1987). Most of these stenoses are just above or below the carina. The usual time of diagnosis is at about 4 weeks of age.

The initial diagnostic approach may be with flexible fiberoptic bronchoscopy in the NICU (Cohn et al, 1988) or with rigid bronchoscopy in the operating room. These infants often are in poor condition; an alternative way to establish the length of the stenosis is by contrast tracheobronchography performed in the NICU. This procedure has been described by Betremieux and coworkers (1995). A fine catheter filled with water-soluble contrast material is positioned with its tip precisely at the end of the endotracheal tube; 0.2 mL of contrast material is injected rapidly, followed by 5 mL of air; then two plain films are taken with 30 seconds of bag tube ventilation in between; the contrast material is suctioned, and mechanical ventilation is resumed. In a significant number of infants, the findings suggest mucous plug obstruction, which responds to chest physical therapy, and further investigation can be avoided.

Mild inflammatory stenosis may respond to topical or inhaled steroids or racemic epinephrine, and systemic steroids may be used (Elkerbout et al, 1993). In some cases, granuloma tissue has been biopsy-excised through the rigid bronchoscope (Miller et al, 1987) or subjected to electroresection (Greenholz et al, 1987). In patients with a mature stenosis, balloon dilation may be undertaken with rigid bronchoscopy in the operating room; several operative sessions may be needed. The success rate is only 50%, however, and the mortality rate is as high as

33% (Betremieux et al, 1995). Alternatively, dilations may be accomplished with bougies through a rigid bronchoscope, which may allow a better “feel” for the operator (Albert, 1995). These infants are small and premature and have frequent complications, such as bronchopulmonary dysplasia and infection; a greatly feared risk is airway rupture by the dilation procedure, with pneumomediastinum or pneumothorax (Messineo et al, 1997). The use of alternative strategies, such as carbon dioxide laser ablation, operative stenting, and surgical resection with grafting, is limited by the small size and severe illness of these infants. If the stenosis is short, however, as is often the case, resection with end-to-end anastomosis can be accomplished with skilled anesthesiology techniques (Albert, 1995). As a last resort, cadaver tracheal transplantation or live donor heart-lung transplantation may be considered in larger and older infants who are candidates for cardiopulmonary bypass.

### Tracheobronchomalacia (Tracheomalacia)

This condition may be primary or associated with tracheoesophageal fistula, bronchopulmonary dysplasia, or extrinsic tracheal compression.

Rarely, development of tracheal cartilage support may be delayed, resulting in an excessively compliant trachea or tracheobronchomalacia, a condition characterized by expiratory wheezing and respiratory distress. Callahan (1998) has described infants with primary tracheomalacia and gastroesophageal reflux; they presented with cough, an unusual sign in the newborn, and with wheezing. In tracheomalacia the chest radiograph shows diffuse overinflation. The abnormalities of the trachea can be well demonstrated with ultrafast cine CT scan (Galvin et al, 1994; Kimura et al, 1990); in particular, a good idea of the peripheral extent of the lesion can be obtained. At bronchoscopy, the anterior and posterior walls of the trachea are approximated during expiration (Salzberg, 1983). The bronchoscope may support the walls of the trachea, so the respiratory distress may be alleviated by passage of the bronchoscope to the carina, but this may disguise the extent of the abnormalities.

Many affected infants with tracheomalacia improve by 6 to 12 months of age. Severe cases may benefit from tracheostomy and treatment with CPAP, which prevents the tracheal collapse; prolonged treatment for 1 to 2 years may be required (Wiseman et al, 1985). Prolonged tracheostomy alone without positive pressure may be useful, with the tube acting as a stent for the compliant trachea (Cogbill et al, 1983), but this is less useful when the bronchi also are involved. In some cases, use of a special long tracheostomy tube has been successful, even with bronchial involvement (Zinman, 1995), and in some patients the positive pressure could be discontinued.

A strong association with tracheoesophageal fistula has been reported (Benjamin et al, 1976), but tracheomalacia does not occur in patients with esophageal atresia without a fistulous connection to the trachea (Rideout et al, 1991). A diffuse insufficiency of tracheal cartilage in these patients has been described, and many of them have ectopic, stenotic, or absent bronchi (Usui et al, 1996). Filler

and associates (1992) have reported a large series of infants in which the flaccid trachea was compressed between the aorta anteriorly and the dilated esophagus posteriorly; most of these patients responded to aortopexy, fixation of the aorta to the sternum, which has the effect of supporting the attached trachea. An alternative is tracheopexy, in which the trachea is fixed directly to the sternum (Benjamin et al, 1976).

Tracheomalacia has been seen in respirator-dependent infants with bronchopulmonary dysplasia (Sotomayor et al, 1986), who present with severe cyanotic episodes (bronchopulmonary dysplasia spells). Many of these patients also have gastroesophageal reflux (Jacobs et al, 1994). Penn and colleagues (1988) have described the effect of prolonged mechanical ventilation on lamb tracheas and demonstrated increased worsening of collapse and increased flow resistance correlated with deformation of the trachea. The trachea of premature infants is very compliant and may be excessively stretched and injured during mechanical ventilation; because the tracheal compliance decreases with maturity, it is the very immature infant who is prone to tracheomalacia. Some premature infants have greatly enlarged tracheas or tracheomegaly after mechanical ventilation (Bhutani et al, 1986). Downing and Kilbride (1995) found that the factors associated with the development of tracheomalacia were immaturity, higher mean airway pressure, and prolonged mechanical ventilation. Infants with bronchopulmonary dysplasia and tracheomalacia may have significant dynamic compression of the trachea; this is caused by reactive lower airway disease with forceful expiration compressing the trachea; such patients may show some improvement from bronchodilator therapy. However, increased smooth muscle tone may help support the trachea during expiration, so bronchodilator therapy may sometimes make the situation worse (McCubbin et al, 1989).

Flexible bronchoscopy in the NICU may be performed after hyperoxygenation with the patient extubated briefly. If the patient must remain intubated, then the ventilator can be turned off for a short time while the ultra thin flexible bronchoscope is passed through the endotracheal tube with the patient breathing spontaneously (Wood, 1985). In the case of rigid bronchoscopy in the operating room, there may be some difficulty in making the diagnosis; collapse of the trachea may be abolished by the positive pressure of the ventilator, and dynamic compression of the trachea during forced expiration may be abolished by general anesthesia (Jacobs et al, 1994). Ultrafast cine CT scan also has proved invaluable to help establish this diagnosis if the infant can be transported to the radiology department.

The usual treatment is continued tracheal intubation with high levels of CPAP or PEEP with mechanical ventilation, and empirical attempts to wean the infant from these modalities as he or she grows older (Jacobs et al, 1994). Many of these patients must have a tracheostomy to avoid laryngeal complications from intubation. McCoy and colleagues (1992) described a group of infants with bronchopulmonary dysplasia and severe cyanotic spells during episodes of agitation. These investigators observed tracheal collapse at flexible bronchoscopy, initiated by agi-

tation and relieved by soothing the patient or by sedation; thus, adequate sedation is an important part of management in patients with bronchopulmonary dysplasia spells. Many of the most severely affected patients respond well to aortopexy (McCoy et al, 1992). Bullard and associates (1997) have described a limited operation using an approach through the mediastinum for aortopexy while avoiding a full thoracotomy.

### **Malignant Lobar Hyperexpansion in Bronchopulmonary Dysplasia**

Azizkhan and colleagues (1992) have described a complication they called *acquired lobar hyperinflation* in infants with bronchopulmonary dysplasia; this condition was due to bronchomalacia with diffuse involvement but more severe involvement in the affected lung lobe. These patients were evaluated by ultra thin flexible videobronchoscopy, performed during mechanical ventilation. Selective intubation of the less involved lung provided only transient benefit. These patients can sometimes be managed medically, but many benefit immediately from surgical lobectomy; a few infants are operated on under emergency circumstances involving malignant hyperexpansion of the affected lobe and compression of surrounding lung. In general, the results of surgery may be good, although some patients eventually die from underlying bronchopulmonary dysplasia and its complications.

### **Tracheal Compression by Vascular Rings**

The trachea may be compressed by (1) a double aortic arch, (2) a right aortic arch, (3) a left-sided origin of the (right) innominate artery, (4) a right-sided origin of the left common carotid artery, or (5) an anomalous origin of the left pulmonary artery from the right pulmonary artery (Hendren and Kim, 1978). With a right aortic arch, the trachea is compressed by the main pulmonary trunk, aortic arch, and ligamentum arteriosus. The anomalous innominate or common carotid arteries form a tight crotch, which impinges on the anterior trachea. The anomalous left pulmonary artery returns to the left by passing between the esophagus and the trachea, compressing the trachea between the right and the left pulmonary arteries. Infants with tracheal compression have inspiratory stridor and expiratory wheezing. The onset of symptoms is usually later in the neonatal period. These infants often lie with the head and neck hyperextended to stretch the trachea and make it less compressible. If the esophagus is compressed, feeding is associated with regurgitation. The chest radiograph may show mild overinflation, a right-sided aorta, and, with appropriate technique, evidence of tracheal narrowing. A barium swallow examination may show indentation of the esophagus. Magnetic resonance imaging (MRI) has proved to be accurate in defining most vascular malformations compressing the airway (Simoneaux et al, 1995). Bronchoscopy should reveal a pulsatile mass at the carina. Echocardiography may not be as accurate as the MRI scan in this situation (Rimell et al, 1997). After surgical relief, the respiratory distress may persist for weeks or

longer because of localized tracheal deformity, either stenosis or tracheomalacia, and in some cases a second operation may be required to repair the trachea further.

### **Tracheal Compression by Extrinsic Masses**

The trachea may be compressed by a bronchogenic cyst, an enteric duplication cyst, a thoracic neurogenic tumor, or a mediastinal teratoma (Benjamin, 1980). These may be demonstrated by anteroposterior and lateral chest films and especially well by CT scan. They also may compress the esophagus and be demonstrated with a barium swallow.

### **Bronchoscopy and Bronchography**

Albert (1995) has described the advantages and disadvantages of the methods used in the diagnostic approach to tracheobronchial obstructions. The instillation of nonionic contrast material for tracheobronchography does not seem to cause serious bronchospasm and, despite the iodine, does not seem to affect thyroid function seriously in premature infants. The lower trachea and main bronchi beyond the stenosis are well demonstrated. The technique does not differentiate a soft stenosis with granulation tissue from a hard stenosis composed of fibrous tissue, and because it is two-dimensional, it does not identify a complete tracheal ring in congenital stenosis. An advantage is that it can be performed in the NICU (Betremieux et al, 1995).

Flexible fiberoptic bronchoscopy also can be performed in the NICU, usually after a period of hyperoxygenation to prevent oxygen desaturation. The instrument may be passed for short intervals through the endotracheal tube during mechanical ventilation (Dab et al, 1993). The smallest readily available flexible bronchoscope is 2.2 mm in outside diameter. It does not have a suction channel; however, it does have the capacity for distal angulation, and it can be passed through a 3.0-mm-internal-diameter endotracheal tube for brief periods. Flexible bronchoscopy can differentiate soft from hard stenoses, in contrast with tracheobronchography, and the instrument may sometimes penetrate easily beyond the stenosis; the images are of lower quality than those with a rigid bronchoscope, however, and continued ventilation is not always easily accomplished. Two other ultra thin flexible bronchoscopes also are available (with outside diameters of 1.8 mm and 2.3 mm), but they do not have a suction channel (Wood, 1985), although they have the capacity for modest distal angulation. These instruments can be passed through a small, 2.5-mm-internal-diameter endotracheal tube during mechanical ventilation to evaluate the lower trachea and the main bronchi in very small infants; they can be advanced and withdrawn repeatedly to assist in the maintenance of adequate ventilation. They may be most useful to evaluate obstruction from granulation tissue or tracheobronchomalacia in infants with bronchopulmonary dysplasia. A 2.7-mm-outside-diameter flexible bronchoscope with capacity for better distal angulation also is available (Wood, 1985); this scope can be passed through a 3.5-mm-internal-diameter endotracheal tube to

examine the lower trachea, main bronchi, and segmental bronchi in larger infants, but there is no suction channel. The standard pediatric flexible bronchoscope is 3.5 mm in outside diameter, and it has a 1.2-mm suction channel for removal of mucous plugs. All flexible bronchoscopes can be used with reasonable-quality video recording, so that examinations can be reviewed later (Wood, 1985).

The rigid bronchoscope with a glass rod telescope requires transfer of the patient to the operating room, extubation, and general anesthesia with continued ventilation through the bronchoscope. It gives better images, anesthesia and ventilation are easily maintained through the bronchoscope, suction is available, biopsies can be performed, solutions can be injected, and it can be used for balloon or bougie dilation procedures. The smallest available rigid bronchoscope is 2.5 mm in outside diameter.

## **DISORDERS OF THE MEDIASTINUM**

In the posterior mediastinal space, thoracic neuroblastomas and neurenteric duplication cysts are most commonly encountered in the newborn. Bronchogenic cysts occur in the middle mediastinal space. An enlarged thymus and a mediastinal teratoma are the masses most often seen in the anterior mediastinum.

### **Thymus**

The thymus occupies the upper anterior mediastinum, and it is more prominent in the newborn period than at any other time of life. It may be so large as to reach the diaphragm or obscure both cardiac borders on radiographs. The normal thymus can be distinguished from an abnormal mass by the absence of tracheal deviation or compression. The thymus changes in position with respiration and is less prominent with deep inspiration. It also involutes with stress as well as with corticosteroid therapy. Absence of the thymic shadow in an infant should alert the clinician to the possibility of severe combined immune deficiency syndrome (SCIDS) or DiGeorge syndrome with hypocalcemia and cardiac anomalies.

The cardiothymic-to-thoracic ratio provides an index of thymic size. The shadow of the enlarged thymus is the most common radiopaque mass visualized in the anterior mediastinum of the newborn. The enlarged thymus causes little if any trouble in the neonatal period.

Fletcher and associates (1979), as well as Gewolb and colleagues (1979), noted that a large thymus is present on the first day of life in infants at risk for hyaline membrane disease, presumably because of less-than-normal levels of glucocorticoids before birth.

### **Congenital Mediastinal Teratoma**

Mediastinal teratomas rarely cause symptoms in the newborn infant. These teratomas are invariably not malignant, and surgical resection is sufficient treatment. When an anterior mediastinal mass is associated with respiratory distress in the newborn, the strong likelihood is that the

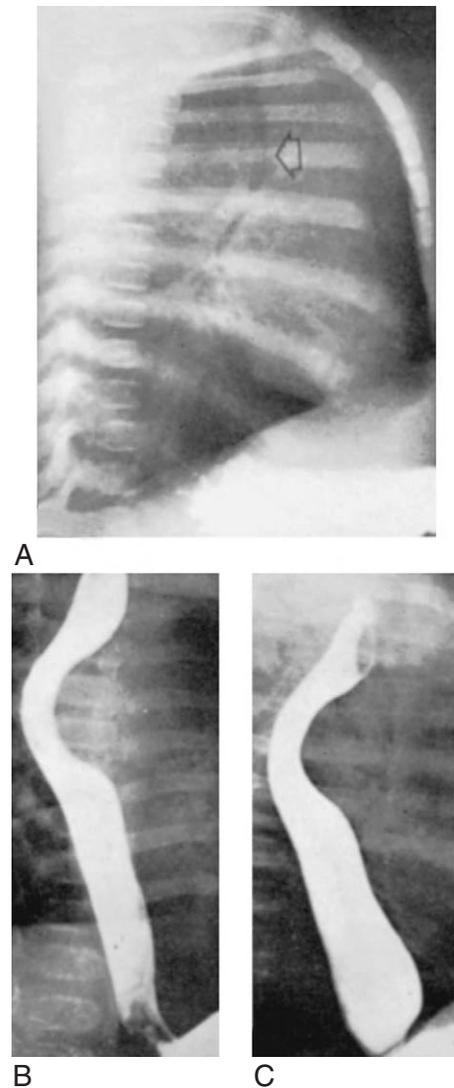

lesion is a mediastinal teratoma. Mogilner and colleagues (1992) described a newborn with severe respiratory distress and tracheal compression who underwent emergency thoracotomy and mediastinal teratoma resection. Another infant had emergency resection for respiratory distress but died with poor cardiac function (Thambi Dorai et al, 1998); as in that case, the tumor may be large enough to cause underdevelopment of the heart with severe circulatory insufficiency. In other cases, the tumor has caused mild lung hypoplasia.

### Congenital Bronchogenic Cysts

In the newborn, bronchogenic cysts are encountered infrequently; most do not come to the attention of the practitioner until later in infancy or childhood. Bronchogenic cysts seldom attain a large size. They contain clear fluid, they are lined with columnar or cuboidal epithelium, and their walls generally contain smooth muscle and cartilage, the latter indicating their bronchial origin. These cysts lie near the carina in the middle mediastinal space. They produce lung overdistention or atelectasis, depending on whether airway obstruction is complete or partial, and this is accompanied by respiratory distress in the newborn infant. Opsahl and Berman (1962) reported a case that showed overinflation on the left followed by clearing and then similar overinflation on the right. Radiographic examination often shows a mass lesion at or just above the carina, and displacing the lower trachea forward (Fig. 50-1). Ultrasonography may help localize the lesion more accurately. The barium swallow examination may reveal indentation of the esophagus, the cyst pushing it backward at the level of the carina (see Fig. 50-1). Bronchoscopy reveals compression of the trachea and sometimes of one major bronchus, usually from the posterior aspect. Sometimes the bronchogenic cyst may communicate with the airway and contain air. In the immediate newborn period, there may be retention of fetal lung fluid in the lung compromised by the bronchogenic cyst; the fluid may take days to be cleared. This phenomenon produces a characteristic appearance on the chest radiograph (Fig. 50-2). Treatment for bronchogenic cyst consists of early surgical excision, with uniformly good results.

### Neurenteric Duplication Cysts

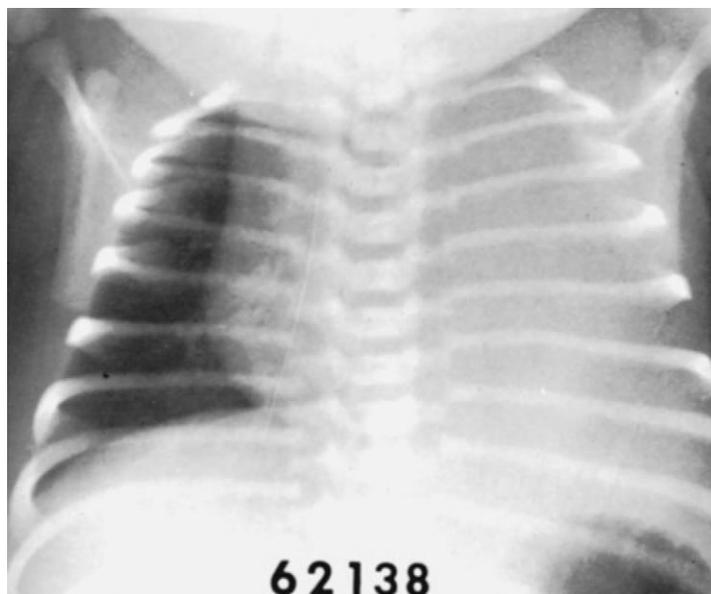

These mediastinal cysts may be derived from the esophagus, stomach, or small bowel, so they may also be called enterogenous cysts. Although they are not encountered frequently, they are far from uncommon in the newborn. They are duplicated segments of the foregut that have become partially or completely detached from the parent viscus. They lie in the posterior mediastinum but with increasing size may project far into one or the other hemithorax. Their walls are composed of a mucosal layer, characteristic of their site of origin, and one or more muscular layers. They contain secreted fluid that is the same as that of their parent viscus; the fluid in a gastrogenic cyst contains pepsin and hydrochloric acid in the same concentration as in gastric juice.

**FIGURE 50-1.** Bronchogenic cyst. **A**, The lateral film shows the trachea displaced anteriorly. **B**, The anteroposterior film shows the barium-filled esophagus displaced to the right. **C**, Another lateral film shows the barium-filled esophagus displaced posteriorly. (From Hope JW, Koop CE: *Differential diagnosis of mediastinal masses*. *Pediatr Clin North Am* 3:379, 1959.)

The foregut becomes duplicated in the course of embryonic development by failure of complete resorption of primitive occluding epithelium, resulting in the formation of a supernumerary wall and eventually a separate lumen and cyst. The high percentage of vertebral anomalies associated with neurenteric duplication cysts led Veeneklaas (1952) to suggest that the primary embryonic defect lies in abnormal persistence of the primitive foregut adherence to the notochord. When the foregut descends from its early position in the neck, this adhesion causes anomalies of the vertebral bodies derived from the notochord. This adhesion also breaks off the duplicated portion of the foregut and prevents its complete descent into the thorax and abdomen along with the mature foregut.

Clinical signs depend on the size and location of the duplication cyst. Because all of these cysts are posterior and lie close to the trachea, esophagus, and great vessels,

**FIGURE 50-2.** Bronchogenic cyst. The left lung shows delayed clearance of lung liquid, associated with bronchial obstruction by a bronchogenic cyst. (From *Griscom NT, Harris GBC, Wohl MEB, et al: Fluid filled lung due to airway obstruction in the newborn. Pediatrics 43:383, 1969.*)

they are seldom present without signs of abnormality. Cyanosis, tachypnea, and dyspnea often are present from birth. Swallowing difficulty and vomiting are less frequent. Recurrent lower respiratory tract infections are findings in a few older infants with such cysts. Frank hemorrhage from the lungs or stomach, or in the form of melena, is not at all uncommon. In most instances, hemorrhage indicates that the cyst is of gastrogenic origin, with peptic acid erosion into the trachea or esophagus. Technetium scans are useful for delineating cysts lined with gastric mucosa. Radiographs of the chest show abnormal densities that are often difficult to distinguish from unusual cardiac contours. The barium swallow examination commonly shows displacement of the esophagus, usually forward because the mass is in the posterior mediastinum. The cyst may partially or totally compress the bronchus, with consequent lung overdistention or atelectasis. Sometimes the symptoms are intermittent as the cyst enlarges or empties. Bronchoscopy may show compression of the trachea or bronchus from without, usually from the posterior aspect. Superina and colleagues (1984) reviewed 25 years of experience with neurenteric duplication cysts; they noted that a spinal component may accompany the mediastinal cyst in as much as 20% of the children. They recommended careful radiographic evaluation of the spinal canal with CT scan and then excision of the intraspinal cyst, if possible, before the onset of neurologic signs in later childhood. The MRI scan may give improved delineation of intraspinal cysts.

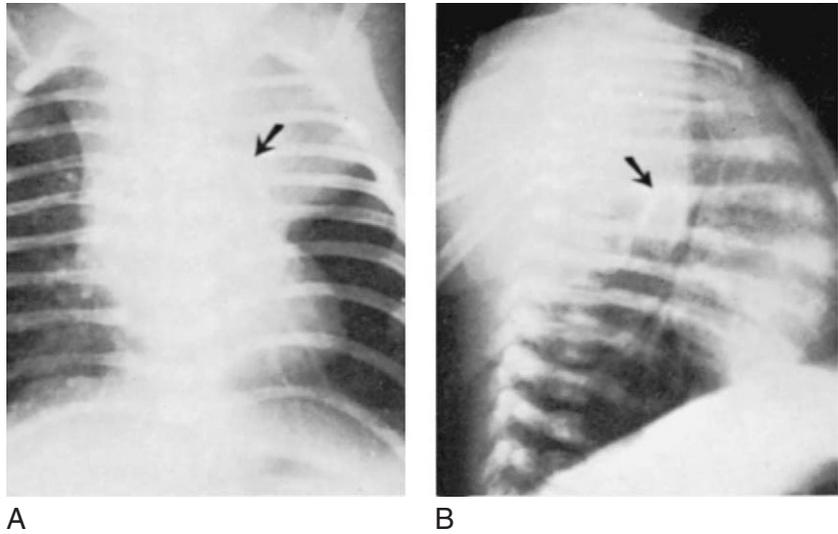

Operation is indicated as soon as the diagnosis of mediastinal mass is made. It is neither necessary nor wise to delay exploration until a specific diagnosis has been made.

### **Congenital Thoracic Neuroblastoma**

Neuroblastoma, the most common solid tumor in the mediastinum of infants, arises from sympathetic neural tissue along the vertebral column and is therefore

located in the posterior mediastinum. It may extend into both lungs, causing respiratory distress, and it may extend into the spinal canal, later causing neurologic signs. The chest mass may be obvious on routine radiographs obtained for unrelated reasons in the newborn (Fig. 50-3), or on chest radiographs taken to evaluate significant respiratory distress (Li et al, 2001). In older infants the diagnosis may follow chest radiography for lower respiratory tract infection, or radiographs may be taken to investigate dyspnea with physical signs of a solid intrathoracic mass. In some cases the tumor mass shows calcification, well visualized with the CT scan. A thoracic neuroblastoma may sometimes be found on fetal ultrasound examination (Moppett et al, 1999).

Differentiation from other posterior mediastinal masses may be impossible before exploration; neuroblastoma is not likely to be so sharply demarcated as a neurenteric duplication cyst. Invasion of neighboring lung parenchyma strongly supports a diagnosis of neuroblastoma. The MRI scan is superior to the CT scan for discerning spread to lymph nodes, spinal canal, and chest wall (Slovic et al, 1997), and also for discerning liver metastases. Elevations of urinary vanillylmandelic acid and homovanillylic acid may be present, but this finding is less common in the newborn, and its absence does not rule out neuroblastoma. If the patient has systemic hypertension, plasma levels of epinephrine, norepinephrine, and dopamine may be elevated, but this has not been reported in a thoracic neuroblastoma. Also, results of assays for various clinical biologic markers may be positive; for example, serum ferritin and serum lactate dehydrogenase may be elevated, but this is not usual in the newborn. A bone marrow aspirate should be obtained for cytologic evaluation, and a nuclear bone scan should be performed to exclude the possible remote spread of metastases. A number of cytogenetic biologic markers may be detected in the excised tumor tissue (e.g., cellular DNA ditetraploidy, increased *N-myc* oncogene copy number); these usually indicate malignancy in older children

**FIGURE 50-3.** Congenital thoracic neuroblastoma. The mass is in the left upper hemithorax (**A**) and in the posterior mediastinum (**B**). (From Hope JW, Koop CE: *Differential diagnosis of mediastinal masses. Pediatr Clin North Am* 6:379, 1959.)

(Ladenstein et al, 2001), but again, they are commonly negative in the newborn.

Surgical exploration is indicated for any intrathoracic mass. If the tumor proves to be a neuroblastoma, as much of it should be excised as is feasible. The tumor should be staged by histologic examination according to the system of Evans and colleagues (1971), and subsequent therapy should be dictated by the stage. In general, chemotherapy is not indicated unless distant metastases are present.

The outlook for neuroblastomas in extra-adrenal locations is better than that for their adrenal counterparts (Young et al, 1970). The outlook for neuroblastomas manifesting in the first year of life also is good. Many of these tumors are cystic in nature, and the histologic examination suggests that the neuroblasts are arranged in clumps rather than in sheets; this “neuroblastoma in situ” feature carries a high likelihood of spontaneous regression and therefore a good prognosis. Most neuroblastomas in the newborn are Evans stage A, with a good outlook. So-called stage D (S) also is quite common (Moppett et al, 1999); although there are metastases to the liver, marrow, or skin, the prognosis is still good because metastases to the bone are rare. The clinical markers are seldom elevated, and results of assays for the cytogenetic markers are seldom positive, all of which indicate a reasonable outlook. If the lesion can be completely removed and no bone metastases are found, then most infants survive. Some authors have suggested that the chance of spontaneous regression is so high in the newborn that even surgery may not be necessary (Li et al, 2001; Morgan, 1995). However, intraspinal spread may occur, in which case the later clinical course is more troublesome, with paraparesis and neurogenic bladder (Moppett et al, 1999); most authors consider surgery to be advisable.

## MALFORMATIONS OF THE LUNG PARENCHYMA

### Congenital Pulmonary Cysts

Congenital lung cysts are not common; they may be single or multiple but are always confined to one lobe of the lung; and other organs are not affected by cystic changes. Congenital cysts are persistent. All cysts have a communi-

cation with the peripheral airways, and for this reason they are filled with air except at birth, when they may be filled with fluid for several hours after birth.

### Diagnosis

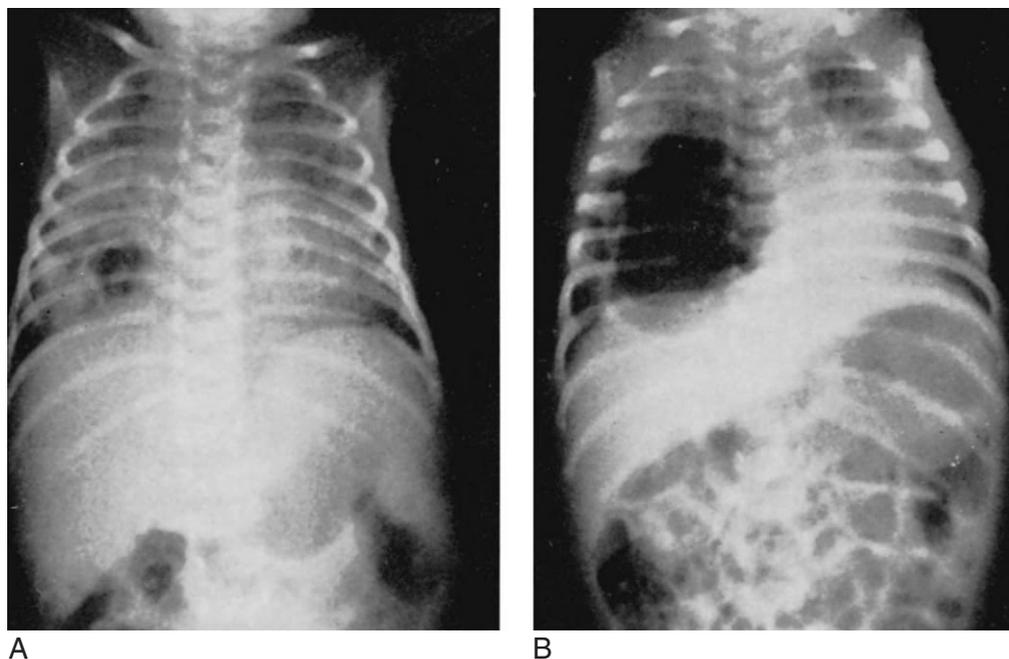

Newborns who develop signs of cystic disease of the lungs usually manifest the effects of rapid expansion of the cysts. The most common presentation is with air trapping, tension cyst, pneumothorax, and severe respiratory distress that necessitates lobectomy (Gwinn et al, 1970). Tachypnea or respiratory distress may begin at birth or any time thereafter and progress rapidly or slowly; the infant's condition may become critical within hours or remain static for weeks or months. In a few cases, older infants may present with recurrent episodes of pneumonia; it may then be difficult to decide whether the cyst is congenital or acquired (Fig. 50-4).

### Radiographic Findings

Large balloon cysts filled with air under tension are often mistaken for a tension pneumothorax. One hemithorax is overfilled, the diaphragm is flattened or even concave, and the mediastinum and heart are pushed to the contralateral side. Points that may distinguish balloon cysts from a pneumothorax are (1) a delicate linear pattern within the translucent area denoting the cyst's fine trabeculation, which is not present in the case of a pneumothorax; (2) the presence of compressed lung at the apex and at the costophrenic and cardiohepatic angles, often demarcated from the cyst by a curving line visible in one or another projection; and (3) the absence of all hilar shadows. In pneumothorax, the collapsed lung often is visible as a dense shadow projecting from the hilar region or upward from the diaphragm. It may be difficult to distinguish between congenital pulmonary cyst and congenital lobar emphysema; a chest CT scan often demonstrates the cystic nature of the former lesion (Kravitz, 1994).

### Treatment

The absolute indication for immediate surgical treatment is increasing air tension within the cyst. Repeated aspirations of air by needle and syringe or constant suction through a catheter introduced into the cyst may be neces-

**FIGURE 50-4.** Congenital pulmonary cyst in right lower lung (A), with increase in size and displacement of the heart at age 30 days (B). (From Swan H, Aragon GE: *Surgical treatment of pulmonary cysts in infancy*. *Pediatrics* 14:651, 1954.)

sary in an emergency situation, but these maneuvers provide only temporary relief. Surgery should then consist of removal of as small a portion of the lung as possible, either a segment of a lobe or the entire lobe. If the older patient has recurrent bouts of infection, associated with a congenital cyst, lobectomy is again indicated.

#### Prenatal Management

Large fluid-filled cysts, producing mass effects, polyhydramnios, and fetal hydrops, have been treated with thoracoamniotic catheters, with resolution of both the cyst and the hydrops condition (Revillon et al, 1993).

#### Acquired Lung Cysts (Pneumatoceles)

Acquired lung cysts are not lung malformations, but they are much more common than congenital cysts. Most pulmonary cysts in the newborn are pneumatoceles acquired after an episode of pneumonia with necrosis of lung tissue, or they are acquired during the course of mechanical ventilation complicated by pulmonary interstitial emphysema or bronchopulmonary dysplasia. Unlike congenital cysts, acquired cysts tend to disappear with time, but like congenital cysts, they too may develop tension enlargement leading to compression of adjacent lung with severe embarrassment, they may rupture with the production of a pneumothorax, and they may ultimately require elective or emergency surgical lobectomy.

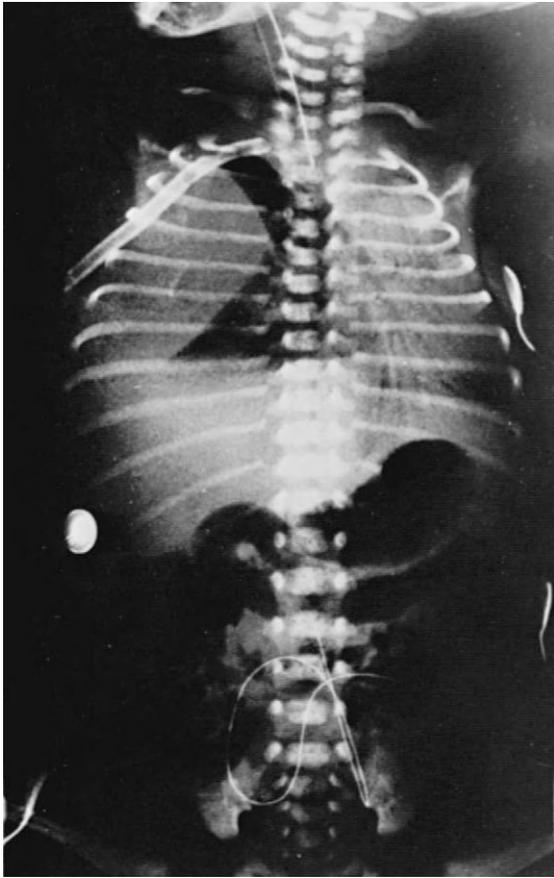

#### Congenital Cystic Adenomatoid Malformation of the Lung

Congenital cystic adenomatoid malformation of the lung (CCAM) is due to an overgrowth of the terminal bronchi-

oles with cysts of various sizes and no development of normal alveoli. This condition may affect any single lobe of the lung, causing a great increase in mass from multiple cystic proliferation (Merenstein, 1969), which may result in lung compression and significant pulmonary hypoplasia in adjacent lobes. The arterial blood supply and the venous drainage are connected with the pulmonary circulation. The lesion is a type of hamartoma with cystic structures, and on rare occasions there may be malignant change. Many of the affected infants are stillborn or premature or both. Associated malformations are present in about 20% of affected infants; there may be renal agenesis, jejunal atresia, diaphragmatic hernia, hydrocephalus, and skeletal anomalies. In the case of congenital heart disease, the lesion is frequently truncus arteriosus or tetralogy of Fallot (Morin et al, 1994). Due to its great mass, this malformation displaces the mediastinum and impedes venous return to the heart, accounting for a 50% incidence of hydrops fetalis. Another complication is polyhydramnios, which may be due to esophageal compression with impaired fetal swallowing (Revillon et al, 1993). In addition, polyhydramnios may occur because the cysts communicate with the airways and secrete fluid actively. After birth, because they are connected to the airways, the multiple cysts fill with air, producing further compression of the adjacent lung. If born alive, these infants have an early onset of respiratory distress, and the diagnosis is made by chest radiography (Fig. 50-5). This condition may be confused with congenital diaphragmatic hernia, but in cystic adenomatoid malformation, the abdominal gas pattern is normal, and a feeding catheter follows the normal path below the diaphragm.

#### Natural Course

There are two major pathologic types of cystic adenomatoid malformation. In the macrocystic type, the cysts are

**FIGURE 50-5.** Cystic adenomatoid malformation of the lung with chest tube on the right side.

more than 5 mm in diameter and are visible and echolucent on fetal ultrasonography, and the prognosis is better. In the microcystic type, the cysts are less than 5 mm in diameter, the mass has a solid appearance on fetal ultrasound examination, and the prognosis is worse; a poor outcome is more commonly associated with large size, mediastinal shift, polyhydramnios, pulmonary hypoplasia, and hydrops fetalis. In a large series of these lesions diagnosed prenatally, Thorpe-Beeston and Nicolaides (1994) reported that 51% were on the left side, 35% were on the right, and 14% were bilateral. In this series, 59% of the cases were macrocystic and 41% were microcystic. In 33% of the cases, there was an elective termination of pregnancy; in 5%, there was intrauterine death; hydrops fetalis developed in 43%; the infant was liveborn in 62%; and in 26%, there was a neonatal death. It was considered that survival was better if the mass was macrocystic and if there was no hydrops or polyhydramnios. Spontaneous regression with near-normal lungs at birth has been described in several series; in one series, 13 out of 32 cases showed regression before birth (Revillon et al, 1993). Masses that disappear are usually the microcystic type, but this phenomenon does not occur in cases with hydrops fetalis (Morin et al, 1994). During the canalicular (acinar) phase of lung development it is thought that platelet growth factor is very active (Liechty et al, 1999); at term gestation, this growth factor activity was much less. These changes
