

# Contributors

---

**Ira Adams-Chapman, M.D.**

Co-Director, Developmental Progress Clinic, Department of Pediatrics, Emory University School of Medicine, Atlanta, Georgia

*Nosocomial Infections in the Nursery*

**Anne M. Ades, M.D.**

Clinical Associate Professor of Neonatology, University of Pennsylvania School of Medicine; Neonatologist, The Children's Hospital of Philadelphia, Philadelphia, Pennsylvania

*Management of Congenital Heart Disease in the Low-Birth-Weight Infant*

**Amina Ahmed, M.D.**

Clinical Assistant Professor, University of North Carolina at Chapel Hill School of Medicine; Pediatric Infectious Disease, Carolinas Medical Center, Charlotte, North Carolina

*Toxoplasmosis, Syphilis, Malaria, and Tuberculosis*

**Simone Albers, M.D.**

Fellow in Pediatrics, Muenster University Faculty of Medicine and University Children's Hospital, Muenster, Germany

*Newborn Screening*

**Marilee C. Allen, M.D.**

Professor of Pediatrics, Johns Hopkins University School of Medicine; Associate Director of Neonatology, Johns Hopkins Hospital, and Co-Director, NICU Developmental Clinic, Kennedy Krieger Institute, Baltimore, Maryland

*Risk Assessment and Neurodevelopmental Outcomes*

**Maureen Andrew, M.D., F.R.C.P.†**

Formerly Professor of Pediatrics, McMaster University and Hamilton Civic Hospitals Research Centre, Hamilton, Ontario; Professor of Pediatrics, The Hospital for Sick Children, Toronto, Ontario, Canada

*Hemostatic Disorders of the Newborn*

**Stephen A. Back, M.D., Ph.D.**

Assistant Professor of Pediatrics and Neurology, Department of Pediatrics, Oregon Health Sciences University, Portland, Oregon

*Developmental Physiology of the Central Nervous System; Congenital Malformations of the Central Nervous System*

**H. Scott Baldwin, M.D.**

Katrina Overall Professor of Pediatrics, Professor of Cell and Developmental Biology, and Vice-Chair for Laboratory Sciences in Pediatrics, Department of Pediatrics, Vanderbilt University School of Medicine; Senior Cardiologist, Vanderbilt Children's Hospital, Nashville, Tennessee

*Embryology and Development of the Cardiovascular System*

**Philip L. Ballard, M.D., Ph.D.**

Gisela and Dennis Alter Professor of Pediatrics, Division of Neonatology, Department of Pediatrics, University of Pennsylvania School of Medicine; Director of Neonatal Research, The Children's Hospital of Philadelphia, Philadelphia, Pennsylvania

*Hormonal Influences on Fetal Development; Lung Development: Embryology, Growth, Maturation, and Developmental Biology*

**Roberta A. Ballard, M.D.**

Professor of Pediatrics, University of Pennsylvania School of Medicine; Neonatologist, The Children's Hospital of Philadelphia and Hospital of the University of Pennsylvania, Philadelphia, Pennsylvania

*Nonimmune Hydrops; Resuscitation in the Delivery Room; Respiratory Failure in the Term Infant; Bronchopulmonary Dysplasia; Disorders of the Chest Wall, Pleural Cavity, and Diaphragm*

**Beverly A. Banks-Randall, M.D., Ph.D., M.H.S.**

Director of Neonatology, Roy Lester Schneider Hospital, St. Thomas, U.S. Virgin Islands

*Bronchopulmonary Dysplasia*

**Stephen Baumgart, M.D.**

Professor of Pediatrics, State University of New York at Stony Brook School of Medicine; NICU Director, University Hospital at Stony Brook, Stony Brook, New York

*Temperature Regulation of the Premature Infant*

**Karen P. Beckerman, M.D.**

Clinical Associate Professor, Department of Obstetrics and Gynecology, New York University School of Medicine, New York, New York

*Identification, Evaluation, and Care of the Human Immunodeficiency Virus-Exposed Neonate*

**Thomas J. Benedetti, M.D., M.H.A.**

Vice Chair/Professor, Department of Obstetrics and Gynecology, University of Washington School of Medicine, Seattle, Washington

*Complicated Deliveries: Overview*

---

†Deceased.

**Gerard T. Berry, M.D.**

Professor of Pediatrics and Vice Dean for Research, Jefferson Medical College, Thomas Jefferson University, Philadelphia, Pennsylvania

*Introduction to the Metabolic and Biochemical Genetic Diseases; Inborn Errors of Carbohydrate, Ammonia, Amino Acid, and Organic Acid Metabolism*

**Carol Lynn Berseth, M.D.**

Director, Medical Affairs, Mead Johnson and Company, Evansville, Indiana

*Developmental Anatomy and Physiology of the Gastrointestinal Tract; Structural Anomalies of the Gastrointestinal Tract; Physiologic and Inflammatory Abnormalities of the Gastrointestinal Tract; Abdominal Wall Problems; Necrotizing Enterocolitis and Short Bowel Syndrome*

**Kathleen E. Bethin, M.D., Ph.D.**

Assistant Professor of Pediatrics, Division of Endocrinology and Diabetology, Indiana University School of Medicine, Indianapolis, Indiana

*Disorders of the Adrenal Gland*

**Diana W. Bianchi, M.D.**

Natalie V. Zucker Professor of Pediatrics, Obstetrics, and Gynecology, Tufts University School of Medicine; Chief, Division of Genetics, Tufts–New England Medical Center, Boston, Massachusetts

*Prenatal Genetic Diagnosis*

**Mitchell S. Cairo, M.D.**

Professor of Pediatrics, Medicine, and Pathology, Columbia University College of Physicians and Surgeons; Chief, Division of Pediatric Hematology and Bone Marrow Transplantation, Children's Hospital of New York–Presbyterian, New York, New York

*Neonatal Leukocyte Physiology and Disorders*

**Anthony Caldamone, M.D.**

Professor of Surgery (Urology) and Pediatrics, Brown School of Medicine; Director, Urology Residency Program, Rhode Island Hospital, Providence, Rhode Island

*Ambiguous Genitalia in the Newborn*

**Sudhish Chandra, M.D.**

Assistant Professor of Pediatrics, Case Western Reserve University School of Medicine; Attending Neonatologist, Rainbow Babies and Children's Hospital, Cleveland, Ohio

*Temperature Regulation of the Premature Infant*

**Ramen Chmait, M.D.**

Staff Physician, Florida Institute for Fetal Diagnosis and Therapy, Florida Perinatal Associates, Tampa, Florida

*Endocrine Disorders in Pregnancy*

**Ronald I. Clyman, M.D.**

Professor of Pediatrics, University of California, San Francisco, School of Medicine; Senior Staff, Cardiovascular Research Institute, San Francisco, California

*Patent Ductus Arteriosus in the Premature Infant*

**Bernard A. Cohen, M.D.**

Associate Professor of Pediatrics and Dermatology, Johns Hopkins University School of Medicine; Director, Pediatric Dermatology, Johns Hopkins Hospital, Baltimore, Maryland

*Newborn Skin: Development and Basic Concepts; Congenital and Hereditary Disorders of the Skin; Infections of the Skin; Common Newborn Dermatoses; Cutaneous Congenital Defects*

**Meryl S. Cohen, M.D.**

Interim Director of Echocardiography Laboratory, The Children's Hospital of Philadelphia, Philadelphia, Pennsylvania

*Echocardiography in the Neonatal Intensive Care Unit*

**Mitchell I. Cohen, M.D.**

Medical Director of Pediatric Cardiology and Director of Pacing and Electrophysiology, Phoenix Children's Hospital, Phoenix, Arizona

*Arrhythmias in the Fetus and Newborn*

**Robert M. Cohn, M.D.**

Associate Professor Emeritus, University of Pennsylvania School of Medicine, Philadelphia, Pennsylvania

*Lysosomal Storage, Peroxisomal, and Glycosylation Disorders and Smith-Lemli-Opitz Syndrome Presenting in the Neonate*

**F. Sessions Cole, M.D.**

Park J. White, M.D., Professor of Pediatrics, Professor of Cell Biology and Physiology, and Vice Chairman, Department of Pediatrics, Washington University School of Medicine; Director, Division of Newborn Medicine, St. Louis Children's Hospital, St. Louis, Missouri

*Immunology of the Fetus and Newborn; Viral Infections of the Fetus and Newborn*

**Anthony Corbet, M.B.**

Clinical Professor of Pediatrics, University of Texas Health Science Center at San Antonio; Partner, Magella Medical Associates (Pediatrix Medical Group); Staff Neonatologist, Christus Santa Rosa Children's Hospital, Methodist Children's Hospital, and St. Luke's Baptist Hospital, San Antonio, Texas

*Control of Breathing; Pulmonary Physiology of the Newborn; Principles of Respiratory Monitoring and Therapy; Respiratory Distress in the Preterm Infant; Respiratory Failure in the Term Infant; Anomalies of the Airways, Mediastinum, and Lung Parenchyma; Disorders of the Chest Wall, Pleural Cavity, and Diaphragm*

**Scott C. Denne, M.D.**

Professor of Pediatrics, Indiana University School of Medicine; Attending Neonatologist, James Whitcomb Riley Hospital for Children, Indianapolis, Indiana

*Parenteral Nutrition*

**Theresa J. Di Maggio, R.N., M.S.N., C.R.N.P.**

Pain Management Nurse Practitioner, Departments of Anesthesiology and Nursing, The Children's Hospital of Philadelphia, Philadelphia, Pennsylvania

*Neonatal Pain Management in the 21st Century*

**Eric C. Eichenwald, M.D.**

Assistant Professor of Pediatrics, Harvard Medical School; Associate Director, Newborn Intensive Care Unit, Brigham and Women's Hospital, Boston, Massachusetts

*Care of the Extremely Low-Birth-Weight Infant*

**Jacquelyn R. Evans, M.D.**

Clinical Professor, Department of Pediatrics, University of Pennsylvania School of Medicine; Clinical Director, Newborn Services, and Medical Director, Neonatal ECMO Program, The Children's Hospital of Philadelphia, Philadelphia, Pennsylvania

*Acid-Base, Fluid, and Electrolyte Management; Clinical Evaluation of Renal and Urinary Tract Disease; Acute and Chronic Renal Failure; Renal Vascular Disease in the Newborn*

**Nick Evans, D.M., M.R.C.P.Ch.**

Clinical Associate Professor of Pediatrics, University of Sydney Faculty of Medicine; Director, NICU, Royal Prince Alfred Hospital, Lamperdown, New South Wales, Australia

*Cardiovascular Compromise in the Newborn Infant*

**Avroy A. Fanaroff, M.D.**

Eliza Henry Barnes Professor in Neonatology and Interim Chair, Department of Pediatrics, and Professor of Reproductive Biology, Case Western Reserve University School of Medicine; Neonatologist, Rainbow Babies and Children's Hospital, Cleveland, Ohio

*Perinatal-Neonatal Epidemiology*

**Donna M. Ferriero, M.D.**

Professor of Neurology and Pediatrics, Division of Child Neurology, University of California, San Francisco, School of Medicine, San Francisco, California

*Central Nervous System Injury and Neuroprotection*

**Delbert A. Fisher, M.D.**

Vice President, Science & Innovation, Quest Diagnostics Nichols Institute, San Juan Capistrano, California

*Disorders of the Thyroid Gland*

**Laura Flores-Sarnat, M.D.**

Postdoctoral Research Fellow in Neuropathology, Cedars-Sinai Medical Center, Los Angeles, California

*Neonatal Neuromuscular Disorders*

**Philippe S. Friedlich, M.D.**

Assistant Professor of Clinical Pediatrics, University of Southern California Keck School of Medicine; Section Head, CHLA Operations, and Medical Director, Center for Newborn and Infant Critical Care, Children's Hospital Los Angeles, Los Angeles, California

*Clinical Evaluation of Renal and Urinary Tract Disease; Acute and Chronic Renal Failure*

**J. William Gaynor, M.D.**

Associate Professor of Surgery, University of Pennsylvania School of Medicine; Daniel M. Tabas Endowed Chair in Pediatric Cardiothoracic Surgery, The Children's Hospital of Philadelphia, Philadelphia, Pennsylvania

*Long-Term Neurologic Outcomes in Children with Congenital Heart Disease*

**Alfred L. Gest, M.D.**

Associate Professor of Clinical Pediatrics, Department of Pediatrics, The Ohio State University School of Medicine and Public Health; Neonatologist, Children's Hospital, Columbus, Ohio

*Principles of Respiratory Monitoring and Therapy*

**Tal Geva, M.D.**

Associate Professor of Pediatrics (Radiology), Department of Pediatrics, Harvard Medical School; Senior Associate in Cardiology, Children's Hospital Boston, Boston, Massachusetts

*Nomenclature and the Segmental Approach to Congenital Heart Disease*

**Mary Ann E. Gibbons, R.N., B.S.N.**

Clinical Nurse IV, Newborn/Infant Center, The Children's Hospital of Philadelphia, Philadelphia, Pennsylvania

*Neonatal Pain Management in the 21st Century*

**William M. Gilbert, M.D.**

Professor and Vice Chair, Department of Obstetrics and Gynecology, University of California, Davis, School of Medicine; Attending Physician, University of California, Davis, Medical Center, Sacramento, California

*Placental Function and Diseases: The Placenta, Fetal Membranes, and Umbilical Cord*

**Bertil E. Glader, M.D., Ph.D.**

Professor of Pediatrics, Stanford University School of Medicine; Attending Pediatrician, Stanford University Hospitals, Stanford, California

*Erythrocyte Disorders in Infancy*

**Christine A. Gleason, M.D.**

Professor of Pediatrics, University of Washington School of Medicine; Head, Division of Neonatology, Children's Hospital and Regional Medical Center, Seattle, Washington

*Developmental Physiology of the Central Nervous System; Appendix 2: Illustrative Forms and Normal Values*

**Michael J. Goldberg, M.D.**

Professor and Chairman, Department of Orthopaedics, Tufts University School of Medicine; Orthopaedist in Chief, Tufts-New England Medical Center, Boston, Massachusetts

*Common Neonatal Orthopedic Ailments*

**William V. Good, M.D.**

Senior Scientist, Smith-Kettlewell Eye Research Institute, San Francisco, California

*Disorders of the Eye*

**Gregory Goodwin, M.D.**

Assistant Professor of Pediatrics, Brown School of Medicine; Director, Pediatric Endocrine Clinic, Rhode Island Hospital, Providence, Rhode Island

*Ambiguous Genitalia in the Newborn*

**Sameer Gopalani, M.D., M.S.**

Acting Instructor and Fellow, Division of Perinatal Medicine, Department of Obstetrics and Gynecology, University of Washington School of Medicine, Seattle, Washington

*Complicated Deliveries: Overview*

**Carol L. Greene, M.D.**

Clinical Professor, George Washington University School of Medicine; Clinical Faculty, Division of Genetics and Metabolism, Department of Pediatrics, Children's National Medical Center, Washington, DC

*Lysosomal Storage, Peroxisomal, and Glycosylation Disorders and Smith-Lemli-Opitz Syndrome Presenting in the Neonate*

**Brian E. Grottkau, M.D.**

Chief of Pediatric Orthopaedics and Adult Spine Surgeon, Massachusetts General Hospital, Boston, Massachusetts

*Common Neonatal Orthopedic Ailments*

**Peter J. Gruber, M.D., Ph.D.**

Assistant Professor of Surgery, University of Pennsylvania School of Medicine; Pediatric Cardiologist, The Children's Hospital of Philadelphia, Philadelphia, Pennsylvania

*Common Congenital Heart Disease: Presentation, Management, and Outcomes*

**Jean-Pierre Guignard, M.D.**

Professor of Pediatric Nephrology, University of Lausanne Faculty of Medicine; Head, Division of Pediatric Nephrology, University Hospital Medical Center, Lausanne, France

*Renal Morphogenesis and Development of Renal Function*

**Susan Guttentag, M.D.**

Assistant Professor of Pediatrics, University of Pennsylvania School of Medicine; Neonatologist, The Children's Hospital of Philadelphia, Philadelphia, Pennsylvania

*Lung Development: Embryology, Growth, Maturation, and Developmental Biology*

**Shannon E. G. Hamrick, M.D.**

Clinical Instructor of Pediatrics, Division of Neonatology, University of California, San Francisco, School of Medicine, San Francisco, California

*Central Nervous System Injury and Neuroprotection*

**Thomas N. Hansen, M.D.**

Professor and Chairman, Department of Pediatrics, The Ohio State University School of Medicine and Public Health; Chief Executive Officer, Children's Hospital, Columbus, Ohio

*Control of Breathing; Pulmonary Physiology of the Newborn; Principles of Respiratory Monitoring and Therapy; Respiratory Distress in the Preterm Infant; Respiratory Failure in the Term Infant; Anomalies of the Airways, Mediastinum, and Lung Parenchyma; Disorders of the Chest Wall, Pleural Cavity, and Diaphragm*

**Margaret K. Hostetter, M.D.**

Professor of Pediatrics and Microbial Pathogenesis, Yale University School of Medicine; Physician-in-Chief, Yale-New Haven Children's Hospital, New Haven, Connecticut

*Fungal Infections in the Neonatal Intensive Care Unit*

**Samuel C. Hughes, M.D.**

Professor of Anesthesia, University of California, San Francisco, School of Medicine; Director, Obstetric Anesthesia, San Francisco General Hospital, San Francisco, California

*Maternal and Fetal Anesthesia and Analgesia*

**Andrew D. Hull, B.Med.Sci., B.M., B.S., F.R.C.O.G., F.A.C.O.G.**

Assistant Professor of Reproductive Medicine and Director of Research, University of California, San Diego, School of Medicine, San Diego, California

*Hypertensive Complications of Pregnancy; Antepartum Fetal Assessment*

**Roy Jedeikin, M.D.**

Medical Director of Pediatric Cardiology, St. Joseph's Hospital and Medical Center, Phoenix, Arizona

*Arrhythmias in the Fetus and Newborn*

**Sandra E. Juul, M.D., Ph.D.**

Associate Professor of Pediatrics, University of Washington School of Medicine, Seattle, Washington

*Developmental Biology of the Hematologic System*

**Bernard S. Kaplan, M.B., B.Ch.**

Professor of Pediatrics and Medicine, University of Pennsylvania School of Medicine; Director of Pediatric Nephrology, The Children's Hospital of Philadelphia, Philadelphia, Pennsylvania

*Developmental Abnormalities of the Kidneys; Glomerulonephropathies and Disorders of Tubular Function*

**Paige Kaplan, M.B., B.Ch.**

Professor of Pediatrics, University of Pennsylvania School of Medicine; Section Chief, Metabolic Diseases, Department of Pediatrics, The Children's Hospital of Philadelphia, Philadelphia, Pennsylvania

*Skeletal Dysplasias and Connective Tissue Disorders*

**Rebecca A. Kazin, M.D.**

Resident in Dermatology, Johns Hopkins Medical Institutions, Baltimore, Maryland

*Common Newborn Dermatoses*

**Thomas F. Kelly, M.D.**

Associate Clinical Professor of Reproductive Medicine, University of California, San Diego, School of Medicine, La Jolla; Director of Maternity Services, UCSD Medical Center, San Diego, California

*Maternal Medical Disorders of Fetal Significance: Seizure Disorders, Isoimmunization, Cancer, and Mental Disorders*

**Stefan Kuhle, M.D.**

Senior Registrar, Department of Neonatology, University Children's Hospital, Tübingen, Germany

*Hemostatic Disorders of the Newborn*

**Ian A. Laing, M.A. M.D., F.R.C.P.E., F.R.C.P.Ch.**

Senior Lecturer, Department of Reproductive and Developmental Sciences, University of Edinburgh Faculty of Medicine; Clinical Director, Neonatal Unit, Simpson Centre for Reproductive Health, Royal Infirmary of Edinburgh, Edinburgh, United Kingdom

*Surfactant Treatment of Respiratory Disorders*

**Harvey L. Levy, M.D.**

Associate Professor of Pediatrics, Harvard Medical School; Senior Associate in Medicine (Genetics), Children's Hospital Boston, Boston, Massachusetts  
*Newborn Screening*

**Mignon L. Loh, M.D.**

Assistant Professor of Clinical Pediatrics, University of California, San Francisco, School of Medicine; Attending Physician, UCSF Children's Hospital, San Francisco, California  
*Congenital Malignant Disorders*

**Scott A. Lorch, M.D., M.S.C.E.**

Assistant Professor, University of Pennsylvania School of Medicine; Clinical Associate, Division of Neonatology, The Children's Hospital of Philadelphia, Philadelphia, Pennsylvania  
*Nonimmune Hydrops*

**Ralph A. Lugo, Pharm.D.**

Associate Professor, University of Utah College of Pharmacy, Salt Lake City, Utah  
*Pharmacologic Principles and Practicalities*

**Geoffrey A. Machin, M.D., Ph.D.**

Fetal/Genetic Pathologist, The Permanente Medical Group, Department of Pathology, Kaiser Oakland, Oakland, California  
*Placental Function and Diseases: The Placenta, Fetal Membranes, and Umbilical Cord; Multiple Birth*

**James R. MacMahon, M.D.**

Associate Professor of Pediatrics, Staff Physician, Maine Medical Center, Portland, Maine  
*Neonatal Hyperbilirubinemia*

**George A. Macones, M.D., M.S.C.E.**

Associate Professor, Department of Obstetrics and Gynecology, University of Pennsylvania School of Medicine; Director, Maternal Fetal Medicine, Hospital of the University of Pennsylvania, Philadelphia, Pennsylvania  
*Prematurity: Causes and Prevention*

**Ashima Madan, M.D.**

Associate Professor of Pediatrics, Stanford University School of Medicine; Staff Physician, Lucile Salter Packard Children's Hospital, Stanford, California  
*Central Nervous System Injury and Neuroprotection; Neonatal Hyperbilirubinemia; Disorders of the Eye*

**Bradley S. Marino, M.D.**

Assistant Professor of Anesthesia and Pediatrics, University of Pennsylvania School of Medicine; Assistant Physician, Division of Cardiology and Division of Critical Care Medicine, The Children's Hospital of Philadelphia, Philadelphia, Pennsylvania  
*Stabilization and Transport of the Neonate with Congenital Heart Disease*

**Alma Martinez, M.D., M.P.H.**

Associate Clinical Professor of Pediatrics, San Francisco General Hospital and University of California, San Francisco, School of Medicine, San Francisco, California  
*Abnormalities of Fetal Growth; Perinatal Substance Abuse*

**Kathryn L. Maschoff, M.D., Ph.D.**

Clinical Associate Professor, Department of Pediatrics, University of Pennsylvania School of Medicine; Attending Neonatologist, The Children's Hospital of Philadelphia and Hospital of the University of Pennsylvania, Philadelphia, Pennsylvania  
*Embryology and Development of the Cardiovascular System*

**Patricia Massicotte, M.D., M.Sc., F.R.C.P.C.**

Professor of Pediatrics, University of Alberta Faculty of Medicine; Attending Physician, Stollery Children's Hospital, Edmonton, Alberta, Canada  
*Hemostatic Disorders of the Newborn*

**Katherine K. Matthay, M.D.**

Professor of Pediatrics, University of California, San Francisco, School of Medicine; Interim Chief, Pediatric Hematology-Oncology, and Director, Pediatric Oncology, UCSF Children's Hospital, San Francisco, California  
*Congenital Malignant Disorders*

**William C. Mentzer, M.D.**

Professor of Pediatrics Emeritus, University of California, San Francisco, School of Medicine; Attending Pediatric Hematologist/Oncologist, University of California Medical Center, San Francisco, California  
*Erythrocyte Disorders in Infancy*

**Jeffrey D. Merrill, M.D.**

Assistant Professor of Pediatrics, University of Pennsylvania School of Medicine; Medical Director, Intensive Care Nursery, Hospital of the University of Pennsylvania, Philadelphia, Pennsylvania  
*Resuscitation in the Delivery Room*

**Carol A. Miller, M.D.**

Clinical Professor, Department of Pediatrics, University of California, San Francisco, School of Medicine, San Francisco, California  
*Routine Newborn Care*

**Lesley Mitchell, A.R.T., M.Sc.**

Associate Professor of Pediatrics, University of Alberta Faculty of Medicine; Scientific Director, Pediatric Thrombosis Program, Stollery Children's Hospital, Edmonton, Alberta, Canada  
*Hemostatic Disorders of the Newborn*

**Alicia A. Moise, M.D.**

Associate Professor of Clinical Pediatrics, Department of Pediatrics, The Ohio State University School of Medicine and Public Health; Neonatologist, Children's Hospital, Columbus, Ohio  
*Principles of Respiratory Monitoring and Therapy*

**Thomas J. Mollen, M.D.**

Instructor, University of Pennsylvania School of Medicine; Clinical Associate, The Children's Hospital of Philadelphia, Philadelphia, Pennsylvania  
*Nonimmune Hydrops*

**Timothy P. Monahan, M.A., M.D.**

Resident in Dermatology, Johns Hopkins Hospital, Baltimore, Maryland  
*Congenital and Hereditary Disorders of the Skin*

**Thomas R. Moore, M.D.**

Professor and Chairman, Department of Reproductive Medicine, University of California, San Diego, School of Medicine; Faculty Physician, UCSD Medical Center, San Diego, California

*Endocrine Disorders in Pregnancy; Maternal Medical Disorders of Fetal Significance: Seizure Disorders, Isoimmunization, Cancer, and Mental Disorders; Hypertensive Complications of Pregnancy; Antepartum Fetal Assessment*

**Louis J. Muglia, M.D., Ph.D.**

Associate Professor of Pediatrics, Molecular Biology and Pharmacology, and Obstetrics and Gynecology, Washington University School of Medicine; Attending Physician, St. Louis Children's Hospital, St. Louis, Missouri

*Disorders of the Adrenal Gland*

**Robert M. Nelson, M.D., Ph.D.**

Associate Professor of Anesthesia and Pediatrics, University of Pennsylvania School of Medicine; Attending Physician, Anesthesiology and Critical Care Medicine, The Children's Hospital of Philadelphia, Philadelphia, Pennsylvania

*Ethical Decisions in the Neonatal-Perinatal Period*

**Thomas B. Newman, M.D., M.P.H.**

Professor of Epidemiology and Biostatistics, Departments of Epidemiology and Biostatistics and Pediatrics, University of California, San Francisco, School of Medicine; Attending Physician, Well Baby Nursery, UCSF Medical Center, San Francisco, California

*Routine Newborn Care*

**Eugenia K. Palotto, M.D.**

Assistant Professor of Pediatrics, University of Missouri-Kansas City School of Medicine; Attending Physician, Section of Neonatology, Department of Pediatrics, Children's Mercy Hospitals and Clinics, Kansas City, Missouri

*Disorders of Carbohydrate Metabolism*

**Erica S. Pan, M.D., M.P.H.**

Clinical Instructor, University of California, San Francisco, School of Medicine; Director, Bioterrorism and Emerging Infections Unit, Community Health Epidemiology and Disease Control, San Francisco Department of Public Health, San Francisco, California

*Viral Infections of the Fetus and Newborn*

**Elvira Parravicini, M.D.**

Assistant Professor of Clinical Pediatrics, Columbia University College of Physicians and Surgeons; Assistant Clinical Attending, Children's Hospital of New York-Presbyterian, New York, New York

*Bacterial Sepsis and Meningitis; Neonatal Leukocyte Physiology and Disorders*

**J. Colin Partridge, M.D., M.P.H.**

Clinical Professor, University of California, San Francisco, School of Medicine; Attending Neonatologist, San Francisco General Hospital, San Francisco, California

*Perinatal Substance Abuse*

**Dan Poenaru, M.D., M.H.P.E., F.R.C.S.C., F.A.C.S., F.I.C.S.**

Adjunct Associate Professor of Surgery and Pediatrics, Queen's University Faculty of Health Sciences, Kingston, Ontario, Canada; Medical Education and Research Director, AIC Kijabe Hospital, Kijabe, Kenya

*Structural Anomalies of the Gastrointestinal Tract; Abdominal Wall Problems; Necrotizing Enterocolitis and Short Bowel Syndrome*

**Brenda B. Poindexter, M.D.**

Assistant Professor of Pediatrics, Indiana University School of Medicine; Attending Neonatologist, James Whitcomb Riley Hospital for Children, Indianapolis, Indiana

*Parenteral Nutrition*

**Richard A. Polin, M.D.**

Professor of Pediatrics, Columbia University College of Physicians and Surgeons; Director, Division of Neonatology, Children's Hospital of New York-Presbyterian, New York, New York

*Bacterial Sepsis and Meningitis*

**Daniel H. Polk, M.D.**

Professor of Pediatrics, Northwestern University Feinberg School of Medicine; Vice Chief, Division of Neonatology, Children's Memorial Hospital, Chicago, Illinois

*Disorders of the Thyroid Gland*

**DeWayne M. Pursley, M.D., M.P.H.**

Assistant Professor of Pediatrics, Harvard Medical School; Neonatologist in Chief, Beth Israel Deaconess Medical Center, Boston, Massachusetts

*Impact of the Human Genome Project on Neonatal Care*

**Rangasamy Ramanathan, M.D.**

Professor of Clinical Pediatrics, University of Southern California Keck School of Medicine; Associate Division Chief and Section Head, USC Division of Neonatology; Director, Neonatal-Perinatal Medicine Fellowship Program, and Director, NICU Women's and Children's Hospital, LAC + USC Women's and Children's Hospital and Children's Hospital Los Angeles, Los Angeles, California

*Acid-Base, Fluid, and Electrolyte Management; Renal Vascular Disease in the Newborn*

**Daniela Ramirez-Schrempp, M.D.**

Clinical Assistant Instructor in Pediatrics, State University of New York; Children's Hospital at Downstate Medical Center, Brooklyn, New York

*Surfactant Treatment of Respiratory Disorders*

**Joan A. Regan, M.D.<sup>†</sup>**

Formerly Associate Professor of Clinical Pediatrics, Columbia University College of Physicians and Surgeons, and Associate Clinical Attending, Children's Hospital of New York–Presbyterian, New York, New York

*Bacterial Sepsis and Meningitis*

**Elisabeth G. Richard, M.D.**

Resident in Dermatology, Johns Hopkins Medical Institutions, Baltimore, Maryland

*Infections of the Skin*

**Richard L. Robertson, M.D.**

Assistant Professor of Radiology, Harvard Medical School; Director of Neuroradiology, Children's Hospital Boston, Boston, Massachusetts

*Neonatal Neuroimaging*

**Mark A. Rosen, M.D.**

Professor of Anesthesia and Obstetrics, Gynecology, and Reproductive Sciences, University of California, San Francisco, School of Medicine; Director, Obstetric Anesthesia, University Hospitals (Moffitt-Long), San Francisco, California

*Maternal and Fetal Anesthesia and Analgesia*

**Lewis P. Rubin, M.Phil., M.D.**

Associate Professor of Pediatrics and Co-Director, Program in Fetal Medicine, Brown Medical School; Staff Neonatologist, Women and Infants Hospital of Rhode Island, Providence, Rhode Island

*Embryology, Developmental Biology, and Anatomy of the Endocrine System; Disorders of Calcium and Phosphorus Metabolism*

**Jack Rychik, M.D., F.A.C.C.**

Associate Professor of Pediatrics, University of Pennsylvania School of Medicine; Medical Director, The Fetal Heart Program, Division of Cardiology, The Children's Hospital of Philadelphia, Philadelphia, Pennsylvania

*Echocardiography in the Neonatal Intensive Care Unit*

**Sulagna C. Saitta, M.D., Ph.D.**

Assistant Professor of Pediatrics, University of Pennsylvania School of Medicine; Attending Physician, Division of Human Genetics, The Children's Hospital of Philadelphia, Philadelphia, Pennsylvania

*Evaluation of the Dysmorphic Infant; Specific Chromosome Disorders in Newborns*

**Pablo J. Sánchez, M.D.**

Professor of Pediatrics, Division of Neonatal-Perinatal Medicine and Division of Pediatric Infectious Diseases, Department of Pediatrics, University of Texas Southwestern Medical Center; Attending Physician, Parkland Memorial Hospital and Children's Medical Center, Dallas, Texas

*Toxoplasmosis, Syphilis, Malaria, and Tuberculosis*

**Harvey B. Sarnat, M.D., F.R.C.P.C.**

Professor of Pediatrics (Neurology) and Pathology (Neuropathology), David Geffen School of Medicine at UCLA; Director, Division of Pediatric Neurology, Neuropathologist, and Director, Neuromuscular Pathology Laboratory, Cedars-Sinai Medical Center, Los Angeles, California

*Neonatal Neuromuscular Disorders*

**Richard J. Schanler, M.D.**

Professor of Pediatrics, Albert Einstein College of Medicine of Yeshiva University, Bronx; Chief, Neonatal-Perinatal Medicine, Schneider Children's Hospital at North Shore, North Shore University Hospital, Manhasset, New York

*Enteral Nutrition for the High-Risk Neonate*

**Mark S. Scher, M.D.**

Professor of Pediatrics and Neurology, Case Western Reserve University School of Medicine; Division Chief, Pediatric Neurology, and Director, Pediatric Sleep/Epilepsy and Fetal/Neonatal Neurology Programs, Rainbow Babies and Children's Hospital, University Hospitals of Cleveland, Cleveland, Ohio

*Neonatal Seizures*

**Istvan Seri, M.D., Ph.D.**

Professor of Pediatrics, University of Southern California Keck School of Medicine; Head, USC Division of Neonatal Medicine, and Medical Director, Institute of Maternal and Fetal Health, Children's Hospital Los Angeles and the LAC + USC Women's and Children's Hospital, Los Angeles, California

*Acid-Base, Fluid, and Electrolyte Management; Cardiovascular Compromise in the Newborn Infant; Clinical Evaluation of Renal and Urinary Tract Disease; Acute and Chronic Renal Failure; Renal Vascular Disease in the Newborn*

**Elaine C. Siegfried, M.D.**

Associate Clinical Professor of Pediatrics and Dermatology, Saint Louis University School of Medicine; Staff Physician, Cardinal Glennon Children's Hospital, St. Louis, Missouri

*Newborn Skin: Development and Basic Concepts; Congenital and Hereditary Disorders of the Skin; Infections of the Skin; Common Newborn Dermatoses; Cutaneous Congenital Defects*

**Gary A. Silverman, M.D., Ph.D.**

Associate Professor of Pediatrics, Harvard Medical School; Children's Hospital, Boston, Massachusetts

*Impact of the Human Genome Project on Neonatal Care*

**Rebecca Simmons, M.D.**

Assistant Professor of Pediatrics, University of Pennsylvania School of Medicine; Attending Neonatologist, The Children's Hospital of Philadelphia and Hospital of the University of Pennsylvania, Philadelphia, Pennsylvania

*Abnormalities of Fetal Growth*

<sup>†</sup>Deceased.

**Susan Sniderman, M.D.**

Professor of Pediatrics, Chief, Neonatal Service, San Francisco General Hospital, University of California-San Francisco, San Francisco, California

*Initial Evaluation: History and Physical Examination of the Newborn*

**Thomas L. Spray, M.D.**

Alice Langdon Warner Professor of Surgery, University of Pennsylvania School of Medicine; Chief, Division of Cardiothoracic Surgery, The Children's Hospital of Philadelphia, Philadelphia, Pennsylvania

*Management of Congenital Heart Disease in the Low-Birth-Weight Infant*

**Charles A. Stanley, M.D.**

Chief, Division of Endocrinology/Diabetes, The Children's Hospital of Philadelphia, Philadelphia, Pennsylvania

*Disorders of Carbohydrate Metabolism*

**David K. Stevenson, M.D.**

Harold K. Faber Professor of Pediatrics and Senior Associate Dean for Academic Affairs, Stanford University School of Medicine; Director, Charles B. and Ann L. Johnson Center for Pregnancy and Newborn Services, and Chief, Division of Neonatal and Developmental Medicine, Lucile Salter Packard Children's Hospital, Stanford, California

*Neonatal Hyperbilirubinemia*

**Barbara J. Stoll, M.D.**

Professor of Pediatrics and Interim Chair, Department of Pediatrics, Emory University School of Medicine, Atlanta, Georgia

*Nosocomial Infections in the Nursery*

**H. William Tausch, M.D.**

Professor and Vice Chair, Department of Pediatrics, University of California, San Francisco, School of Medicine; Chief, Pediatric Service, San Francisco General Hospital, San Francisco, California

*Perinatal Substance Abuse; Initial Evaluation: History and Physical Examination of the Newborn; Bacterial Sepsis and Meningitis; Surfactant Treatment of Respiratory Disorders*

**Peter Tarczy-Hornoch, M.D.**

Associate Professor, Division of Neonatology, Department of Pediatrics, and Associate Professor and Head, Division of Biomedical and Health Informatics, University of Washington School of Medicine, Seattle, Washington

*Evaluation of Therapeutic Recommendations, Database Management, and Information Retrieval*

**George A. Taylor, M.D.**

John A. Kirkpatrick Professor of Radiology, Harvard Medical School; Radiologist-in-Chief and Chairman, Department of Radiology, Children's Hospital Boston, Boston, Massachusetts

*Neonatal Neuroimaging*

**Janet A. Thomas, M.D.**

Assistant Professor of Pediatrics, University of Colorado School of Medicine; Director, Inherited Metabolic Diseases Clinic, University of Colorado Health Sciences Center and The Children's Hospital, Denver, Colorado

*Lysosomal Storage, Peroxisomal, and Glycosylation Disorders and Smith-Lemli-Opitz Syndrome Presenting in the Neonate*

**Tivadar Tulassay, M.D., D.Sc.**

# Preface

---

Dr. Alexander Shaffer, a noted Baltimore pediatrician and a former chief resident in pediatrics at Johns Hopkins Hospital, wrote the first edition of *Diseases of the Newborn*, which was published in 1960. At that time, he recognized that the care of newborns would become a subspecialty, which he termed *neonatology*. Composed from extensive case records, his book was of use mainly for diagnosis but included reference to the work of many who, with difficulty, studied the needs of newborns by applying techniques developed by such physiologists and biochemists as Barcroft and Gamble, who were fascinated by complexities of the fetus and newborn. The senior editor of this edition had the opportunity to see Dr. Shaffer diagnose the extent of an empyema in a 1-week-old infant by gentle percussion of the chest. This disease (thankfully) and this technique (regretfully) are now much less commonly observed. Many of the great names in pediatrics were contemporaries of Shaffer, and they, too, wed careful observation of newborns to clinical research in neonatology: Ethel Dunham, Warkany, Gamble, Gordon, Julius Hess, Levine, Clement Smith, Taussig, Diamond, Lubchenco, Rudolph, James, Apgar, and Silverman. With the use mainly of antibiotics, warmth, and attention to feeding techniques, the infant mortality rate in the United States dropped from 47/1000 live births in 1940 to 26/1000 in 1960.

Shaffer's book preceded the advent of ventilator management of newborn infants that, coupled with micro blood gas analysis and expertise in the use of umbilical artery catheterization, led to the development of neonatal intensive care for newborns in the 1960s on both sides of the Atlantic. Advances in neonatal surgery and cardiology and further developments in technology paralleled the rise of neonatal intensive care units (NICUs) and regionalization of care for sick newborn infants. Some of the leaders in North America were Stahlman in Nashville; Tooley and colleagues in San Francisco; Avery in Baltimore; Auld in New York; Usher and Stern in Montreal; Swyer in Toronto; Oh and Hodgman in Los Angeles; Battaglia, Meschia, and Butterfield in Denver; Sinclair in Hamilton; Sunshine in Palo Alto; and Lucey in Burlington.

Mary Ellen Avery joined Shaffer for the third edition of this book in 1971. A further drop in the infant mortality rate occurred by 1974, to 16.5/1000 live births. By 1977 and the fourth edition, the need for multiple contributors with subspecialty expertise was clear. In the preface for that edition, Shaffer wrote, "We have also seen the application of some fundamental advances in molecular biology to the management of our fetal and newborn patients." At that time he was referring to the new knowledge of hemoglobinopathies. In 1981, Shaffer died at the age of 79. Taeusch

joined Avery for the fifth edition, and Ballard, for the sixth in 1991, with the addition of Gleason for this edition.

The need for updating and revision is constant. Despite the use of the Internet for the latest knowledge, textbooks of neonatology, along with even more "subspecialized" books, lie dog-eared, broken-spined, and coffee-stained on countless conference room tables where caregivers congregate in nurseries. In looking over past editions, we note not that what was said was wrong but that the right things were not said as extensively, or as insightfully, or as clearly, as we now understand them. This edition has been completely and often painfully revised by some of the best clinicians/investigators in the field. They did this despite the demands of their day jobs in the hopes that their syntheses could, as Ethel Dunham wrote, "spread more widely what is already known, . . . and make it possible to apply these facts," as well as stimulating the search for new knowledge.

This edition is notable for its breadth—from the classic history and physical examination of a full-term newborn to the details of tiny DNA perturbations that result in lethal problems after birth. There are new sections on genetics and prenatal diagnosis. Eighty-four new authors contributed to this edition, and every section of the book has been updated. New diagnostic and therapeutic techniques are included for virtually every organ system, along with countless other changes to this new edition. Thanks to the newest member of our editorial team, Christine Gleason, the neurology section has been thoroughly updated; Gil Wernovsky, working with Roberta Ballard, has done the same for the cardiology section. The discussion of eye disorders has been expanded to include structural defects, transient motility disorders, and infection, as well as retinopathy of prematurity. An excellent new section on nutrition has been added, as has a discussion of fetal origins of adult disease.

In the era of sudden infant death syndrome (SIDS) prevention, fetal diagnosis of anomalies and genetic disorders, surfactant therapy, and improved techniques for cardiorespiratory support, the infant mortality rate for 2002 was 6.9/1000. Huge areas remain frustratingly intractable, however. Premature birth rates have increased. The problems of fetal exposure to addicting drugs and intoxicants remain ever present. Common germs are brilliantly adaptable in the face of formidable anti-infectives. Garden-variety problems of the NICU such as chronic lung disease, recurrent apneas, retinopathy, necrotizing enterocolitis, intracranial bleeding, and hypoxic ischemic encephalopathy continue to impair the well-being of thousands of infants each year. Problems so simple they are almost silly remain unsolved (what's a safe level of bilirubin? of blood glucose?). Basic questions concerning the nature of growth and development remain, and

the search for answers is underfunded, as resources are diverted in ways that hurt the children of the world. Many, if not most, of the neonatal medical problems that occur worldwide (like those of medicine in general) are rooted in poverty, a problem that can be markedly reduced if we do what is obvious.

As usual, we invite your comments and feedback, so that the next edition can correct any shortcomings or errors of this one.

We wish to thank key staff at Elsevier—Deborah Thorp, Managing Editor, Developmental Editorial, and Judith Fletcher, Executive Publisher, both of whom

demonstrated endless patience and persistence, and Jeff Gunning, Project Manager for our book—and our colleagues, families, and academic institutions for their continued support of this effort. Last, we would like to thank Mary Ellen Avery for her wise influence on the field of pediatrics, on the lives of many children throughout the world, and on us, the editors of the eighth edition of this text.

H. William Taeusch

# 1

## Perinatal-Neonatal Epidemiology

Linda L. Wright, Betty R. Vohr, and  
Avroy A. Fanaroff

Application of knowledge from biomedical research and improved public health have resulted in dramatic improvements in the health of Americans during the 20th century. During this period, the population has grown 2.7 fold, from 75,994,575 to 281,421,906. The increase in size and change in composition of the population during the last century reflect trends in the number of births and the fertility rate (births per 1000 women of childbearing age). Fertility rates declined steadily between 1900 and 1936 and then rose again between 1937 and 1957, peaking in the post-war baby boom, when 123 of every 1000 women of childbearing age gave birth. With the advent of more effective contraception in the 1960s and the legalization of abortion in the 1970s, fertility rates fell by nearly 50%. Since 1976, fertility rates have been relatively stable at approximately 65 per 1000. Trends in the number of births generally parallel trends in the fertility rate; however, there was a sharp rise in the number of births between 1975 and 1990 despite a stable fertility rate, reflecting childbearing of the baby-boom generation (Guyer et al, 2000).

The 1990s saw a steady decline in both the number of births and the fertility rates. This trend was interrupted between 1998 and 2000, when both increased (Martin et al, 2002a). However, preliminary data for 2001 suggest that the overall number of births and the fertility rates declined slightly again. Although they have differed historically, the current fertility rates among racial groups are quite similar (range 58 to 70 per 1000) except among Hispanic women (107 per 1000). Births to Hispanic women represented 21% of all U.S. births in 2001, an increase from 14% in 1989.

Other notable trends over the last decade include a continued dramatic decline in the teenage birth rate and a rise in birth rates among older women. In 2001, the teenage birth rate fell for the tenth consecutive year to a 60-year low of 49.5, a 5% decline from the 2000 rate and a 26% decrease from 1991. The 2001 decline in teenage birth rates

was consistent for all racial groups but was largest among black teenagers (whose birth rate fell from 80 to 73 per 1000 in 1 year). The birth rate among women 20 to 24 years old decreased by 2%, whereas that in women 25 to 44 years old continued to increase. The birth rate for women 30 years and older was the highest seen in three decades, reflecting both a delay in childbearing and greater use of assisted reproduction. The number and rate of twin births also rose each year since 1980; the absolute number increased by 74% between 1980 and 2000 (from 68,339 to 118,916). In contrast, the number and rate of triplet and other higher-order multiple births declined between 1998 and 2000 after soaring between 1980 and 1998 (37.0 to 193.5 per 100,000 live births) (Martin et al, 2002a). The “plateauing” of higher-order multiples reflects a decrease in the aging baby-boomer generation and refinements in assisted reproductive technologies designed to prevent higher-order multiple pregnancies.

Age-adjusted death rates have declined steadily over the last century as the life expectancy has risen from 49.2 to 76.5 years. The largest reductions in mortality were among children and infants: Between 1915 and 1998, the infant mortality rate (IMR; deaths in the first year of life per 1000 live births) declined by 93%, the neonatal mortality rate (NNR; deaths in the first 28 days of life) fell by 89%, and the post-neonatal mortality rate (PNMR; deaths between 29 days and 1 year of age) dropped by 96%.

Approximately half of the decreases in infant, neonatal, and post-neonatal mortality rates achieved in the 20th century occurred between 1980 and 2000 (Table 1–1). These trends in mortality cannot be attributed to decreases in the rate of preterm (<37 weeks of gestation) or low-birth-weight babies (LBW, <2500 g): between 1981 and 1999, the percentage of preterm births rose steadily from 9.4% to 11.8%. The rate of very preterm births (<32 weeks of gestation) also rose between 1981 and 1999, increasing from 1.81% of live births to 1.92% in 1990 and remaining essentially unchanged in the subsequent years. The 11.6% preterm birth rate for 2000 represents the first decline since 1992.

Birth weight data over the last two decades reflect similar trends: both LBW and very low-birth-weight (VLBW, <1500 g) rates rose in the 1990s after declining during the 1970s and early 1980s (Fig. 1–1). In the mid-1980s the LBW rate was 6.8%, but it rose to 7.6% between 1998 and 2001. In 2000 and 2001, VLBW infants represented 1.43% of the annual live births, a rise from less than 1.15% in 1980 (Martin et al, 2002b).

The racial disparity in LBW births among black and white women remains a complex, persistent problem. Infant mortality dropped among all races between 1980

\*NOTE: Infant, fetal, and perinatal deaths are tabulated separately by race and Hispanic origin; persons of Hispanic origin may be of any race. IMRs, NMRs, and PNMRs by race from unlinked data may differ slightly from those based on the linked file. Source: Centers for Disease Control and Prevention/National Center for Health Statistics, National Vital Statistics System, natality, mortality (unlinked file) and fetal death files.

<sup>†</sup>Includes races other than white and black.

<sup>‡</sup>Rate per 1000 live births.

<sup>§</sup>States not reporting Hispanic origin for 1998 for fetal deaths are Maryland and Oklahoma.

<sup>||</sup>Number of fetal deaths at  $\geq 20$  weeks of gestation per 1000 live births plus fetal deaths.

<sup>¶</sup>Percentage change is from 1980 to 1998 because data for 1999 and 2000 are not available.

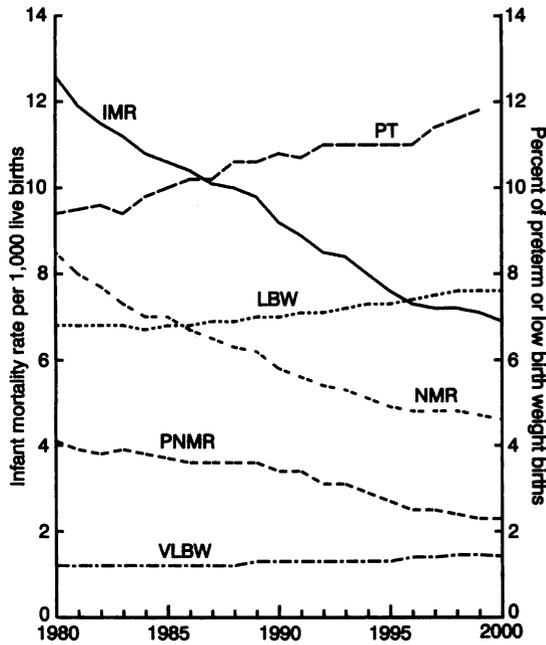

<sup>oo</sup>Number of fetal deaths at  $\geq 28$  weeks of gestation plus number of infant deaths at  $< 7$  days of age per 1000 live births plus fetal deaths.

—, Data not available.

Modified from Hoyert DL, Freedman A, Strobino DM, Guyer B: Annual summary of vital statistics: 2000. *Pediatrics* 108:1241-1255, 2001.

and 2000. The overall gap between black and white infant mortality rates widened because of (1) the two- to three-fold greater risk for LBW and VLBW babies among black women, (2) the relatively smaller reductions in birth weight-specific mortality rates (BWSMRs) among black infants, and (3) a relatively greater increase in the percentage of LBW and VLBW births among whites (Infant, 2002). The historically lower BWSMRs among moder-

ately LBW and VLBW black infants disappeared during the 1990s. The LBW rate among black women in 2000 and 2001 was 12.9%, a decrease from a 1991 high of 13.6%. The LBW rate was 6.5% over the same period among Hispanic mothers, and 6.7% among non-Hispanic white mothers. Multiple births, the rate of which has risen by one third since 1989, are a major factor in the increase in LBW babies among non-Hispanic white women in the

**FIGURE 1-1.** Infant mortality rate (IMR), neonatal mortality rate (NMR), and post-neonatal mortality rate (PNMR), and rates of low birth weight (LBW), very low birth weight (VLBW), and preterm delivery (PT), United States, 1980 to 2000. IMR is expressed as infant deaths per 1000 live births, and PNMR as post-neonatal deaths per 1000 live births. LBW rate is the percentage of babies born with low birth weight (<2500 g); VLBW rate is the percentage of babies born with VLBW (<1500 g); and PT rate is percentage of babies born preterm (<37 weeks of gestation). (From Hoyert DL, Freedman A, Strobino DM, Guyer B: *Annual summary of vital statistics: 2000. Pediatrics* 108:1241-1255, 2001.)

last two decades. Ten percent of singletons, 57% of twins, and 93% of triplets were born at less than 37 weeks of gestation in 2000. The risk of infant mortality is more than 6 times greater for multiple births than for singleton births (Mathews et al, 2002).

The dramatic decline in the infant mortality rate over the last two decades (from 12.6 to 6.9 deaths per 1000 live births) is directly attributable to decreases in BWSMRs. Between 1995 and 2000, the IMR decreased by nearly 17% for infants weighing 2500 g or more, by 8% for LBW infants, and by 9% for VLBW infants. In 2000, the IMR for infants weighing 2500 g or more at birth was 2.5 per 1000; it was 59.4 per 1000 for LBW infants, and 244.3 per 1000 for VLBW infants. Overall, more than 65% of all infant deaths occurred in LBW infants (7.6% of all births), and 51% of infant deaths occurred in VLBW infants (1.4% of births). Comparable gestational age-specific data from the 2000 linked birth/death data set document an IMR of 180.9 per 1000 for very preterm infants (<32 weeks of gestation), more than 69 times the rate of 2.6 per 1000 for term infants. Among moderately preterm infants (32 to 36 weeks), the IMR was 9.4 per 1000, more than 3.5 times the rate for term births (Mathews et al, 2002).

More than half of neonatal deaths in the United States still occur in the approximately 60,000 VLBW infants born each year, but advances in neonatal and perinatal care have

improved the chances of survival for such infants. A number of research networks, including the National Institute of Child Health and Human Development (NICHD) Neonatal Research Network, the Vermont Oxford Network, and the Canadian NICU (Neonatal Intensive Care Unit) Network, have been developed to track changes in the morbidity and mortality of VLBW infants and to improve neonatal outcomes by conducting large randomized controlled trials, observational studies, and outcomes research. Although each infant's prognosis depends on individual risk factors as well as the organization and aggressiveness of care, data from these research networks suggest that approximately 85% of VLBW infants born in U.S. level III facilities survive to hospital discharge.

Established in 1986, the NICHD Neonatal Research Network reports morbidity and mortality rates to discharge for VLBW infants admitted to the participating tertiary care centers and neurodevelopmental outcome for the subset of extremely LBW (ELBW) infants (<1000 g at birth). Data from the 4438 VLBW infants born in 14 participating centers from 1995 to 1996 documented the dramatic improvements in VLBW morbidity and mortality achieved in the 1990s. In 1995 to 1996, 84% of the VLBW cohort survived to discharge, compared with 80% in 1991 and 74% in 1988 (Lemons et al, 2001).

Table 1-2 presents perinatal and survival data from 11,733 VLBW infants born in 16 Network centers between 1997 and 2000. The mean gestational age was 28 weeks, and the mean birth weight was 1038 g. Overall, 26% of the cohort were from multiple gestations, 80% received antenatal glucocorticoids for fetal maturation, 70% received antenatal antibiotics, 57% were delivered by cesarean section, and 53% were intubated in the delivery room. Eighty-five percent of the cohort survived until discharge to home or a long-term care facility. Survival rose with increasing birth weight and gestational age up to 1000 g and 27 weeks, respectively, leveling off thereafter. Only 17% of infants who weighed 401 to 500 g at birth survived; however, 56% of 501- to 750-g infants, 88% of 751- to 1000-g infants, and 95% of 1001- to 1500-g infants survived to hospital discharge. Survival nearly doubled between 23 and 24 weeks (32% vs. 61%, respectively), increased steadily between 25 and 27 weeks, and leveled off thereafter (78% at 25 weeks, 85% at 26 weeks, 90% at 27 weeks, and 92% at 28 weeks). More girls than boys survived at each birth weight and in each gestational age group.

In contrast to the dramatic improvements in VLBW survival observed between 1988 and 1995, there was not a significant increase in VLBW survival between 1997 and 2000. Birth weight-specific survival rose by 2% among the subsets of infants 501 to 750 g (from 54% to 56%) and 751 to 1000 g (from 86% to 88%), but there was no increase in survival among infants weighing 1001 to 1500 g at birth.

The most common neonatal disorders were growth failure (93%), bronchopulmonary dysplasia (BPD; 23%) and nosocomial infection (22%). The rate of early-onset sepsis was 1.5%, unchanged since the early 1990s, despite the greater use of antibiotics during labor to reduce the risk of neonatal group B streptococcal infection and neonatal illness after preterm rupture of the membranes (Stoll et al, 2002). Eight percent of the cohort was diagnosed with

\*Data to initial hospital discharge or 120 days for infants surviving at least 12 hours.

<sup>†</sup>An infant was determined to have RDS if he or she (1) required oxygen at 6 hours of life continuing to age 24 hours, (2) demonstrated clinical features within age 24 hours, (3) needed respiratory support to age 24 hours, and (4) had an abnormal chest x-ray within age 24 hours.

<sup>‡</sup>Morbidity defined as a diagnosis of BPD, grade III to IV ICH, or proven NEC.

severe intracranial hemorrhage (ICH), 3% had periventricular leukomalacia (PVL), and 7% experienced proven necrotizing enterocolitis (NEC).

Overall, 71% of the cohort survived without major neonatal morbidity, including bronchopulmonary dysplasia, severe intracranial hemorrhage, periventricular leukomalacia, and confirmed necrotizing enterocolitis. Survival without major neonatal morbidity was only 36% among infants 750 g or less, but approximately 60% of infants 751 to 1000 g, 80% of infants 1000 to 1250 g, and 90% of infants 1251 to 1500 g at birth survived without major neonatal morbidity.

A similar plateauing of VLBW neonatal survival between 1991 and 1999 was reported by the Vermont Oxford Net-

work, a large voluntary network of international investigators (Horbar et al, 2002). The study documented the many changes in obstetric and neonatal management and associated outcomes among 31,219 VLBW infants cared for in the 39 institutions that participated in the Vermont Oxford Network between 1991 and 1999. Over the study period, the mean birth weight decreased significantly from 1061 to 1032 g. Changes in obstetric management included a three-fold increase in VLBW infants treated with antenatal steroids (from 23.8% to 71.6%), and significant rises in the proportion of mothers receiving prenatal care and cesarean delivery. Changes in neonatal management during the study period included increases in the proportions of

infants treated with surfactant (from 54.5% to 63.4%), nasal continuous positive airway pressure (from 36.3% to 62.5%), high-frequency ventilation (from 6.7% to 26.2%), and postnatal steroids (from 19.1% to 28.1%). The proportion of infants treated with any assisted ventilation fell from 81.5% to 76.2%. Overall mortality diminished significantly, from approximately 18% in 1991 to approximately 15% in 1996, but did not decrease significantly after 1995. Mortality rates by 250-g birth weight categories reflected similar trends, decreasing in all categories from 1991 to 1995 but remaining stable from 1995 to 1999. These data from two major U.S. networks document that the decades-long trend of improving VLBW neonatal morbidity and mortality has slowed or stopped altogether after 1995.

Whether the dramatic improvements in survival of extremely preterm infants have resulted in higher rates and higher absolute numbers of disabled survivors has been a matter of much debate and concern for physicians caring for these infants. This is especially true in the United States, where care of extremely preterm neonates tends to be more aggressive than in Europe (Lorenz et al, 2001), New Zealand, and Australia. These differences in approach to support of the extremely preterm infant are reflected in differences in survival rates as well as rates of long-term neurodevelopmental disability. Interpretation of the literature on long-term outcome of extremely preterm infants is limited by small sample sizes, lack of samples based on population and gestational age, differing proportions of inborn infants, different ages at assessment and outcome measures, inconsistent classification of neurodevelopmental impairment, and excessive loss to follow-up (Lorenz et al, 1998).

Gestational age-specific survival of extremely preterm infants from large population-based or regional studies in the United Kingdom and Ireland, Australia, and the United States (North Carolina and Rhode Island) are compared with survival data from the NICHD Neonatal Research Network in Table 1–3. These data illustrate that the threshold of viability (defined as survival of at least 50% of infants) in the United States remains 24 weeks, with a stepwise increase in survival for each additional week of gestation. At 24 weeks, 50% to 60% survive; at 25 weeks, 70% to 80% survive; and at 26 weeks, approximately 85% survive.

The two large population-based studies from Australia and the United Kingdom and Ireland represent a similar approach to the support of extremely preterm infants, but survival without neurodevelopment impairment is nearly 1.5-fold higher at follow-up among Australian children than among the United Kingdom and Irish children of comparable gestational ages. In Australia, Doyle and colleagues (2001) studied a geographically determined sample of infants born between 23 and 27 weeks of gestation in 1991 to 1992. They compared these infants with matched controls of normal birth weight and examined neurodevelopmental outcomes at 5 years. Fifty-six percent of the preterm sample ( $n = 225$ ) survived to 5 years of age. The survival rate for preterm infants born at level III centers was higher than for those born outside a level III center (odds ratio [OR], 3.1; 95% confidence interval [CI], 1.6 to 5.9, adjusted for gestational age). The rate of preterm survival without major sensorineural disability at 2 years, based on infants who had survived to initial hospital discharge,

was 80%. Twenty percent of the children had a major sensorineural disability (bilateral blindness, deafness, or cerebral palsy of such severity that the child did not walk or walked with great difficulty or had an intelligence quotient greater than 2 standard deviations below the mean); 11% had cerebral palsy. Risk factors during the initial hospitalization for major disability at 5 years of age were grade 3 or 4 cerebrowentricular hemorrhage, cystic periventricular leukomalacia, postnatal steroid therapy, and surgery before discharge. Among the nearly one half of the cohort that had none of these risk factors, the rate of survival without major sensorineural disability was 93%, similar to the rate among the controls with normal birth weight.

Wood and associates (2000) examined a population-based cohort of 283 infants born at 25 weeks or less in the United Kingdom and Ireland in 1995, and then evaluated them at a median corrected age of 30 months. Twenty-six percent of the cohort survived to initial hospital discharge; 2% died after discharge. Among infants who lived to discharge, the overall rate of disability was 49%; nearly half (23% of the sample) were severely disabled and required assistance for daily living. Thirty percent of survivors had developmental delay (Bayley Scales of Infant Development, Second Edition, Mental Developmental Index [Bayley II MDI] score  $<70$ ); 10% had a severe neuromotor disability, 2% were blind, and 3% had severe hearing impairment.

Very few large population or gestational age-based studies of the long-term outcome of extremely preterm infants have been conducted in the United States. The NICHD Neonatal Research Network published a large prospective multicenter study of outcome among U.S. ELBW infants born from 1993 to 1994 (Vohr et al, 2000). Neurodevelopmental and functional outcomes at 18 months corrected age were reported for the 1151 ELBW survivors (401–1000 g at birth, 63% survival) who were cared for in 12 participating Network centers. The mean birth weight of the cohort was  $796 \text{ gm} \pm 135 \text{ g}$  and the mean gestational age was  $26 \pm 2$  weeks. Forty-nine percent of the cohort had one or more major neurodevelopmental and/or neurosensory abnormality (Bayley II MDI or physical developmental index [PDI] score  $<70$ , blindness, deafness requiring hearing aids, or cerebral palsy); 17% had cerebral palsy. Specific impairments of the 401- to 700-g survivors (mean gestational age 25 weeks) included a 53% rate of major impairment and a 20% rate of cerebral palsy; 6% were unable to sit. Forty-two percent of infants weighing 401 to 700 g at birth had significant developmental delay (a Bayley II MDI score  $<70$ ); 4% had bilateral blindness; and 5% required a hearing aid. Risk factors for neurodevelopmental morbidity in the Network ELBW survivors included lower birth weight, bronchopulmonary dysplasia, severe intracranial hemorrhage, periventricular leukomalacia, postnatal administration of glucocorticoids for bronchopulmonary dysplasia, necrotizing enterocolitis, and male gender.

The results of large outcome studies of extremely preterm infants born in the early 1990s suggest that both survival to hospital discharge and neurodevelopmental outcome are variable. However, approximately half of extremely preterm infants born in 1990 to 1995 survived

without neurodevelopmental impairment at follow-up (Vohr et al, 2000; Hack et al, 2000; Wood et al, 2000). The high rate of survival without neurodevelopmental impairment may be explained in part by the inclusion of more mature infants in the Australian and North Carolina studies and by differences in outcome definitions. The rates of specific disabilities among the Australian infants were comparable with those reported from the United Kingdom and Ireland and the Neonatal Research Network (Table 1-4).

Whether neurodevelopmental outcome is improving among ELBW infants born in the late 1990s has not been established. In the North Carolina geographic cohorts reported by Washburn and colleagues (2002), there were no differences in the rates of survival to discharge or survival without developmental impairment at 1-year follow-up between the early 1990s (1990 to 1995) and the late 1990s (1995 to 2000). However, outcome in the 1995 to 2000 North Carolina cohort is among the highest reported—68% of the cohort survived and 89% survived without developmental impairment. Data from the NICHD Neonatal Research Network demonstrate that neurodevelopmental outcome improved in the late 1990s: The overall rate of neurodevelopmental impairment in infants born between 22 and 32 weeks decreased from 49% in 1993 to 39% in 1998. Survival improved and disability diminished in 22- to 26-week survivors (Fig. 1-2) as well as in infants 28 to 32 weeks, among whom survival increased from 84% to 97%, the rate of cerebral palsy decreased from 18% to 11%, and the rate of developmental impairment (MDI score <70) dropped from 29% to 22% over the study period (Vohr et al, 2001).

Parents and physicians of extremely preterm neonates require reliable information on their children's prognosis for survival and survival without disability in order to make informed decisions about how to best provide for their care. This information is, of necessity, offset in time from current practice and is often not specific to the institution caring for the infant or to the individual infant. Current estimates of survival without impairment (calculated from the product of the lowest survival and the lowest survival without impairment rates vs. the highest survival and highest survival without impairment rates), at 23 weeks range from 4% to 28%; at 24 weeks, from 12% to 49%; and at 25 weeks, from 23% to 78% (see Table 1-3). Given the limitations of the data, the estimated probability of survival without neurodevelopmental impairment for a 23-week neonate is 1/20 to 1/4; for a 24-week neonate, 1/5 to 1/2; and for a 25-week neonate, 1/4 to 4/5. Survival is rare with birth at 22 weeks of gestation.

Although preterm infants may not be neurodevelopmentally impaired at follow-up, they are at significant risk for academic difficulties. Studies of ELBW infants followed to school age report that 45% to 50% receive resource or special education services (Halsey et al, 1996; Saigal et al, 1990; Saigal et al, 1991). Bhutta and associates (2002), who performed a meta-analysis of case-control studies of 1556 preterm infants (<37 weeks) born between 1975 and 1988 and evaluated between 5 and 14 years of age, found that cognitive scores were directly proportional to birth weight and gestational age ( $P < .001$ ) and significantly lower than those of the term controls (weighted mean difference, 10.9; 95% CI 9.2, 12.5). The preterm survivors were 50% more likely to be enrolled in special education classes and had a 2.64-fold higher risk for development of attention deficit hyperactivity disorder (ADHD) compared with the term controls. A subsequent report of the outcome at 20 years of age of 242 VLBW survivors born between 1977 and 1999 (mean birth weight 1179 g and gestational age 29.7 weeks) and 233 term controls reported similar findings (Hack et al, 2002). The VLBW participants had lower mean cognitive scores (87 vs. 92) and lower achievement scores than the term controls. They had significantly higher rates of neurosensory impairment (10% vs. <1%) and shorter stature

than the controls. Fewer VLBW young adults had graduated from high school, and the VLBW males were less likely to be enrolled in post-secondary education (30% vs. 50%), after adjustment for maternal sociodemographic status. Of interest, the VLBW participants were also less likely to participate in risk-taking behavior (pregnancy, alcohol and drug use, and criminal activity) than the controls.

In summary, advances in perinatal care have led to the survival of growing numbers of children born at the lower limits of viability. Very low birth weight children have poorer outcomes compared with normal-birth-weight term controls in neurologic and health status, cognitive-neuropsychological skills, school performance, academic achievement, and behavior. Outcomes are highly variable but are related to medical risk factors, neonatal medical complications of prematurity, and social risk factors. Attention is increasingly focused on long-term outcome as an indicator of the individual infant's medical and social risk factors as well as the quality of the medical care the infant received. Systematic evaluation of risk factors (e.g., inflammatory exposures, nutritional status, brain injury on magnetic resonance imaging) and care practices (e.g., ventilatory management) may identify strategies and interventions needed to achieve further improvements in the outcome of babies born at the limits of viability.

# Evaluation of Therapeutic Recommendations, Database Management, and Information Retrieval

Peter Tarczy-Hornoch

## BACKGROUND

At a fundamental level, the practice of neonatology can be considered an information management problem. The care provider is combining patient-specific information (history, findings of physical examination, and results of physiologic monitoring, laboratory tests, and radiologic evaluation) with generalized information (medical knowledge, practice guidelines, clinical trials, personal experience) to make medical decisions (diagnostic, therapeutic, and management). Though medicine remains a quintessentially human endeavor, computers are playing a growing role in information management in general and in neonatology in particular. Both patient-specific information and generalized information are becoming increasingly available in electronic form. In the United States, a growing number of hospitals are adopting electronic medical record systems to manage patient-specific information, the approaches ranging from electronic flow sheets in the intensive care unit (ICU) to paperless hospitals. Around the world, the Internet has made possible a revolution in the sharing and dissemination of knowledge in all fields, including medicine.

Parallel with and related to the adoption of information technology is the growth of societal pressures to improve the quality of medical care while controlling costs. These changes are beginning to affect the way in which medicine and neonatology are practiced. In turn, it is becoming important for neonatologists to understand basic principles related to biomedical and health informatics, databases and electronic medical record systems, evaluation of therapeutic recommendations, and online information retrieval.

This expansion of information technology in clinical practice and the concurrent growth of medical knowledge have great promise but also potential pitfalls. One pitfall that must not be underestimated, and which is as great a danger today as when Blois (1984) first cautioned against it, is the unquestioning adoption of information technology: "And, since the thing that computers do is frequently done by them more rapidly than it is by brains, there has been an irresistible urge to apply computers to medicine, but considerably less of an urge to attempt to understand where and how they can best be used." A present and

very real challenge is information overload. Bero and Rennie (1995) observed, "Although well over 1 million clinical trials have been conducted, hundreds of thousands remain unpublished or are hard to find and may be in various languages. In the unlikely event that the physician finds all the relevant trials of a treatment, these are rarely accompanied by any comprehensive systematic review attempting to assess and make sense of the evidence." The potential of just-in-time information at the point of care is thus particularly appealing. "New information tools are needed: they are likely to be electronic, portable, fast, easy to use, connected to both a large valid database of medical knowledge and the patient record" (Smith, 1996).

## BIOMEDICAL AND HEALTH INFORMATICS

In the 1970s, clinicians with expertise in computers became intrigued by the potential that these tools had to help improve the practice of medicine, and the field of medical informatics was born. The importance of this field to address the issues of information management in health care is growing rapidly, as can be seen in the activities of the American Medical Informatics Association (AMIA) (American Medical, on line). *Medical informatics* can be concisely defined as "the rapidly developing scientific field that deals with the storage, retrieval, and optimal use of biomedical information, data, and knowledge for problem solving and decision making" (Blois and Shortliffe, 1990). Further definitions are available in the "Frequently Asked Questions" section of the AMIA's home page, in "About AMIA." The field includes both applied and basic research, with the focus here on the applied aspects. Examples of basic research are artificial intelligence in medicine, genome data analysis, and data mining (sorting through data to identify patterns and establish relationships). As our knowledge about the genetic mechanisms of disease expands and more data about patients and outcomes are available electronically, the role of informatics in medicine in general and neonatology in particular will expand.

The applied focus of the field in the 1960s and 1970s was data oriented, focusing on signal processing and statistical data analysis. In neonatology, the earliest applications of computers were for physiologic data monitoring in the neonatal ICU (NICU). As the field matured in the 1980s, applied work focused on systems to manage patient information and medical knowledge on a limited basis. Examples are laboratory systems, radiology systems, centralized transcription systems, and, probably the best-known medical knowledge management system, the database of published medical articles maintained by the National Library of Medicine known first as MEDLARS, then as Medline, and currently as PubMed (PubMed, on line). For instance, neonatologists began to develop tools to aid in the management of NICU patients, such as computer-assisted algorithms to help manage ventilators, although the algorithms have not been successfully deployed on a large scale in the clinical setting.

As computers and networking became mainstream in the workplace and home in the 1990s, informatics researchers

began to develop integrated and networked systems (Fuller, 1992, 1997). With the explosion of information from the Human Genome Project, the intersection between bioinformatics and medical informatics began to blur, leading to the adoption of the term *biomedical informatics*. This decade saw the development of a number of important systems. In terms of patient-specific information retrieval, they included integrated electronic medical record systems that in their full implementation can encompass, in a single piece of easy-to-use software, interfaces to physiologic monitors, electronic flow sheets, access to laboratory and radiology data as well as tools for electronic documentation (charting), electronic order entry, integrated billing, and modules to help reduce medical errors. The Internet has permitted ready access and sharing of this information within health-care organizations and, in some instances, limited secured remote access to this information from home. In terms of patient population information retrieval, a number of tools were developed to help clinicians and researchers look at aggregate data in these electronic medical records to document outcomes and help improve quality of care. The Internet and particularly the World Wide Web have transformed access to medical knowledge (Fuller et al, 1999). Health sciences libraries are becoming digital as well as paper repositories. Journals are available on line. Knowledge is now available at the point of care in ways it never has been before (Tarczy-Hornoch et al, 1997).

Evidence-based medicine as an approach to the evaluation of therapeutic recommendations has increased in prominence (see later discussion). In 1988, neonatologists established and expanded the Vermont Oxford Network to improve the quality and safety of medical care for newborn infants and their families (Vermont, on line). As part of the activities, they established and maintain a nationwide database about the care and outcome of high-risk newborn infants. Duncan (on line) maintains an excellent bibliographic database on the literature about computer applications in neonatology.

## DATABASES

In broad terms, a *database* is an organized, structured collection of data designed for a particular purpose. Thus, a stack of  $3 \times 5$  cards with patient information is a database, as is the typical paper prenatal record. Most frequently, the term is used to refer to an electronic collection of information, such as a database of clinical trial data for a group of patients in a study. Databases come in a variety of fundamental types, such as single-table, relational, and object-oriented.

A *simple database* can be set up using a single table by means of a spreadsheet program (such as Microsoft's Excel) or a database program (such as Microsoft's Access). The advantage of such a database is that it is very easy to set up and maintain. For an outcomes database in a neonatology unit, each row can represent a patient and each column represents information about the patients (for example name, medical record number, gestational age, birth date, length of stay, PDA [patent ductus arteriosus] yes/no, NEC [necrotizing enterocolitis] yes/no). The major limitation of such a database is that each time the researcher wants to

track another outcome (e.g., maple syrup urine disease), a column must be added to store the information. This can result in tables with dozens to hundreds of columns, which then become difficult to fill out and maintain.

The vast majority of databases and electronic medical records in neonatology is built using *relational database software*. To set up a simple outcomes relational database that permits easy adding of new outcome measures, one could use a three-table database design (Fig. 2-1). The first table would contain all the information for each patient has (e.g., basic demographic information—name, medical record number, gestation, birth date, admit date, discharge date). The second table would be a dictionary that would assign a code number to each diagnosis or outcome one wanted to track (e.g., PDA = 1, NEC = 2, plus dozens of rare diagnoses, like maple syrup urine disease = 10234). The third table would be the diagnosis tracking table—it would tie a patient number to a particular code and assign a value to that code. Adding a new diagnosis to track would require adding an entry to the diagnosis dictionary table. To add a diagnosis to a patient, one would add an entry to the tracking table. For example, Girl Smith (medical record number 00-00-01) is diagnosed with NEC. To add the diagnosis, one would add to the diagnosis table an entry that has a value of 00-00-01 in the medical record column, a value of 2 (code for NEC) in the code column, and a value of 2 in the value column (code for surgical). Though relational databases are harder to set up, they provide much more flexibility for expansion and maintenance and thus are the preferred implementation for clinical databases.

The distinction between a NICU quality assessment/quality improvement (a.k.a., outcomes) database and an electronic medical record is largely a matter of degree. Some characteristics typical of a neonatal outcomes database are data collection and data entry after the fact, limited amount of data collected (a small subset of the information needed for daily care), lack of narrative text, lack of interfaces to laboratory and other information systems, and the episodic (e.g., quarterly) use of the system for report generation. Some characteristics typical of an electronic medical record are “real-time” (daily or more frequent) entry of data, a large amount of data collected (approximating all the information needed for daily care), narrative text (e.g., progress notes, radiology reports, pathology reports), interfaces to laboratory and other information systems, and, most importantly, the use of the system for daily patient care.

In the past, the majority of neonatal databases and first-generation NICU electronic medical record systems were developed locally by and for neonatologists. The literature describing these efforts is available on line (Duncan, on line). Unfortunately, the majority of these systems were never published or publicly documented, and thus, a number of important and useful innovations are lost or must be repeatedly rediscovered. Anybody thinking about building his or her own neonatology database would be well advised to review the existing literature and existing commercial products before embarking on this path. That said, there is room for improvement of the existing products, and neonatologists continue to develop their own databases today.

Tables in the database:

**FIGURE 2-1.** Example of a relational database.

The largest neonatal outcomes database is the centralized database maintained by the nonprofit organization Vermont Oxford Network (Vermont, on line), with the mission of improving the quality and safety of medical care for infants and their families. One of the key activities of the network is their outcomes database, which involves more than 400 participating intensive care nurseries. Other activities of the network are clinical trials, follow-up of extremely low birth weight (ELBW) infants, and NICU quality and safety studies. The focus of the database has been very low birth weight (VLBW) infants (401 to 1500 g). At present, the network collects data on more than 50% of the VLBW infants born in the United States (>30,000 infants per year). Participants in the network submit data and in return receive both outcome data for their own institution and comparative data from other nurseries nationwide. All data except their own are anonymous for all participants. The network does have access to both the individual and aggregate data. The network database is maintained centrally, and data quality monitoring and data entry are centralized. Initially, the process involved paper submission of data by participating nurseries. Now a number of the commercial and custom NICU databases and electronic medical record systems can export their data in the format required by the Vermont Oxford Network. Submissions of data today are thus a combination of paper forms and reports generated by commercial and custom software packages.

The data tracked in the database focuses on tracking outcomes. With the passage of the Health Insurance Portability

and Accountability Act of 1996 (HIPAA), federal regulations governing the confidentiality of electronic patient data, some of the anonymous demographic data that was collected by the Network in the past has decreased. This change has grown from concerns that, in combination with identity of the referring center, these data could be used to uniquely identify patients, a violation of the HIPAA.

## **ELECTRONIC MEDICAL RECORD**

An electronic medical record is much more complex than an outcomes database, because the system is intended to be used continually on a daily basis to replace electronically some if not all of the record keeping, laboratory result review, and order writing that occur in a neonatal intensive care nursery. The complexity of this task becomes rapidly evident if one imagines that for a paperless medical record environment, every paper form in a nursery would need to be replaced with an electronic equivalent. Organizations are moving in this direction because of a combination of forces, of which the desires to reduce error in and to control the spiraling costs of health care are particularly important. These reasons are addressed at great length in two reports from the Institute of Medicine (Institute, 1997; Kohm et al, 2000). These benefits are typically achieved when information is not only available electronically (e.g., results of laboratory tests, radiology procedures, and transcription) but is also input into the system (e.g., problem lists, allergies) and when both sets of information are combined and checked

against electronic orders. Only with electronic orders has it been shown that errors can be reduced and care provider behavior clearly changed. Combining just electronic laboratory results (e.g., creatinine level) and electronic order entry (e.g., a drug order), for example, enables one to verify drug dosages have been correctly adjusted for renal failure. This approach would work well in adults, but in neonates, whose renal function is more difficult to assess and for whom drug dosage norms depend on gestational age and post-delivery age, additional information must be entered into the system (e.g., urine output, gestational age).

Results review systems include basic demographic data, such as name, age, and address from the hospital registration system. These systems require a moderate amount of work to tie them to the various laboratory, radiology, and other systems and to train users. The benefits are hard to quantify, but users typically prefer them to the paper alternative because of the more rapid access to information. The challenge in moving beyond the results review level to the integrated system level is that the documentation level and order entry level are essentially prerequisites for the integrated system level but, in and of themselves, have marginal benefit, particularly given the human and financial costs. Integrated systems require significant work to implement, including the presence of computers virtually at each bedside, as well as significant work to train users. The benefits accrue mainly to the organization, in the form of reduced costs of filing, printing, and maintaining paper records and, if providers are forced to enter notes instead of dictate them, significant savings in transcription costs. The challenge is that the end users often find it takes much longer to do their daily work with electronic documentation. Without moving to at least electronic order entry, if not an integrated system, the users do not realize major day-to-day benefits.

The benefits start to clearly accrue to both providers and institutions at the next level, electronic order entry. The complexity of implementing and deploying an electronic order entry system cannot be overstated. Interfaces need to be built not only with all the systems that are part of results review but also with other systems. Furthermore, a huge database of possible orders must be created to allow users to pick the right orders. This database and the menu of choices are needed because computers are poor at recognizing and interpreting a narrative text typed by a human. Finally and most importantly, there is a huge training challenge, because writing orders electronically is more complex and time consuming than handwriting them. The change management issues become apparent when one considers that typically, these systems take the unit assistant out of the loop; thus, a lot of the oversight that can occur at the unit assistant level does not, or the burden of oversight is now borne by the person entering the orders.

Once one overcomes the barriers to electronic order entry, organizations can start to benefit from integrated systems. For this reason, the trend today is not a stepwise move from results review to documentation of integrated systems but, rather, a big leap from results review straight to integrated systems. Interestingly, the technical complexities and the training and usage complexities of integrated systems are not that much higher than those for

order entry. Essentially, integrated systems add tools to make life easier for care providers using all the data in the system. An analogy might help one understand this issue. An integrated electronic medical record system is like an office software suite that encompasses a word processor, a spreadsheet, a slide presentation tool, a graphic drawing tool, and a database, all of which can “talk” to one another, making it easy to put a picture from the drawing tool or a graph from a spreadsheet into a slide show. Integrated systems include (1) error checking of orders, (2) alerts and reminders triggered by orders or by problems on the problem list or other data in the system, (3) care plans tied to patient-specific information, (4) charting modules customized to the problem list, (5) charting and progress notes that automatically pull in information from laboratory tests, flow sheets, and so on, and that help generate orders for the day as the documentation occurs, (6) modules to facilitate hyperalimentation ordering, and (7) modules to assist in management. For example one could imagine a system in which reminders for screening studies (e.g. for retinopathy of prematurity [ROP], intraventricular hemorrhage [IVH], and brainstem auditory evoked response [BAER]) were triggered by gestational age, problem list, and previous results of screening studies. Similarly, admission of a neonate at a particular gestational age with a particular set of problems could trigger pathways, orders, and reminders specific to that clinical scenario. An important caveat is that all such systems are only as good as the data and rules put into them. The issues raised in the section on evaluation of therapeutic recommendations are very important to consider in the context of electronic order entry and integrated systems.

The electronic medical record market is still relatively young and continually evolving. This is true of both products designed specifically for the neonatal intensive care unit and more generic products designed to be used throughout a hospital or health-care system. Order entry and documentation systems are in their adolescence, and integrated systems in their infancy. The major reason for this situation is that the needs of different health-care systems vary significantly, and the existing products are not flexible enough to meet all these needs in one system. Furthermore, there is a trend among health-care organizations and electronic medical record developers and vendors to move away from niche systems tailored to particular subsets of care providers, such as neonatology, and toward a focus on systems that are generically useful. There are two important drivers behind this trend.

The first and most important reason for adopting a single integrated system is that the benefits of an electronic medical record system begin to accrue only when an entire organization uses the same one. Consider the following scenario: A woman receives prenatal care in the clinic of an institution and then presents in preterm labor to the emergency department (ED). Her infant is delivered in the labor and delivery department, is hospitalized in the neonatal intensive care nursery, and is discharged to an affiliated pediatric follow-up clinic. In the current era of paper medical records, paper is used to convey information from one site to the other. In an integrated electronic medical record system, all the information for both mother and infant is in one place for all providers to

see. If the institution were to adopt niche software tailored to the needs of each site, a provider caring for the infant might need to access an ED system, an obstetric system, an NICU system, and an outpatient pediatric system to gather all the pertinent information. Each system would require the user to learn a separate piece of software (for example, four different word processors). Learning a site-specific piece of software is a considerably greater burden on care providers than learning to use a site-specific paper form.

The second factor driving adoption of integrated systems is economies of scale. The ideal electronic medical record system contains electronic interfaces that automatically pull into the system data from laboratory, pharmacy, radiology, transcription as well as integrated electronic orders, error checking, and electronic documentation by care providers. Given that development of these interfaces and provision of training and maintenance of the system cost more than the purchase of the system itself, it is far more cost effective to install one system with one set of interfaces and one set of training and maintenance issues than to replicate the process multiple times.

The neonatal intensive care environment poses some unique challenges for electronic medical records. Thus, it is important to try to ensure that when health-care systems are making decisions about the purchase of an electronic medical record, neonatologists and other neonatal health-care providers are involved in the process. An excellent source of information about NICU medical record systems and databases is an article by Stavis (1999). Neonatologists in the position of helping select an electronic medical record system must acquire the necessary background through reading some basic introductory texts on medical informatics, focusing on electronic medical records. It is then critical that they survey other organizations similar to their own to find out what systems have worked in that environment and what systems have not. For example, the needs of a level III academic nursery that performs extracorporeal membrane oxygenation (ECMO) are very different from those of a community level II hospital that does not perform mechanical ventilation of infants. Most important, using a medical informatics framework, the neonatologists must develop a list of prioritized criteria specific to their institution and compare available products in the marketplace with this list.

All end user needs must also be considered; thus, if residents, nurse practitioners, nutritionists, pharmacists, and respiratory therapists are expected to use the system, their input must be solicited as well. Ensuring broad-based input is especially relevant if the goal is an electronic medical record system into which it is expected that a lot of data will be entered by health-care providers (i.e., electronic charting, note writing, medication administration records, order entry). The reason to ensure “buy-in” by all the users into systems that require data entry is that a significant percentage of systems requiring data entry has ultimately been unsuccessful because of lack of user acceptance. Unfortunately, there is little literature on this issue, because institutions rarely publicize and publish their failures in this arena, although the situation is beginning to change. Lack of adoption is rarely a problem when the system is a results review system.

The final step in evaluating a potential system is to develop a series of use scenarios and to have potential users sit down in front of the system and test the scenarios. Evaluating use scenarios typically involves visits to sites that have installed the electronic medical record system under consideration. An example of a use scenario might be for a nurse, a respiratory therapist, a resident, and an attending physician to try to electronically replicate, on a given system under consideration, the bedside charting, progress note charting, and order writing for a critically ill patient who undergoes ECMO and then decannulation. The reason for developing and testing such scenarios is that this approach is the best way to ensure that aspects of charting, note writing, and documentation unique to the NICU are supported by the system.

## EVALUATING THERAPEUTIC RECOMMENDATIONS

Once all the data about a patient, whether in electronic or paper form, is in hand, the clinician is faced with the challenge of medical decision-making and applying all that he or she knows to the problem at hand. This, in turn, means it is vital that the clinician understand what is known and what is still uncertain in terms of the validity of therapeutic recommendations. The evaluation of new recommendations arising from a variety of sources, including journal articles, meta-analyses, and systematic reviews, is thus a critical skill that all neonatologists must master. Broadly speaking, this approach has been termed *evidence-based medicine*. A full discussion of this approach to evaluation of new approaches in clinical medicine is beyond the scope of this discussion. Two outstanding sources of information are the works by Guyatt and colleagues (2002) and Sackett and associates (2000). An important caveat is that evidence-based medicine is not a panacea. It is not helpful when the primary literature does not address a particular clinical situation because of its rarity or complexity, for example. This approach also does not necessarily address broader concerns, such as clinical importance or cost effectiveness (although it sometimes does).

In the early days of medicine, the “gold standard” was observation of individual patients and subjective description of aggregate experiences from similar patients. As the science of medicine evolved, formal scientific methods were applied to help assess possible therapeutic and management interventions. Important tools in this effort are epidemiology, statistics, and clinical trial design. Today, medicine in general and neonatology in particular are faced with an interesting paradox. For some areas, there is a wealth of information in the form of the gold standard randomized controlled clinical trial, whereas for others, there is scant information to guide clinical practice. A wealth of well-designed clinical trials on the use of surfactant has been published, for example, but there are essentially none addressing the management of chylothorax. One might assume that the practice of medicine reflects the available evidence, but this is not the case. McDonald (1996) summarized the problem as follows: “Although we assume that medical decisions are driven by established scientific fact, even a cursory review of practice patterns shows that they are not.” Investigators have examined medical practice

(generally in the outpatient primary care setting) and have determined that of all medical interventions, roughly 50% are not adequately addressed by the medical literature, 30% continue despite evidence against their efficacy in the medical literature, and only about 20% are well supported by the literature. Thus, neonatologists have a responsibility to identify what knowledge is available in the literature and elsewhere and to critically evaluate this information before applying it to practice. Furthermore, because this information is constantly evolving, one must continually revisit the underlying literature as it expands; a good example is the recommendations regarding the use of steroids for chronic lung disease.

The evidence-based practice of medicine is an approach that addresses these issues. It is helpful to consider the process as involving two steps—the critical review of the primary literature and the synthesis of the information offered in the primary literature. Critical review of the primary literature is an area that most neonatologists have a lot of experience with through journal clubs and other similar forums. The approach involves systematically reviewing each section of an article (i.e., background, methods, results, discussion) and, for each section, asking critical questions (e.g., for the methods section: Is the statistical methodology valid? Were power calculations made? Was a hypothesis clearly stated? Do the methods address the hypothesis? Do the methods address alternative hypotheses? Do the methods address confounding variables?). The formal evaluation of each section must then be synthesized into some conclusions. A helpful question to ask is “Does this paper change my clinical practice, and if so, then how?” Further resources for systematic review of the primary literature are listed in the Selected Readings. It is important to note that guidelines for systematic review of a single article differ according to whether it describes (1) a preventive or therapeutic trial (e.g., use of nitrous oxide for chronic lung disease), (2) evaluation of a diagnostic study (e.g., use of C-reactive protein level for prediction of infection), or (3) prognosis (e.g., prediction of outcome from a Score for Neonatal Acute Physiology [SNAP] score).

The second, and arguably the more important, step is to determine not the affect of one article on one’s practice but the overall impact of the body of relevant literature on one’s practice. For example, if the preponderance of the literature favors one therapeutic recommendation, then a single article opposing the recommendation must be weighed against the other articles that favor it. This is a complex task, and the most complete and formal statistical approach to combining the results of multiple studies (meta-analysis) requires significant investment of time and effort. Part of the evidence-based practice of medicine approach therefore involves the collaborative development of evidence-based systematic reviews and meta-analyses by communities of care providers. Within the field of neonatology, Sinclair and associates (1992) laid the seminal groundwork for this approach. Their textbook, *Effective Care on the Newborn*, remains an important milestone but illustrates the problem of information currency. Because the textbook was published in 1992, none of the clinical trials in neonatology in the last decade are included. The Internet has permitted creation and

continual maintenance of up-to-date information by a distributed group of collaborators, lending itself beautifully to the maintenance of a database of evidence-based medicine reviews of the literature. This international effort is termed the Cochrane Collaboration, and the *Cochrane Neonatal Review* is devoted to neonatology (Cochrane, online). A limitation of the Cochrane approach is illustrated by the relatively restricted scope of topics covered at the National Institute of Child and Human Development (NICHD) Web site ([www.nichd.nih.gov/cochrane/cochrane.htm](http://www.nichd.nih.gov/cochrane/cochrane.htm))—existence of a review requires adequate literature on a topic and a dedicated and committed clinician to create and update the review.

It is important to distinguish between these formal approaches to reviewing the literature (systematic literature reviews and meta-analyses) that have specific methodologies and more ad hoc reviews of the literature. Evidence-based medicine aggregate resources such as the Cochrane Collaboration take a more systematic approach, but review articles published in the literature vary in their approach. Meta-analyses are easy to distinguish but systematic reviews versus ad hoc reviews are harder to distinguish. Systematic reviews focus on quality primary literature (e.g., controlled studies rather than case series or case reports) and must include (1) a methods section for the review article that explicitly specifies how articles were identified for possible inclusion and (2) what criteria were used to assess the validity of each study as well as to include or exclude primary literature articles in the systematic review. Systematic reviews also tend to present the literature in aggregate tabular form even when meta-analyses of statistics of all the articles cannot be done. One commonly used source of overview information in neonatology—the *Clinics in Perinatology* series—is a mix of opinion (written in the style of a book chapter), ad hoc literature review, systematic literature review, and meta-analysis. Guidelines (such as screening recommendations for group B streptococcal [GBS] infection), although based on primary literature review, are typically neither meta-analyses nor systematic reviews of the literature. Whereas formal methods are used to derive conclusions with meta-analyses and systematic review, guidelines are developed frequently instead by consensus among committee members (true of both national and local practice guidelines). General textbooks of neonatology are typically based on ad hoc literature review that includes both primary literature and systematic literature review. When one is reading overviews of the aggregate state of current knowledge on a given topic in neonatology, it is important to keep these distinctions in mind.

Anyone interested in developing his or her own evidence-based reviews on a particular topic should review some of the textbooks on evidence-based practice listed at the end of the chapter; initially, he or she should collaborate (in person or by e-mail and telephone) with someone who has experience in systematic review and meta-analyses. The process consists of the following steps: (1) identification of the relevant clinical question (e.g., management of bronchopulmonary dysplasia [BPD]), (2) narrowing of the question to a focus that enables one to determine whether a given article in the primary literature answers it or not (e.g., Does prophylactic high-frequency ventilation have positive

or negative effects on acute and chronic morbidity—pulmonary and otherwise?), (3) extensively searching the primary literature (frequently in collaboration with a librarian with expertise searching the biomedical literature) and retrieving the articles, (4) critically, formally, and systematically reviewing each article for inclusion, validity, utility, and applicability, and (5) formally summarizing the results of the preceding process, including conclusions valid throughout the body of included primary literature.

## ONLINE INFORMATION RETRIEVAL

In the long run, because of the rapid growth of biomedical information and the fact it changes over time, both investigators in informatics and publishers believe that print (paper) media will soon no longer be the way that biomedical information is shared and distributed (Weatherall, 1995; Smith, 1996). Economic realities will dictate, however, that quality information will generally come at a price. The medical digital library at the University of Washington (available on line at [www.healthlinks.washington.edu](http://www.healthlinks.washington.edu), then click on the Care Provider tab) serves to illustrate the current state of the art. The information available is a combination of locally developed material (e.g., University of Washington faculty writing practice guidelines), material developed by institutions elsewhere (faculty elsewhere writing such guidelines), material developed by organizations (e.g., the neonatal Cochrane Collaboration), and ever increasingly electronic forms of journals and textbooks and evidence-based medicine databases. The last (journals, textbooks, databases) are generally not free, and the University of Washington pays a “subscription fee” (termed a *site license*) to provide access to these resources for their faculty, staff, and students. Libraries will likely remain the primary source of information but will shift their attention from paper to electronic materials. Health sciences libraries can provide invaluable training in the efficient use of online medical resources, and most offer training sessions and consultation.

A number of online resources are valuable for neonatologists. For accessing the primary literature, the most valuable resource is the National Library of Medicine’s database of the published medical literature accessible (PubMed, on line) along with many other databases accessible from the Health Information Web site (National Library, on line). The PubMed system is continually being enhanced; thus, it is very useful to review the help documentation on line and to regularly look at the New/Noteworthy section to see what has changed. One of the most powerful and most frequently under-utilized tools is the “Find Related” link that appears next to each article listed on PubMed. This link locates articles that are related to the one selected (Liu and Altman, 1998). The PubMed system applies a powerful statistical algorithm with complex weightings to the article selected to each word in the title, to each author, to each major and minor keyword (Medical Subject heading [MeSH]), and to each word in the abstract and then finds statistically similar articles in the database. In general, this system outperforms the novice to advanced health-care provider performing a complex search and begins to approach the accuracy of an

experience medical librarian. All the major pediatric journals are available on line either through a package at local hospital libraries or by subscription (instead of or in addition to a print/paper subscription). The value of having an electronic subscription to a journal is that it provides access not only to the current issue but also to past issues. The best online free source of information on evidence-based practice is the *Cochrane Neonatal Review* (Cochrane, on line). Subscriptions to the full Cochrane database can be purchased on line as well.

Given the growing role of genetics in health care and, in particular, the importance of genetic diseases in infants, one should consider accessing two genetics databases that are available free of charge on line. The first is Online Mendelian Inheritance in Man (OMIM), accessible at the National Library of Medicine through their menus or directly at the Web site (OMIM, on line). This database, a catalog of human genes and genetic disorders, is an online version of the textbook by the same name. It is a diachronic collection of information on genetic disorders, meaning that each disease entry chronologically cites and summarizes key papers in the field. The second is the GeneTests database (GeneTests, on line), which is both a yellow pages of genetic testing (what testing is available on a clinical and research basis, where, and how one sends a specimen) as well as a user manual (how to apply genetic testing). The user’s manual section consists of entries for a growing number of diseases or clinical phenotypes of particular importance (>200). Entries are written by experts, peer reviewed both internally and externally, subject to a formal process similar to a systematic review, and updated regularly on line. An excellent site that maintains links to the majority of locally developed neonatology-specific content around the country is the site maintained by Duncan (on line). In addition to a database of links to clinical resources around the country, the site also has a jobs listing and a database of the literature on computer applications in medicine.

The clinician must realize that, unlike journals, textbooks, and guidelines, the material on the World Wide Web (whether accessed from Duncan’s site or whether based on a search of the World Wide Web), is not necessarily subject to any editorial or other oversight as to what is published; thus, as Silberg and associates (1997), put it, “caveat lector” (reader beware). A number of articles and Web sites address criteria for assessing the validity and reliability of material on a Web site (Mitretrek Systems, on line; Health, on line). If one keeps this caution in mind, a search on the entire World Wide Web using a sophisticated search engine (such as Google, available at [www.google.com](http://www.google.com)) can yield very valuable information, though with a lot of chaff for a little wheat. Google also has a sophisticated statistical algorithm that allows a user to find similar web pages once he or she has identified one of interest.

## Ethical Decisions in the Neonatal-Perinatal Period

Robert M. Nelson

In 1973, Duff and Campbell published a groundbreaking article supporting the withdrawal of life-sustaining medical treatment (LSMT) from 43 infants described as severely impaired from congenital disorders. One infant, who suffered from Down syndrome and intestinal atresia, died without surgical intervention at the request of his parents. Seven other infants had meningomyeloceles (spina bifida), which also were not surgically corrected (Duff and Campbell, 1973). A year earlier, Lorber (1972) had advocated the “selective non-treatment” of infants with spina bifida who met certain diagnostic criteria associated with a poor neurologic prognosis, functional prognosis, or both. The following decade saw a vigorous professional debate about the treatment of newborns with congenital disorders on the basis of their anticipated quality of life, with widespread support for withholding otherwise standard medical or surgical treatment from infants with either Down syndrome or spina bifida.

This debate burst onto the public stage with the 1982 birth of an infant known as “Baby Doe.” Born with Down syndrome and a tracheoesophageal fistula, Baby Doe died at 6 days of age of a pulmonary hemorrhage while lawyers were seeking court-ordered treatment over the parents’ objection. Aligned with disability rights and antiabortion activists, the Reagan Administration issued a regulation, based on section 504 of the Rehabilitation Act of 1973, that failure to treat disabled newborns was a violation of their rights to equal access. This version of the “Baby Doe” regulations was struck down in 1986 by the U.S. Supreme Court; however, the federal child abuse statutes had already been amended in 1984 to include “failure to provide medically necessary treatment” to disabled newborns under the definition of *child abuse*. The statute provided for only three exceptions; medically necessary treatment could be withheld from a disabled newborn if (1) the infant was irreversibly comatose, (2) the treatment was futile, or (3) providing treatment was inhumane because it would merely prolong suffering for an infant whose death was imminent. Enforcement of these statutes was tied to funding for state child abuse programs, resulting in a patchwork of responses from state legislators. Some states made no change (without any adverse funding consequences); other states simply made procedural changes, such as establishing a special office for disability rights; and yet other states incorporated the revised definition of *child abuse* into specific regulations guiding parent and provider conduct—a situation that remains true today. Thus, the

political and legal effects of the “Baby Doe” regulations on parent and provider conduct vary tremendously from state to state.

Significant advances in the care of critically ill newborns were made during this time of social and political controversy. In the 1980s, improvements in technology led to high-profile innovations such as extracorporeal membrane oxygenation (ECMO) for infants with persistent pulmonary hypertension and surgical advances in the treatment of infants with hypoplastic left heart syndrome. As more and more premature infants began to survive, attention shifted to the extremely low birth weight (ELBW) infant. Surfactant replacement for hyaline membrane disease progressed, so that the routine use of surfactant in the 1990s significantly increased the overall survival for ELBW infants. At the same time, public attention shifted to the alleged over-treatment of ELBW premature infants who may have a poor prognosis for meaningful survival. Improvements in fetal imaging and surgical techniques have also made possible fetal surgical interventions both at mid-gestation and just before delivery. Although previously the debate had focused on “selective non-intervention” for infants born with spina bifida, controversy has shifted to the selection criteria for operating on unborn fetuses with spina bifida in hopes of improving neurologic and functional outcomes (Sutton et al, 1999).

### WORKING AT THE EDGES OF VIABILITY

The debate as to whether an ELBW infant should be resuscitated at birth has generally focused on the question of *viability*, defined as the lowest gestational age (GA) at which extrauterine biologic existence is possible. A related distinction between terminal and nonterminal is also used in some state legislation (such as that in Texas) to demarcate when a parent may or may not withhold LSMT (such as resuscitation). However, understanding viability as a biologic property that is either present or absent at birth reinforces the aggressive resuscitation of ELBW infants pending later resolution of the uncertainty by the infant’s either living or dying. This simplistic concept of viability fails to capture the complex medical, ethical, and social considerations involved in treatment decisions for ELBW infants. Instead, ELBW infants should be divided into the following three groups (Lorenz and Paneth, 2000):

*Viable*: ELBW infants whom nearly all neonatal clinicians agree should be treated (e.g., GA  $\geq$  25 weeks)

*Nonviable*: ELBW infants whom nearly all neonatal clinicians agree should not be treated (e.g., GA  $\leq$  22 weeks)

*Viability uncertain*: ELBW infants about whom there is much disagreement about whether they should undergo resuscitation, intensive treatment, or both (e.g., GA 23 to 24 weeks).

Although surfactant replacement therapy has allowed survival at 23 to 24 weeks of gestation to approach 50% in a few centers, reports of neurodevelopmental outcomes suggest that a significant number of survivors will suffer major disabilities in later childhood (Vohr et al, 2000). The widespread professional disagreement over how to treat

an ELBW infant of uncertain viability renders problematic the notion of an accepted standard of medical care for this population (Lorenz and Paneth, 2000). The argument that biologic survival regardless of neurodevelopmental outcome justifies, in retrospect, the resuscitation of an ELBW infant over parental objections dishonors the appropriate moral boundaries of parental discretion.

Grouping ELBW infants in this manner clarifies when a clinician may take unilateral action regardless of parental wishes, and when parental choice should prevail. First, resuscitating a nonviable ELBW infant born at or before 22 weeks of gestation is *strictly futile*, in that endotracheal intubation and ventilation will not be successful in reversing the premature infant's physiologic limitations. Given this restricted definition of futility, unilateral action by a clinician to withhold resuscitation is ethically appropriate and arguably mandatory. Second, for an ELBW infant of uncertain viability, born at 23 to 24 weeks of gestation, reasonable persons may disagree whether the burden of treatment is proportionate to the benefits that can reasonably be expected. The informed judgment of the parent or parents should prevail in this instance over the personal choice of the clinician, resuscitation being withheld if the treatment is judged to be *disproportionately burdensome*. Third, failure to resuscitate an ELBW infant born at 25 weeks of gestation or later may be considered *medical neglect*, in light of such an infant's more favorable chance of an acceptable long-term outcome, and may perhaps justify resuscitation regardless of parental wishes (depending on the presence or absence of other prognostic factors). The use of GA to distinguish these three groups does not imply that GA is a sufficient diagnostic criterion for determining the viability of any given ELBW infant.

## COUNSELING PARENTS AND INFORMED CONSENT

When faced with treatment decisions, new or prospective parents should be fully informed of all the relevant facts, helped to understand and appreciate the meaning of these facts in light of their own beliefs, values, and circumstances, and supported in acting on their choice (if a choice is available). At a minimum, the information that should be provided is as follows: (1) the probable morbidity and mortality associated with the infant's condition, (2) the interventions that are medically indicated, (3) the effect of intervention (and no intervention, if appropriate) on the morbidity and mortality, and (4) the level of uncertainty of these predictions (Harrison, 2001). If the prognosis is reasonably certain either with intervention (i.e., for a viable ELBW infant) or without intervention (i.e., for a nonviable ELBW infant), the clinician can be fairly directive with the parents. If no medical intervention can prevent the imminent death of the infant, counseling should be directed toward the provision of comfort and nurture for the infant and support for the bereaved family. If medical intervention is clearly in the infant's best interest, counseling should be directed to enhance parental understanding and appreciation of the infant's condition, the necessary intervention, and the continued importance of the parental role (Hulac, 2001).

Situations of prognostic uncertainty, such as the ELBW infant of uncertain viability, require a less directive and

more collaborative approach to counseling. Sufficient time for such an approach may not be available, given the need for immediate intervention to preserve the possibility of parental choice. Even so, informed consent is not a moment but a process that requires helping the parent or parents understand and appreciate the importance and effect of various interventions (including the undoing of an intervention already performed).

Some clinicians argue that, in addition to information about anticipated morbidity and mortality, parents should be told that most physicians would not want intensive care for their own ELBW infant (Harrison, 2001). Consistently, however, health professionals have been found to value living with a severe disability at a much lower level compared with the reported views of children with disabilities and their parents (Saigal et al, 1999). These findings are often used to argue that medical professionals discriminate against the disabled by pressuring parents to forgo treatment (in spite of lack of evidence of such discrimination even at the height of the "Baby Doe" controversy). Other investigators interpret the positive outlook reported by disabled children and parents as the politically correct "brave face we instinctively offer to the public," contrasted with the private reality of guilt, shame, and regret (Harrison, 2001). Some researchers argue that parents of an ELBW infant of uncertain viability should be informed of the apparent conflict of interest created by financial and professional incentives to provide intensive care as well as the lack of properly conducted research studies for some "recommended" interventions (Harrison, 2001).

Because of the diversity of strongly held opinions, the use of a videotape may help clinicians give a consistent and balanced presentation of the alternatives to parents faced with the difficult choice between continued medical or surgical intervention and supportive care only (Hulac, 2001). Although it is difficult under these trying circumstances, a clinician should try to establish a relationship of trust based on open and honest communication about the various treatment options.

Conversations (and interventions) before birth introduce new complexities. First, there is the added uncertainty of estimating fetal weight and GA before a premature infant can actually be weighed or examined. As a result, most clinicians try to reserve some margin for clinical judgment after an infant's birth. If an infant may be of "uncertain viability," the clinician should discuss the upper and lower boundaries of the classification and seek input from the prospective parent or parents about preferences for resuscitation. Second, until an infant is delivered, clinical decision-making about interventions on behalf of the fetus must balance the best interests of the fetus with a pregnant woman's self-interest in health and freedom from unwanted bodily invasion. Pregnant women almost always accept a recommendation for fetal intervention that is of proven efficacy and low maternal risk. For procedures presenting greater maternal risk, the assessment and choice of the pregnant woman should be respected even if they place the fetus at risk of harm. Interventions of unproven efficacy should be performed only with the informed and voluntary consent of the pregnant woman and should be conducted according to an institutionally approved research protocol (Chervenak and McCullough, 2002). At times, neonatal

clinicians may be drawn into situations of conflict when a pregnant woman refuses a recommended intervention.

The American Academy of Pediatrics proposes three conditions that must be met before a clinician opposes the woman's refusal: (1) there is reasonable certainty that the fetus will suffer irrevocable and substantial harm without the intervention, (2) the intervention has been shown to be effective, and (3) the risk to the health and well-being of the pregnant woman is negligible (AAP, 1999). All health care institutions should have a procedure in place for conflict resolution, such as consultation with other clinicians or a clinical ethics committee.

### THE FETUS AS PATIENT

Improvements in fetal diagnosis and imaging, anesthetic management, and surgical techniques provide new approaches for treating neonatal diseases that manifest during pregnancy. Generally, interventions that place the pregnant woman at risk of serious morbidity or mortality have been reserved for fetal conditions believed to have a high risk of mortality with postnatal treatment. Innovative approaches to surgical palliation or correction have been tried (and later abandoned) for severe hydrocephalus and congenital diaphragmatic hernia (CDH). Placement of ventriculoamniotic shunts for aqueductal stenosis did not improve outcome, resulting in a voluntary moratorium on such procedures. An open surgical approach to the repair of CDH failed to better the results of modern neonatal intensive care in one of the few randomized controlled trials of fetal surgery and so was abandoned in favor of clipping the trachea in hopes of improving fetal lung growth (Flake et al, 2000; Harrison et al, 1997). With the development of appropriate selection criteria, maternal-fetal surgical interventions for life-threatening malformations such as fetal urinary tract obstruction, congenital cystic adenomatoid malformation, and sacrococcygeal teratoma have been successful (Harrison, 1996). Amnioreduction and laser photocoagulation have both been used for treatment of twin-twin transfusion syndrome, with a randomized comparative trial currently under way (2004) to determine the optimal approach. Because improved care for the pregnant woman appears to have minimized the risks of fetal intervention, a willingness to develop surgical approaches to nonfatal and disabling conditions, such as myelomeningocele, is emerging (Sutton et al, 1999). A randomized controlled trial comparing prenatal maternal-fetal surgery with standard postnatal surgery for myelomeningocele is currently under way (2004).

The uncontrolled use of maternal-fetal surgery for the prenatal correction of fetal myelomeningocele has generated much controversy (Chervenak and McCullough, 1999; Flake, 2001; Lyerly et al, 2001). The decision for the performance of surgery on a pregnant woman and fetus in hopes of ameliorating the subsequent disability of a child with myelomeningocele involves a complex balancing of risks and benefits to two parties. Invariably, the fetus is delivered prematurely, with the subsequent risks of death and neurodevelopmental disability. The potential benefit is either a reduction in secondary hydrocephalus and the need for shunting or an (unlikely) improvement in lower

extremity function. For what may be a marginal gain in neurodevelopmental outcome for the child, the pregnant woman places herself at risk of operative morbidity and mortality as well as the need for future deliveries by cesarean section (Lyerly et al, 2001). Prospective parents choose to risk the death of their unborn child in hopes of avoiding a nonfatal albeit serious disability. In the absence of properly controlled studies, passionate advocates exist on both sides of the debate, including parents convinced that maternal-fetal surgery saved the life and health of their children. Once the feasibility of a surgical innovation has been established, physicians are morally obligated to subject an innovation to the rigors of an appropriately designed research protocol (Chervenak and McCullough, 1999; Lyerly et al, 2001). Otherwise, we are unable to answer the parents' question, "Is the intervention going to help our child?"

### CONGENITAL HEART DISEASE: THE EXAMPLE OF HYPOPLASTIC LEFT HEART SYNDROME

The surgical treatment of infants born with hypoplastic left heart syndrome (HLHS) is a useful example of innovative approaches that evolved over the past 25 years despite the lack of concurrently controlled clinical trials. First reported in 1980, the initial Norwood operation served to prepare the infant for a subsequent modified Fontan procedure (Norwood et al, 1980). In 1991, Norwood described the currently used three-stage approach, in which a hemi-Fontan procedure is performed as an intermediate step to reduce the morbidity and mortality associated with the subsequent Fontan operation. In this report, the rate of survival through the first two stages was 64%, with no early mortality among the 27 patients who underwent the third stage, the Fontan procedure (Norwood et al, 1991).

With the introduction of cyclosporine to control rejection, cardiac transplantation became the treatment of choice at some centers, most notably Loma Linda Health Center. Of 111 infants with HLHS referred for transplant between 1985 and 1991 at Loma Linda, 27 infants died while waiting for a donor heart, and 84 infants underwent cardiac transplantation. Transplant recipients had a 5-year survival rate of 81%, yielding an overall 5-year actuarial survival rate of 61% when all infants are included (Chiavarelli et al, 1993). By the early 1990s, parents were usually offered one of three alternatives (weighed according to clinician and institutional preference): a three-stage surgical repair, cardiac transplantation, or nonoperative supportive care (Gutgesell and Massaro, 1995).

Compared with the mortality rate of historical controls, surgical intervention (whether staged repair or transplant) clearly improved overall survival; however, the perceived burden of treatment and doubts about neurodevelopmental outcomes lent support to nonsurgical supportive care as an acceptable option for parents to consider. However, the options presented to parents began to shift in the mid-1990s. A 1996 survey of 93 neonatology section chiefs indicated that 78% discussed and 24% recommended "comfort care only"; the remaining clinicians recommended either staged repair or transplantation. Although the clinicians perceived the surgical survival rate and subsequent

quality of life to favor transplantation, the majority recommended the staged surgical repair, presumably reflecting the lack of availability of infant donor hearts (Caplan et al, 1996). As survival after staged surgical repair continued to improve, reports of neurodevelopmental outcome in children with HLHS were mixed. In one report, cognitive testing of school-age children who previously underwent staged repair of HLHS demonstrated a medial full scale IQ of 86, with one third of the children receiving some form of special education and 18% scoring below 70 (i.e., mental retardation) (Mahle et al, 2000). By comparison, patient actuarial survival for cardiac transplantation as a primary treatment for HLHS was 70% at both 7 years and 10 years, with late deaths occurring from rejection or graft vasculopathy. School-age children who underwent cardiac transplantation in infancy demonstrated average achievement and low average intelligence scores on testing (Fortuna et al, 1999).

Although a head-to-head comparison of staged surgical repair and cardiac transplantation has not been performed, decision analysis based on data from 1989 through 1994 suggests that staged surgical repair optimizes first-year survival in the presence of a low (<10%) organ donation rate and stage I mortality of less than 20% (Jenkins et al, 2001). Later reports suggest that a stage I survival rate of 80% is achievable at selected centers, a rate consistent with the finding that staged surgical repair has become the most common management strategy for infants born with HLHS (Gutgesell and Gibson, 2002).

The uncontrolled surgical experiment of the 1980s and 1990s demonstrates the efficacy of both staged surgical repair and cardiac transplantation for HLHS when compared with untreated nonsurgical historical controls. Even though questions remain about the comparative advantages of the two surgical approaches, should parents continue to be offered the option of “comfort care only” for an infant born with HLHS? In experienced centers, such an infant now has a greater than 50% chance of surviving through all three staged surgical procedures, and the majority of infants so treated have an acceptable neurodevelopmental outcome. Therefore, some (perhaps most) clinicians believe that parents should no longer have the option of “comfort care only.” Others remain concerned that the overall burden of treatment for both child and family remains significant, arguing that parents should continue to have a choice whether to bear that burden. In addition, some infants are born at a significant distance from an experienced center, adding the burden of transfer and perhaps family relocation to the equation. Nevertheless, it is increasingly difficult to justify the withholding of surgical treatment from infants born with HLHS in the absence of new information about an unacceptable burden of treatment or poor neurodevelopmental outcomes.

### **PALLIATIVE CARE AND THE NEONATAL INTENSIVE CARE UNIT**

Recent years have seen a growing concern about limiting or withdrawing LSMT in favor of supportive or palliative care for infants whose prospects for meaningful survival are uncertain at best (Catlin and Carter, 2002; Fost, 1999).

In general, there is no obligation to either initiate or continue to provide LSMT when doing so would be either futile or unduly burdensome. Although there may be widespread agreement with this principle, knowing when any given treatment is either futile or unduly burdensome for a particular infant may be difficult. Many neonatologists support the strategy of treating each infant on the basis of an individualized prognosis, but the ability to predict an unacceptable outcome to a reasonable degree of certainty is problematic (Meadow et al, 2002). Limitation or withdrawal of LSMT may be a consideration for ELBW newborns who are of uncertain viability or who suffer a life-limiting complication, newborns with complex or multiple congenital anomalies that are incompatible with prolonged life, and newborns who are not responding to intervention, are deteriorating despite all appropriate efforts, or suffer a life-threatening event (Catlin and Carter, 2002). Agreeing on an appropriate course of action requires a collaborative relationship with a family based on trust and open communication, supplemented as needed with an ethics or other consultation.

Clinicians may fear that once a treatment is started, it is more difficult to stop. Legally, there is no difference between not starting a treatment that is either futile or unduly burdensome and stopping it (Meisel et al, 2000). The general view is that there is no moral difference between starting and stopping treatment that is not medically indicated, and that the fear that there is a difference stems from the psychological difficulty of removing LSMT. This view, however, assumes that our technology is value-neutral. The application of current technology brings with it the moral and social values that shape it, as, for example, in the decision to perform a tracheostomy for long-term ventilator support. The moral and social landscape shifts in a way that is not value-neutral once the tracheostomy has been performed. Although a trial of therapy may be necessary before one decides to withdraw LSMT, it may be best to delay certain decisions (such as placement of a tracheostomy or a gastrostomy tube) until after the family has resolved any uncertainty about continuing LSMT.

The concept of futility has been proposed as a justification for physicians to unilaterally withhold or withdraw LSMT over the objections of family members. However, the concept of futility is subject to different interpretations, from the more restrictive “strictly futile”—meaning that a treatment simply will not work physiologically—to the broader “disproportionate burden”—meaning that the burden of treatment outweighs any potential benefit. Judgments about the disproportionate burden of treatment involve the relative value and risk (or probability) of different outcomes and should not be imposed unilaterally. Treatments that are strictly futile can be withdrawn or withheld unilaterally, but this label applies to an extremely limited set of interventions. For example, continued endotracheal intubation and mechanical ventilation are not strictly futile even for an anencephalic infant, because such support corrects the physiologic abnormality of respiratory insufficiency. Every institution should have a policy for conflict resolution that makes available to staff and parents a stepwise process consisting of enhanced communication, followed by negotiation, mediation, and, in instances of

irresolvable conflict, court proceedings. The policy should emphasize the importance of communication in preventing differences of opinion escalating into conflict and should also support and empower parents as the primary decision-makers when an infant's prospects for meaningful survival are unavoidably uncertain.

Whether or not a parent agrees to a “do not attempt resuscitation” (DNAR) order should be placed in the context of the infant's overall care plan. A physician may decide not to perform cardiopulmonary resuscitation (CPR) in the absence of a DNAR order, on the basis of an assessment of strict futility. The details and duration of CPR should be tailored to the needs and condition of the infant, with CPR perhaps limited to a short but focused intervention. The presence of a DNAR order allows nursing and other ancillary personnel to not start CPR while waiting for a physician to arrive. Obtaining a DNAR order is often more important to the staff than to parents, relieving staff anxiety and serving as a “symbol” that the parents have accepted the infant's condition. However, prematurely pushing a parent to agree to a DNAR order without proper preparation through previous discussions of palliative care may precipitate a defensive posture (i.e., premature closure on the decision to “do everything” for the child). Parents also should be persuaded, through the actions of all medical personnel, of the truth of the oft-quoted cliché “*Do not resuscitate* does not mean *do not care*.” A DNAR order can be consistent with continued treatment with the hope for recovery, however remote. Finally, the interventions associated with CPR have different effects on the perceived burden of care, lending support for customized DNAR orders, such as allowing for the use of bag-valve-mask ventilation or the administration of medication but not chest compressions.

Attention should always be paid to the relief of an infant's pain and agitation. Once a decision is made to either limit or withdraw LSMT, relieving an infant's pain and agitation should become a primary goal regardless of the risks of undesired consequences, such as hypotension and respiratory depression. Although an infant's life may be shortened by the appropriate administration of sedatives and analgesics, a clinician should not administer medications with the primary purpose of killing the infant. Neuromuscular blocking agents mask signs of distress and should not be administered when ventilatory support is being withdrawn. In addition, such medications should ideally be withdrawn to allow for the proper assessment and treatment of an infant's pain and agitation (Truog et al, 2000). In some limited circumstances, waiting for the effects of neuromuscular blockade to dissipate will impose an undue burden on the infant and family; the discussion with the family about this issue should be documented, and careful attention paid to providing adequate sedation and analgesia in light of the difficulty in assessment (Catlin and Carter, 2002). Finally, there may be other interventions that can and should be withdrawn, such as inotropic and other cardiovascular support, as part of a decision to withdraw LSMT. For a number of infants, limitation or withdrawal of cardiovascular support may be an acceptable option for parents who are reluctant to limit or withdraw mechanical ventilation.

## NEONATAL RESEARCH

Absent significant mortality in historical controls, advancements in neonatal care will require concurrently controlled clinical trials. The continued use of unproven or innovative therapies that have not been validated through properly designed clinical trials does little to advance our knowledge of those interventions that truly benefit critically ill neonates (Tyson, 1995). Recognizing the difficulty of obtaining informed and voluntary consent from the parents in situations of stress, we should nevertheless provide unproven treatments within the context of a clinical trial (Mason and Allmark, 2000; Tyson and Knudsen, 2000). Clinical trials usually involve a number of interventions, with the risks and benefits requiring individual consideration. Interventions or procedures that do not offer the prospect of direct benefit must present no more than a minor increase over minimal risk, assuming that the information to be obtained is vital to the understanding or amelioration of the infant's condition. Interventions or procedures that offer the prospect of direct benefit may present more than a minor increase over minimal risk but can only be offered if there is genuine uncertainty on the part of the expert medical community about the comparative therapeutic merits of the experimental interventions and standard medical care (Freedman, 1987).

## JUSTICE AND THE DISTRIBUTION OF HEALTH CARE

Ethnic and racial disparities continue to exist in the provision of prenatal and neonatal medical care, with subsequent differences in infant mortality. Improvements in infant mortality based on the provision of neonatal intensive care to premature infants appear to have leveled off since 1995, suggesting that further investments in such care will have limited impact. There have been isolated efforts to redistribute available health care resources away from extremely premature infants toward more effective services, most notably in Oregon (Demissie et al, 2001; Horbar et al, 2002; Merkens and Garland, 2001). These efforts have been unsuccessful in shifting resources away from the provision of neonatal intensive care to the prevention of the birth of premature infants through equalizing access to known effective interventions such as prenatal care. The continued racial disparity in the provision of appropriate and effective prenatal and neonatal medical care remains the most egregious ethical problem facing neonatology today.

# FETAL DEVELOPMENT

Editor: ROBERTA A. BALLARD

## CHAPTER 4

### Placental Function and Diseases: The Placenta, Fetal Membranes, and Umbilical Cord

William M. Gilbert and Geoffrey A. Machin

In most normal pregnancies, the newborn is healthy and goes home in a day or two with the mother. If unexpected complications develop in the newborn period, the placenta has quite often been discarded and is therefore unavailable for examination for clues to help determine possible causes of these problems. Physicians involved in the delivery of high-risk pregnancies usually send the placenta to the pathology department for a pathologic examination. A detailed examination often yields clues helpful in the management of such high-risk pregnancies. The same is not necessarily true of the normal pregnancy. Thorough examination of the placenta at the time of birth may identify some abnormality that would be of assistance in explaining complications in the newborn. For this reason, anyone involved in the care of pregnant women or their newborns should be able to examine a placenta and know the basics of normal and abnormal architecture.

This chapter examines the normal development of the placenta and the development of particular disease states relating to it. In addition, placental hormones, the immunology of the placenta, and abnormalities of amniotic fluid volume are summarized. Finally, an extensive list of placental findings associated with disease conditions is presented in an easy-to-read table format.

#### EMBRYOLOGIC DEVELOPMENT OF THE PLACENTA

Shortly after fertilization takes place in the ampullary portion of the fallopian tube, the fertilized ovum or zygote begins dividing into a ball of cells called a morula. As the morula enters the uterus (by the fourth day after fertilization), it forms a central cystic area and is called a blastocyst.

The blastocyst implants within the endometrium by day 7 (Moore, 1988).

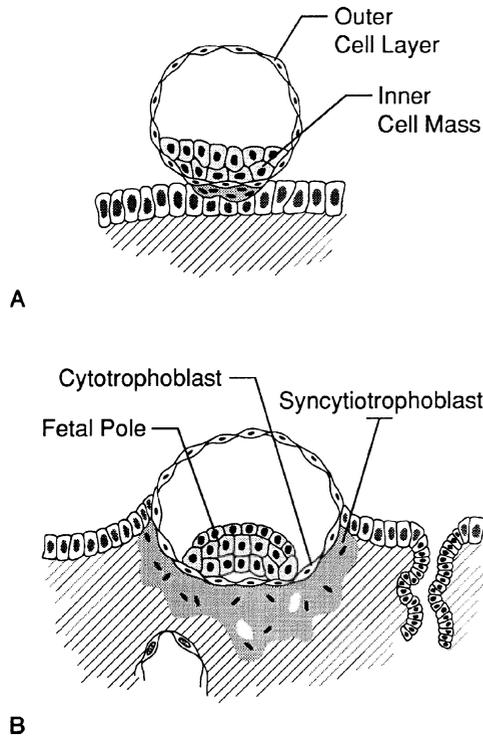

The blastocyst has two components, an inner cell mass, which becomes the developing embryo, and the outer cell layer, which becomes the placenta and fetal membranes (Hertig, 1968). The cells of the developing *blastocyst*, which eventually become the placenta, are differentiated quite early in gestation (within 7 days after fertilization). The outer cell layer, the *trophoblast*, invades the endometrium to the level of the decidua basalis. Maternal blood vessels are also invaded en route (Fig. 4-1). Once entered and controlled by the trophoblast, these maternal blood vessels form *lacunae*, which provide nutrition and substrates for the developing products of conception. The trophoblast differentiates into two cell types, the inner cytotrophoblast and the outer syncytiotrophoblast (see Fig. 4-1). The former has distinct cell walls and is thought to represent the more immature form of trophoblast. The syncytiotrophoblast, which is essentially acellular, is the site of most placental hormone and metabolic activity. Once the trophoblast has invaded the endometrium, it begins to form outpouchings called *villi*, which extend into the blood-filled maternal lacunae or further invade the endometrium to attach more solidly with the decidua, forming anchoring villi.

The three types of villi are related to the location and stage of development. Figure 4-2 shows primary, secondary, and tertiary villi; they are classified according to whether they contain cytotrophoblastic tissue with or without fetal blood vessels. In Figure 4-3, a scanning electron micrograph of terminal villi is shown.

#### PLACENTAL CIRCULATION

With the formation of the tertiary villi (19 days after fertilization), a direct vascular connection is made between the developing embryo and the placenta (Moore, 1988). Umbilical circulation between the placenta and the embryo is evident by 5½ weeks of gestation. Figure 4-4 demonstrates aspects of the maternal and fetal circulation in the mature placenta. The umbilical arteries from the fetus reach the placenta and then divide repetitively to cover the fetal surface of the placenta. Terminal arteries then penetrate the individual cotyledons, forming capillary beds for substrate exchange within the tertiary villi. These capillaries then re-form into tributaries of the umbilical venous system, which carries oxygenated blood back to the fetus.

It is evident that the fetal circulatory system is a closed system having no direct connection with the maternal blood. Indeed, maternally delivered substrates must cross

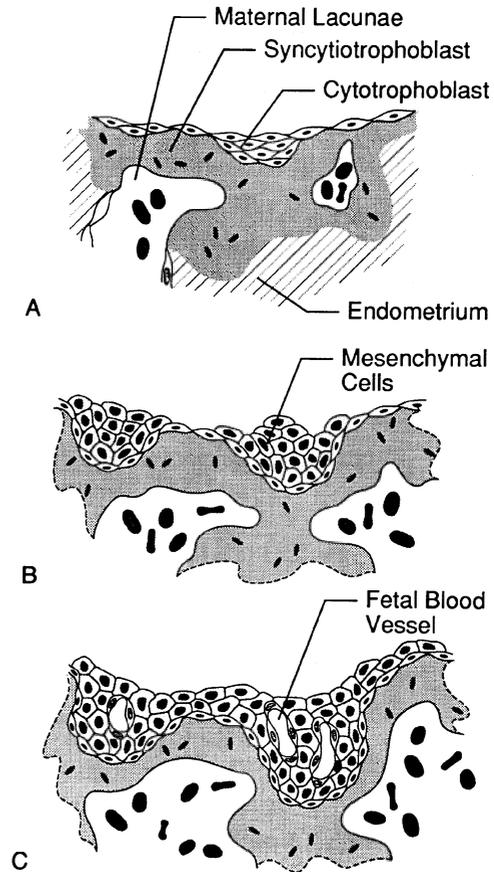

**FIGURE 4-1.** **A**, The human blastocyst contains two portions, an inner cell mass, which develops into the embryo, and an outer cell layer, which develops into the placenta and membranes. **B**, The outer acellular layer is the syncytiotrophoblast, and the inner cellular layer is the cytotrophoblast. (In Moore TR, Reiter RC, Rebar RW, Baker VV [eds]: *Gynecology and Obstetrics: A Longitudinal Approach*. New York, Churchill Livingstone, 1993, p 209. From Gilbert WM: *Anatomy and physiology of the placenta, fetal membranes, and amniotic fluid*.)

three tissue layers within the villus in order to reach the fetal blood. Despite this barrier, however, fetal cells have been identified within the maternal circulation and vice versa. Research attempting to use these cells of fetal origin within the maternal circulation for prenatal diagnosis is under way (Steel et al, 1996).

Maternal blood enters the intervillous space in a pulsatile fashion with each maternal heartbeat, bathing the fetal villi with blood and providing a site for exchange of nutrients and waste products. The maternal blood then collects in sinuses at the basilar layer of the intervillous space and flows into the uterine vein. This type of placenta, in which the maternal blood is in contact only with the fetal trophoblast, is *hemochorial*.

### PLACENTAL ANATOMY

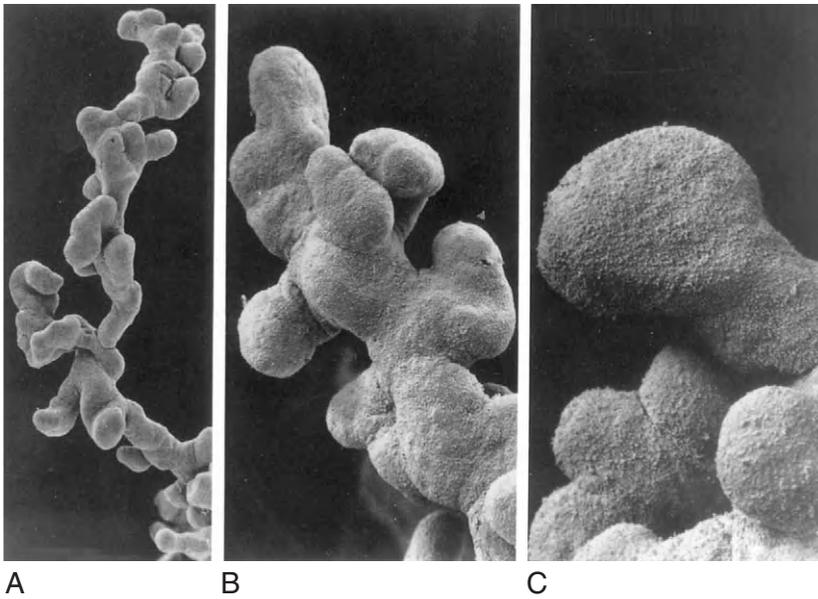

At term, the normal placenta covers roughly one third of the interior portion of the uterus and weighs approximately 500 g. The appearance is of a flat circular disc about 2 to 3 cm thick and 15 to 20 cm across (Benirschke and Kaufmann, 2000). Placental and fetal weights throughout gestation are presented in Table 4-1. During the first trimester and into the second, the placenta weighs more

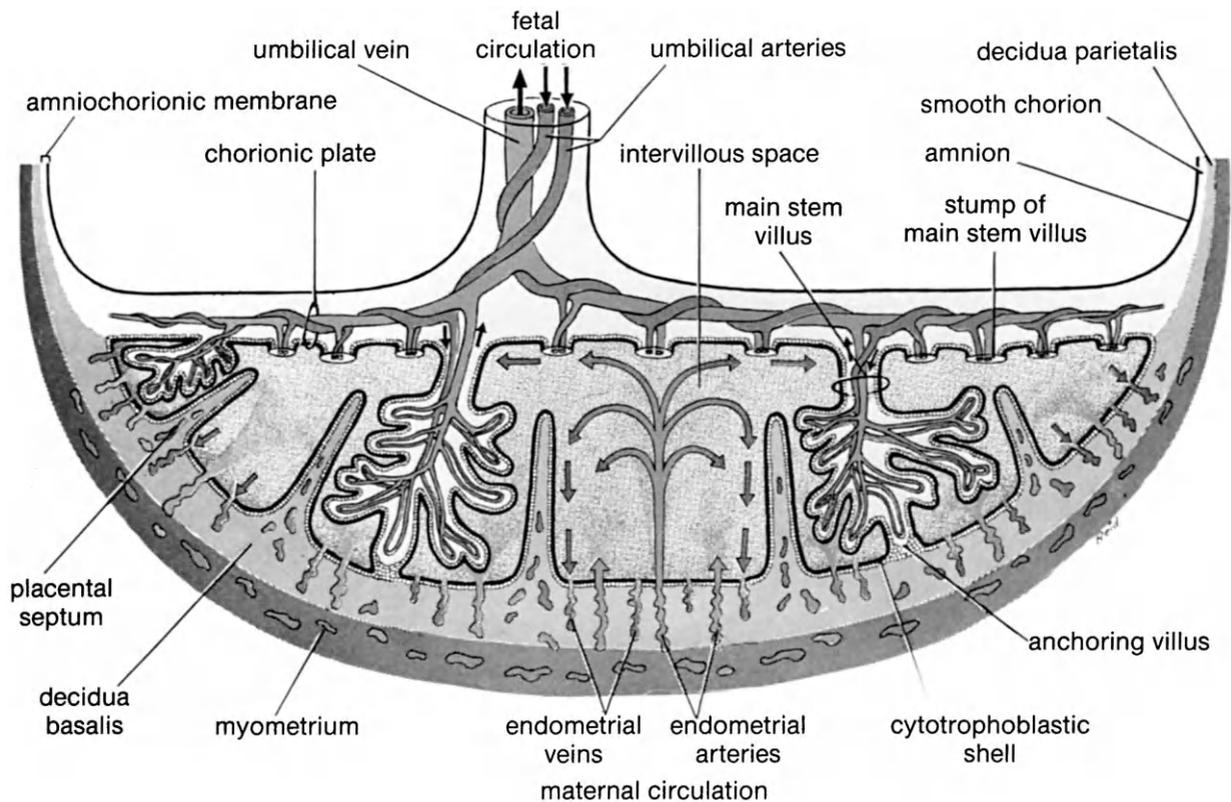

**FIGURE 4-2.** **A**, The cytotrophoblast indents the syncytiotrophoblast to form primary villi. **B**, Mesenchymal cells invade the cytotrophoblast 2 days after formation of the primary villi to form secondary villi. **C**, Blood vessels arise de novo and eventually connect with blood vessels from the embryo, forming tertiary villi. (In Moore TR, Reiter RC, Rebar RW, Baker VV [eds]: *Gynecology and Obstetrics: A Longitudinal Approach*. New York, Churchill Livingstone, 1993, p 209. From Gilbert WM: *Anatomy and physiology of the placenta, fetal membranes, and amniotic fluid*.)

than the fetus; after that period, the fetus outweighs the placenta.

The umbilical cord normally inserts into the center of the placenta but may insert in other locations, such as the margin (*marginal* or *battledore* insertion) or onto the membranes (*velamentous* insertion) (Fig. 4-5) before they join the border of the placenta. In the case of a *velamentous* insertion, in which the umbilical cord inserts into the amniotic membrane and fetal blood vessels travel within the membranes for a distance, perinatal outcome may be poor (Case Study 1). If the fetal vessels cross the cervical os, a high-risk condition called *vasa previa* is present (Pent, 1979). Rupture of the amniotic membrane in labor may rupture fetal vessels near the cervical os, resulting in fatal hemorrhage. Most vaginal bleeding before and during labor is of maternal origin, but with new-onset vaginal bleeding and simultaneous evidence of fetal distress, the diagnosis of *vasa previa* must be considered if fetal death from exsanguination is to be prevented.

**FIGURE 4-3.** Scanning electron microscopic appearance of terminal villi. **A**, A single, long, mature intermediate villus shows the characteristic bends of its longitudinal axis and multiple grape-like terminal villi. Note the terminal villi largely have the same diameter as the mature intermediate villus from which they branch ( $\times 180$ ). **B**, Tip of mature intermediate villus with rich final branching into terminal villi ( $\times 470$ ). **C**, A group of terminal villi, the central one showing a typical constricted neck region and a dilated final portion ( $\times 500$ ). (From Kauffmann P, Sen DK, Schweikhart G: *Classification of human placental villi. I: Histology and scanning electron microscopy. Cell Tissue Res* 200:409, 1979.)

**FIGURE 4-4.** Schematic drawing of a section of a mature placenta showing (1) the relation of the villous chorion (fetal part of the placenta) to the decidua basalis (maternal part of the placenta), (2) the fetal placental circulation, and (3) the maternal placental circulation. Maternal blood flows into the intervillous spaces in funnel-shaped spurts, and exchanges occur with the fetal blood as the maternal blood flows around the villi. Note that the umbilical arteries carry deoxygenated fetal blood to the placenta, and the umbilical vein carries oxygenated blood to the fetus. Note also that the cotyledons are separated from each other by decidual septa of the maternal portion of the placenta. Each cotyledon consists of two or more main-stem villi and their main branches. In this drawing, only one main-stem villus is shown in each cotyledon, but the stumps of those that have been removed are shown. (From Moore KL: *The Developing Human: Clinically Oriented Embryology*, 5th ed. Philadelphia, WB Saunders, 1993, p 117.)

TABLE 4-1

## Fetal and Placental Weights Throughout Gestation

Gestational Age (wks)	Placental Weight (mg)	Fetal Weight (g)
14	45	—
16	65	59
18	90	155
20	115	250
22	150	405
24	185	560
26	217	780
28	250	1000
30	282	1270
32	315	1550
34	352	1925
36	390	2300
38	430	2850
40	470	3400

Adapted from Benirschke K, Kaufmann P: Pathology of the Human Placenta, 4th ed. New York, Springer-Verlag, 2000.

In early pregnancy the placenta covers most of the inside of the uterus. At 20 weeks of gestation, approximately 5% of placentas cover the cervix and thus are classified as *placenta previa* (Townsend et al, 1986). By 37 weeks, however, fewer than 1% are still “previa” (Newton et al, 1984). This apparent placental movement away from the cervical os is *placental migration*. The placenta does not actually migrate; further differential growth of the uterus and the placenta results in positioning of the placenta away from the cervix. When the placental tissue remains centrally placed over the cervix, a diagnosis of *complete placenta previa* is made. The complications of pregnancy associated with placenta previa derive from the risk of massive hemorrhage when the cervix begins to dilate. Patients with placenta previa almost always require a cesarean section, although rare cases of successful vaginal delivery through a complete placenta previa have been reported.

Other abnormalities of placental development include the presence of an accessory lobe of placenta, which may

## CASE STUDY 1

A 29-year-old woman presented in her first pregnancy at 41 weeks of gestation with a stillbirth. The patient had noted good fetal movement until one day before admission, at which point she noted the sudden loss of movement. A nonstress test conducted 3 days before presentation demonstrated a reactive fetal heart rate tracing with one variable deceleration. The amniotic fluid index (AFI) was normal at 12 cm. An ultrasonographic examination on admission demonstrated no amniotic fluid and the stillbirth. The patient underwent induction of labor with the delivery of a 3100-g female fetus. An autopsy did not demonstrate any congenital defects, and there was no sign of chorioamnionitis. The only abnormal finding on placental examination was the presence of a velamentous insertion of the umbilical cord (see Fig. 4-5). A velamentous insertion of the umbilical cord often exposes the umbilical blood vessels to compression from fetal parts, because the vessels are not protected by Wharton’s jelly within the normal umbilical cord.

FIGURE 4-5. Velamentous insertion of the umbilical cord onto the membranes with fetal vessels running onto the placenta.

be connected to the main portion of the placenta by only a strand of fetal blood vessels and membranes. This condition, called *succenturiate placenta* (Fig. 4-6), may be problematic if the accessory lobe of placenta is inadvertently left within the uterus at the time of delivery. The retained placental tissue may cause postpartum hemorrhage or infection, requiring curettage for removal. For this reason, placental examination after delivery should include inspection of the placental edges to look for ragged portions suggestive of a succenturiate lobe.

In another recognized placental abnormality, the chorionic portion of the fetal membranes does not insert at the edge of the placenta but rather inserts some distance more centrally. This condition, called *circumvallate placenta*, occurs in about 5% of pregnancies (Fig. 4-7) and is associated with antepartum bleeding, preterm labor, intrauterine growth restriction (IUGR), and a single umbilical artery (Naftolin et al, 1973). The cause of this condition is largely unknown (Case Study 2).

## CASE STUDY 2

A 2075-g newborn male infant was delivered by forceps because of increased vaginal bleeding during the second stage of labor. The Apgar scores were 6 at 1 minute and 8 at 5 minutes. The gestational age at delivery was 39 weeks, and the baby was given the diagnosis small for gestational age (SGA), with a birth weight below the 10th percentile for gestational age. The maternal history included continued bleeding and spotting throughout the second and third trimesters with increasing contractions but no cervical dilation. Ultrasonographic examinations had demonstrated a picture consistent with asymmetrical intrauterine growth restriction and low-normal amniotic fluid volume. The placental examination demonstrated a circumvallate placenta (see Fig. 4-7).

## FETAL MEMBRANES

After delivery, the placenta and membranes should be inspected for completeness. What appears at delivery to be a single membrane is actually made up of two closely

**FIGURE 4-6.** Succenturiate placenta, or accessory lobe. Note the membrane connecting the separate lobes of placental tissue.

applied membranes, an inner amnion and outer chorion. The chorion is covered with villi early in pregnancy. Later, the majority of the villi degenerate, except in the area where the placenta is located. The inner membrane is derived from the developing embryo and grows and expands to fill the extraembryonic coelom, which is the fluid-filled area surrounding the early embryo. By 13 weeks of gestation, the amnion joins with the chorion. Before this time, the amnion may be seen on ultrasonographic examination as a thin inner membrane surrounding the embryo. The two membranes remain closely applied for the remainder of the pregnancy and can be manually separated after birth.

### UMBILICAL CORD

The umbilical cord averages 50 cm in length, although a wide range of normal lengths is recognized. The cord should be measured only if it is at one or the other

extremes of length (Benirschke and Kaufmann, 2000). The overall length of the umbilical cord is determined by fetal activity in utero, cords being longer for more active fetuses and shorter in association with less activity. The umbilical cord usually contains two umbilical arteries and one umbilical vein. An umbilical cord with only two vessels (one artery, one vein) occurs about 1% of the time and is associated with an increase in fetal structural malformations and chromosomal abnormalities (Leung and Robson, 1989). If the diagnosis of a single umbilical artery is made either before or after birth, the fetus or newborn should undergo complete examination for other abnormalities, with particular attention to the fetal kidneys and heart. In some cases, a two-vessel cord should be an indication for an amniocentesis and chromosomal analysis (Nicolaidis et al, 1993).

### EXAMINATION OF THE PLACENTA

A renaissance in placental pathology has led to a new relevance of the placenta to neonatology and early infant life, including issues of preterm birth, growth restriction, and cerebral, renal, and myocardial diseases. The placenta can give some clues to the timing and extent of important adverse prenatal or neonatal events as well as to the relative effects of sepsis and asphyxia on the causation of neonatal diseases. This section reviews placental disorders that can be noted immediately in the delivery room and others that are diagnosed through detailed gross and microscopic examinations over the ensuing 48 hours but that remain important for early childhood development and also have medical-legal significance. Every placenta should be examined at the time of birth regardless of whether the newborn has any immediate problems. Most placentas invert with traction at the time of delivery, and the fetal membranes cover the maternal surface. It is important to reinvert the membranes and examine all surfaces of the placenta and membranes, looking for abnormalities. Table 4-2 lists pregnancy complications or conditions diagnosable at birth through gross examination of the placenta.

The initial placental examination should include checking the edges for completeness. The membranes and fetal surface should be shiny and translucent. An odor may

**FIGURE 4-7.** Circumvallate placenta. Note the insertion of the membranes into the placenta halfway between the edge of the placenta and the center.

**TABLE 4-2****Pregnancy Conditions Diagnosable at Birth by Gross Placental Examination and Associated Neonatal Outcomes**

Monochorionic twinning	Twin-twin transfusion (TTT) syndrome donor/recipient status, pump twin in TRAP, survivor status after fetal demise, selective termination, severe growth discordance without TTT
Dichorionic twinning	Less likelihood of survivor brain disease in event of fetal demise of one
Purulent acute chorioamnionitis	Risk of fetal sepsis, fetal inflammatory response syndrome, cerebral palsy
Chorangiooma	Hydrops, cardiac failure, consumptive coagulopathy
Abnormal cord coiling	IUGR, fetal intolerance of labor
Maternal floor infarction	IUGR, cerebral disease
Abruption	Asphyxial brain disease
Velamentous cord	IUGR, vasa previa
Cord knot	Asphyxia
Chronic abruption oligohydramnios syndrome (CAOS)	IUGR
Single umbilical artery	Malformation, IUGR
Umbilical vein thrombosis	Asphyxia
Amnion nodosum	Severe oligohydramnios leading to pulmonary hypoplasia
Meconium staining	Possible asphyxia, aspiration lung disease
Amniotic bands	Fetal limb reduction abnormalities
Chorionic plate vascular thrombosis	Asphyxia, possible thrombophilia
Breus mole	Asphyxia, ?IUGR

IUGR, intrauterine growth retardation; TRAP, twin reversed arterial perfusion; TTT, twin-to-twin transfusion.

suggest infection, and cultures of the placenta may be beneficial (Benirschke and Kaufmann, 2000). Greenish discoloration may represent meconium staining or old blood; placentas with such discoloration should be sent to the pathologist for complete histologic examination. The finding of deep meconium staining of the membranes and umbilical cord suggests that the meconium was passed at least 2 hours before delivery; this fact may be helpful in cases of meconium aspiration syndrome, for which legal questions may arise as to whether or not the aspiration occurred before or during labor. If the membranes are deeply stained, the passage of meconium by the fetus may have predated onset of labor; thus, the aspiration could have occurred before labor.

The umbilical cord should also be examined for the number of vessels and their insertion into the placenta. Vessels on the fetal surface of the placenta should be examined for evidence of clot or thrombosis. Table 4-3

**TABLE 4-3****Gross Placental Lesions Seen in the Pathology Laboratory (Mostly Parenchymal)**

Lesion	Possible Neonatal Outcome(s)
Intervillous thrombosis	Fetomaternal hemorrhage
Massive perivillous fibrin deposition	Intrauterine growth retardation (IUGR), asphyxia
Standard infarcts	Maternal vascular disease, IUGR, asphyxia
Stem villous arterial thrombosis-induced infarction	Fetal thrombophilia and sequelae

lists the gross placental lesions that can be seen in the pathology laboratory (mostly parenchymal in nature) and possible associated neonatal outcomes. Normally, the fetal arteries cross superficially over the veins. Clots or thrombosis may be firm, whitish knots on the placental surface.

Microscopic features of the placenta, which are discovered only after preparation by the pathologist, are listed in Table 4-4, along with their associated maternal and neonatal clinical conditions. Finally, Table 4-5 summarizes the placental findings associated with acquired or genetic thrombophilia, and Table 4-6 lists the tests that should be performed for further investigation.

**TABLE 4-4****Microscopic Pathologic Findings in the Placenta**

Finding	Associated Maternal or Neonatal Conditions
Funisitis	Fetal inflammation, cerebral palsy
Villitis	Transplacental (usually viral) infection, especially cytomegalovirus
Chorangiosis	Fetal stress or a nonspecific finding
Stem villous thrombosis	Fetal thrombophilia, cerebral disease
<i>Listeria</i> abscesses	Preterm labor, fetal demise
Abnormal villous maturation, especially acceleration	—
Maternal vascular disease (decidua)	Intrauterine growth retardation

TABLE 4-5

**Lesions Associated with Acquired and Genetic Thrombophilia**

Placental lesions	Chorionic plate vein thrombosis in absence of abnormal cord coiling Maternal floor infarction/massive perivillous fibrin deposition Stem villous arterial thrombosis–fetal induced infarction.
Clinical lesions	Porencephalic cysts Perinatal stroke Terminal transverse limb defects

TABLE 4-6

**Parental and/or Neonatal Laboratory Investigations for Thrombophilia**

Acquired thrombophilia	Anticardiolipin, lupus anticoagulant measurements
Genetic thrombophilia	Screening for protein S and protein C deficiencies, antithrombin III deficiency, factor V Leiden mutation, prothrombin 20121A mutation; fasting homocysteine evaluation (screen for MTHFR mutations)

MTHFR, methyltetrahydrofolate reductase.

TABLE 4-7

**Mechanisms of Placental Transport**

Mechanism	Substance
Simple diffusion	Oxygen, carbon dioxide, sodium, chloride
Facilitated diffusion	Glucose
Active transport	Certain amino acids, calcium
Pinocytosis	Immunoglobulins

**Water Transport**

The fetus is capable of producing water as a byproduct of the breakdown of glucose and the formation of energy. This water, however, is insufficient for fetal requirements. Water is also driven into the fetal compartment by pure hydrostatic forces and osmotic forces, measured in milliosmole per kilogram (Schroder, 1989). Both forces are important for fluid movement, but the interplay between them in the human placenta is poorly understood.

In the past, the fluid homeostasis of the mother and that of the developing fetus were thought to be largely independent. However, mounting evidence indicates that they are intricately intertwined. With maternal dehydration in the sheep, for example, amniotic fluid is observed to decrease (*oligohydramnios*). With maternal rehydration, normal amniotic fluid volume returns. A study in humans demonstrated that maternal oral hydration in cases of decreased amniotic fluid volume resulted in a rise in amniotic fluid volume as measured ultrasonographically by the amniotic fluid index. These studies provide strong evidence of the interconnectedness of maternal and fetal fluid spaces across the membranes and placenta (Kilpatrick et al, 1991).

**PLACENTAL PHYSIOLOGY****Placental Transport**

The developing embryo obtains all of its nutrients from the mother during gestation. Initial transport of nutrients to the conceptus is via simple diffusion from the maternal blood in the decidua. The early primitive vitelline circulation, which circulates blood from the yolk sac to the embryo at 5 to 6 weeks, is replaced by a true umbilical circulation by 7 weeks. This circulation functions as the mature transport system throughout pregnancy until delivery.

The four main substrate transport mechanisms across the placenta are simple diffusion, facilitated diffusion, active transport, and pinocytosis. Examples of substances that are delivered to the fetus by each of these routes are shown in Table 4-7. The major osmotic ions of sodium, chloride, and free water move by simple diffusion. Fetal concentrations of amino acids may be 20 times the maternal concentrations as a result of active transport (Faber and Thornburg, 1985). Glucose moves by both simple and facilitated diffusion, resulting in fetal glucose levels that are about 80% of maternal levels.

**HORMONE PRODUCTION**

Shortly after fertilization, the blastocyst synthesizes and releases human chorionic gonadotropin (hCG) into the maternal circulation as it implants into the endometrium. This embryonic control of maternal hCG levels is vital to maintaining the corpus luteum and preventing ejection of the conceptus. The hCG molecule is very similar in structure to the luteinizing hormone released by the pituitary gland, with a primary difference in the hCG beta chain. Placental production of hCG peaks at 8 to 10 weeks of gestation, after which its levels drop markedly. The hCG maintains the production of progesterone from the corpus luteum until the placenta takes over at about 9 weeks of gestation. Progesterone, produced in the syncytiotrophoblast, is the primary hormone of pregnancy involved in maintaining uterine and other smooth muscle relaxation. It also functions in immune suppression. Many of the vasodilatory and gastrointestinal symptoms of pregnancy noted by the mother are due to the action of progesterone.

Several estrogens are produced by the placenta, with the greatest proportion secreted into the maternal compartment.

A primary role of estrogens is to increase uterine blood flow and help maintain the pregnancy (Resnik et al, 1974). The synthetic pathway of estriol involves both the fetal adrenal gland and the placenta. Measurement of this hormone in maternal urine or plasma was historically believed to be an effective method of fetal surveillance in high-risk pregnancies because the estriol concentration reflected both fetal and placental well-being. With a significant decrease in maternal estriol levels, placental function was supposed to be declining as well. However, studies have shown that measurement of estriol is not predictive of fetal jeopardy. Interestingly, other studies have shown that abrupt elevations of estriol in saliva may be predictive of preterm labor (Hedriana et al, 1996). In the future, a simple saliva test may predict the onset of labor either before term or at term.

The final major hormone of pregnancy is human chorionic somatomammotropin (hCS), which is also called human placental lactogen. This hormone is a growth factor primarily involved with mobilization of maternal stores of glucose, fatty acids, and ketones (Speroff et al, 1989). The level of hCS increases with placental mass, and the hormone is a major mediator of glucose intolerance in pregnancy. With the larger placental mass associated with multiple gestations, there is likewise a higher rate of glucose intolerance.

## IMMUNOLOGY

Pregnancy is a unique state in which the mother has a functionally intact immune system, able to eliminate infection and suppress neoplasia while allowing a genetically different “tumor” (the fetus) to grow relatively unchecked within the uterus. The uterus itself does not prevent rejection because intra-abdominal pregnancies are not immunologically rejected. Although the exact mechanisms that prevent maternal rejection are not completely clear, several key facts are known.

The invading trophoblast does not express the major histocompatibility complex (MHC) human leukocyte antigens (HLA-A, -B, and -C), which are expressed on almost all somatic cells and induce specific immune responses by presenting peptide antigens to T cells (Blaschitz et al, 2001). The nonclassic HLA antigens, HLA-G and HLA-E, are preferentially expressed in trophoblastic tissue and are thought to be involved in immune tolerance by acting as ligands for inhibitory receptors present on natural killer (NK) cells and macrophages (Blaschitz et al, 2001; Colbern and Main, 1991). The exact mechanisms by which HLA-G prevents rejection by the mother are still unknown or are debated (Bainbridge et al, 2001).

In addition, the trophoblast secretes a sialomucin coating over its outer surface, which shields the trophoblast from maternal recognition. Finally, the trophoblast produces extremely high levels of progesterone, which is known to effectively suppress mitogen activation, mixed lymphocyte reactions, and cytotoxic T-cell generation in human blood lymphocytes (Stites et al, 1985; Szekeres-Bartho et al, 1985).

Historically, one mechanism that was thought to prevent maternal rejection of the embryo was the develop-

ment of “blocking antibodies” (Rocklin et al, 1976). These antibodies, produced by the mother in response to the antigenically foreign embryo, were thought to bind antigens that were found on the trophoblast. By blocking these fetal antigens, the mother would not reject the fetus. The follow-up studies examining these antibodies have not supported the initial studies, and further work in this area is needed (Neppert et al, 1989). It appears that the maternal-fetal immune interaction is largely a local one occurring at the placental interface and is not related to systemic factors.

## AMNIOTIC FLUID VOLUME

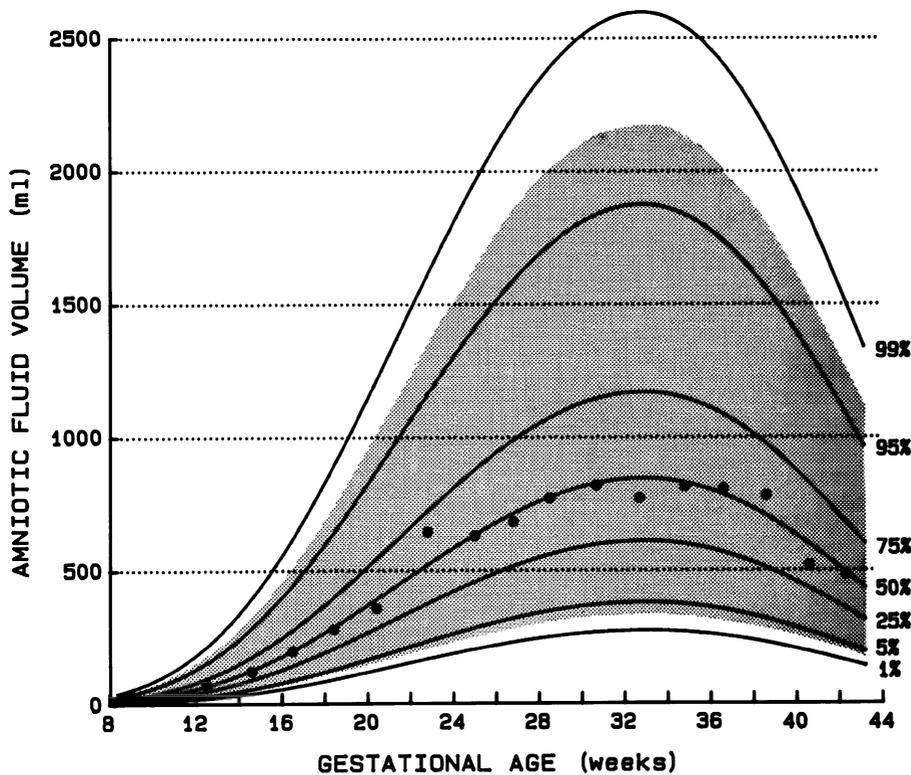

Amniotic fluid is an integral part of and is closely connected with the fetus, placenta, and membranes. All of these tissues contribute at one time or another to amniotic fluid formation and removal. Structural or physiologic abnormalities of either the fetus or the placenta may first manifest as too much (*polyhydramnios*) or too little (*oligohydramnios*) amniotic fluid. To understand the associations with abnormal amniotic fluid, one must conceptualize the mechanisms involved in formation and removal of amniotic fluid. However, the mechanisms that regulate amniotic fluid volume in the normal state are only rudimentarily understood.

It is known that the main contributor to the formation of amniotic fluid is fetal urination, and either absence or obstruction of the fetal urinary system results in severe oligohydramnios and fetal or neonatal death. With uteroplacental insufficiency, which is often associated with maternal conditions such as chronic hypertension and preeclampsia, oligohydramnios may be the first presenting sign of fetal compromise (Wladimiroff and Campbell, 1974). The fetal lung is another major source of amniotic fluid. (See also Chapter 45.)

Fetal swallowing is the main route by which amniotic fluid is removed, and any interruption in fetal swallowing, such as is found with duodenal atresia, may result in polyhydramnios. Whenever extremes of amniotic fluid volume are suspected, a detailed ultrasonographic examination of the fetus should be performed. Particular attention should be given to identifying structural abnormalities in the gastrointestinal and genitourinary systems. Under normal conditions, the fetus is able to maintain the amniotic fluid volume in a relatively narrow range of normal (800 to 1200 mL), as shown in Figure 4–8 (Brace and Wolf, 1989).

## SUMMARY

It is common for the importance of the placenta, membranes, and amniotic fluid to be underappreciated, because all attention is focused on the fetus during pregnancy and the newborn after birth. Abnormalities in amniotic fluid volume may suggest structural or developmental abnormalities in the growing fetus that require further examination. A simple but complete examination of the placenta and membranes at the time of delivery may provide important clues that may be helpful in the future care of the mother and newborn.

**FIGURE 4-8.** Nomogram showing amniotic fluid volumes as a function of gestational age. Dots indicate means for 2-week intervals. Percentiles are calculated from polynomial regression equation and standard deviation of residuals. The shaded area covers the 95% confidence interval. # Abnormalities of Fetal Growth

Alma Martinez and Rebecca Simmons

Normal fetal growth pattern is determined by a number of factors, including genetic potential, the ability of the mother to provide sufficient nutrients, the ability of the placenta to transfer nutrients, and intrauterine hormones and growth factors. The pattern of normal fetal growth involves rapid increases in fetal weight, length, and head circumference during the last half of gestation, with leveling off toward term gestation. The birth weight for gestational measurements among populations have been shown to increase over time, and thus, standards for normal fetal growth require periodic reevaluation for clinical relevance. These increases in birth weight for gestational age over time are attributed to improvements in living conditions and maternal nutrition and changes in obstetric management. Variations in fetal growth have been identified in diverse populations and are associated with geographic locations (sea level versus high altitude), populations (white, African-American, Latino), maternal constitutional factors, parity, maternal nutrition, fetal gender, and multiple gestations. In this chapter, we discuss these factors in greater detail and critically review the long-term effects of abnormal fetal growth.

## **INTRAUTERINE GROWTH RESTRICTION/RETARDATION AND INFANTS WHO ARE SMALL FOR GESTATIONAL AGE**

There is an important distinction in identifying the fetus that suffers from IUGR or retardation (IUGR), and the fetus that is constitutionally small. IUGR represents deviation and reduction in the expected fetal growth pattern, complicates about 5% to 8% of all pregnancies, and is associated with higher perinatal mortality and morbidity rates. A large cohort study of 37,377 pregnancies found a fivefold to sixfold greater risk of perinatal death for both preterm and term fetuses that had IUGR (Lackman et al, 2001). Epidemiologic evidence shows that IUGR can lead to higher rates of complications such as stillbirth, prematurity, and perinatal morbidity (Cnattingius et al, 1998; Mongelli and Gardosi, 2000). Causes of fetal growth restriction are identified in less than 40% of cases in the United States, with the majority of cases labeled “idiopathic.” Postnatal growth after IUGR depends on the cause of growth retardation, postnatal nutritional intake, and the infant’s social environment.

Although the growth-restricted fetus may show symmetric or asymmetric growth at birth, it is unclear

whether the proportionality of the fetus with IUGR truly affects outcomes or is related to the timing, the type, or the severity of the insult. Infants with symmetric IUGR have reduced weight, length, and head circumference at birth. Weight (and then length) of infants with asymmetric growth retardation is affected, with a relatively normal or “head-sparing” growth pattern. Historically, for infants with symmetric IUGR, higher rates of intrauterine infections, chromosomal abnormalities, dysmorphic syndromes, and intrauterine toxins (alcohol) were described as reasons for the growth restriction; and asymmetric IUGR was associated with maternal medical conditions such as preeclampsia, chronic hypertension, and uterine anomalies.

Lin and colleagues (1991) suggest that the timing of the risk factor is more important than the risk factor itself in determining whether symmetric or asymmetric growth restriction is seen. They report that asymmetric growth restriction is more commonly seen from effects on the fetus later in gestation. In their study, symmetric IUGR resulted in higher levels of prematurity and higher rates of neonatal morbidity. In contrast, Villar and associates (1990) have shown that infants with asymmetric IUGR have higher morbidity rates at birth. They found that infants with low ponderal index measurements (which they defined as weight/length<sup>3</sup>) had higher risk for low Apgar scores, long hospitalization, hypoglycemia, and asphyxia at birth than infants with symmetric IUGR. There is evidence to suggest that infants with asymmetric IUGR show better gains in weight and length in the postnatal period than symmetrically restricted infants (May et al, 2001). Other investigators propose that IUGR represents a continuum, with asymmetric IUGR occurring as the severity of the growth retardation increases. Data also suggest that the more severe the growth restriction, the worse the neonatal outcomes, including risk of stillbirth, fetal distress, neonatal hypoglycemia, hypocalcemia, polycythemia, low Apgar scores, and mortality (Kramer et al, 1990; Spinillo et al, 1995).

A fetus with IUGR may be born small for gestational age (SGA) or appropriate for gestational age (AGA) according to population reference charts. There is no universal agreement in the definition of a SGA (or large for gestational age [LGA]) infant. Various definitions appear in the medical literature, making comparisons between studies difficult. Additionally, investigators have shown that the prevalence of fetal growth restriction varies according to the fetal growth curve used (Alexander et al, 1996). Historically, SGA infants were defined as those with measurements below the tenth percentile (Battaglia and Lubchenco, 1967). Some investigators, however, also use measurements below the third percentile, or two standard deviations below the mean derived from population charts, to define SGA. McIntire and colleagues (1999) reported a “threshold” of increased adverse outcomes in infants born with measurements below the third percentile and suggested that this level of restriction represents a clinically relevant measurement. Other researchers have found higher rates of neonatal complications when the 15th percentile of birth weight is used as a cutoff level (Seeds and Peng, 1998).

Similarly, AGA infants are defined as those with measurements between the 10th and 90th percentiles, or between the 3rd and 97th percentiles, or between two standard deviations below and standard deviations above the mean. LGA infants are defined as those with measurements greater than 90th percentile, greater than 97th percentile, or more than two standard deviations above the mean.

## Etiology

### National and International Perspectives

The epidemiology of fetal growth restriction varies internationally (Keirse, 2000). In developed countries, the most frequently identified cause of growth restriction is smoking, while in developing countries, maternal nutritional factors (pre-pregnancy weight, maternal stature) and infections (malaria) are the leading identified causes (Kramer, 2000; Robinson et al, 2000). Additionally, in developing countries, there is a direct correlation between the incidence of low birth weight (<2500 g) and IUGR. In developing countries, the high incidence of low-birth-weight (LBW) infants is almost exclusively due to the incidence of IUGR. Data from developed countries show the opposite, rates of low birth weight being explained almost exclusively by prematurity rates.

Numerous factors have been identified as influencing size at birth. In a simplified manner, these factors can be grouped as fetal, placental, or maternal in origin. Recognized causes of IUGR are listed in Table 5-1. In the United States, the cause of IUGR is identified in only about 40% of cases, with the remainder of cases labeled “idiopathic.”

### Fetal Causes of Growth Restriction

Fetal factors affecting growth include fetal gender, familial genetic inheritance, and chromosomal abnormalities or dysmorphic syndromes. In one large population-based study, the frequency of IUGR among infants with congen-

ital malformations was 22%. The majority of the infants affected had chromosomal abnormalities. Other studies have similarly found that fetal growth restriction is more common among infants with malformations. Fetal gender also influences size, with male infants showing greater intrauterine growth than female infants (Glinianaia et al, 2000; Skjaerven et al, 2000; Thomas et al, 2000).

### Placental Causes of Growth Restriction

Placental factors are known to influence fetal growth. The transfer of nutrients across the placenta depends on uterine blood flow, which normally increases throughout gestation. Maternal health conditions associated with chronic decreases in uteroplacental blood flow (maternal vascular diseases, preeclampsia, hypertension, maternal smoking) are associated with poor fetal growth and nutrition. Preeclampsia has been shown to be associated with fetal growth restriction (Ødegård et al, 2000; Spinillo et al, 1994; Xiong et al, 1999). Investigators have shown that the extent of growth restriction correlates with the severity and the onset during pregnancy of the preeclampsia. Ødegård et al, 2000, showed that fetuses exposed to preeclampsia from early in pregnancy had the most serious growth restriction, and more than half of these infants were born SGA. Chronic maternal diseases (cardiac, renal) may decrease the normal uteroplacental blood flow to the fetus and thus may also be associated with poor fetal growth (Spinillo et al, 1994).

Placental maturation at the end of pregnancy is associated with an increase in substrate transfer, a slowing (but not cessation) of placental growth, and a plateau in fetal growth near term (Fox, 1997). Abnormalities of placental growth, senescence, and infarction have been shown to affect fetal growth. The placentas from pregnancies complicated by poor fetal growth have a higher incidence of vascular damage and abnormalities (Pardi et al, 1997). Fetal size and placental growth are directly related, and placentas from pregnancies yielding growth-retarded infants demonstrate a higher incidence of smallness and abnormality than those from pregnancies with appropriately

**TABLE 5-1**

#### Causes of Intrauterine Growth Restriction (IUGR)

Genetic	Inheritance, chromosomal abnormalities, fetal gender
Maternal constitutional effects	Low maternal pre-pregnancy weight, low pregnancy weight gain, ethnicity, socioeconomic status, history of IUGR
Nutrition	Low pre-pregnancy weight (body mass index), low pregnancy weight gain, malnutrition (macronutrients, micronutrients), maternal anemia
Infections	TORCH infections (toxoplasmosis, rubella, cytomegalovirus, syphilis)
Decreased O <sub>2</sub> -carrying capacity	High altitude, maternal congenital heart disease, hemoglobinopathies, chronic anemia, maternal asthma
Uterine/placental anatomy	Abnormal uterine anatomy, uterine fibroid, vascular abnormalities (single umbilical artery, velamentous umbilical cord insertion, twin-twin transfusion), placenta previa, placental abruption
Uterine/placental function	Maternal vasculitis (system lupus erythematosus), decreased uteroplacental perfusion, maternal illness (preeclampsia, chronic hypertension, diabetes, renal disease)
Toxins	Tobacco, ethanol, lead, arsenic

grown infants. The difference in size is seen even in a comparison of placentas associated with growth-restricted infants and those associated with AGA infants of the same birth weight (Heinonen et al, 2001). Placental growth in the second trimester correlates with placental weight and function and, thus, with weight at birth (Godfrey et al, 1996). Clinical conditions associated with reduced placental size (and subsequent reduced fetal weight) include maternal vascular disease, uterine anomalies (fibroids, abnormal uterine anatomy), placental infarctions, unusual cord insertions, and abnormalities of placentation.

Investigators have also shown fetal growth restriction in infants born with placental abruption. Abruption is increasingly common in older, multiparous women, smokers, and drug abusers (cocaine), with multiple births, and in women with hypertensive disorders. Using a large population-based study, Ananth and coworkers (2001) showed a downward shift of birth weight in infants with placental abruption from about 28 weeks of gestation through term gestation. These investigators speculate that although placental abruption is an acute peripartum event, the strong association between placental abruption and growth restriction suggests that chronic and underlying processes contribute to fetal outcome in abruption. Although associated with a small increase in fetal growth restriction, placenta previa appears to affect fetal growth more significantly through its association with prematurity.

Multiple gestations are associated with greater risk for fetal growth restriction. The higher risk stems from crowding and from abnormalities with placentation, vascular communications, and umbilical cord insertions. Divergence in fetal growth appears from about 30 to 32 weeks in twin gestation compared with singleton pregnancies (Alexander et al, 1996; Glinianaia et al, 2000; Skjaerven et al, 2000). Others have identified differences in fetal growth between twins and singletons as occurring earlier in gestation, at about 21 weeks (Devoe and Ware, 1995). Larger effects on fetal growth are seen with increasing number of fetal multiples. Abnormalities in placentation are also more common with multiple gestations (Benirschke, 1995). Monochorionic twins can share placental vascular communication (twin-twin transfusion), leading to fetal growth restriction during gestation. Fetal “competition” for placental transfer of nutrients raises the incidence of growth restriction and discordance in growth between fetuses. The rate of birth weights less than the fifth percentile is higher in monochorionic twins. Placental growth is restricted in utero because of limitation in space, leading to a higher incidence of placenta previa in multiple-gestation pregnancies. Additionally, abnormalities in cord insertions (marginal and velamentous cord insertions) and occurrence of a single umbilical artery are more frequently found in multiple gestations. The higher incidence of growth restriction in multiple gestation pregnancies is strongly associated with monochorionic gestations, the presence of vascular anastomoses, and discordant fetal growth (Hollier et al, 1999; Sonntag et al, 1996; Victoria et al, 2001). Placentas of smaller fetuses with discordant growth are significantly smaller than those of their larger twin counterparts (Victoria et al, 2001). (See also Chapter 7.)

Investigators have shown an effect of altitude on fetal growth, with infants born at high altitudes having lower birth weights (Galan et al, 2001). Differences in fetal growth are detected from about 25 weeks with pregnancies at 4000 meters. In these high-altitude pregnancies, the abdominal circumference is most affected (Krampl et al, 2000). At tremendously high altitudes, the incidence of LGA infant births is markedly reduced. In the United States (and at less severe altitudes), infants born at higher altitudes are lighter at birth, but those differences are not pronounced. Interestingly, investigators have shown that adaptation to high altitude during pregnancy is also possible. Tibetan infants have higher birth weights than infants of more recent immigrants of ethnic Chinese living at the same high-altitude (2700 to 4700 m) region of Tibet (Moore et al, 2001). Tibetan infants also have less IUGR than infants born to more recent immigrants to the area.

### Maternal Causes of Growth Restriction

Maternal constitutional factors have a significant effect on fetal growth. Maternal weight (pre-pregnancy), maternal stature, and maternal weight gain during pregnancy are directly associated with maternal nutrition and correlate with fetal growth (Clausson et al, 1998; Doctor et al, 2001; Goldenberg et al, 1997; Mongelli and Gardosi, 2000). Numerous studies show that these findings are often confounded by highly associated cultural and socioeconomic factors. The woman with a previous SGA infant has a higher risk of a subsequent small infant (Robinson et al, 2000). Investigators have shown a higher incidence of SGA infants to be associated with lower levels of maternal education (Clausson et al, 1998). Parity of the mother also affects fetal size, nulliparous women having a higher incidence of SGA infants (Cnattingius et al, 1998). A large population-based study in Sweden found that women who were older than 30 years, were nulliparous, or had hypertensive disease were at increased risk of preterm and term growth-restricted infants.

Studies have shown differential fetal growth for women of diverse ethnicities, with Latina and white women having higher rates of LGA infants, and African-American women having a higher incidence of SGA infants (Alexander et al, 1999; Fuentes-Afflick et al, 1998). These gender and ethnic differences in birth weight become pronounced after 30 weeks of gestation (Thomas et al, 2000). Investigators in California have shown that U.S.-born black women have higher rates of prematurity and LBW infants than foreign-born black women, the difference being associated with higher rates of tobacco use and inadequate prenatal care in the former group. Other researchers have found that even among women with very low risk of LBW infants (married, age 20 to 34 years, 13 or more years of education, adequate prenatal care, and absence of maternal health risk factors and of tobacco or alcohol use), the risk of delivering an SGA infant is still higher for African-American women than for white women (Alexander et al, 1999). It is unclear whether these differences in fetal growth are due to inherent differences or to differential exposure to environmental factors.

Maternal nutrition and supply of nutrients to the fetus affect fetal growth. Evidence shows a relationship

between maternal nutrition during pregnancy and infant birth weight. Investigators have found a significant relation between maternal energy intake and placental and infant weights (Godfrey et al, 1996). Maternal nutritional status both before and during pregnancy is associated with fetal growth patterns (Doctor et al, 2001). Pre-pregnancy weight influences fetal size and may be a potential marker for intergenerational effects on infant weight in developing countries. A woman's birth weight has been shown to correlate with her infant's weight as well as the placental weight during pregnancy. Maternal nutrition and maternal weight gain during pregnancy are associated with infant weight (Neggers et al, 1997; Robinson et al, 2000; Zeitlin et al, 2001). Strauss and Dietz (1999) report that low maternal weight gains in the second and third trimesters are associated with double the risk of IUGR, whereas poor maternal weight gain in the first trimester has no such effect on fetal growth (Strauss and Dietz, 1999). These investigators also showed that older women (>35 years) as well as smokers were at increased risk of IUGR associated with lower weight gains in late pregnancy. Others have shown low intakes of meat protein in late pregnancy to be associated with lower birth weights.

Teen pregnancy represents a special condition in which fetal weight is highly influenced by maternal nutrition. Teen mothers (<15 years) have been shown to have a higher risk for delivering a growth-restricted infant (Ghidini, 1996). Teen pregnancies are complicated by the additional nutritional needs of a pregnant mother, who is still actively growing, as well as by socioeconomic status of pregnant teens in developed countries (Scholl and Hediger, 1995). Maternal nutrition and maternal weight gain are adversely affected by inadequate or poorly balanced intake in conditions such as alcoholism, drug abuse, and poverty.

The effects of micronutrients on pregnancy outcomes and fetal growth have been less well studied. Maternal intake of certain micronutrients has also been found to affect fetal growth. Zinc deficiency has been associated with fetal growth restriction as well as other abnormalities, such as infertility and spontaneous abortion (Jameson, 1993; Shah and Sachdev, 2001). Additionally, dietary intake of vitamin C during early pregnancy has been shown to be associated with an increase in birth weight (Mathews et al, 1999). Others have shown strong associations between maternal intake of folate and iron and infant and placental weights (Godfrey et al, 1996). In developing countries, the effects of nutritional deficiencies during pregnancy are more prevalent and easier to detect. For example, Rao and colleagues (2001) have estimated that one third of infants in India are born weighing less than 2500 g, mainly because of maternal malnutrition. These investigators have shown significant associations between infant birth weight and maternal intake of milk, leafy greens, fruits, and folate during pregnancy.

Although toxins such as cigarette smoke and alcohol have a direct effect on placental function, they may also affect fetal growth through an associated compromise in maternal nutrition. Other environmental toxins (lead, arsenic, mercury) are associated with IUGR and are believed to affect fetal growth by entering the food chain and depleting body stores of iron, vitamin C, and possibly other nutrients (Iynengar and Nair, 2000; Srivastava et al, 2001).

Numerous studies have shown associations between birth weight and maternal intake of macronutrients and micronutrients, but the effects of nutritional supplements used during pregnancy have not been proved to have a beneficial effect on fetal growth (de Onis et al, 1998; Jackson and Robinson, 2001; Rush, 2001; Say, Gülmezoglu and Hofmeyr, 2003). Studies of the effects of supplements during pregnancy have been undertaken in mainly developed countries and among women with adequate nutrition. It seems more likely that supplementation programs for pregnant women in developing countries or among women with severe nutritional imbalances may show benefit for their infants (Ladipo, 2000).

Maternal illness and conditions leading to decreased oxygen availability in the mother (e.g., maternal anemia, cyanotic heart disease, hemoglobinopathy, respiratory failure), as well as maternal hypertension, pre-eclampsia, and diabetes all have been shown to have adverse effects on fetal growth. Women with systemic lupus erythematosus (SLE) have a higher prevalence of fetal growth restriction (Yasmeen et al, 2001). Some researchers have shown that the majority of adverse fetal outcomes associated with SLE are related to maternal antiphospholipid antibodies (Khamashta and Hughes, 1996).

Maternal socioeconomic status and ethnicity have also been identified as risk factors for IUGR and poor health outcomes in infants. Numerous investigators have shown a significant effect of socioeconomic status on birth outcomes, including fetal growth restriction, in both developing and developed countries (Wilcox et al, 1995). In the United States, low levels of maternal and paternal education, certain maternal and paternal occupations, and low family income are associated with lower birth weights in children of both African-American and white women (Parker et al, 1994). In a large population-based study from Sweden, investigators have similarly shown a higher incidence of fetal growth restriction in association with low maternal education (Clausson et al, 1998). Researchers have also shown that rates of compromised birth outcome are higher among African-American women than among Mexican-American and non-Hispanic white women (Collins and Butler, 1997; Frisbie et al, 1997; Thomas et al, 2000). Some of these studies also show that the risk of IUGR is higher in women without medical insurance. In the United States, the incidence of IUGR is significantly higher among African-American women than among white women; this higher incidence is seen even among African-American women with higher socioeconomic status (Alexander et al, 1999).

In a study from Arizona, the incidence of IUGR was found to be lower in Mexican-American women than in white women (Balcazar, 1994). Other researchers have shown that Mexican-born immigrants in California have better perinatal outcomes (including birth weight) than both African Americans and U.S.-born women of Mexican descent (Fuentes-Afflick et al, 1998). The reasons for this apparent paradox are unclear, but one postulate is the tendency of recent immigrants to maintain the favorable nutritional and behavioral characteristics of their country of origin (Guendelman and English, 1995). These studies support the speculation that the differences in fetal growth between groups do not reflect inherent differences in fetal

growth, but rather stem from inequalities in nutrition, health care, and other environmental factors (Keirse, 2000; Kramer et al, 2000).

### Smoking

Cigarette smoking is consistently found to adversely affect intrauterine growth in all studies in which this factor is considered. In developed countries, cigarette smoking is the single most important cause of poor fetal growth (Kramer et al, 2000). The incidence of IUGR in smokers is estimated to be 3 to 4.5 times higher than in nonsmokers (Nordentoft et al, 1996). Cigarette smoking has a significant effect on abdominal circumference and fetal weight but not on head circumference (Bernstein et al, 2000b). Lieberman and associates (1994) report that cigarette smoking also appears to have a dose-dependent effect on the incidence of IUGR, with this effect being seen especially with heavy smoking and smoking during the third trimester. These investigators have shown that if women stop smoking during the third trimester, their infants' birth weights are indistinguishable from those of infants born to the normal population. Other researchers have shown that even a reduction in smoking is associated with improved fetal growth (Li et al, 1993; Walsh et al, 2001). Numerous potential causes of the effects of smoking on fetal growth have been suggested, including direct effects of nicotine on placental vasoconstriction, decreased uterine blood flow, higher levels of fetal carboxyhemoglobin, fetal hypoxia, adverse maternal nutritional intake, and altered maternal and placental metabolism (Andres and Day, 2000; Pastrakuljic et al, 1999). See Chapter 12 for further discussion of the effects of cigarette smoking during pregnancy.

### Infections

A number of infections are associated with IUGR. They include viral infections from the TORCH (toxoplasmosis, rubella, cytomegalovirus, herpes simplex virus) group. Unless there are other findings on examination of the neonate suggestive of intrauterine TORCH infection, growth restriction alone may not justify an evaluation for these uncommon perinatal infections. Investigators have shown a low yield (and significant associated costs) in these evaluations for infants with growth restriction (Khan and Kazzi, 2000). See Chapter 37 for further discussion of intrauterine infections.

### Antenatal Diagnosis of Intrauterine Growth Restriction/Retardation

Despite the use of various screening techniques and fetal measurements to assess fetal growth, antenatal diagnosis of IUGR is difficult. Such a diagnosis relies on established fetal growth charts as an estimation of fetal growth. There are inherent difficulties with using established growth charts, including population variations and maternal constitutional factors (parity, pre-pregnancy weight, stature, multiple gestations). These factors must be considered by

clinicians evaluating the adequacy of growth. The diagnosis of fetal growth restriction may vary according to the fetal growth curve used. Using U.S.-wide population data for more than 3 million births, Alexander and coworkers (1996) have published current national fetal growth curves. Others have done similar work for infants in Europe (Skjaerven et al, 2000). Investigators have recommended using customized growth charts that take maternal characteristics as well as fetal characteristics into consideration (Mongelli et al, 2000). Additionally, various researchers suggest that estimation of fetal growth rate or velocity in the third trimester may be a better predictor of fetal outcome than a calculation of fetal size (Owen and Khan, 1998), although others have not found this approach to be helpful (Williams and Nwebube, 2001).

With ultrasound measurement, it is possible to estimate fetal weight, brain size, and placental size and morphology. Prenatal ultrasound examinations are used to detect abnormalities in fetal growth and fetal structural abnormalities associated with chromosomal abnormalities, and to assess fetal well-being during gestation. Despite limitations, fetal ultrasonography remains the most widespread and most accurate method for detecting growth restriction. Ultrasound biometry is considered the most reliable method of assessing fetal growth (see also Chapter 13).

Investigators have shown that because the liver size of the fetus is affected profoundly by IUGR, the abdominal circumference is the earliest and most sensitive ultrasound biometric measurement for predicting fetal growth abnormalities (Degani, 2001; Hobbins, 1997; Jazayeri et al, 1999; Williams and Nwebube, 2001). In a large retrospective study, Smith and colleagues (1997) found a linear correlation between abdominal circumference and subsequent birth weight. These investigators estimated the error in predicting birth weight was close to 7% and was greatest for the largest infants. Others have shown that abdominal circumference measurement less than the fifth percentile was associated with higher incidence of fetal distress and the need for cesarean section. Owen and Kahn (1998) have suggested that measurement of abdominal circumference growth rate (but not a single measurement) may be a better predictor of the need for cesarean section or abnormal fetal growth.

Despite the growing use of the modalities discussed here and in Chapter 13, investigators have questioned whether current antenatal detection and surveillance of, and subsequent obstetric intervention for, growth-restricted fetuses improves infant outcomes (Jahn et al, 1998). These concerns are greater regarding management of the preterm infant with suspected IUGR. SGA preterm infants have a higher incidence of neonatal morbidities, and gestational age continues to be a significant determinant of perinatal mortality and neurologic outcomes for growth-restricted fetuses (Hershkovitz et al, 2001; Scherjon et al, 1998; Sung et al, 1993). These data suggest that the adverse effects of severe prematurity may outweigh the benefit of the early delivery of a growth-restricted fetus. Judicial use of measurement techniques and data from studies of fetal well-being, in addition to sound clinical judgment for each case of suspected fetal growth abnormality, is required.

## Medical Complications and Outcomes

Fetal growth restriction is associated with intrauterine demise. Almost 40% of term stillbirths and 63% of preterm stillbirths are SGA (Mongelli and Gardosi, 2000). Both short-term and long-term effects of abnormalities in SGA fetuses have been described. Perinatal mortality for intrauterine SGA infants is higher overall than that for appropriately grown term and preterm infants (Clausson et al, 1998). The risk of perinatal death is estimated to be fivefold to sixfold greater for both preterm and term fetuses with IUGR (Lackman et al, 2001). In a large population-based study in Sweden, the risk of fetal death for fetuses “mildly” SGA was double that for term LGA infants, and was 16 times greater for more severely affected SGA infants (Cnattingius et al, 1998). Overall, intrauterine death, perinatal asphyxia, and congenital anomalies are the main contributing factors to the higher mortality rate in SGA infants. The effects of acute fetal hypoxia may be superimposed on chronic fetal hypoxia, and placental insufficiency may be an important etiologic factor in these outcomes. Investigators have described higher incidences of low Apgar scores, umbilical artery acidosis, need for intubation at delivery, seizures on the first day of life, and sepsis in SGA infants (McIntire et al, 1999). The incidence of adverse perinatal effects correlates with the severity of the growth restriction, the highest rates of respiratory distress syndrome, metabolic abnormalities, and sepsis being found in the most severely growth-restricted infants (Spinillo et al, 1995). As previously described, Villar and associates (1990) reported that infants with asymmetric IUGR and low ponderal index measurements (weight/length<sup>3</sup>) had higher risk of low Apgar scores, hypoglycemia, asphyxia, and long hospitalization.

Preterm infants with growth abnormalities also have higher risk of adverse outcomes. In a large multicountry study conducted in Europe, more than 40% of preterm infants whose births were induced were shown to be SGA (Zeitlin et al, 2000). Other researchers have similarly found a higher incidence of SGA infants among preterm deliveries than among term deliveries (Hershkovitz et al, 2001). Preterm SGA infants have been shown to have a higher incidence of a number of complications, including sepsis, severe intraventricular hemorrhage, respiratory distress syndrome, necrotizing enterocolitis, and death, than normally grown preterm infants (Gortner et al, 1999; McIntire et al, 1999; Simchen et al, 2000). In the United States, administration of antenatal steroids was found to be beneficial in reducing the incidence of respiratory distress syndrome, intraventricular hemorrhage, and mortality in SGA preterm infants (Bernstein et al, 2000a). These benefits were similar to those seen in normally grown preterm infants. Additionally, SGA infants have higher incidence of chronic lung disease at corrected gestational ages of 28 days and 36 weeks.

Neonatal hypoglycemia and hypothermia occur more frequently in growth-restricted infants (Doctor et al, 2001). These metabolic abnormalities presumably occur from decreased glycogen stores, inadequate lipid stores, and impaired gluconeogenesis in the growth-restricted neonate. Such infants are also more vulnerable to starva-

tion. Growth-restricted neonates have inadequate fuel stores and are at increased risk for hypoglycemia during fasting, and these risks are increased in preterm SGA infants. Infants with IUGR also have a higher incidence of hypocalcemia, the incidence correlating strongly with the severity of the growth restriction (Spinillo et al, 1995).

### Developmental Outcomes: Early Childhood

Neurologic outcomes, including intellectual and neurologic function, are affected by growth restriction. Overall, neurologic morbidity is higher for SGA infants than for AGA infants.

Even without identified perinatal events, SGA infants have a higher incidence of long-term neurologic or developmental handicaps. Investigators have found the incidence of cerebral palsy to be greater in IUGR infants than in a population with normal fetal growth (Blair and Stanley, 1990; Spinillo et al, 1995; Uvebrant and Hagberg, 1992). SGA infants born at term appear to have double or triple the risk for cerebral palsy, between 1 to 2 per 1000 live births and 2 to 6 per 1000 live births (Goldenberg et al, 1998). The rate of cerebral palsy is also higher in preterm growth-restricted infants than in preterm infants with appropriate fetal growth (Gray et al, 2001). At 7 years of age, children whose birth was associated with hypoxia-related factors had a higher risk for adverse neurologic outcomes. Infants with symmetric IUGR (or perhaps more severe restriction) were at higher risk than infants with asymmetric IUGR. Other researchers have shown higher rates of learning deficits, lower IQ scores, and increased behavioral problems in children with a history of fetal growth restriction, even at 9 to 11 years of age (Low et al, 1992).

### Long-Term Consequences: The Fetal Origins of Adult Disease

#### Programming

The period from conception to birth is a time of rapid growth, cellular replication and differentiation, and functional maturation of organ systems. These processes are very sensitive to alterations in the intrauterine milieu. *Programming* describes the mechanisms whereby a stimulus or insult at a critical period of development has lasting or lifelong effects. The “thrifty phenotype” hypothesis proposes that the fetus adapts to an adverse intrauterine milieu by optimizing the use of a reduced nutrient supply to ensure survival; but because this adaptation favors the development of certain organs over that of others, it leads to persistent alterations in the growth and function of developing tissues (Hales and Barker, 1992). Also, although the adaptations may aid in survival of the fetus, they become a liability in situations of nutritional abundance.

#### Epidemiology

It has been recognized for nearly 70 years that the early environment in which a child grows and develops can have long-term effects on subsequent health and survival

(Kermack, 1934). The landmark cohort study of 300,000 men by Ravelli and colleagues (1976) showed that men who were exposed in utero to the effects of the Dutch famine of 1944 and 1945 during the first half of gestation had significantly higher obesity rates at age 19 years. Subsequent studies demonstrated a relation between low birth weight and the later development of cardiovascular disease (Barker et al, 1989) and impaired glucose tolerance (Fall et al, 1995) in men in England. Those men who were smallest at birth (2500 g) were nearly seven times more likely to have impaired glucose tolerance or type 2 diabetes than those who were largest at birth. Barker and colleagues (1993) also found a similar relationship between lower birth weight and higher systolic blood pressure and triglyceride levels.

Valdez and associates (1994) observed a similar association between birth weight and subsequent glucose intolerance, hypertension, and hyperlipidemia in a study of young adult Mexican-American and non-Hispanic white men and women participants in the San Antonio Heart Study. Normotensive, nondiabetic individuals whose birth weights were in the lowest tertile had significantly higher rates of insulin resistance, obesity, and hypertension than subjects whose birth weights were normal. In the Pima Indians, a population with extraordinarily high rates of type 2 diabetes, McCance and coworkers (1994) found that the development of diabetes in the offspring was related to both extremes of birth weight. In their study, the prevalence of diabetes in subjects 20 to 39 years old was 30% for those weighing less than 2500 g at birth, 17% for those weighing 2500 to 4499 g, and 32% for those weighing 4500 g or more. The risk for development of type 2 diabetes was nearly fourfold higher for those whose birth weight was less than 2500 grams. Other studies of populations in the United States (Curhan et al, 1996), Sweden (Lithell et al, 1996; McKeigue et al, 1998), France (Leger et al, 1997; Jaquet et al, 2000), Norway (Egeland et al, 2000), and Finland (Forsen et al, 2000) have all demonstrated a significant correlation between low birth weight and the later development of adult diseases.

Studies controlling for the confounding factors of socioeconomic status and lifestyle have further strengthened the association between low birth weight and higher risk of coronary heart disease, stroke, and type 2 diabetes. In 1976, the Nurses' Health Study was initiated, and a large cohort of American women born from 1921 to 1946 established. The association between low birth weight and increased risks of coronary heart disease, stroke, and type 2 diabetes remained strong even after adjustment for lifestyle factors such as smoking, physical activity, occupation, income, dietary habits, and childhood socioeconomic status (Rich-Edwards et al, 1999).

### The Role of Catch-up Growth

Many studies have suggested that the associations between birth size with later disease can be modified by body mass index (BMI) in childhood. The highest risk for the development of type 2 diabetes is among adults who were born small and become overweight during childhood (Eriksson et al, 2000). Insulin resistance is most prominent in Indian children who were SGA at birth but

had a high fat mass at 8 years of age (Bavdekar et al, 1999). Similar findings were reported in 10-year-old children in the United Kingdom (Whincup et al, 1997). In a Finnish cohort, adult hypertension was associated with both lower birth weight and accelerated growth in the first 7 years of life. In contrast, in two preliminary studies from the UK, catch-up growth in the first 6 months of life was not clearly related to blood pressure in young adulthood, although birth weight was (McCarthy et al, 2001).

Interpretation of the findings of these studies is complicated by the vague definitions of *catch-up growth*. The term, which can encompass either the first 6 to 12 months only or as much as the first 2 years after birth, usually refers to realignment of one's genetic growth potential after IUGR. This definition allows for fetal growth retardation at any birth weight; even large fetuses can be growth retarded in relation to their genetic potential. However, postnatal factors can obviously affect infant growth in the first few months of life. For example, breast-feeding appears to protect against obesity later in childhood, yet breast-fed infants usually exhibit higher body mass during the first year of life than formula-fed infants. Although it is likely that accelerated growth confers an additional risk to the growth-retarded fetus, these conflicting results demonstrate the need for additional, carefully designed studies to determine just how childhood growth rates affect the later development of cardiovascular disease and type 2 diabetes.

### Size at Birth, Insulin Secretion, and Insulin Action

The mechanisms underlying the association between size at birth and impaired glucose tolerance or type 2 diabetes are unclear. A number of studies in children and adults have shown that nondiabetic or prediabetic subjects with low birth weight are insulin resistant and thus are predisposed to development of type 2 diabetes (Bavdekar et al, 1999; Clausen et al, 1997; Flanagan et al, 2000; Hoffman et al, 1997; Leger et al, 1997; Li et al, 2001; Lithell et al, 1996; McKeigue et al, 1998; Phillips et al, 1994; Yajnik et al, 1995). IUGR is known to alter the fetal development of adipose tissue, which is closely linked to the development of insulin resistance (Lapillonne et al, 1997; Widdowson et al, 1979). In a well-designed case-control study of 25 year-old-adults, Jaquet and colleagues (2000) demonstrated that individuals who were born SGA at 37 weeks or later had a significantly higher percentage of body fat (15%). Insulin sensitivity, even after adjustment for BMI or total fat mass, was markedly impaired in these SGA subjects. There were no significant differences between the SGA and control groups with respect to parental history of type 2 diabetes, cardiovascular disease, hypertension, or dyslipidemia. Of importance to generalization of the findings to other populations, the causes of IUGR in these subjects were gestational hypertension (50%), smoking (30%), maternal short stature (7%), congenital anomalies (7%), and unknown (6%).

The adverse effect of IUGR on glucose homeostasis was originally thought to be mediated through programming of the fetal endocrine pancreas. Growth-retarded fetuses and newborns have been shown to have a reduced

population of pancreatic  $\beta$ -cells (Van Assche et al, 1977). Low birth weight has been associated with reduced insulin response after glucose ingestion in young nondiabetic men; however, a number of other studies have found no effect of low birth weight on insulin secretion in humans (Clausen et al, 1997; Flanagan et al, 2000; Lithell et al, 1996). However, none of these earlier studies had adjusted for the corresponding insulin sensitivity, which has a profound impact on insulin secretion. Therefore, Jensen and colleagues (2002) measured insulin secretion and insulin sensitivity in a well-matched population of 19-year-old, glucose-tolerant white men whose birth weights were either below the 10th percentile (SGA) or between the 50th and 75th percentiles (controls). To eliminate the major confounding factors, such as “diabetes genes,” the researchers ensured that none of the participants had a family history of diabetes, hypertension, or ischemic heart disease. They found no differences between the groups with regard to current weight, BMI, body composition, and lipid profile. When data were controlled for insulin sensitivity, insulin secretion was found to be lower by 30%. However, insulin sensitivity was normal in the SGA subjects. These investigators hypothesized that defects in insulin secretion may precede defects in insulin action and that once SGA individuals accumulate body fat, they do demonstrate insulin resistance.

### Epidemiologic Challenges

The data described in the preceding section suggest that low birth weight is associated with glucose intolerance, type 2 diabetes, and cardiovascular disease. However, the question remains whether these associations reflect fetal nutrition or other factors that contribute to birth weight and the observed glucose intolerance. Because of the retrospective nature of the cohort identification, many confounding variables were not always recorded, such as lifestyle, socioeconomic status, education, maternal age, parental build, birth order, obstetric complications, smoking, and maternal health. Maternal nutritional status, either directly in the form of diet histories, or indirectly in the form of BMI, height, and pregnancy weight gain, were usually not recorded. Instead, birth anthropometric measures were used as proxies for presumed undernutrition in pregnancy.

### Size at Birth Cannot Be Used as a Proxy for Fetal Growth

Birth weight is determined by the sum of multiple known and unknown factors, including gestational age, maternal age, birth order, genetics, maternal pre-pregnancy BMI, and pregnancy weight gain, plus multiple environmental factors, such as smoking, drug use, infection, and maternal hypertension. Some of these determinants may be related to susceptibility to adult disease, and others may not. Conversely, some prenatal determinants of adult outcomes may not be related to fetal growth. A good example of how size at birth may potentially be a proxy for an underlying causal pathway is the hypothesis that essential hypertension in the adult is due to a con-

genital nephron deficit (Brenner et al, 1993). A study has now shown that kidney volume is smaller in adults who were thinner at birth, after adjustment for current body size. In contrast, maternal cigarette smoking is a good example of a prenatal exposure that restricts fetal growth, but to date, no association has been found between cigarette smoking and adverse long-term outcome in offspring.

### Genetics versus Environment

Several epidemiologic and metabolic studies of twins and first-degree relatives of patients with type 2 diabetes have demonstrated an important genetic component of diabetes (Vaag et al, 1995). The association between low birth weight and risk of type 2 diabetes in some studies could theoretically be explained by a genetically determined reduced fetal growth rate. In other words, the genotype responsible for type 2 diabetes may itself restrict fetal growth. This possibility forms the basis for the *fetal insulin hypothesis*, which suggests that genetically determined insulin resistance could result in insulin-mediated low growth rate in utero as well as insulin resistance in childhood and adulthood (Hattersley et al, 1999). Insulin is one of the major growth factors in fetal life, and monogenic disorders that affect the fetus’s insulin secretion or insulin resistance also affect its growth (Elsas et al, 1985; Froguel et al, 1993; Hattersley et al, 1998; Stoffers et al, 1997). Mutations in the gene encoding glucokinase have been identified that result in low birth weight and maturity-onset diabetes of the young. However, such mutations are rare, and no analogous common allelic variation has yet been discovered, but it is likely that some variations exist that, once identified, will explain a proportion of the cases of diabetes in LBW subjects.

There is obviously a close relationship between genes and the environment. Not only can maternal gene expression alter the fetal environment, the maternal intrauterine environment also affects fetal gene expression. An adverse intrauterine milieu is likely to have profound long-term effects on the developing organism that may not be reflected in birth weight.

### Cellular Mechanisms

Fetal malnutrition has two main causes, poor maternal nutrition and placental insufficiency. In the extensive literature about the fetal origins hypothesis, these two concepts have not been clearly discerned. Such a distinction is necessary, however, because maternal nutrition has probably been adequate in the majority of populations in which the hypothesis has been tested. Only extreme maternal undernutrition, such as occurred in the Dutch famine, reduces the birth weight to an extent that could be expected to raise the risk of adult disease (Lumey et al, 1995). Thus, it is reasonable that placental insufficiency has been a main cause of low birth weight in these populations. The oxygen and nutrients that support fetal growth and development rely on the entire nutrient supply line, beginning with maternal consumption and body size but extending also to uterine perfusion, placental

function, and fetal metabolism. Interruptions of the supply line at any point could result in programming of the fetus for the future risk of adult diseases.

The intrauterine environment influences development of the fetus by modifying gene expression in both pluripotential cells and terminally differentiated, poorly replicating cells. The long-range effects on the offspring (into adulthood) are determined by which cells are undergoing differentiation, proliferation, or functional maturation at the time of the disturbance in maternal fuel economy. The fetus also adapts to an inadequate supply of substrates (such as glucose, amino acids, fatty acids, and oxygen) through metabolic changes, redistribution of blood flow, and changes in the production of fetal and placental hormones that control growth.

The fetus's immediate metabolic response to placental insufficiency is catabolism, consuming its own substrates to provide energy. A more prolonged reduction in availability of substrates leads to a slowing in growth. This enhances the fetus's ability to survive by reducing the use of substrates and lowering the metabolic rate. Slowing of growth in late gestation leads to disproportion in organ size, because the organs and tissues that are growing rapidly at the time are affected the most. Placental insufficiency in late gestation may, for example, lead to reduced growth of the kidney, which is developing rapidly at that time. Reduced replication of kidney cells may permanently reduce cell numbers, because there seems to be no capacity for renal cell division to catch up after birth.

Substrate availability has profound effects on fetal hormones and on the hormonal and metabolic interactions between the fetus, placenta, and mother. These effects are most apparent in the fetus of the mother with diabetes. Higher maternal concentrations of glucose and amino acids stimulate the fetal pancreas to secrete exaggerated amounts of insulin, and the fetal liver to produce higher levels of insulin-like growth factors (IGFs). Fetal hyperinsulinism stimulates the growth of adipose tissue and of other insulin-responsive tissues in the fetus, often leading to macrosomia. However, many offspring of diabetic mothers with fetal hyperinsulinism are not overgrown by usual standards, and many with later obesity and glucose intolerance were not macrosomic at birth (Pettitt et al, 1987; Silverman et al, 1995). These observations suggest that birth weight is not a good indication of intrauterine nutrition.

### What Animal Models Can Tell Us

Animal models have a normal genetic background which environmental effects can be tested for their role in inducing diabetes. In the rat, maternal dietary protein restriction (approximately 40% to 50% of normal intake) throughout gestation and lactation has been reported to alter glucose homeostasis and cause hypertension in the adult offspring (Berney et al, 1997; Burns et al, 1997; Dahri et al, 1991; Langley-Evans et al, 1996; Ozanne et al, 1996; Snoeck et al, 1990; Wilson and Hughes, 1997). Offspring are significantly growth retarded, remain growth retarded throughout life, and demonstrate mild  $\beta$ -cell

secretory abnormalities in some cases and insulin resistance in others. However, none of these animal models results in the development of type 2 diabetes.

To extend these experimental studies of growth retardation, a model of IUGR in the rat was developed that does in fact lead to diabetes in later life (Boloker et al, 2002; Simmons et al, 2001). This model of fetal growth retardation has the following advantages over other animal models: (1) bilateral uterine artery ligation induces uteroplacental insufficiency, one of the most common causes of human IUGR, (2) growth-retarded fetal rats have critical features of a metabolic profile characteristic of growth-retarded human fetuses—decreased levels of glucose, insulin, IGF-1, amino acids, and oxygen (Ogata et al, 1986; Simmons et al, 1991; Unterman et al, 1990)—and, most importantly, (3) the diabetes that develops in IUGR rats has a phenotype remarkably similar to that observed in the human with type 2 diabetes—progressive dysfunction in insulin secretion and insulin action. Because of this IUGR model's similarity to human growth retardation and subsequent disease states, the IUGR rat represents one of the best experimental tools for studying the effect of uteroplacental insufficiency on the evolution of diabetes.

Although insulin resistance is a critical component of human type 2 diabetes, it is the failure of  $\beta$ -cell function and growth that determines progression to the diabetic phenotype (Gerich, 1998). Most pancreatic islet growth takes place during the fetal and neonatal periods, but replication of existing  $\beta$  cells and neogenesis of precursor cells occur throughout life. Insufficient proliferation and neogenesis have been hypothesized to be the underlying cause of the lack of  $\beta$ -cell compensation that leads to type 2 diabetes. Thus, uteroplacental insufficiency during the last trimester in the fetus permanently impairs the processes of neogenesis, proliferation, and differentiation. If new  $\beta$  cells are not generated to replace the normal loss of existing  $\beta$  cells,  $\beta$ -cell mass will eventually be reduced, and diabetes will ensue.

$\beta$  cells are particularly vulnerable to changes in substrate and hormone availability. Indeed, SGA infants have reduced plasma insulin concentrations (Economides et al, 1989) and pancreatic  $\beta$ -cell numbers, whereas  $\beta$ -cell growth is enhanced in the fetus exposed to excess nutrients and hormones in the diabetic milieu of diabetes in pregnancy.

A major consequence of uteroplacental insufficiency is oxidative stress in the fetus (Bowen et al, 2001; Ejima et al, 1999; Karowicz-Billinska et al, 2002; Kato et al, 1997; Myatt et al, 1997). Decreased substrate supply alters the redox state in susceptible tissues, leading to an imbalance between the production of reactive oxygen species (ROS) and antioxidant capacity that results in mitochondrial dysfunction and oxidative stress. The  $\beta$  cell is particularly vulnerable to oxidative stress because expression of antioxidant enzymes in the pancreatic islets is very low (Lenzen et al, 1996; Tiedge et al, 1997), and the pancreas has a high oxidative energy requirement. Animal studies in the IUGR rat support the concept that oxidative stress plays a major role in the impairment of  $\beta$ -cell function and maturation that is observed in the human growth-retarded fetus (Simmons and Gertz, 1998).

## Conclusions

The combined epidemiologic, clinical, and animal studies clearly demonstrate that the intrauterine environment influences both growth and development of the fetus and the subsequent development of adult diseases. There are specific, critical windows during development, often coincident with periods of rapid cell division, during which a stimulus or insult may have long-lasting consequences on tissue or organ function after birth. Birth weight is only one marker of an adverse fetal environment, and confining studies to the LBW population may lead to erroneous conclusions regarding etiology of growth retardation. Studies using animal models of uteroplacental insufficiency can provide some insights into possible mechanisms underlying the fetal origins hypothesis; however, much work remains to be done.

## MACROSOMIA

Excessive fetal growth (macrosomia, being large for gestational age) is found in 9% to 13% of all deliveries and can lead to significant complications in the perinatal period (Gregory et al, 1998; Wollschlaeger et al, 1999). Maternal factors associated with macrosomia during pregnancy include increasing parity, higher maternal age, and maternal height. Additionally, the previous delivery of a macrosomic infant, prolonged pregnancy, maternal glucose intolerance, high pre-pregnancy weight or obesity, and large pregnancy weight gain have all been found to raise the risk of delivering a macrosomic infant (Mocanu et al, 2000).

Maternal complications of macrosomia include morbidities related to labor and delivery. Prolonged labor, arrest of labor, and higher rates of cesarean section and instrumentation during labor have been reported. Also, the risks of maternal lacerations and trauma, delayed placental detachment, and postpartum hemorrhage are higher for the woman delivering a macrosomic infant (Lipscomb et al, 1995; Perlow et al, 1996). Complications of labor are more pronounced in primiparous women than in multiparous women (Mocanu et al, 2000). The neonatal complications of macrosomia include traumatic events such as shoulder dystocia, brachial nerve palsy, birth trauma, and associated perinatal asphyxia. Other complications for the neonate are elevated insulin levels and metabolic derangements, such as hypoglycemia and hypocalcemia (Wollschlaeger et al, 1999). In a large population-based study in the United States, macrosomia (defined as birth weight greater than 4000 g) was detected in 13% of births. Of these, shoulder dystocia was noted in 11% (Gregory et al, 1998).

Macrosomia is often not detected during pregnancy and labor. The clinical estimation of fetal size is difficult and has significant false-positive and false-negative rates. Ultrasonography estimates of fetal weight are not always accurate, and the literature reports a wide range of sensitivity estimates for the ultrasound detection of macrosomia. Additionally, there is controversy in how to define macrosomia and which ultrasound measurement is most sensitive in predicting macrosomia. Smith and colleagues (1997) have demonstrated a linear relation between abdominal circumference and birth weight. They showed

that the equations commonly used for estimated fetal weight (EFW) have a median error rate of 7%, with greater errors seen with larger infants. Using receiver operating characteristics (ROC) curves to measure the diagnostic accuracy of ultrasound, O'Reilly-Green and Divon (1997) reported sensitivity and specificity rates of 85% and 72%, respectively, for estimation of birth weight exceeding 4000 g. In their study, the positive predictive value (i.e., a positive test result represents a truly macrosomic infant) is about 49%. Chauhan and associates (2000) found lower sensitivity for the use of ultrasound measurement of abdominal and head circumference and femur length (72% sensitivity), similar to the sensitivity of using clinical measurements alone (73%). Other investigators have shown that clinical estimation of fetal weight (43% sensitivity) had higher sensitivity and specificity than ultrasound evaluation in predicting macrosomia (Gonen et al, 1996). In a retrospective study, Jazayeri and coworkers (1999) showed that ultrasound measurement of abdominal circumference of greater than 35 cm predicts macrosomia in 93% of cases and is superior to measurements of biparietal diameter or femur. Other researchers have reported that an abdominal circumference of either more than 37 cm or more than 38 cm to be a better predictor (Al-Inany et al, 2001; Gilby et al, 2000).

Numerous investigators have also questioned whether antenatal diagnosis improves birth outcomes in macrosomic infants. Investigators point to the low rates of specificity of antenatal tests resulting in high rates of false-positive results (Bryant et al, 1998, O'Reilly-Green and Divon, 1997). Antenatal identification of macrosomia (or possible macrosomia) may lead to a higher rate of cesarean section performed for infants with normal birth weights (Gonen et al, 2000; Mocanu et al, 2000; Parry et al, 2000). Macrosomia is a risk factor for shoulder dystocia, but the majority of cases of shoulder dystocia and birth trauma occurs in nonmacrosomic infants (Gonen et al, 1996). A retrospective study of infants weighing more than 4200 g at birth showed a cesarean section rate of 52% in infants predicted antenatally to have macrosomia, compared with 30% in infants without such an antenatal prediction. The antenatal prediction of fetal macrosomia is also associated with a higher incidence of failed induction of labor and no reduction in the rate of shoulder dystocia (Zamorski and Biggs, 2001). Using retrospective data from a 12-year period, Bryant and colleagues (1998) estimated that a policy of routine cesarean section for all infants with estimated fetal weight greater than 4500 g would require between 155 and 588 cesarean sections to prevent a single case of permanent brachial nerve palsy.

## SUMMARY

We have described many identified biologic and genetic factors associated with fetal growth and with abnormalities of fetal growth. Physicians are limited in the ability to identify a causative agent in every case. Modification of fetal growth is possible and occurs from such diverse influences as socioeconomic status, maternal nutrition, and maternal constitutional factors. Abnormal fetal growth influences not only acute perinatal outcomes but also

health during infancy, childhood, and, intriguingly, adulthood. In schools of public health, students are taught to search “up river” for solutions to health problems. Solutions for ill health in adulthood may lie in the identification of methods to improve the health of the fetus.

# Hormonal Influences on Fetal Development

Philip L. Ballard

The physiology of the fetal endocrine system differs from that of the adult endocrine system with regard to the hormonal milieu, production sites, plasma levels, rates and pathways of degradation, and biologic function. The unique endocrine environment of the fetus and placenta is important for both normal growth and differentiation of the fetus and timely parturition. Although there are major differences in endocrine physiology and regulated genes between the fetus and adult, the basic cellular mechanisms of hormone action do not change during development.

## SITES OF PRODUCTION AND ACTION

### Autocrine

Hormones in the autocrine system act primarily on the cells where they are synthesized. Hormones are synthesized within the cells, secreted at the cell surface into the extracellular domain, and then bind to specific cell surface receptors on the same cell. This interaction initiates a series of intracellular events, as described subsequently, that modify growth, differentiation, or function of the cell.

### Paracrine

In the paracrine system, hormones are secreted by one cell type and act on adjacent neighboring cells of another type. This mechanism provides for cell-cell communication within a tissue and is involved in regulating both growth and differentiation. In the fetal lung and other tissues, for example, insulin-like growth factors (IGFs) are produced and secreted by mesenchymal cells and influence the growth of adjacent epithelial cells.

### Endocrine

Most hormones are produced in a specific cell type of a tissue, are secreted into the circulation, and exert their regulatory effects on distant tissues. Included in this category, the endocrine system, are polypeptide hormones synthesized in the hypothalamus, pituitary, placenta, and other tissues as well as the steroid hormones (androgens, estrogens, progestins, mineralocorticoids, vitamin D, and glucocorticoids). The steroid hormones and many of the protein hormones are bound to specific binding proteins

in the plasma, providing a hormone reservoir that is less susceptible to degradation. For most hormones, the plasma concentration of free (unbound) hormones represents the physiologically active hormones available to target cells. After secretion, the activity of hormones may be modified by metabolism in the circulation or tissues. For example, inactive cortisone may be converted to active cortisol by target tissues (e.g., lung and liver), and thyroxine ( $T_4$ ) can undergo deiodination to either active triiodothyronine ( $T_3$ ) or inactive reverse triiodothyronine ( $rT_3$ ) in the adult or fetus, respectively.

## CELLULAR MECHANISMS

The signal inherent in a hormone is expressed through its binding to specific receptors, which initiates a series of biochemical events within the cell leading to altered replication or function. In general, the steps in this process of signal transduction are identical for adult and fetal cells, although different genes or proteins (or both) of a given cell type may be responsive during the developmental process. Furthermore, in the fetus, developmental immaturity or deficiency of specific components in the signal transduction system can alter hormone responsiveness.

### Membrane Receptors

The protein and peptide hormones as well as biogenic amines exert their effects on cells by binding to specific receptor proteins located on the cell membrane. The receptors are membrane-spanning proteins with an extracellular domain containing the binding site for the hormone and a cytoplasmic domain that transmits the hormonal signal to intracellular molecules. For many hormonal systems, binding of hormone to receptor results in higher intracellular levels of a second messenger, such as cyclic adenosine monophosphate (cAMP). Membrane receptors are capable of moving within the cell membrane and may aggregate and undergo endocytosis after binding of the hormone. Receptors are also substrates for various protein kinases, and in some cases, phosphorylation depends on the binding of hormones. These processes can produce a transient deficiency or inactivity of receptors (down-regulation) and relative unresponsiveness of the cells to continued hormonal exposure. For example, down-regulation and hormone refractoriness may be observed clinically with continued administration of a  $\beta$ -adrenergic agonist.

The membrane receptor system for  $\beta$ -adrenergic agonists has been well characterized. The cytoplasmic domain of the receptor is associated with G (GTP [guanosine triphosphate]-binding) proteins, which either activate or inhibit the catalytic component of adenylyl cyclase. In the case of activation, binding of the hormone results within minutes in increased production of cAMP from adenosine triphosphate (ATP); the response is transient, and levels rapidly return to near baseline values through degradation by cAMP phosphodiesterase. This enzyme is inhibited by drugs such as methylxanthines. Cyclic AMP,

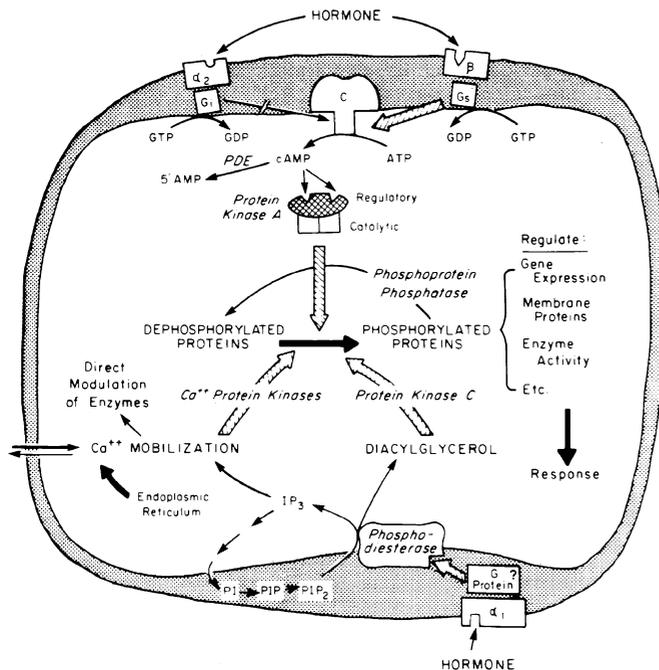

in turn, binds to the regulatory subunit of protein kinase A, releasing and activating the catalytic subunit. This enzyme phosphorylates specific cellular proteins that contain the amino acid sequence Arg-Arg-x-Ser, resulting in either activation or inactivation with subsequent effects on enzyme activity (e.g., glycogen phosphorylase), intracellular structure (e.g., in the cytoskeleton), or gene expression in the nucleus. This sequence of events is summarized in Figure 6-1.

### Intracellular Receptors

Thyroid hormones, steroid hormones, and certain polypeptide hormones enter target cells and bind to specific receptors in the cytoplasm or within the nucleus. In the case of steroid hormones, interaction with a receptor protein modifies receptor structure and increases its affinity for specific binding sites (response elements) on regulated genes. This process alters the rate of gene transcription and, subsequently, the levels of the encoded protein. Hormones can also alter messenger RNA levels by influencing stability or efficiency of translation of the transcript. When the hormone is removed, steroid dissociates from the receptor through the law of

mass action, and the response is reversed. Although binding of hormones to membrane receptors often produces responses within minutes (e.g., adrenocorticotrophic hormone [ACTH] stimulation of cortisol production), steroid and other hormones that regulate gene expression require several hours to increase the content of specific messenger RNAs and the encoded proteins. The mechanism of steroid hormone action is depicted in Figure 6-2.

Hormonal responsiveness of a cell is determined by both the levels of circulating hormone and the concentration and activity of cellular receptors and other mediating proteins. In the undisturbed adult organism, for example, responsiveness is determined primarily by the level of circulating hormone that normally fluctuates over a relatively limited range (e.g., diurnal variation). As hormone levels rise, the percentage of receptors occupied by hormone also increases, often in a nearly linear fashion, resulting in a highly responsive and tightly regulated stimulus-response system. In the fetus, particularly early in gestation, hormonal responsiveness is limited by developmental deficiencies in hormone levels, number of receptors, necessary cofactors, or mediating proteins. In the adrenergic system, for example, low receptor number and altered ratio of G protein subunits result in relative insensitivity of fetal tissues to adrenergic stimulation. Furthermore, cells may be hormonally unresponsive at certain points in development owing to alterations in chromatin structure that prevent receptor-hormone binding.

**FIGURE 6-1.** Molecular mechanism of catecholamine action. This model applies for a variety of hormones that act through either cyclic adenosine monophosphate (cAMP) or inositol trisphosphate (IP<sub>3</sub>) as secondary messengers. 5'-AMP, adenosine-5'-monophosphate; ATP, adenosine triphosphate; C, catalytic subunit of adenylate cyclase; G, guanine nucleotide regulatory protein (stimulatory or inhibitory); GDP, guanosine-5'-diphosphate; GTP, guanosine-5'-triphosphate; PDE, phosphodiesterase; PI, phosphatidylinositol; PIP, phosphatidylinositol-4-phosphate; PIP<sub>2</sub>, phosphatidylinositol-4,5-diphosphate. (From Ballard PL. Mechanism of hormone action. In Rudolph AM, Hoffman JIE [eds]: *Pediatrics*, 18th ed. Norwalk, CT, Appleton & Lange, 1987, p 1450.)

### Postreceptor Events

Hormones have diverse effects on cells, but their mechanism of action is in general limited to one of the following three categories: (1) direct modification of an enzyme or a protein and alteration of function (e.g., phosphorylation), (2) activation of specific genes that increase synthesis and content of the encoded protein, or (3) repression of the expression of a gene. All three processes occur during fetal life. Hormones that act via membrane receptors trigger a variety of different intracellular signaling cascades. The G proteins, which are composed of three subunits, are associated with the cytoplasmic side of the plasma membrane. There are a variety of alpha subunits, which mediate different hormonal responses, including cAMP-mediated effects. Both inositol triphosphate and diacylglycerol are generated through activation of phosphodiesterase and lipid kinase enzymes in the cell membrane. These agents cause phosphorylation of specific signaling proteins via mobilization of calcium and activation of protein kinase C, respectively. Initial phosphorylation events lead to activation of other major pathways of signal transduction, such as the mitogen-activated protein kinase (MAPK) pathway, the phosphatidylinositol 3-kinase-protein kinase B (PI3-Akt) pathway, the Janus-activated kinase-signal transducer and activator transcription factor (JAK-STAT) pathway, the Smad pathway for transforming growth factor- $\beta$  (TGF- $\beta$ ), and production of ceramide from sphingomyelin in response to tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ).

## UNIQUE FEATURES OF THE FETAL ENDOCRINE SYSTEM

The endocrine environment of the fetus is unique with regard to the endocrine organs, the presence of certain hormones, developmental regulation of circulating hormone concentration, hormone metabolism, and specialized responses related to in utero development. The pattern of fetal growth and development is not generally dependent on hormones, but with some important exceptions, the timing of these events is modulated by levels of endogenous hormones and by exposure to hormone treatment.

### Hormones and Sources

During pregnancy, various steroid hormones are produced through the complex interactions of mother, fetus, and placenta. Progesterone is initially synthesized by the maternal corpus luteum, whereas during the second and third trimesters, the placenta is the major source. Progesterone is synthesized from maternal low-density lipoprotein and occurs independent of the fetus. The high levels of progesterone appear to serve at least two functions, suppressing uterine activity and decreasing maternal immune responses against fetal antigens. One clinical trial indicates that weekly administration of progesterone reduces the rate of premature delivery in high-risk women (Brancazio et al, 2003).

The adult zone of the fetal adrenal gland produces cortisol (in increasing amounts during gestation), and the inner fetal zone acts in concert with the placenta to produce estrogens and their precursors. The fetal zone is deficient in  $\delta$ -5,3- $\beta$ -hydroxysteroid dehydrogenase and  $\delta$ -4,5,3-ketosteroid isomerase and has considerable steroid sulfokinase activity, resulting in production of dehydroepiandrosterone

sulfate (DHAS) from pregnenolone supplied by the placenta. DHAS undergoes 16-hydroxylation in the fetal liver and then is transported to the placenta, where 16-hydroxyDHAS as well as DHAS (of both fetal and maternal origins) are the major substrates for estrogen synthesis. Much of the estrogen, predominantly estriol, enters the maternal circulation and is subsequently excreted in the urine. High levels of estrogen also accumulate in the fetus and amniotic fluid, and appear to influence ovarian folliculogenesis and activation of the hypothalamic-pituitary-adrenal axis. Estrogen biosynthesis is greatly reduced in infants with steroid sulfatase deficiencies; development of the fetus under these circumstances, however, appears to be normal.

In addition to production of progesterone, the placenta synthesizes a number of polypeptide hormones throughout pregnancy. These include human chorionic somatomammotropin (hCS), human chorionic gonadotropin (hCG), human chorionic corticotropin (hCC), human chorionic thyrotropin (hCT),  $\beta$ -endorphin,  $\alpha$ -melanocyte-stimulating hormone ( $\alpha$ -MSH), and both  $\beta$ -lipoprotein and  $\alpha$ -lipotropin. The placenta also produces most, if not all, of the releasing hormones synthesized by the hypothalamus. Thus, the placenta contributes to the circulating pool of pituitary and hypothalamic hormones in the fetus. Other fetal tissues in addition to the placenta, particularly the gut and pancreas, synthesize a number of the releasing hormones characteristic of the hypothalamus. The presence of extrahypothalamic peptides is established, but their role in fetal development is not certain.

Another unique source of hormone production in the fetus is the para-aortic chromaffin system. The extramedullary paraganglia of this system, the largest of which are referred to as the organs of Zuckerkandl, are located along the abdominal and pelvic sympathetic plexuses during fetal life and disappear completely in the first years

after birth. By the second trimester of gestation, this tissue actively produces norepinephrine but relatively little epinephrine because of low levels of phenylethanolamine-N-methyl transferase. The chromaffin cells of the para-aortic system as well as the sympathetic nerve cells are derived from a neuroectodermal stem cell and are responsive to nerve growth factor.

The catecholamine responses at birth are due in part to the para-aortic chromaffin system as well as increased postganglionic sympathetic neuronal and adrenal medullary secretion of catecholamines. Levels of circulating catecholamines (norepinephrine, epinephrine, and dopamine) rise exponentially after delivery and cord cutting. In the newborn sheep, which lacks para-aortic chromaffin tissue, the increased circulating norepinephrine is derived predominantly from the spillover of postganglionic sympathetic neurons, whereas the increased epinephrine derives solely from adrenal medullary secretion. Lacking complete organ sympathetic innervation and maturation of adrenergic receptor mechanisms, the fetus and newborn exhibit profound dependence on circulating catecholamines for maintenance of cardiovascular and metabolic homeostasis in response to physiologic stress such as the transition to extrauterine life. Adrenalectomized animals, lacking the normally increased levels of circulating epinephrine in the newborn period, are impaired in the ability to increase cardiac output and myocardial contractility, secrete surfactant, and mobilize energy substrates for successful postnatal adaptation. It is not known precisely how long this dependence on circulating catecholamines persists postnatally, but basal myocardial function and the high resting cardiac output characteristic of the first weeks of life remain dependent on an intact sympathoadrenal system. Survival during hypoxic stress in newborn rats has been shown to depend on similar mechanisms.

In addition to the anterior and posterior lobes, the fetal pituitary gland has an intermediate lobe that regresses after birth and is not found in adults. In animals, however, the intermediate lobe is maintained throughout adult life. The intermediate lobe secretes primarily  $\alpha$ -MSH and  $\beta$ -endorphin, which are derived from proopiomelanocortin (POMC). In the anterior lobe of the pituitary, POMC is cleaved primarily to  $\beta$ -lipotropin and ACTH. By the second trimester of gestation, the fetal neurohypophysis contains arginine vasopressin (AVP), oxytocin, and arginine vasotocin (AVT). The pituitary gland contains AVT throughout fetal life, but this hormone disappears after birth. AVT is also present in the pineal glands of both fetuses and adults.

### Ontogeny

The response to hormones in the fetus is determined primarily by the developmental patterns of hormone concentrations and functional receptor systems. In general, most endocrine systems of the fetus are functional by the end of the first trimester, although circulating levels of many hormones rise substantially only during the third trimester. One exception to this pattern is illustrated by the hypothalamus-pituitary-gonad axis. Secretion of hypothalamic gonadotropin-releasing hormone (GRH) becomes active in the first trimester, resulting in the pulsatile release

of luteinizing hormone (LH) and follicle-stimulating hormone (FSH), which stimulates production of testosterone or estradiol by the fetal gonads. Throughout the rest of fetal life and childhood, until the onset of puberty, this hormonal axis remains quiescent. Control of this hormonal system is believed to reside in the central nervous system.

Hormones known to influence terminal *differentiation* (acquisition of specialized functions by cells) have developmental patterns consistent with this role. For example, cortisol is detected in fetal plasma at low levels during the second trimester and then increases exponentially during the third trimester (Murphy, 1982). Glucocorticoid receptors are detected relatively early in gestation in many fetal tissues and appear to be fully functional. The influence of endogenous cortisol on fetal development, therefore, is determined by the rate of adrenal production of cortisol and perhaps by postreceptor responsiveness in target tissues. Similarly, plasma levels of  $T_3$  and  $T_4$  increase only during the third trimester, whereas thyroid hormone receptors are present throughout the second trimester (Ballard, 1989).

Other hormones also display developmental patterns, but their roles in fetal growth and differentiation have not been defined. Prolactin levels in plasma and amniotic fluid rise throughout the third trimester to levels much greater than those found in the adult or in the mother. In pregnant animals, prolactin promotes olfactory neurogenesis and development of both pancreatic islets and mammary glands (Shingo et al, 2003). Effects of prolactin in the fetus are less well defined and may include chondrogenesis and development of pancreatic and adipose tissue (Freemark, 2001). Levels of growth hormone in the fetus increase during the first two thirds of gestation and then decline toward term; however, there are no known effects during most of gestation owing to the absence of functional receptors.

The adrenergic response system appears to be constrained throughout most of gestation. The catecholamine response to the stress of delivery is greater at term than in preterm deliveries, and in the fetal lung and heart, for example, the number of  $\beta$ -adrenergic receptors and the ability to provoke cAMP are low in the midgestation fetus compared with the adult.

### Metabolism

In the human fetus, the levels of circulating cortisol (an active glucocorticoid) and cortisone (inactive) are similar. Although most adult tissues, particularly the liver, readily convert cortisone to cortisol, fetal tissues generally lack this ability because of a deficiency of enzyme 17 $\beta$ -hydroxysteroid dehydrogenase or cofactors nicotinamide adenine dinucleotide phosphate (NADP) and its oxidized form, NADPH. The low enzymatic activity in most tissues reduces the possible contribution of cortisone to tissue glucocorticoid activity. In the fetal lung of animals, the ability to convert cortisone to cortisol increases markedly during the third trimester, coincident with lung maturation. Lung tissue from the second-trimester human fetus is similarly responsive to cortisone and cortisol during

explant culture, reflecting rapid conversion of cortisone to cortisol (Ballard, 1989). In this tissue, therefore, cortisone contributes to the pool of circulating glucocorticoids. Administered corticosteroids are rapidly cleared from the fetal circulation by metabolism in the maternal liver, whereas similar doses administered to the newborn are metabolized slowly because of liver immaturity.

Thyroid hormone metabolism also varies markedly in the fetus compared with that of the adult (see Chapter 92). In the fetus,  $T_4$  is deiodinated preferentially to inactive  $rT_3$  rather than active  $T_3$ . This occurs in most fetal tissues but particularly the placenta. In fetal sheep, at least, the switch from production of  $rT_3$  to  $T_3$  is regulated by endogenous cortisol (levels increase greatly in late gestation) and is stimulated precociously by administered glucocorticoids. Compared with the mother, the fetus has relatively high levels of iodothyronine sulfates, which may represent a mechanism for reversible inactivation of circulating thyroid hormones. The generalized inactivation of  $T_4$  during most of fetal life appears to have at least two beneficial effects in the fetus: (1) to protect most fetal tissues from the catabolic effects of thyroid hormone and (2) to provide a mechanism whereby selected tissues could increase their exposure to active  $T_3$  by increasing local  $T_3$  production. Moreover, several fetal tissues in animals are relatively unresponsive to administered  $T_3$  with regard to thermogenesis, a function that is not needed by the fetus before birth.

## HORMONES AND TISSUE DEVELOPMENT

The developmental processes of organogenesis and subsequent maturation of tissue structure and function are, for the most part, programmed and occur in the absence of hormonal influences. Chapter 17 reviews the current understanding of the genetic control of tissue development, which involves coordination and interaction of multiple gene products. Maintenance of the differentiated state appears to be an active process requiring continued synthesis of specific regulatory proteins. Hormones and growth factors have three general roles in the process of differentiation. First, they modulate the rate of tissue development by virtue of increased concentrations or tissue responsiveness during normal gestation. Hormonal effects involve both enzyme induction, which results in differentiated tissue function (e.g., pulmonary surfactant production), and repression of specific genes (e.g., hepatic  $\alpha$ -fetoprotein) with loss of a fetal-specific protein. Within a given tissue, the response to a particular hormone typically involves a specific subset of cellular proteins (e.g., glucose-metabolizing enzymes of the intestine), providing a coordinated maturational response. Second, hormones can accelerate the normal timetable of development, resulting in precocious organ maturation. This accelerating effect is observed with exogenous hormone treatment and at times of increased hormone production, such as during chronic in utero stress, during both premature and term labor and delivery, in the immediate postnatal period, and, in animals, around the time of weaning. The third area of hormonal influence relates to tumorigenesis, in which there is loss of growth control and dedifferentia-

tion. A number of oncogenes have been described, the overexpression of which is associated with the genesis of cancer. The oncogenes of retroviruses represent slightly mutated cellular genes that have been obtained by the virus and that are constitutively expressed on viral infection. Many of the oncogenes encode growth factors, their receptors, other hormone receptors, or proteins involved in signal transduction. For example, oncogenes encode for proteins related to epidermal growth factor receptor (*erbB*), platelet-derived growth factor (*sis*), fibroblast growth factor (*int-2*), the G proteins of adenyl cyclase (*ras*), and thyroid hormone receptor (*erbA*). Thus, appropriate expression of hormones, growth factors, and receptors is important in both initial differentiation and maintenance of the differentiated state. Table 6-1 gives a partial listing of hormones that probably play a role in fetal development.

## Intrinsic Timetable

Experiments of nature, such as anencephaly with panhypopituitarism, indicate that fetal growth and development proceed in a near-normal fashion in the absence of hypothalamic and pituitary input. Such fetuses are still exposed to hormones from the mother and placenta. Circulating levels of many hormones are much lower than in normal fetuses but apparently sufficient to ensure organ maturity at term. In experimental animals with a genetically engineered knockout of corticotropin-releasing hormone, rendering homozygous fetuses deficient in both fetal-derived and maternal-derived corticosteroids, newborns died of respiratory failure because of inadequate surfactant and air space development (Muglia et al, 1995). Absence of corticosteroids, however, did not appear to interfere with organogenesis (e.g., airway branching in the lung). When fetal tissue is placed in explant culture in the absence of serum or added hormones, growth, structural development, and biochemical differentiation continue at a rate equal to or greater than the in vivo rate. Fetal lung, for example, undergoes airway branching, formation of peripheral air spaces, and cytodifferentiation of epithelial cells into surfactant-producing type II cells (Fig. 6-3). This process requires the presence of lung mesenchymal tissue and paracrine factors.

The findings in vivo and in vitro suggest that tissue growth and differentiation proceed even in the absence of circulating hormones as a result of gene expression that is apparently determined by cell lineage and cell interactions. It is likely that tissue interactions, which are essential for normal development, are mediated in part through the production of growth factors and possibly other regulators acting in an autocrine or a paracrine fashion. The primary role of circulating hormones in the fetus, therefore, is to modulate the rate of differentiation, in part as a response to changes in the fetal environment.

## Terminal Differentiation

In addition to modulating normal tissue development, circulating hormones accelerate the process in stressful conditions (e.g., placental insufficiency, prolonged rupture of mem-

TABLE 6-1

**Hormones of the Fetus that Influence Growth or Differentiation (in vitro and/or in vivo)**

Hormone or Growth Factor	Sources	Fetal Effects
Adrenocorticotrophic hormone (ACTH)	Pituitary, placenta	Activates fetal adrenal gland
Androgens (testosterone)	Testes, adrenal gland, liver	Produce male sexual differentiation Delay lung maturation <sup>?</sup>
$\beta$ -Endorphin	Pituitary, placenta	Maintains vasoregulation <sup>?</sup>
Calcitonin	Thyroid	Promotes bone mineralization and anabolism <sup>?</sup>
Catecholamines	Adrenal gland	Produce lung differentiation Increase cardiac output, thermogenesis, and glycogen and fat mobilization
Human chorionic corticotropin (hCC)	Placenta	Regulates fetal adrenal cortex
Human chorionic gonadotropin (hCG)	Placenta	Luteotropic; stimulates steroid production by the fetal testes and adrenals
Human chorionic somatomammotropin (hCS), human placental lactogen (hPL)	Placenta	Promotes secretion of insulin-like growth factors (IGFs) <sup>?</sup>
Cortisol	Adrenal adult zone	Needed for parturition and differentiation of numerous tissues
Eicosanoids (prostaglandins, leukotrienes, and thromboxanes)	Most tissues	Initiate uterus contraction Regulate vessel tone and lung maturation Activate fetal adrenals
Epidermal growth factor (EGF)	Multiple tissues	Regulates epithelial cell division
Estrogens (estrone, estradiol, and estriol)	Placenta	Regulate lung differentiation <sup>?</sup> Increase uteroplacental blood flow
Fibroblast growth factors (FGFs)	Fibroblasts	Regulate cell division
Insulin-like growth factors (IGFs)	Multiple tissues	Regulate cell division (and differentiation <sup>?</sup> )
$\alpha$ -Melanocyte-stimulating hormone ( $\alpha$ -MSH)	Pituitary and placenta	Activates fetal adrenals
Müllerian-inhibiting factor (MIF)	Testes (Sertoli cells)	Activates involution müllerian ducts
Nerve growth factor (NGF)		Needed for development and maintenance of neurons and Sertoli cells <sup>?</sup>
Parathyroid hormone	Parathyroids	Produce 1,25-vitamin D
Platelet-derived growth factor (PDGF)	Platelets, other tissues	Needed for cell replication
Progesterone	Placenta	Precursor for fetal steroids Needed for pregnancy maintenance
Prolactin	Pituitary	Needed for water balance
Releasing hormones (TRH, SRIF, CRF, GRH)	Hypothalamus, placenta, gut	Augment output of fetal pituitary hormones and placental hormones <sup>?</sup>
Thyroid hormones (thyroxine [T <sub>4</sub> ], triiodothyronine [T <sub>3</sub> ])	Thyroid, liver	Activate lung and heart differentiation
Transforming growth factor (TGF)	Multiple tissues	Regulates cell division, deposition of extracellular matrix, and differentiation
Vasopressin, vasotocin	Neurohypophysis, pineal gland	Maintain placental and lung water transport Stimulate ACTH release from fetal pituitary <sup>?</sup>
Vitamin D	Maternal skin, liver, kidney	Placental calcium transport

CRF, coagulase-reacting factor; GRH, gonadotropin-releasing hormone; SRIF, somatotropin-releasing inhibiting factor; TRH, thyroid-releasing hormone.

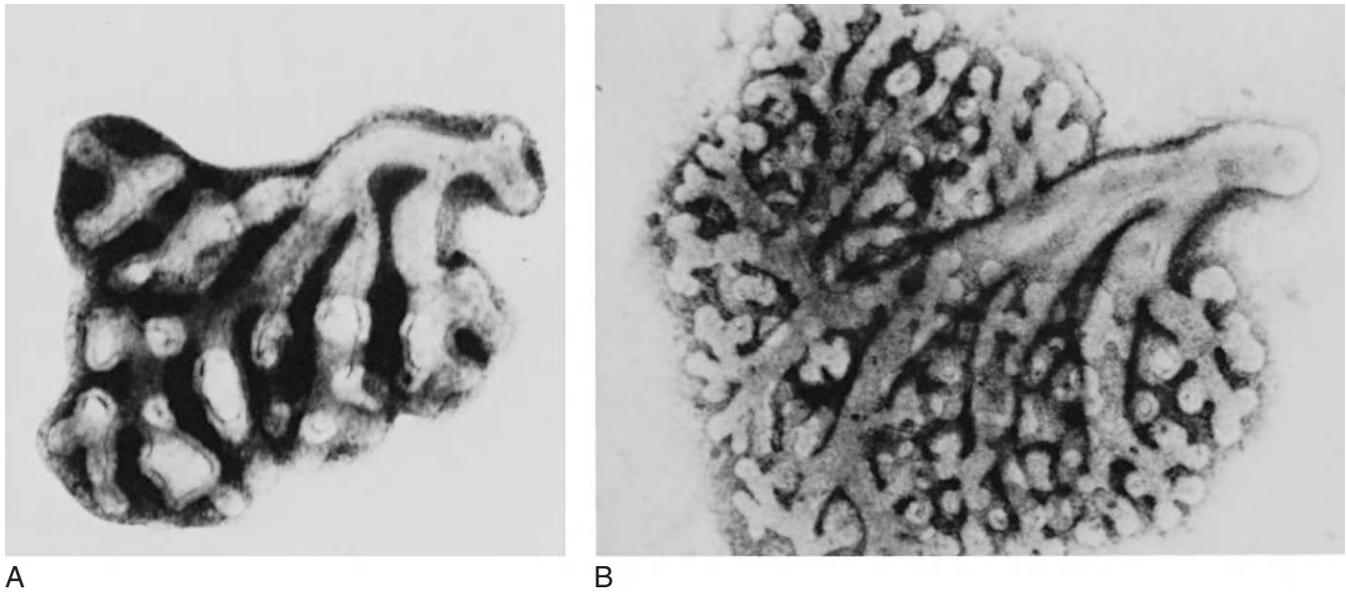

branes, premature labor), a process that has been described as preparation for birth. Several different hormones, as described subsequently, are involved in the stress response, and in several tissues there is an interaction between hormones to stimulate maturation. Many of the problems encountered by the premature infant may be thought of as developmental deficiencies or immaturity of critical functions in select tissues. Table 6-2 lists diseases that result from immaturity of hormonally regulated systems.

### Glucocorticoids

Endogenous cortisol—and in some tissues, cortisone—is the most important hormone regulating tissue maturation.

Cortisol levels increase continually through the third trimester and are elevated in both acutely and chronically stressful situations. Glucocorticoids have maturational effects in a variety of fetal and newborn tissues of animals. Experimentally, the findings about glucocorticoids arise from studies of administered hormone, ablation procedures (e.g., hypophysectomy or adrenalectomy) that delay organ maturation, and temporal associations between circulating corticosteroids and inducible responses. A prepartum rise in circulating fetal corticosteroids occurs in all species that have been studied, and the experimental manipulations of steroid treatment or withdrawal provide consistent results in a variety of animal models.

In many tissues, the maturational effects of glucocorticoids require or are synergistic with effects of other

**FIGURE 6-3.** Development of the fetal lung in vitro. Intact lungs from 14-day rat fetuses were cultured as explants in medium without hormones for 1 day (**A**) and 4 days (**B**). Branching morphogenesis proceeds without the addition of hormones or growth factors but requires the presence of the mesenchymal tissue. (From Gross I, Wilson CM: *Fetal rat lung maturation: Initiation and modulation*. *J Appl Physiol* 55:1725, 1731, 1983.)

hormones, such as  $T_3$  and catecholamines (cAMP). Although it is not possible to extrapolate all of the findings in animals to the human infant, a number of these regulatory events appear to occur in the human and has clinical implications (see Table 6-2).

The effects and physiologic role of glucocorticoids are best described with regard to maturation of the fetal lung. Studies with explant cultures of human tissue have established that glucocorticoids affect both lung structure and production of surfactant by type II cells (Ballard, 1989).

**TABLE 6-2**

**Abnormalities of the Newborn that may be Related to Hormonal Conditions**

Abnormality	Hormone	Cause (Known or Postulated)
Male pseudohermaphroditism	Testosterone	Genetic defects in testosterone biosynthesis, metabolism ( $5\alpha$ -reductase), or responsiveness (receptor deficiency or abnormality)
Testicular feminization	Dihydrotestosterone	Decreased receptors in androgen target tissues yield female phenotype in genetic male
Female pseudohermaphroditism (congenital hyperplasia)	Cortisol, insulin	Enzymatic defects in cortisol biosynthesis with excess androgen
Infant of diabetic mother	Insulin	Fetal hyperinsulinemia increases growth and fat deposition and delays lung development
Infant leprechaunism	Insulin	Decreased insulin receptors with intrauterine growth retardation
Congenital hypothyroidism	Thyroxine, triiodothyronine ( $T_3$ )	Hormone deficiency alters development of brain, heart, lung, and other tissues
Respiratory distress syndrome	Cortisol, $T_3$ , catecholamines	Developmental deficiency in one or more hormones may delay lung development
Transient tachypnea of newborn	Cortisol, catecholamines, arginine vasopressin, and others?	Decreased hormone levels or responsiveness of lung epithelium for fluid clearance
Lung hypoplasia	Unknown growth factors	Presumed to be decreased production of lung factors
Persistent pulmonary hypertension of newborn	?	Stress-related hormones may delay pulmonary vascular development in utero
Patent ductus arteriosus	Cortisol, prostaglandins?	Possible imbalance in levels and/or responsiveness for dilating and constricting prostaglandins
Necrotizing enterocolitis	Cortisol, glucagon?	Developmental deficiency in hormones may delay gut development

Treatment accelerates differentiation of the epithelial cells into type II cells, reduces mesenchymal volume, narrows the intra-alveolar septal distance, and increases maximal lung volume and compliance. Surfactant production and secretion are increased, and the response includes all of the known components of pulmonary surfactant (saturated phosphatidylcholine and the three surfactant-associated proteins, SP-A, SP-B, and SP-C). The response to glucocorticoids in the fetal lung is mediated by glucocorticoid receptors and involves greater gene expression (i.e., higher content of messenger RNA) for SPs, SP-processing enzymes, (e.g., cathepsin H), lipogenic enzymes (e.g., fatty acid synthetase), and lipid transporters. It is likely that glucocorticoids have other maturational effects in the lung, because a number of as yet unidentified proteins are induced by glucocorticoid treatment of cultured lung cells (Gonzales et al, 2002). Glucocorticoids also act by receptor-mediated inactivation of the NF- $\kappa$ B (a transcription factor) system, decreasing synthesis of cytokines, but it is uncertain whether this mechanism contributes to enhanced organ maturation. The clinical effects of prenatal corticosteroid therapy are discussed in Chapters 42 and 45. The improved survival rates in treated infants result from precocious maturation of the lung as well as other organs.

### Thyroid Hormones

Levels of both  $T_3$  and  $T_4$  rise in the human fetus during the third trimester. Although thyroid hormones are important for normal postnatal growth, the athyroid human fetus grows normally (see Chapter 92). Thyroid hormones, however, contribute to fetal lung maturation and are important for development of other tissues. Surfactant production and structural pulmonary development are retarded in hypothyroid sheep fetuses. Treatment with thyroid hormone accelerates phospholipid synthesis in cultured lung, and thyroid hormones are necessary for maximal response to cortisol treatment in fetal sheep. These and other observations on the interactions of glucocorticoids and thyroid hormones led to clinical trials of prenatal therapy with betamethasone plus thyrotropin-releasing hormone (TRH) for prevention of respiratory distress syndrome (RDS). Initial results indicated benefit with regard to incidence of RDS and chronic lung disease for treated infants; however, later trials have not found benefit (Australian collaborative trial, 1995; Ballard et al, 1998).

Thyroid hormones are important for cardiac development. In the sheep fetus, thyroidectomy during late gestation blunts the increases in heart rate, cardiac output, and oxygen consumption normally seen after birth, and replacement  $T_3$  therapy before birth is corrective. This  $T_3$  effect appears to be mediated through  $\beta$ -adrenergic receptor concentration and responsiveness to endogenous catecholamines. The normal hypertrophic growth of the myocardium also depends on thyroid hormones but apparently does not involve the  $\beta$ -adrenergic system.

The role of thyroid hormones in normal postnatal brain development is well recognized. There is accumulating epidemiologic evidence that the level of maternal thyroxine in the first trimester of pregnancy influences fetal

neurodevelopment. Maternal iodine deficiency and other causes of hypothyroidism reduce placental transfer of thyroxine, the primary source of intracellular  $T_3$  in the fetus.

### Catecholamines

Circulating catecholamine concentrations increase dramatically with labor and delivery, and amniotic fluid levels, which probably reflect production by the fetus, are generally elevated in complicated pregnancies. A well-described effect of catecholamines on terminal differentiation occurs in the fetal lung. Treatment with  $\beta$ -adrenergic agonists causes a prompt increase in surfactant secretion both in vivo and in isolated type II cells, and endogenous catecholamines contribute to release of surfactant at the time of birth. For example, the amount of surfactant in airways of fetal animals is decreased by blockade of the  $\beta$ -adrenergic receptors with an irreversible antagonist, by treatment with an inhibitor of catecholamine biosynthesis, and by adrenalectomy.

A second effect of catecholamines is to stimulate the rate of surfactant synthesis. In cultured lung tissue, treatment with analogues of cAMP, inhibitors of cAMP phosphodiesterase,  $\beta$ -agonists, and other agents that induce cAMP increases synthesis of surfactant phospholipids, SP-A and SP-B. Alveolar structure in cultured lung explants is also modified by these treatments, probably as a result of altered ion and fluid transport.

A third effect of catecholamines is reduction of lung fluid. In fetal animals,  $\beta$ -agonists decrease fluid accumulation in the air spaces by inhibiting the chloride pump and promoting fluid reabsorption through a sodium pump in epithelial cells. The physiologic relevance of these responses has been demonstrated in the fetal lamb, in which there is a close correlation between fluid flux and endogenous levels of catecholamines during labor. Responsiveness to catecholamines normally increases during the third trimester; the response is markedly blunted in thyroidectomized fetuses but is restored by combined treatment with  $T_3$  and hydrocortisone, although not by treatment with either hormone alone (Barker et al, 1989). These findings suggest that rising concentrations of cortisol and  $T_3$  during development enhance the sensitivity of epithelial cells for responding to catecholamines. This system illustrates the interaction of hormones in regulating a developmental process important for successful adaptation to extrauterine life. Clinical aspects of lung fluid are discussed in Chapters 44 and 45.

Catecholamines are also involved in increasing myocardial contractility and systemic vascular resistance and in triggering the onset of thermogenesis through mobilization of energy substrates. Infants born prematurely are thus at greater risks with regard to cardiac function and thermal stability because of both decreased metabolic reserves and suboptimal catecholamine levels.

### Insulin

The infant of a diabetic mother is at increased risk for a number of abnormalities, including macrosomia with organomegaly, placental hypertrophy, polyhydramnios, congenital

anomalies, and intrauterine death (see Chapter 7). On the basis of animal models of diabetes, it is generally believed that fetal hyperinsulinemia also delays the appearance of pulmonary surfactant and may alter surfactant composition (and therefore its function), alveolar structure, or both. One possible explanation for this effect relates to the mitogenic activity of insulin and the general biologic principle that cell differentiation (e.g., production of surfactant) is associated with decreased cell division. Thus, under the stimulation of increased circulating insulin, lung type II cells may remain in an active cell cycle, not entering the G<sub>0</sub> stage when specialized cell products are synthesized. Another possible explanation is an inhibitory effect of insulin on synthesis of surfactant per se. Experiments with cultured lung tissue found that insulin can inhibit synthesis of surfactant proteins A, B, and C, which are required for normal surfactant structure and function (Guttentag et al, 1992). A third possible explanation suggested by *in vitro* studies is that insulin blocks cortisol stimulation of lung structure and type II cell function. Infants of diabetic mothers also have a higher incidence of respiratory distress because of delayed fluid clearance. The mechanism of this abnormality is not known but could relate to either increased cell division or antagonism of glucocorticoid effects in the lung.

### Eicosanoids

Eicosanoids, which include prostaglandins, thromboxanes, and leukotrienes, are produced from arachidonic acid (released from phospholipids) in the placenta and various fetal tissues. Although many effects of prostaglandins are paracrine, these hormones are present in the circulation, and levels of some (e.g., prostaglandin E<sub>2</sub> [PGE<sub>2</sub>]) are much higher in the fetus than the adult, reflecting in part the lower metabolic clearance by the poorly perfused fetal lung. Synthesis of prostaglandins is increased by a variety of stimuli, many of which involve perturbation of cell membrane integrity, and their production is inhibited by glucocorticoids (induction of lipocortin, which blocks phospholipase A<sub>2</sub>) and drugs that block synthetic enzymes, such as xanthine derivatives. Effects of prostaglandins are mediated through membrane receptors (primarily on the cell surface) and, at least in part, by the generation of cAMP.

In addition to their important role in initiation of parturition, prostaglandins have several known effects in maturational events of the cardiopulmonary system. Prostaglandins, in particular PGE<sub>2</sub>, maintain the patency of the ductus arteriosus in fetal life; in fetal sheep, sensitivity to PGE<sub>2</sub> decreases during late gestation and in response to glucocorticoid treatment, allowing greater responsiveness to the contracting influence of oxygen. The higher incidence of patent ductus arteriosus in premature infants (and closure with prenatal glucocorticoid and postnatal indomethacin treatment) probably results from changing prostaglandin levels and sensitivity. Prostaglandins also influence the tone of the pulmonary vessels in utero and after birth. Maintenance of pulmonary vasoconstriction in the fetus is due in part to leukotrienes produced within the lung. The rapid fall in

pulmonary vascular resistance at the time of birth results in part from the vasodilating effects of prostacyclin as well as other agents (e.g., prostaglandin D<sub>2</sub>, bradykinin, and histamine) that are released by stretching the lung. Thus, an alteration in prostaglandin production or responsiveness could conceivably contribute to the development of persistent pulmonary hypertension in some newborn infants.

Prostaglandins may also play physiologic roles in other aspects of lung development. Treatment of fetal sheep with inhibitors of prostaglandin synthesis increases fetal breathing movements and in some studies reduces both the rate of lung fluid production and its surfactant content. In newborn lambs, treatment with PGE<sub>2</sub> produces hyperventilation and apnea. In cultured lung tissue, PGE<sub>2</sub> and PGE<sub>1</sub>, presumably acting through cAMP, stimulate syntheses of surfactant lipids and SP-A and promote the release of surfactant from type II cells. Thus, endogenous prostaglandins may contribute to lung growth (via fluid production and breathing movements) and maturation of the surfactant system in utero. Conceivably, the administration of inhibitors of prostaglandin synthesis such as tocolytics might adversely affect lung maturation in the human fetus.

### Arginine Vasopressin and Arginine Vasotocin

Although AVP and AVT are present in the pituitary gland of the human fetus, it is not known whether they have a unique physiologic role in the fetus. In addition to its role in conserving water for the fetus, vasopressin is increased in response to hypoxic stress to levels greater than those occurring with osmolar stimuli. As a stress response hormone, AVP may contribute to maintenance of fetal blood pressure during hemorrhage or hypoxia. Administration of AVP to fetal animals decreases production of fetal lung fluid without affecting fluid osmolarity. This response is greater in older fetuses, indicating developmental changes in responsiveness. Plasma AVP is higher in infants delivered vaginally than in those delivered by cesarean section, and exposure to labor reduces the incidence of respiratory distress after birth. It is possible, therefore, that the higher levels of endogenous AVP or AVT associated with labor and delivery contribute to the clearance of lung water.

### Atrial Natriuretic Peptide

Fluid production, and possibly other lung functions, may be influenced by atrial natriuretic peptide (ANP), which is secreted from atrial myocytes under glucocorticoid regulation. ANP is also synthesized in pulmonary type II cells of newborn rats, and high-affinity binding sites for this peptide occur within lung tissue. In fetal sheep, infusion of ANP or saline reduces production of lung fluid. In the human, plasma concentrations of ANP are higher in term newborns than in adults and are further elevated in infants with RDS. Thus, ANP, levels of which are regulated by cortisol, may have a developmental influence in fluid production by both the kidney and the lung. ANP also has vasodilatory properties and thus could have an

effect on pulmonary blood flow and the occurrence of patent ductus arteriosus in the newborn.

Studies indicate that ANP is also synthesized in a number of extra-atrial tissues, such as adrenal, gut, pancreas, nerve, and endocrine cells of the adult animal. The presence of ANP receptors in many of these same tissues suggests possible autocrine or paracrine roles of ANP in addition to its regulation of water and salt homeostasis. Possible roles of ANP in developing tissues other than the lung have not yet been investigated.

### Neuropeptides

A variety of regulatory peptides are synthesized and secreted by a diffuse endocrine system of small granule cells of the intestine, pancreas, thyroid, lung, and other organs. Products of these cells are the biogenic amines and neuropeptides such as bombesin (gastrin-releasing peptide), bombesin-related compounds, calcitonin, calcitonin gene-related peptides, leucine enkephalin, somatostatin, and cholecystokinin. The neuroendocrine cells and their products are present in the fetus from early gestation, increase during fetal life, and then generally decline during childhood. The developmental pattern and distribution of these endocrine and paracrine systems suggest that the neuropeptides may have a role in fetal growth and development. At present, specific biologic functions have not been defined, although there is evidence for stimulatory effects on lung development.

### FETAL GROWTH

Growth of the fetus is determined primarily by genetic factors, the capacity of the mother to provide nutrients, and the ability of the placenta to transfer nutrients. Relatively little is known about the role of hormones and growth factors in the complex process of fetal growth. Although growth hormone and thyroid hormones are important for postnatal growth, they appear to have no growth-promoting role in utero. In fact, growth retardation is not a feature of anencephaly, which often involves complete absence of hypothalamic and pituitary hormones.

It is likely that tissue growth in the fetus is determined in large part by the interplay of locally produced growth factors. Studies in cell lines indicate that stimulation of cell division requires both competence factors (e.g., platelet-derived growth factor [PDGF] and fibroblast growth factor [FGF]), which render growth-arrested cells capable of entering the cell cycle ( $G_0$  to  $G_1$ ), and progression factors (e.g., IGFs) that promote entry into the DNA synthesis phase of the cell cycle.

One fetal hormone known to influence fetal growth is insulin. It is present in the human fetal pancreas and circulation by 10 weeks of gestation, and its levels are influenced by the blood glucose concentration. The rare condition of congenital absence of the pancreas is associated with marked reduction in birth length and weight. The syndrome of leprechaunism, which involves a genetic deficiency of insulin receptors and therefore lack of responsiveness, is also characterized by severe growth

retardation. In animals, experimental hypoinsulinism leads to fetal growth retardation, and infusion of insulin increases fetal weight and causes organomegaly. Infants of diabetic mothers with poorly controlled disease are often macrosomic; this overgrowth is not observed when the diabetes is well controlled. In mothers with severe diabetes, with vascular disease and decreased uterine blood flow, fetuses are growth retarded because of nutrient deprivation. Infants with the Beckwith-Wiedemann syndrome are macrosomic with generalized organomegaly and appear to be hypersensitive to circulating insulin. The mechanism of insulin action in fetal growth is not fully defined but probably includes a direct stimulation of cell division through insulin receptors (insulin promotes cell division in culture), enhanced glucose and amino acid uptake into cells, and possible interactions with IGFs.

IGFs (or somatomedins) are a family of proteins that are structurally related to insulin, have some insulin-like metabolic activities, and mediate the action of growth hormone on postnatal growth. They circulate bound to specific binding proteins (IGF-binding proteins [IGF-BPs]) and act via cell membrane receptors. IGFs and their receptors are present in most fetal tissues (except the brain) and undoubtedly have a role in both organ and somatic growth. There is a correlation between size at birth and levels of IGFs in cord blood consistent with a physiologic role. Production of IGFs by tissues is developmentally controlled and cell specific. For example, in the lung, messenger RNA for IGF-II is high in the fetus, drops markedly by term, and is not detected in adult lung; by contrast, IGF-I messenger RNA is found in both fetal and adult tissue. IGF-II messenger RNA is found only in lung mesenchymal cells, indicating the cellular site of synthesis, whereas immunostaining occurs in epithelial cells but not mesenchymal fibroblasts. These and other findings suggest that IGFs are produced by certain cell types (e.g., fibroblasts), are secreted, and stimulate proliferation of neighboring cells after binding to cell surface receptors. Agents or hormones that influence either IGFs or their receptors could potentially influence the rate of fetal growth. The six different IGF binding proteins, for example, sequester IGFs from their receptors and inhibit IGF action. The binding proteins also have separate effects, independent of IGF receptors, on cell functions that are important in fetal development, such as adhesion, migration, proliferation, and apoptosis.

Epidermal growth factor (EGF) was first identified as a protein from the mouse submaxillary gland, which accelerated eruption of the incisors and eyelid opening in the newborn animal. EGF has generalized effects on epithelial growth and keratinization in several species and in a variety of cell types (mammary epithelial cells, chondrocytes, corneal cells, vascular smooth muscle cells, prostatic cells, glial cells, fibroblasts, and epithelial cells of the female reproductive organs). In vitro, EGF stimulates DNA synthesis in cultured cells. In explant culture of fetal lung, EGF stimulates both cell division and phospholipid biosynthesis. Infusion of EGF into fetuses stimulates epithelial growth in many tissues, with major effects on the weight of the placenta, intestine, kidneys, and adrenals, but does not affect general somatic growth. These observations suggest that endogenous EGF may have a

role in growth and maturation of the kidney, adrenal cortex, intestine, and lung.

Nerve growth factor (NGF) was also first isolated from mouse salivary glands but has been detected in various tissues, including human placenta. Treatment of chick embryos with NGF increases the size of sensory and sympathetic ganglia owing to survival of neurons that normally degenerate. Sympathetic ganglia of newborn animals contain more NGF than adult ganglia and are more responsive in terms of transformation of sympathetic neuroblasts into differentiated neurons. It has been postulated that locally produced NGF is important in the maturation of adrenergic neurons, the sympathetic nervous system, and fetal brain development in general.

Basic FGF (B-FGF) and related proteins (A-FGF, K-FGF, int-2, and FGF-5) appear to play an important role in early embryonic induction, angiogenesis of myocardial and vascular disease, and wound healing. They are mitogenic for vascular endothelial cells through an autocrine mechanism, and they promote endothelial cell migration and invasion as well as production of plasminogen activator, which are all necessary features of angiogenesis *in vivo*. Acidic FGF appears to be essential for branching morphogenesis in embryonic lung, on the basis of observations in animals with FGF receptor knockout (Peters et al, 1994). PDGF, in combination with other growth factors, stimulates division of glial cells, muscle cells, ovarian granulosa cells, pancreatic beta cells, and certain cell types of the immune system.

The transforming growth factors, in particular TGF- $\beta$ , have multiple effects on a variety of tissues. For example, TGF- $\beta$  stimulates growth and extracellular matrix production by fibroblasts, promotes a switch from chondrocytic to osteoblastic phenotype, and inhibits the synthesis of surfactant components in cultured lung (Beers et al, 1998). Cardiac development is regulated at multiple developmental stages by members of the TGF- $\beta$  superfamily. These findings indicate that TGF- $\beta$  may act in early embryogenesis (e.g., heart) as a growth stimulator (e.g., of bone), and as a differentiation inhibitor (e.g., in the lung). It is also conceivable that TGF- $\beta$  (and other growth factors) play a role in the disordered growth and repair process that is a part of bronchopulmonary dysplasia in infants.

## Multiple Birth

Geoffrey A. Machin

The present epidemic of twin and higher-order multiple births (multiple-fetus pregnancy [MFP]) brings many young patients to the neonatal intensive care nursery (NICU). Twin births occur at a rate of 1 per 45 gestations in the United States today (contribution of assisted reproductive technology, 2000). The frequency of preterm delivery increases from singletons through twins to quadruplets and quintuplets (Botting et al, 1990) (Fig 7-1). MFP neonates are over-represented in the NICU; 10 times as many MFP neonates as newborns from singleton births received NICU care. Preterm delivery and complications of preterm birth are caused not only by spontaneous preterm labor or preterm rupture of membranes but also by a higher frequency of interventions for gestational complications, such as severe pregnancy-induced hypertension. The impact on NICU occupation by preterm birth in MFPs cannot be underestimated, but this chapter concentrates on special issues and disorders that are found in MFPs and that must be considered in clinical care.

### SPONTANEOUSLY AND ARTIFICIALLY CONCEIVED MULTIPLE-FETUS PREGNANCIES

Spontaneously conceived MFPs vary in frequency by ethnic origin, maternal age, and maternal nutritional status. The prevalence of monozygotic (MZ) twins is virtually constant worldwide, at 4 in 1000 births. But the prevalence of dizygotic (DZ) twins varies widely, being common in parts of West Africa and rarer in Southeast Asia. Both MZ and DZ twins may occur with greater frequency in some families. Therefore, it is not possible to give an overall ratio of MZ and DZ twins, but 35:65 is a reasonable estimate in an ethnically mixed population. Very few sets of spontaneously conceived triplets are trizygotic. The majority contains at least a pair of MZ twins, and more than one third of triplet sets are totally MZ (Machin and Bamforth, 1996). Zygosity in quadruplets is not well documented, but several MZ sets are known. The Dionne quintuplets appear to have been MZ.

Artificially conceived MFPs contain MZ twins in 6% to 10% of cases. This rate may relate to mechanical factors, such as manipulation of the zona pellucida during *in vitro* fertilization (IVF) (Sheen et al, 2001). The high frequency of MZ twins in artificial reproduction is not widely known and can cause confusion for caregivers and parents alike. For instance, implantation of three IVF embryos may result in the birth of triplets. However, two of the triplets may be MZ twins from one embryo, and the third the

singleton of the second embryo; the third IVF embryo in such a case has not survived. The prevalence of sex chromosome aneuploidy is higher in embryos produced by intracytoplasmic sperm injection for treatment of oligospermia. The two main reasons are (1) a greater prevalence of sex chromosome aneuploidy in the oligospermic fathers results in aneuploid sperm and (2) sex chromosomes in the sperm head are normally located in the subacrosomal region, and may not enter appropriately into the union of male and female pronuclei (Sbracia et al, 2002).

### CHORIONICITY IN MULTIPLE-FETUS PREGNANCIES

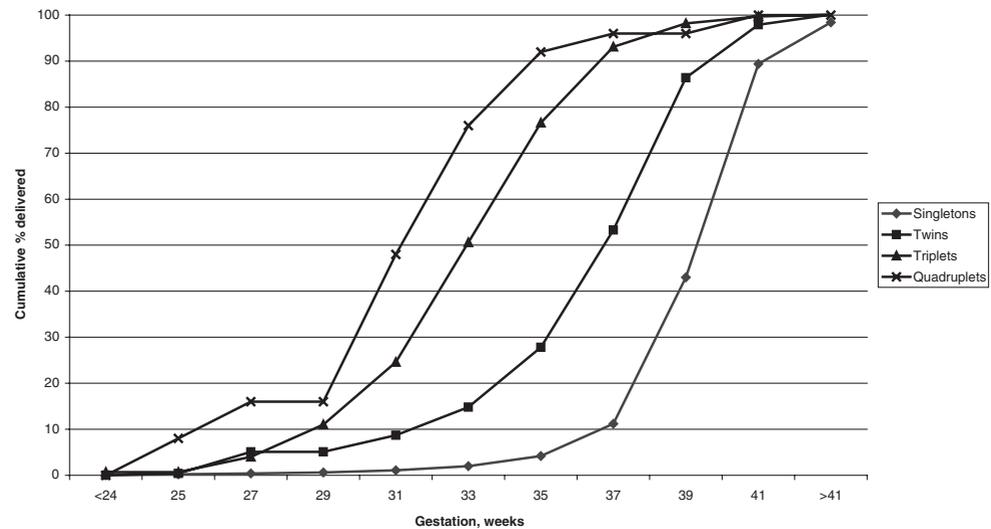

In prenatal life, the importance of chorion number is overwhelming in terms of mortality and morbidity. This fact has been known for several years, but unfortunately, chorionicity is not always diagnosed accurately by ultrasound in MFPs. This is partly due to the restriction on the number of ultrasound examinations in pregnancy. A dating ultrasound at 16 to 18 weeks is usually too late to determine chorionicity, because the septal membranes of dichorionic (DC) gestations will already have thinned out to resemble the septum of monochorionic (MC) twins. Ideally, chorionicity should be determined in the first trimester. DC twin placentas, whether separate or fused, show bright placental tissue in the septum, with a “twin peak,” “lambda,” or “delta” sign. The placentas of DC twins collide like tectonic plates, throwing ridges of placental tissue up into the septal area. This chorionic ridge effectively separates the two gestations, so that any adverse effect on the integrity of one DC twin will not affect the other because there are no interfetal vascular communications.

In MC twins, the chorion surrounds the whole gestation but is not present in the septal membranes which consist only of two layers of amnion in 95% of MC twins, who are diamniotic (DA). About 5% of MC twins are monoamniotic (MA). The cords of MC-MA twins are usually entwined from early in pregnancy, causing greater risks of vascular problems than in MC-DA twins. MC twin placentas are designed and developed for a singleton pregnancy and do not always adapt well to the demands of twin circulations. About 90% of MC twin placentas have connecting vessels between the twins that run on the surface of the placenta, into the parenchyma, or both. This is the main reason for higher rates of complications in MC than in DC twin pregnancies, because adverse events in one twin usually affect the other twin.

### Complications of Monochorionicity

Two vascular characteristics of MC twin placentas affect outcomes. First, the parenchyma of the single placenta is often not shared equally between the twins, usually because of asymmetric cord insertions. Velamentous cord insertion is found in about 10% of MC twins, compared with 1% of singletons. If one twin's cord is inserted more toward the center of the placenta, that twin will control a much larger proportion of the placenta than the twin with the velamentous cord. This is the usual cause of significant

**FIGURE 7-1.** Cumulative percentages of singletons, twins, triplets, and quadruplets born at a given gestational age.

growth discordance in MC twins. Paradoxically, the growth rate of the twin with the central cord is often equal to or better than that of a singleton, because the MC twin placenta is larger than a singleton placenta.

Second, there are three kinds of intertwin vascular connections (anastomoses) in MC placentas, as follows: (1) direct arterio-arterial (AA), (2) direct venovenous (VV), and (3) indirect arteriovenous (AV). The characteristics of these anastomoses are shown in Table 7-1.

Blood in AV connections transfuses steadily from donor (arterial end) to recipient (venous end) down the pressure gradient. The artery and vein abut very closely on the fetal surface, but blood flow occurs in the underlying parenchyma. If not adequately compensated by other types of connections, unopposed arteriovenous flow inevitably leads to twin-twin transfusion (TTT). Blood shunts back and forth readily in direct, surface AA, and VV connections, but there is little net flow if the twin cardiac outputs are roughly equal. This has good effects (allows blood to flow back from recipient to donor) and bad effects (rapid transfer of blood to a twin if its circulation fails or the fetus dies). Thus, the outcomes in MC twins depend largely on the types and combinations of vascular connections. The more connections there are, the less likely are the twins to decompensate into TTT. Fortunately, most

MC twins have several connections (usually a combination of AA and VV), and TTT does not develop.

Combinations of such connections are shown in Figure 7-2. This illustration shows the types and combinations of connections in those 90% of MC placentas that have connections. AA connections are found in three quarters of placentas, frequently in combination with other types of connections, especially AV. AV connections are also very common, but one third of them occur alone, without compensation, putting the twins at risk for TTT. VV connections are much less common (20%), but they are potentially dangerous, because large blood volumes at low pressure, can rapidly cross the placenta from twin to twin if the cardiovascular status of one twin deteriorates.

## Complications of Intertwin Vascular Connections in Monochorionic Twins

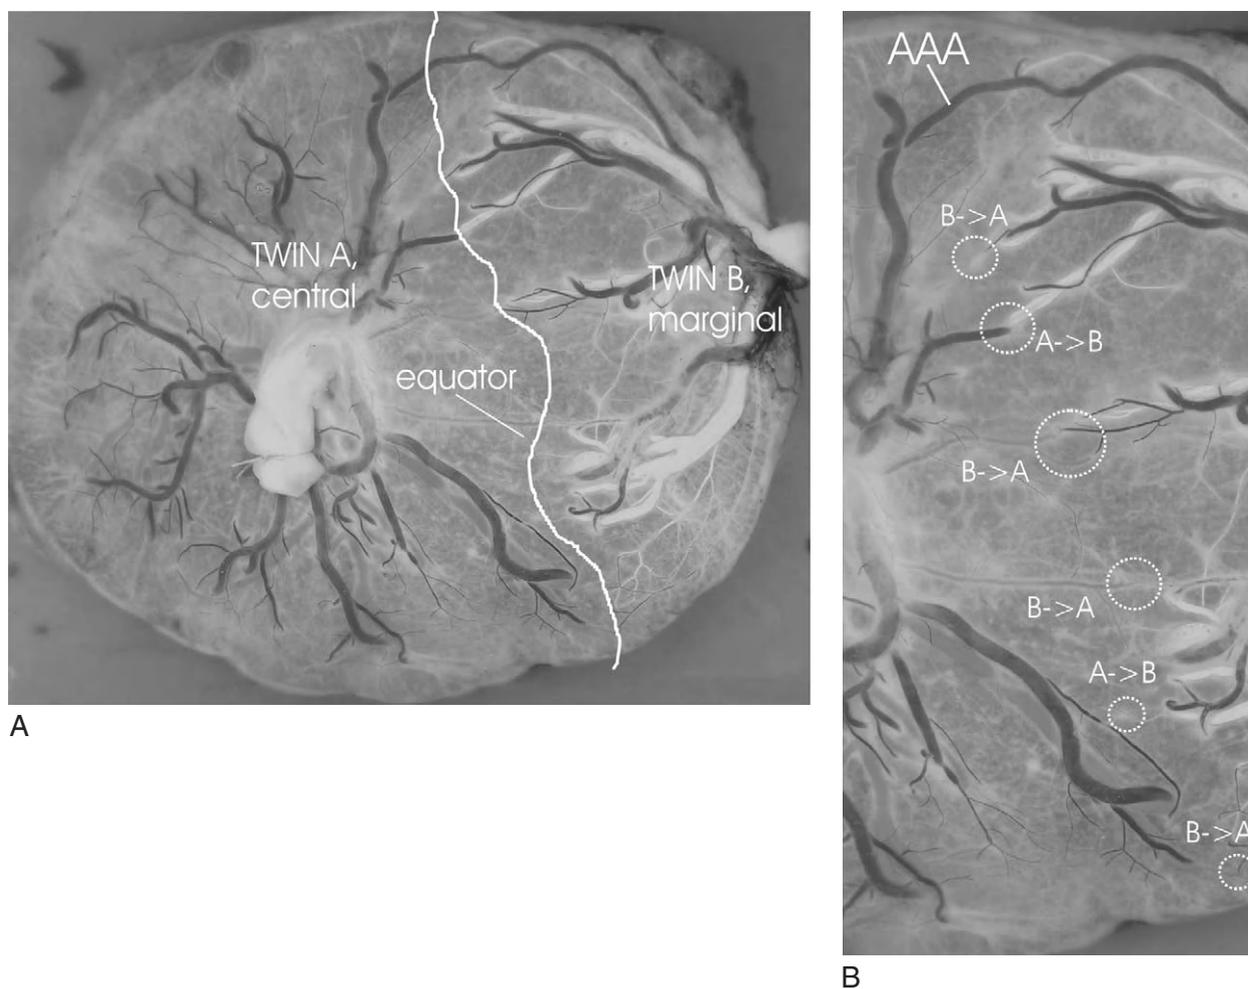

### Chronic Prenatal Twin-Twin Transfusion

Uncompensated AV connections allow steady blood transfusion, probably at the rate of a few milliliters every 24 hours. Diagnosis is signified by simultaneous oligohydramnios and

**TABLE 7-1**

### Types and Effects of Interfetal Vascular Anastomoses

Characteristic	Type of Anastomosis		
	Arterio-arterial	Venovenous	Arteriovenous
Location	Fetal surface	Fetal surface	In underlying villi, but feeder vessels on fetal surface
Net flow	Little	Little	Arteriovenous transfusion
Pressure/resistance	High	Low	Intermediate
Flow	Low	High	Very low
Effect on twin-twin transfusion	Protective	?	Causative

**FIGURE 7-2.** (See also Color Plate 7-2.) **A**, Monochorionic twin placenta. Twin A (*left*) has a centrally inserted cord, whereas the cord of twin B (*right*) is marginally inserted. The *line* represents the vascular equatorial zone between the circulations of the twins. This is the region where intertwin vascular connections are found. There is markedly unequal sharing of the parenchyma, with growth discordance. **B**, Close-up view of the equator, showing a direct arterio-arterial connection (AAA) and multiple bidirectional arteriovenous connections (*circles*) from A to B and from B to A. This resulted in no net transfusion. Although twin-twin transfusion syndrome did not occur, there was growth discordance.

polyhydramnios (oli/poly). The donor is often (but not always) growth restricted because of peripheral cord insertion. Severe growth restriction causes oligohydramnios. The recipient responds to transfusion with polyuria or polyhydramnios, and the blood becomes hyperviscous, leading to low cardiac output because of resistance to forward flow. Tricuspid valve regurgitation leads to pulsatile umbilical venous flow and, eventually, hydrops. Treatment options include amnioreduction and fetoscopic laser coagulation of connecting placental vessels. In survivors, early exchange transfusion and correction of metabolic disturbances may be necessary. However, there are also chronic sequelae of TTT, with typical patterns affecting each fetus (Table 7-2).

Long-term follow-up studies of TTT have been published. In a series of 17 twin pairs with antenatal TTT treated conservatively or by amnioreduction, there were five fetal deaths, and a further six neonatal deaths among the 29 surviving twins (neonatal death rate 21%) (Cincotta

et al, 2000). Of the survivors, 14 were donors and 15 were recipients. The most significant morbidities were resolving oliguria (7 of 14 donors and 7 of 15 recipients), periventricular leukomalacia in three infants and cerebral atrophy in two infants. These five neurologic injuries were distributed in 3 donors and 2 recipients. At long-term follow-up, two infants had cerebral palsy (CP) with developmental delay (DD), one infant had CP only, and two infants had DD only. Thus, of the 29 newborns, 62% were intact survivors.

In another study of 33 TTT pairs treated with aggressive amnioreduction, there were 51 newborns, of whom 9 died in infancy (18% postnatal mortality) (Mari et al, 2000). Two survivors had CP. Ten recipients had resolving cardiomegaly. Seven other cases of recipient cardiomegaly occurred in newborns who died. In this series, the majority of neonatal deaths and complications occurred in recipients. In a third study, detailed neurologic analyses of

TABLE 7-2

**Chronic Sequelae of Twin-Twin Transfusion and Typical Patterns Affecting Each Fetus**

Sequelae	Donor Affected	Recipient Affected
Cerebral hypoxia/hemorrhage	Yes	Yes
Cardiomyopathy	No	Yes
Acquired prenatal heart disease (flow defects) (Nizard et al, 2001)	Left	Right
Limb gangrene (Dawkins et al, 1995; Scott et al, 1995)	No	Yes
Arterial distensibility (Gardiner, 2001)	No	Yes
Oliguria (Genest et al, 1991)*	Yes	Yes

\*Renal tubular dysgenesis is a malformation of renal tubules in which convoluted tubules fail to differentiate. It occurs in an autosomal recessive form but is also associated with the donor fetus in twin-twin transfusion. The defect is one cause of postnatal oliguria and does not resolve.

40 survivors of TTT showed only 18 (45%) intact children (Haverkamp et al, 2001). Thirteen of the survivors had specific delayed language development, minor neurologic dysfunction, or both. Nine survivors had severe psychomotor retardation and CP; these major neurologic problems occurred in 6 of 19 recipients and 3 of 21 donors. One of the reported advantages of laser coagulation over amnioreduction is a lower prevalence of cerebral disease in survivors. However, it has been suggested that this lower prevalence arises from the demise of some severely affected fetuses during and after the more invasive procedure of laser therapy.

**Acute Perinatal Twin-Twin Transfusion**

After the cord of the first-born twin is clamped, the second twin has full access to the whole MC placenta and may receive a significant boost transfusion before birth. Thus, the second-born MC twin frequently has a higher hematocrit than the first born. In the context of chronic prenatal TTT, the donor is often born second, but may be paradoxically plethoric because of acute perinatal transfusion. Exchange transfusion may be required.

**Fetal Death of One Twin**

With or without TTT, there are serious potential sequelae if one MC twin fetus dies. The fetal body, cord, and portion of the placenta previously perfused by the dying fetus now have zero blood pressure, and the surviving twin may acutely hemorrhage into these zones via interfetal vascular connections, suffering catastrophic hypotension, and ischemia. In the second trimester, the skin and bowel are affected (aplasia cutis and jejunal atresia), whereas in the third trimester, cystic encephalomalacia is common (Weig et al, 1995). Similar considerations apply to ill-considered attempts at selective termination of an anomalous fetus of an MC pair; appropriate care must be taken to isolate the two circulations during the termination procedure.

**Twin Reversed Arterial Perfusion**

In twin reversed arterial perfusion, a “pump twin” fetus maintains an “acardiac” fetus as a passive tissue culture. In so doing, the pump twin may develop high-output cardiac failure. In addition, the pump twin receives back from the acardiac fetus stale blood that has not been circulated through the placenta. This blood may be toxic to the brain of the pump twin. Blood flows slowly across VV connections between the cord insertion points, and there may be thrombosis in the vessels, with potential for thromboembolism to the brain of the pump twin. Selective termination of the acardiac fetus can be achieved through obliteration of cord vessels or aorta. Long-term survival characteristics of pump twins are not well documented.

**COMPLICATIONS OF MONOAMNIONICITY**

Monoamniotic twins almost always have intertwined umbilical cords. Most investigators recommend early delivery of MA twins by cesarean section. TTT occurs in MC-MA twins but may be less common than in MC-DA twins, because the cords of MC-MA twins are often inserted close together, usually with large AA and VV anastomoses. Complications are usually asphyxial either because of tight cord intertwining or, during vaginal delivery, because the cord around the neck of twin A actually belongs to twin B.

**CONJOINED TWINNING**

Many conjoined twins are prenatally diagnosed, and the parents opt for termination. Some anatomic subtypes (thoracopagus, omphalopagus) are potentially separable. Newborn care involves maintenance of pulmonary-cardiovascular status while imaging studies are performed to determine whether the extent of interpenetration of the organ systems will permit surgical separation. In some subtypes, one twin is quite hypoplastic compared with the other. In these cases, separation may be considered in the hopes of saving one life. Several procedures, including “skin expansion,” may be required before separation surgery.

**CHROMOSOME ABNORMALITIES AND CONGENITAL ANOMALIES IN TWINS**

The maternal age effect in induction of DZ twins also affects the prevalence of Down syndrome. The risks of trisomy 21 in DZ twins, however, are higher per pregnancy than for singletons at any age (Rodis et al, 1990). Thus, separate risk figures for Down syndrome are required for DZ twins.

Several environmental and non-mendelian genetic events occurring soon after conception ensure that MZ twins are never “identical” (Rodis et al, 1990). MZ twins (whether MC or DC) may be discordant for chromosome status; this is a special form of mosaicism. Chromosomal discordance in MZ twins is the result of mitotic nondisjunction during early postzygotic cell divisions. Examples of discordant MZ twins are (1) one twin with Down

syndrome and the other normal and (2) one twin with a 46,XX or 46,XY karyotype and the other with 45,X. When a 46,XY zygote loses a Y chromosome in one cell line at an early stage in cell division, the result may be MZ twins of different sexes. This is surely a good reason for never calling MZ twins “identical.”

Because MC-MZ twins usually have interfetal vascular connections, they exchange hematopoietic stem cells throughout gestation. Therefore, results of blood lymphocyte chromosome analysis may not accurately reflect the distribution of normal and aneuploid cell lines in “fixed,” somatic cells. Such results may adequately indicate the number and types of the cell lines derived from the single zygote but are not reliable in explaining discordant phenotypes caused by uneven distribution of somatic cell lines in different organs and tissues of the twins themselves.

MZ twins may also be discordant as the result of unequal X chromosome inactivation (lyonization) and gene imprinting (Machin, 1996).

In DZ twins, blood chimerism is well known but the mechanism is less clear. Male-female pairs may show blood chimerism for male and female cell lines (as well as blood group chimerism). Because DZ (DC) twins seldom if ever have interfetal vascular anastomoses, it seems likely that hematopoietic stem cells are exchanged when the placentas are disrupted at delivery. In one study, a fertile woman had a 46,XY karyotype in 99% of lymphocytes, but 100% of the cells in fibroblasts from skin, muscle, and ovary had 46,XX chromosomes. Her male co-twin had died early in the neonatal period (Sudik et al, 2001). In a series using a sensitive fluorescent antibody technique, blood group chimerism was found in 32 of 415 twins (8%) and 12 of 57 triplets (21%) (van Dijk et al, 1996). Unusual blood group results should therefore be anticipated in DZ newborn twins and triplets.

Both MZ and DZ twins are commonly discordant for congenital malformations. In fact, it is relatively rare for MZ twins to be concordant for major malformations, with a few exceptions (anencephaly and sacral agenesis). Discordant congenital heart disease in MC-MZ twins usually involves “flow” lesions, suggesting that interfetal vascular connections are already operating during cardiogenesis, allowing interfetal transfusion and transient alterations in blood volume that affect the growth and development of the cardiac outflow tracts. This is particularly true in twins with TTT. When malformations in MZ twins are caused by aneuploidy or single genes, phenotypic severity is usually discordant between the twins, suggesting that some modifying factors also exist.

### NEONATAL FOLLOW-UP CLINICS AND MULTIPLE-FETUS PREGNANCIES

A case can be made for following all products of MFPs in the perinatal clinic. MC-MZ twins have a number of problems that involve understanding of the embryology and genetics of MZ twinning as well as the complications of MC placentation. Parents may need education on these issues, which may not have been explored during the prenatal and postnatal periods. The terms *identical* and *fraternal* can be discarded in favor of *monozygotic* and

*dizygotic*, and parents can easily learn the reasons why their MZ twins are not “identical.” MC twins are at high risk for neurodevelopmental problems secondary to transfusional events, even in the absence of classic TTT. There is anecdotal evidence that TTT recipients may die of cardiomyopathy in infancy, but no statistics are available. Few studies have followed severely growth-discordant DZ and MZ twins to early childhood, and no good prognostic advice is available about growth potential. Long-term iron level monitoring may be needed in TTT survivors.

### PARENTAL CONCERNS ABOUT ZYGOSITY

Parents are often uninformed or misinformed by their health-care providers about zygosity issues. MC twins are definitely MZ, and parents can be strongly reassured about this at the time of the twins’ birth or later at follow-up clinic. However, many parents are told that their DC twins are necessarily DZ, which is quite untrue. Like-sexed DC twins may be MZ or DZ. Screening tests could include simple blood typing. If the results fail to show dizygosity, formal DNA-based testing is needed; such testing is not, however, a medical benefit covered by most insurance carriers. About 1 in 4 like-sexed DC twin pairs is MZ. The majority of naturally conceived sets of triplets or quadruplets contain at least MZ twins. Zygosity is not just a matter of curiosity, and parents feel foolish when they do not know the zygosity of their twins. Concordance rates in MZ twins are high (on average, 60% to 70%) for a wide range of medical disorders that have at least one component of genetic predisposition. The availability of a rejection-free donor co-twin for solid organ transplantation and skin grafting is clearly important. However, the healthy member of an MZ twin pair cannot donate bone marrow for transplantation to his or her co-twin unless it is known that they are DC. If one MC-MZ twin demonstrates an early hematopoietic malignancy, the same disease will develop in the other twin sooner or later, because of prenatal transplacental transfusion of pre-mutated blood stem cells (Wiemels et al, 1999).

### POTENTIAL FOR NEONATAL RESEARCH IN TWINS

Some suggested research topics in twins include:

- Longitudinal anthropometric studies in growth-discordant twins, according to zygosity-chorionicity and cause (if known)
- Studies of cerebral and physical lateralities (“mirroring”) in MZ-DZ twins
- Long-term multidisciplinary studies of the natural history of MC twins surviving transplacental transfusional events, including TTT and its treatment, TRAP, fetal death, and selective termination
- Long-term studies of iron storage and utilization after TTT
- Long-term studies of chromosome mosaicism ratios in mosaic MZ twins
- Studies of the effects of fetal sex hormone secretions on brain and gonadal development in unlike-sexed DZ twin pairs

# Nonimmune Hydrops

Scott A. Lorch, Thomas J. Mollen, and  
Roberta A. Ballard

An infant with *hydrops* has abnormal accumulation of excess fluid. The condition varies from mild, generalized edema to massive edema, with effusions in multiple body cavities and with peripheral edema so severe that the extremities are fixed in extension. Severely hydropic fetuses may die in utero; if delivered alive, they may die in the neonatal period from the severity of their underlying disease or from severe cardiorespiratory failure.

The first description of a hydropic newborn, in a twin gestation, appeared in 1609. In 1892, Ballantyne suggested that the finding of hydrops was an outcome for many different causes, in contrast to the belief at that time that hydrops was a single entity. Potter (1943) first distinguished between hydrops secondary to erythroblastosis fetalis and nonimmune hydrops, by describing a group of infants with generalized body edema who did not have hepatosplenomegaly or abnormal erythropoiesis. His description of more than 100 cases of hydrops included two sets of twins in which one of the infants was hydropic and the other was not, thus presenting the first description of twin-twin transfusion syndrome. With the nearly universal use of anti-D globulin and refinement of the schedule and doses for its administration, the occurrence of immune-mediated hydrops has steadily declined. Later studies have suggested that immune-mediated causes account for only 6% to 10% of all cases of hydrops (Heinonen et al, 2000; Machin, 1989). The reported incidence of nonimmune hydrops in the general population has been highly variable, ranging from 6 per 1000 pregnancies in a high-risk referral clinic in the United Kingdom between 1993 and 1999 (Sohan et al, 2001) to 1 in 4000 pregnancies (Norton, 1994); other published rates are 6 per 1000 pregnancies (Santolaya et al, 1992), 1.3 per 1000 pregnancies (Wafelman et al, 1999), and 1 per 1700 pregnancies (Heinonen et al, 2000). However, all of the published studies come from single institutions, with the at-risk populations ranging from that of a high-risk pregnancy clinic to infants in a neonatal intensive care unit (NICU). No study yet published has monitored all pregnant women in one geographic area to calculate the true population incidence of nonimmune hydrops. Geography also affects the incidence; several causes of nonimmune hydrops, such as  $\alpha$ -thalassemia, are more common in certain areas of the world. Finally, the incidence of nonimmune hydrops may be rising because of the more routine use of ultrasound investigation in the late first trimester of pregnancy (Iskaros et al, 1997).

## ETIOLOGY

Nonimmune hydrops has been associated with a wide range of conditions (Table 8–1). In many of these conditions, edema formation results from one of the following possible processes:

- Elevated central venous pressure, in which the cardiac output is less than the rate of venous return
- Anemia, resulting in high-output cardiac failure
- Decreased lymphatic flow
- Capillary leak

The actual pathophysiology of hydrops for many of the conditions in Table 8–1, however, is still not understood.

The most common causes of nonimmune hydrops are chromosomal, cardiovascular, thoracic, infectious, and related to twinning (Wilkins, 1999). As with reported incidence rates, the relative contribution of these causes varies from study to study. Those studies that focus on early fetal presentation of hydrops (postconceptual age of less than 24 weeks) have found that chromosomal abnormalities, such as Turner syndrome and trisomies 13, 18, and 21, are the causes of 32% to 78% of all cases of hydrops (Boyd and Keeling, 1992; Heinonen et al, 2000; Iskaros et al, 1997; McCoy et al, 1995; Sohan et al, 2001). For infants whose hydrops becomes evident after 24 weeks of postconceptual age, cardiovascular and thoracic causes are most prevalent, with rates ranging between 30% and 50% (Machin, 1989; McCoy et al, 1995; Sohan et al, 2001). Studies from Asia have noted a higher percentage of cases from hematologic causes, probably because of the higher rates of  $\alpha$ -thalassemia in the population of that continent (Lin et al, 1991; Nakayama et al, 1999).

The percentage of infants with “idiopathic” hydrops, or hydrops of unknown etiology, varies from 5.2% to 50%, depending on the ability of the clinicians to complete their diagnostic evaluation (Heinonen et al, 2000; Iskaros et al, 1997; Machin, 1989; McCoy et al, 1995; Nakayama et al, 1999; Santolaya et al, 1992; Sohan et al, 2001; Wafelman et al, 1999; Wy et al, 1999). Yaegashi and associates (1998) used enzyme-linked immunosorbent assay (ELISA) and polymerase chain reaction (PCR) techniques to improve the detection of parvovirus infection. In both their own institution, and in eight other series of patients, these investigators found evidence of parvovirus infection in 15% to 19% of all infants previously diagnosed with “idiopathic” hydrops. It is likely that, as we improve the understanding of and testing for many of the conditions listed in Table 8–1, the number of infants diagnosed with “idiopathic” nonimmune hydrops will continue to decline.

## PATHOPHYSIOLOGY

### Normal Fluid Homeostasis

Abnormal body fluid homeostasis is the underlying cause of edema, whether local or generalized. To understand the pathogenesis of hydrops, the clinician must consider the forces underlying normal fluid homeostasis. The regulation of net fluid movement across a capillary membrane depends

TABLE 8-1

**Conditions Associated with Hydrops Fetalis**

Hemolytic anemias	Alloimmune, Rh, Kell, c α-chain hemoglobinopathies (homozygous α-thalassemia) Red blood cell enzyme deficiencies (glucose phosphate isomerase deficiency, glucose-6-phosphate dehydrogenase)
Other anemias	Fetomaternal hemorrhage Twin-twin transfusion
Cardiac conditions	Premature closure of foramen ovale Ebstein anomaly Hypoplastic left or right heart Subaortic stenosis with fibroelastosis Cardiomyopathy, myocardial fibroelastosis Atrioventricular canal Myocarditis Right atrial hemangioma Intracardiac hamartoma or fibroma Tuberous sclerosis with cardiac rhabdomyoma
Cardiac arrhythmias	Supraventricular tachycardia Atrial flutter Congenital heart block
Vascular malformations	Hemangioma of the liver Any large arteriovenous malformation Klippel-Trenaunay syndrome
Vascular accidents	Thrombosis of umbilical vein or inferior vena cava Recipient in twin-twin transfusion
Infections	Cytomegalovirus, congenital hepatitis, human parvovirus, other viruses Toxoplasmosis, Chagas disease Coxsackie virus Syphilis Leptospirosis
Lymphatic abnormalities	Lymphangiectasia Cystic hygroma Noonan syndrome
Nervous system lesions	Multiple pterygium syndrome Absence of corpus callosum Encephalocele Cerebral arteriovenous malformation Intracranial hemorrhage (massive) Holoprosencephaly Fetal akinesia sequence
Pulmonary conditions	Cystic adenomatoid malformation of the lung Mediastinal teratoma Diaphragmatic hernia Lung sequestration syndrome Lymphangiectasia
Renal conditions	Urinary ascites Congenital nephrosis Renal vein thrombosis Invasive processes and storage disorders Tuberous sclerosis Gaucher disease Mucopolysaccharidosis Mucopolipidosis
Chromosome abnormalities	Trisomy 13, trisomy 18, trisomy 21 Turner syndrome XXXY
Bone diseases	Osteogenesis imperfecta Achondroplasia Asphyxiating thoracic dystrophy
Gastrointestinal conditions	Bowel obstruction with perforation and meconium peritonitis Small bowel volvulus Other intestinal obstructions Prune-belly syndrome

Miscellaneous	Systemic lupus erythematosus Neu-Laxova syndrome
Idiopathic	Myotonic dystrophy

on the Starling forces—first described by E.H. Starling in 1896. Flow between intravascular and interstitial fluid compartments is determined by the balance among (1) capillary hydrostatic pressure, (2) serum colloid oncotic pressure, (3) interstitial hydrostatic pressure or tissue turgor pressure, and (4) interstitial osmotic pressure, which depends on lymphatic flow. The Starling equation defines the relationship among these forces and their net effect on net fluid movement, or filtration, across a semipermeable membrane (such as the capillary membrane) as

$$\text{filtration} = K [(P_c - P_t) - R(O_p - O_t)]$$

where  $K$  = capillary filtration coefficient, representing the extent of permeability of a membrane to water and thus describing capillary integrity;  $P_c$  = capillary hydrostatic pressure;  $P_t$  = interstitial hydrostatic pressure or tissue turgor pressure;  $R$  = reflection coefficient for a solute, representing the extent of permeability of the capillary wall to that solute;  $O_p$  = plasma oncotic pressure as determined by plasma proteins and other solutes; and  $O_t$  = interstitial osmotic pressure (Fig. 8-1).

Although an abnormality of any of the components of this equation may, in theory, result in accumulation of

**FIGURE 8-1.** Starling forces and net effect on fluid homeostasis. Arrows represent net effect of movement of fluid across the capillary membrane for each factor under normal conditions.  $P_c$  = capillary hydrostatic pressure;  $P_t$  = interstitial hydrostatic pressure or tissue turgor pressure;  $O_p$  = plasma oncotic pressure as determined by plasma proteins and other solutes;  $O_t$  = interstitial osmotic pressure.

edema fluid, the fetal-placental unit presents a unique physiologic condition that effectively eliminates two of the factors, assuming unimpeded fetal-placental flow and an appropriately functioning maternal-placental interface. Because approximately 40% of fetal cardiac output is allocated to the placenta, there is rapid transport of water between fetus and mother. Any condition resulting in elevated fetal capillary hydrostatic pressure or low plasma colloid oncotic pressure would likely cause the net flow of water from fetal villi in the placenta to the maternal blood stream, where it can be effectively eliminated. This elimination of fluid would counteract the accumulation of interstitial fluid by the fetus. Although the placenta of a hydropic fetus is also edematous, these changes are believed to occur along with, and not prior to, fetal fluid accumulation.

### Derangements in Fluid Homeostasis

Diamond and coworkers (1932) suggested three possible mechanisms that might be relevant in infants with hydrops: anemia, low colloid osmotic pressure with hypoproteinemia, and congestive heart failure with hypervolemia. Others have reviewed these potential mechanisms (Phibbs, 1998), which remain among the central hypotheses addressed by investigators in this area. The causes of hydrops appear to be multifactorial, however, with mechanisms that produce elevated central venous pressure (CVP), capillary leakage, and impaired lymphatic drainage all contributing to its development.

Infants with alloimmune hydrops (and several of the nonimmune hydrops conditions as well) have significant anemia. It has been proposed that anemia leads to congestive heart failure with increased hydrostatic pressure in the capillaries, causing vascular damage that results in edema. However, the hematocrit values of infants with and without hydrops overlap significantly, suggesting that anemia alone is not the complete explanation. A rapidly lowered hemoglobin concentration results in greater cardiac output to maintain adequate oxygen delivery. This results in higher oxygen demands by the myocardium, which may be difficult to meet because of the anemia.

The hypoxic myocardium may become less contractile and less compliant, with ventricular stiffness causing increased afterload to the atria. High-output congestive heart failure may then exist, resulting in elevated CVP. Raised CVP leads to increased capillary filtration pressures and impairment of lymphatic return (Weiner, 1993). Also, reduced compliance of a right ventricle may result in flow reversal in the inferior vena cava (IVC), which may in turn cause end-organ damage to the liver, with consequent hypoalbuminemia and portal hypertension enhancing formation of both edema and ascites. Hydrops has been produced in fetal lambs (Blair et al, 1994), in which the hemoglobin content was lowered in 12 fetuses through exchange transfusion using cell-free plasma; six became hydropic. Anemia developed more rapidly with a higher CVP in the hydropic fetuses than in the fetuses without hydrops. In the most severely anemic fetuses, it is probable that decreased oxygen transport causes tissue hypoxia, which in turn increases capillary permeability to both water and protein. These changes in capillary permeability also likely contribute to the development of hydrops.

Infants who have erythroblastosis and hydrops seem to demonstrate a correlation between serum albumin concentration and the severity of hydrops (Phibbs et al, 1974). Initial therapy after birth, however, tends to raise the serum albumin value toward normal rapidly, and with diuresis, the infants have normal albumin concentrations. This finding suggests that hypoalbuminemia may be the result of dilution rather than the cause of the hydrops.

To elucidate the role of isolated hypoproteinemia in the genesis of hydrops, Moise and colleagues (1991) have induced hypoproteinemia in sets of twin fetal lambs. One twin of each set underwent serum protein reduction through repeated removal of plasma and replacement with normal saline; the other twin served as the control. Over 3 days, plasma protein concentrations were reduced by an average of 41%, with a 44% reduction in colloid osmotic pressure, in the experimental subjects. No fetuses became edematous, and total body water content values were similar in experimental and control animals. Thus, hypoproteinemia alone was not sufficient to cause hydrops fetalis over the course of the study. Transcapillary filtration probably increased with hypoproteinemia but was compensated by lymphatic return. Human fetuses with hypoproteinemia due to nephrotic syndrome or albuminuria rarely experience hydrops, further supporting the hypothesis that hypoproteinemia alone is not sufficient to cause hydrops. Hypoproteinemia may, however, lower the threshold for edema formation in the presence of impaired lymphatic return or increased intravascular hydrostatic pressures.

The most commonly diagnosed causes of nonimmune hydrops that appears in fetuses older than 24 weeks post-conceptual age are cardiac disorders. Any state in which cardiac output is lower than the rate of venous return results in an elevated CVP. Increased CVP raises capillary filtration pressures and, if high enough, restricts lymphatic return. Both of these mechanisms may then contribute to interstitial accumulation of fluid. Structural cardiac causes of elevated CVP include right-sided obstructive lesions and valvular regurgitation. The most

common single cause of nonimmune hydrops, and fortunately also the most easily reversible cause, is supraventricular tachycardia (SVT). In general, cardiac output rises with heart rate. At the increasingly high rates seen in SVT, however, cardiac output plateaus and then diminishes. The rates observed with SVT are often associated with decreased cardiac output. Impaired cardiac output results in elevated CVP, which may give rise to edema through mechanisms discussed previously (Gest, 1990). Myocardial hypoxia (most often due to severe anemia) and myocarditis (usually infectious) reduce both the contractility and compliance of the myocardium and can also cause an increase in CVP.

A fourth factor that contributes to hydrops is decreased lymph flow. If the rate of fluid filtration from plasma to tissues exceeds the rate of lymph return to the central venous system, edema and effusions may form. A structural impediment or increased CVP that opposes lymphatic return to the heart may impair lymph flow. To determine the effects of alterations in CVP on lymphatic return, Gest and colleagues (1992) applied an opposing hydrostatic pressure to the thoracic duct in fetal lambs. They inserted catheters into the thoracic ducts of 10 fetuses. Varying the height of the catheter altered the thoracic duct outflow pressure. Thoracic duct flow was nearly constant over the physiologic range of CVP, but sharply decreased at elevated pressures. Thus, lymphatic flow may be reduced or essentially blocked in pathologic states associated with elevated CVP.

## PRENATAL DIAGNOSIS

The initial presentation of fetal hydrops varies by report. Watson and Campbell (1986) found that two thirds of prenatally diagnosed cases were discovered on routine ultrasonographic examinations, and the other one third referred for evaluation because of suspected polyhydramnios. Graves and Baskett (1984) reported that hydrops was more commonly discovered after referral for polyhydramnios, fetus large for dates, fetal tachycardia, or pregnancy-induced hypertension. Despite the underlying etiology of hydrops or the clinical presentation, the prenatal diagnosis is made via the ultrasonographic finding of excess fluid in the form of ascites, pleural or pericardial effusions, skin edema, placental edema, or polyhydramnios. Several definitions for ultrasonographic diagnosis based on quantity and distribution of excess fluid have been proposed. One widely accepted set of criteria consists of the presence of excess fluid in any two of the previously listed compartments. Because this definition is based on the presence of excess fluid alone, the degree of severity is generally subjective.

Swain and colleagues (1999) outlined a multidisciplinary approach to the evaluation and management of the mother and fetus with hydrops. Table 8-2 provides recommendations for the investigation of fetal hydrops. Patient history should focus on ethnic background, familial history of consanguinity, genetic or congenital anomalies, and complications of pregnancy, including recent maternal illness and environmental exposures. Maternal disorders such as diabetes, systemic lupus erythematosus, myotonic

TABLE 8-2

**Antenatal Investigation of Fetal Hydrops**

Maternal	History, including: Age, parity, gestation Medical and family histories Recent illnesses or exposures Medications Complete blood count and indices Blood typing and indirect Coombs antibody screening Hemoglobin electrophoresis Kleihauer-Betke stain of peripheral blood Syphilis, TORCH (toxoplasmosis, other infections, rubella, cytomegalovirus, and herpes simplex), and parvovirus B19 titers Anti-Ro and anti-La, systemic lupus erythematosus preparation Oral glucose tolerance test Glucose-6-phosphate dehydrogenase, pyruvate kinase deficiency screening

dystrophy, and any type of liver disease should also be noted. Initial laboratory investigation includes blood typing and Coombs test to rule out immune-mediated hydrops. Other blood tests are a screening for hemoglobinopathies, a Kleihauer-Betke test to eliminate fetal-maternal hemorrhage, and testing for the TORCH diseases (toxoplasmosis, other infections, rubella, cytomegalovirus infection, and herpes simplex), including syphilis and parvovirus B19.

Further evaluation is directed at identifying possible causes (Forouzan, 1997). Rapid evaluation is necessary to determine whether intervention is possible and to estimate the prognosis for the fetus. Many fetal conditions, such as arrhythmias, twin-twin transfusion, large vascular masses, and congenital diaphragmatic hernias and other chest-occupying lesions, are discovered during the initial ultrasonographic evaluation (Coleman, 2002). If the

examination is not helpful in identifying a cause, ultrasonography should be repeated at a later date to reassess fetal anatomy, monitor progression of the hydrops, and evaluate the well-being of the fetus.

Fetal echocardiography should also be performed to evaluate for cardiac malformations and arrhythmia. Amniotic fluid can be obtained for fetal karyotyping, cultures, and lecithin to sphingomyelin ratio to assess lung maturity. Fetal blood sampling allows for other tests, such as a complete blood cell count, routine chemical analyses, karyotyping, bacterial and viral cultures, metabolic studies, and serum immunoglobulin measurements.

**PRENATAL MANAGEMENT**

The goals of antenatal evaluation of fetal hydrops depend on the underlying cause. In diagnoses in which therapy is futile, the goal is to avoid unnecessary invasive testing and cesarean section. The prognosis should be discussed frankly with the parents, who should be given the option of terminating the pregnancy. If the underlying cause is amenable to fetal therapy, the risks and benefits of such therapy, as well as the warning that diagnostic error is possible, should be discussed with the family.

SVT is the most common known cause of nonimmune hydrops and is also the most amenable to treatment (Newburger, 1979). Usually, the mother is given antiarrhythmic agents, and the fetus is monitored closely for resolution of the SVT. Digoxin is most commonly administered, although quinidine, procainamide, or other drugs may be used. Transplacental transfer of digoxin may be impaired in the setting of hydrops. In extreme circumstances, such as fetal tachyarrhythmia refractory to maternal treatment, direct fetal administration of antiarrhythmic agents via percutaneous umbilical blood sampling (PUBS), although untested and highly risky, has met with some success.

If anemia is the cause of hydrops, transfusions of packed red blood cells may be administered to the fetus. Often a single transfusion reverses the edema, although serial transfusions may be necessary. Parvovirus B19 (Anand, 1987) and fetal-maternal hemorrhage are examples of diagnoses amenable to this therapy. Other diagnoses involving anemias that are refractory to transfusions, such as  $\alpha$ -thalassemia, may require neonatal stem cell transplantation. Transfusions should be given, with the use of ultrasonographic guidance, into the intraperitoneal space or umbilical vein. Blood instilled into the abdominal cavity is taken up by lymphatics, but elevated CVPs present in hydropic fetuses may impair this uptake. If uptake of intraperitoneal blood is incomplete, treatment for the hydrops is less successful; degeneration of the remaining hemoglobin may create a substantial bilirubin load, necessitating phototherapy or exchange transfusion after the infant is delivered.

Fetal surgery is emerging as a promising therapy for select cases of fetal hydrops (Kitano, 1999). Fetal lung lesions such as congenital cystic adenomatoid malformation (CCAM) and pulmonary sequestration can, in the most extreme cases, result in mediastinal shift,

pulmonary hypoplasia, cardiovascular compromise, and hydrops. Adzick and colleagues (1998) reported on the outcome of 175 cases of fetal lung masses, including 134 cases of CCAM and 41 of extralobar pulmonary sequestration. The 76 fetuses with CCAM lesions without associated hydrops were all managed expectantly (maternal transport to a high-risk center, planned delivery near term, and resection in the newborn period). CCAMs frequently involute and may disappear before delivery. Thus, there were no deaths in the nonhydropic group of fetuses in this study. Twenty-five fetuses with hydrops were managed expectantly, and all 25 died before or after preterm labor at 25 to 26 weeks of gestation. These results highlight the fact that fetuses with lung lesions leading to hydrops have high mortality rates. Thirteen fetuses with CCAM and associated hydrops underwent open fetal resection or lobectomy. Eight survived and were reported as healthy at 1 to 7 years of follow-up. Maternal morbidities related to fetal intervention ranged from uterine wound infection with dehiscence to mild postoperative interstitial pulmonary edema, which was treated with diuretics.

Fetal intervention has met with some success in other diagnoses with associated hydrops. Thoracoamniotic shunts for large unicystic lesions and pleuroamniotic shunts for hydrothorax have reportedly enhanced survival in extreme cases. Similarly, in cases of massive urinary ascites, urinary diversion via peritoneal shunts has been reported but with poor long-term prognosis (Crombleholme, 1990). Finally, laser coagulation of aberrant interfetal vascular connections has resulted in the resolution of hydrops in the recipient twin in twin-twin transfusion syndrome (Milner, 1999). These studies have been promising enough to warrant a randomized controlled trial, sponsored by the National Institutes of Health (NIH), comparing this intervention with conservative management strategies such as serial amnioreduction.

In cases in which the cause can be corrected by appropriate care at the time of delivery, such as elimination of a chorioangioma, and in cases in which no cause can be ascertained, close observation for fetal demise is the focus of prenatal management. Many cases of nonimmune hydrops manifest in the third trimester as preterm labor. It is difficult to decide whether to attempt tocolysis and delay delivery so as to allow the potentially beneficial administration of steroids before birth or to deliver the fetus immediately. If tocolysis is possible, expectant management should include usual biophysical testing, although fetal decompensation may be difficult to measure. Abnormal fetal heart tracings, oligohydramnios, decreased fetal movement, and poor fetal tone are all ominous signs. There is no indication to prolong pregnancy beyond attainment of a mature lung profile unless available evidence indicates improvement or resolution of the hydrops.

## NEONATAL EVALUATION

Table 8–3 summarizes the diagnostic evaluations recommended for newborn infants with nonimmune hydrops of unknown cause.

**TABLE 8–3**

### Diagnostic Evaluation of Newborns with Nonimmune Hydrops

System	Type of Evaluation
Cardiovascular Pulmonary	Echocardiogram, electrocardiogram Chest radiograph, pleural fluid examination
Hematologic	Complete blood cell count, differential platelet count, blood type and Coombs test, blood smear for morphologic analysis
Gastrointestinal	Abdominal radiograph, abdominal ultrasonography, liver function tests, peritoneal fluid examination, total protein and albumin levels
Renal	Urinalysis, blood urea nitrogen and creatinine measurements
Genetic	Chromosomal analysis, skeletal radiographs, genetic consultation
Congenital infections	Viral cultures or serologic testing, including TORCH (toxoplasmosis, other infections, rubella, cytomegalovirus, and herpes simplex) agents and parvovirus
Pathologic	Complete autopsy, placental examination

## Intensive Care of the Infant with Hydrops Fetalis

After successful resuscitation, including intubation, administration of surfactant, and placement of umbilical catheters, the clinical management can address both the cause and the complications of hydrops. Morbidity and mortality may result from the hydropic state, the underlying conditions giving rise to hydrops, or both. A hydropic fetus who is delivered prematurely is subject to the additional complications of prematurity. If there is massive ascites or pleural effusions, initial resuscitation may require thoracentesis or tapping of the ascites. Because of pulmonary edema, hydropic infants are susceptible to pulmonary hemorrhage and require high levels of positive end-expiratory pressure (PEEP).

## Respiratory Management

Virtually all infants with hydrops require mechanical ventilation because of pleural and peritoneal effusions, pulmonary hypoplasia, surfactant deficiency, pulmonary edema, poor chest wall compliance due to edema, or persistent pulmonary hypertension of the newborn. The presence of persistent pleural effusions may necessitate placement of chest tubes. Ascites may also compress the diaphragm and impair lung expansion. Breath sounds, chest movement, blood gas levels, and radiographs must all be monitored frequently, so that ventilator support can be reduced in response to improvements in lung compliance

and water clearance. Pneumothoraces and pulmonary interstitial emphysema remain potential complications as long as ventilator support is continued. Infants who need a prolonged course of ventilation, particularly those born prematurely, may have bronchopulmonary dysplasia. Chronic lung disease results in a longer and more complicated hospital course and contributes to the late mortality of hydrops.

### Fluid and Electrolyte Management

A primary goal of fluid management is resolution of the hydrops itself. Maintenance fluids should be restricted, with volume boluses given only in response to clear signs of inadequate intravascular volume. The hydropic newborn has not only an excess of free extracellular water but also an excess of sodium. Fluids given during resuscitation further increase the amount of water and sodium that must be removed during the immediate neonatal period. Initial maintenance fluids should not contain sodium. Serum and urine sodium levels, urine volume, and daily weights should be monitored carefully to guide administration of fluids and electrolytes. Urinary sodium levels may help differentiate between hyponatremia due to hemodilution and that due to urinary losses.

### Cardiovascular Management

Shock may be a prominent feature of patients with hydrops. Hydropic infants may have hypovolemia as a result of capillary leakage, poor vascular tone, and impaired myocardial contractility from hypoxia or infection, impaired venous return due to shifting or compression of mediastinal structures, or pericardial effusion. Adequate intravascular volume must be maintained, and correctable causes of impaired venous return should be addressed. Peripheral perfusion, heart rate, blood pressure, and acid-base status should be monitored carefully.

### CLINICAL COURSE AND OUTCOME

Despite improvements in diagnosis and management, mortality from nonimmune hydrops remains high. Reported survival rates for all fetuses diagnosed antenatally with hydrops range from 12% to 24% (Heinonen et al, 2000; McCoy et al, 1995; Negishi et al, 1997). Higher survival rates have been reported in infants born alive, but the highest rates are still only 40% to 50% (Wy et al, 1999). Improved ultrasonography techniques and earlier testing may actually lead to lower survival rates as more first-trimester infants are diagnosed with hydrops. These infants are more likely to have chromosomal abnormalities that are incompatible with survival, but were previously not included in populations of hydropic fetuses. The best predictor of survival is the cause of the hydrops. Highest survival rates are seen in infants with parvovirus infection, chylothorax, or SVT. The lowest survival rates are for hydrops from chromosomal cause, although the figures may be biased because a significant number of the pregnancies in such cases are terminated (Heinonen et al, 2000; Sohan et al, 2001).

Carlton and coworkers (1989) reported on a group of 36 infants with nonimmune hydrops and noted that 90% of the infants who died within 24 hours had pleural effusions, compared with only 50% of those who survived. More than one third of the infants in this study required thoracentesis in the delivery room to aid in lung expansion. All of the infants who lived more than 24 hours were treated with mechanical ventilation and received supplemental oxygen. They needed ventilation for an average of 11 days (range 2 to 48 days). Most hydropic infants lose a minimum of 15% of their birth weight, and some lose as much as 30%. Ordinarily, diuresis begins on the second or third day after birth and continues for a period of 2 to 4 days. Once the edema has resolved, the infants have normal levels of circulating protein and eventually recover from their apparent capillary leak syndrome. No specific management strategies during the neonatal period, such as the use of high-frequency oscillatory ventilation, have been shown to improve outcome, although the published studies are small and not powered sufficiently to detect small differences in survival (Wy et al, 1999).

For infants who survive the immediate neonatal period, long-term outcomes appear to be excellent. Non-immune hydrops by itself does not seem to lead to residual developmental delay. A small study from Japan found that 13 of 19 surviving infants with nonimmune hydrops had normal development at 1 to 8 years of age (Nakayama et al, 1999). The six infants with mild or severe delays in this study had other morbidities, such as extreme prematurity, structural cardiac lesions, or chromosomal anomalies. Thus, long-term morbidities from nonimmune hydrops appear to result from the underlying cause of the hydrops as well as from complications arising immediately after delivery.

# MATERNAL HEALTH AFFECTING NEONATAL OUTCOME

Editor: ROBERTA A. BALLARD

## CHAPTER 9

### Endocrine Disorders in Pregnancy

Ramen Chmait and Thomas R. Moore

#### DIABETES IN PREGNANCY

Currently, 17 million people in the United States have some form of diagnosed diabetes. Alarming, 2002 data indicate that new cases of type 2 diabetes are occurring at an increasing rate among American Indian, African American, and Hispanic and Latino children and adolescents (National Institute of Diabetes, 2002). Continued immigration among populations with high rates of type 2 diabetes and the effects of changes in diet (increases in number of calories and fat content) and lifestyle (sedentary) portend marked rises in the percentage of patients with preexisting diabetes who will become pregnant in the future. The epidemic of childhood obesity currently under way in the United States will lead to a sharp rise in childhood and adolescent diabetes over the next two decades. This trend will have a profound effect on obstetrics and pediatric practice in the future. Expanded efforts to reach the populations at risk are necessary if a significant increase in maternal and newborn morbidity is to be avoided (Persson and Hanson, 1998).

Depending on the population surveyed, abnormalities of glucose regulation occur in 3% to 8% of pregnant women. Although more than 80% of this glucose intolerance arises only during pregnancy (gestational diabetes) and involves relatively modest episodes of hyperglycemia, the attendant fetal and newborn morbidity is disproportionate. Compared with weight-matched controls, infants of diabetic mothers (IDMs) have double the risk of serious birth injury, triple the likelihood of cesarean section, and quadruple the incidence of admission to a newborn intensive care unit. Studies indicate that the magnitude of risk of these maloccurrences is proportional to the level of maternal hyperglycemia. Therefore, to some extent, the excessive fetal and neonatal morbidity of diabetes in pregnancy is preventable or at least reducible through meticulous prenatal and intrapartum care.

#### Maternal-Fetal Metabolism in Normal Pregnancy and Diabetic Pregnancy

##### Normal Maternal Glucose Regulation

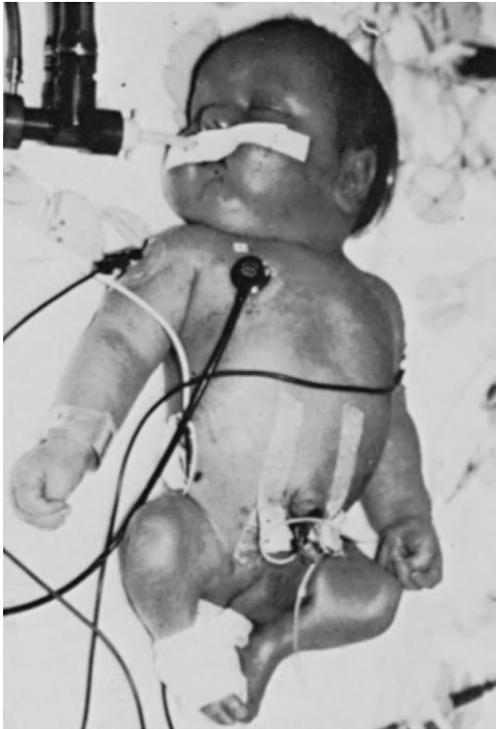

With each meal, a complex combination of maternal hormonal actions, including the secretion of pancreatic insulin, glucagon, somatomedins, and adrenal catecholamines, ensures an ample but not excessive supply of glucose to the mother and fetus during pregnancy. The key effects of pregnancy on maternal metabolic regulation are as follows:

- Because the fetus continues to draw glucose from the maternal blood stream across the placenta even during periods of fasting, the tendency to maternal hypoglycemia between meals becomes increasingly marked as pregnancy progresses and fetal glucose demand grows.
- Placental steroid and peptide hormone production (estrogens, progesterone, and chorionic somatomammotropin) rises linearly throughout the second and third trimesters, resulting in a progressively increasing tissue resistance to maternal insulin action.
- Progressive maternal *insulin resistance* requires a significant augmentation in pancreatic insulin production (more than twice nonpregnant levels) during feeding to maintain euglycemia. Twenty-four hour mean insulin levels are 30% higher in the third trimester than in the nonpregnant state.
- If pancreatic insulin output is not adequately augmented, maternal hyperglycemia and then fetal hyperglycemia result. The severity of hyperglycemia and its timing depend on the relative inadequacy of insulin production.

#### Fetal Effects of Maternal Hyperglycemia

##### Congenital Anomalies

A major threat to the IDM is the possibility of a life-threatening structural anomaly. In the normoglycemic pregnancy, the risk of a major birth defect is 1% to 2%. Among women with pregestational diabetes, the risk of a fetal structural anomaly is fourfold to eightfold higher (Fig. 9-1). The typical defects and their frequency of occurrence noted in a prospective study of infants with major malformations are listed in Table 9-1. The majority of lesions involve the central nervous and cardiovascular systems, although other series have reported an excess of genitourinary and limb defects as well (Cousins, 1991).

**FIGURE 9-1.** Newborn with caudal regression syndrome, macrosomia, and respiratory distress. The mother had type 1 diabetes and a glycosylated hemoglobin (HbA<sub>1c</sub>) concentration of 13.5% when first seen for prenatal care at 12 weeks of gestation. (From Creasy RK, Resnik R [eds]: *Maternal-Fetal Medicine: Principles and Practice*, 2nd ed. Philadelphia, WB Saunders, 1989.)

There is no increase in birth defects among offspring of diabetic fathers, nondiabetic women, or women in whom gestational diabetes develops after the first trimester. These findings suggest that glycemic control during embryogenesis is a critical factor in the genesis of diabetes-associated birth defects. In a study by Miller and colleagues (1981), the frequency of congenital anomalies was proportional to the maternal glycohemoglobin (HbA<sub>1c</sub>) value in the first trimester (rate of anomalies 3.4% with HbA<sub>1c</sub> <8.5%, and 22.4% with HbA<sub>1c</sub> >8.5%). Lucas and associates (1989) reported a similar experience with 105

diabetic patients, finding an overall malformation rate of 13.3%. The risk of delivering a malformed infant, however, was nil for a woman with an HbA<sub>1c</sub> value of less than 7.1%, 14% with an HbA<sub>1c</sub> value of 7.2% to 9.1%, 23% with an HbA<sub>1c</sub> value of 9.2% to 11.1%, and 25% with an HbA<sub>1c</sub> value of higher than 11.2%.

### Pathogenesis

The specific mechanisms by which hyperglycemia disturbs embryonic development are incompletely elucidated, but reduced levels of arachidonic acid and *myo*-inositol and accumulation of sorbitol and trace metals in the embryo have been demonstrated in animal models (Pinter et al, 1986). Fetal hyperglycemia may promote excessive formation of oxygen radicals in the mitochondria of susceptible tissues, leading to the formation of hydroperoxides, which inhibit prostacyclin. The resulting overabundance of thromboxanes and other prostaglandins may then disrupt vascularization of developing tissues. In support of this theory, the addition of prostaglandin inhibitors to mouse embryos in culture medium prevents glucose-induced embryopathy.

### Prevention

Because the critical period for teratogenesis is the first 3 to 6 weeks after conception, normal glycemic control must be instituted before pregnancy to prevent these birth defects. Several clinical trials of meticulous preconception glycemic control in women with diabetes have demonstrated malformation rates equivalent to those in the general population (Fuhrmann et al, 1983). The threshold level of glycemic control, as evidenced by the HbA<sub>1c</sub> value, necessary to normalize a patient's risk of congenital anomalies appears to be a near-normal value. Any elevation of the HbA<sub>1c</sub> above normal increases the risk of teratogenesis proportionately.

### Macrosomia

Fetal overgrowth is a major problem in pregnancies complicated by diabetes, leading to unnecessary cesarean sections and potentially avoidable birth injuries. A 1992 study of birth weights in the previous 20 years indicated that 21% of infants with birth weights of 4540 g or greater were born to mothers who were glucose intolerant, a rate clearly disproportionate to the only 2% to 5% of gravidas with some form of diabetes (Shelley-Jones et al, 1992). Thus the problem of abnormal fetal growth in diabetic pregnancy remains an important clinical challenge.

Defined variously as birth weight above the 90th percentile for gestational age or birth weight greater than 4000 g, *macrosomia* occurs in 15% to 45% of diabetic pregnancies. Excessive fetal size contributes to a greater frequency of intrapartum injury (shoulder dystocia, brachial plexus palsy, and asphyxia). Macrosomia is also a major factor in the higher rate of cesarean delivery among diabetic women. Because the risk of macrosomia is fairly constant for all classes of diabetes, it is likely that first-trimester metabolic control has less effect on fetal growth than glycemic regulation in the second and third trimesters.

**TABLE 9-1**

#### Congenital Malformations in Infants of Insulin-Dependent Diabetic Mothers

Anomaly	Appropriate Risk Ratio	Percent Risk
All cardiac defects	18×	8.5
All central nervous system anomalies	16×	5.3
Anencephaly	13×	
Spina bifida	20×	
All congenital anomalies	8×	18.4

Data from Becerra et al (1990).

### Growth Dynamics

The macrosomic IDM does follow a unique pattern of in utero growth compared with fetuses in euglycemic pregnancies. During the first and second trimesters, differences in size between diabetic and nondiabetic fetuses are usually undetectable with ultrasound measurements. After 24 weeks, however, the growth velocity of the IDM fetus's abdominal circumference typically begins to rise above normal (Ogata et al, 1980). Reece and colleagues (1990) have demonstrated that the IDM fetus has normal head growth, despite even marked degrees of hyperglycemia. Landon and coworkers (1989) have reported that although head growth and femur growth of IDM fetuses were similar to those of normal fetuses, abdominal circumference growth significantly exceeded that of controls beginning at 32 weeks (abdominal circumference growth in IDM fetuses is 1.36 cm/week, versus 0.901 cm/week in normal subjects).

Morphometric studies of the IDM newborn indicate that the greater growth of the abdominal circumference is due to deposition of fat in the abdominal and interscapular areas. This central deposition of fat is a key characteristic of diabetic macrosomia and underlies the pathology associated with vaginal delivery in these pregnancies. Acker and colleagues (1986) showed that although the incidence of shoulder dystocia is 3% among infants weighing more than 4000 g, the incidence in infants from diabetic pregnancies who weigh more than 4000 g is 16%.

### Childhood Effects

Higher growth velocity, begun in fetal life during a pregnancy complicated by diabetes, may extend into childhood and adult life. Silverman and coworkers (1995) reported follow-up of IDMs through age 8 years in which half the infants weighed more than the 90th percentile for gestational age at birth. By age 8 years, approximately half of the IDMs weighed more than the heaviest 10% of the nondiabetic children. The asymmetry index was 30% higher in diabetic offspring than the controls by age 8 years. These investigators also showed that diabetic offspring have permanent derangement of glucose-insulin kinetics, resulting in a higher incidence of impaired glucose tolerance.

### Pathophysiology

The pathophysiology of excessive fetal growth is complex and reflects the delivery of an abnormal nutrient mixture to the fetoplacental unit, regulated by an abnormal confluence of growth factors. Pedersen (1952) hypothesized that maternal hyperglycemia stimulates fetal hyperinsulinemia, which in turn mediates acceleration of fuel utilization and growth. The features of the abnormal growth in diabetic pregnancy include excessive adipose deposition, visceral organ hypertrophy, and acceleration of body mass accretion (Ogata et al, 1980).

Data from the Diabetes in Early Pregnancy (DIEP) project suggest that maternal metabolic control is a critical factor leading to fetal macrosomia (Jovanovic-Peterson et al, 1991). In this study, in which meticulous glycemic care was maintained in early pregnancy and beyond, fetal weight did not correlate significantly with fasting glucose

levels. During the second and third trimesters, however, *postprandial* blood glucose levels were strongly predictive of both birth weight and the overall percentage of macrosomic infants. With postprandial glucose values averaging 120 mg/dL, approximately 20% of infants were macrosomic; a 30% rise in postprandial levels to 160 mg/dL resulted in a predicted percentage of macrosomia of 35%.

The Pedersen hypothesis presumes that abnormal fuel milieu in the maternal blood stream is reflected contemporaneously in the fetal compartment: *Maternal hyperglycemia = fetal hyperglycemia*. Studies by Hollingsworth and Cousins (1981) have confirmed much of Pedersen's hypothesis and note the following features of normal pregnancy:

- Maternal fasting blood glucose levels decline from about 85 mg/dL to about 75 mg/dL. Mean blood glucose also declines.
- At night, maternal glucose levels drop markedly as the fetus continues to draw glucose stores from the maternal circulation.
- Postprandial peaks in maternal blood glucose rarely exceed 120 mg/dL at 2 hours or 130 mg/dL at 1 hour.
- If maternal glucose levels surge excessively after a meal, the consequent fetal hyperglycemia is accompanied by fetal pancreatic beta-cell hyperplasia and hyperinsulinemia.
- Fetal hyperinsulinemia, lasting only episodically for 1 to 2 hours, has detrimental consequences to fetal growth and well-being, in that it (1) promotes storage of excess nutrients, resulting in macrosomia, and (2) drives catabolism of the oversupply of fuel, using energy and depleting fetal oxygen stores.
- Episodic fetal hypoxia stimulated by episodic maternal hyperglycemia leads to an outpouring of adrenal catecholamines, which in turn causes hypertension, cardiac remodeling, and cardiac hypertrophy.

### Prevention of Macrosomia

Because macrosomic fetuses are at an increased risk for immediate complications related to birth injury as well as for potential long-term consequences such as late childhood obesity and insulin resistance, measures for prevention of macrosomia have been recommended. As described previously, fetal hyperinsulinemia, which acts as a fetal growth factor, occurs in response to fetal hyperglycemia, which in turn reflects the maternal hyperglycemic condition. Therefore, measures that promote consistent maternal euglycemia may prevent macrosomia. Several prospective trials have shown that strict maternal glycemic control utilizing insulin and dietary therapy and fastidious blood glucose monitoring can reduce the incidence of macrosomia (Coustan and Lewis, 1978, Langer et al, 1994; Thompson et al, 1990). Langer and associates (1994) compared outcomes of conventional management (four blood glucose measurements a day) of intensely monitored pregnancies (seven blood glucose measurements a day) in which fasting blood glucose values were maintained between 60 and 90 mg/dL and 2-hour postprandial values at less than 120 mg/dL, and of control subjects without diabetes. The rate of infants born weighing more than 4000 g was 14% in the conventionally managed

group, 7% in the intensely managed group, and 8% in nondiabetic controls. Similarly, the rate of shoulder dystocia was 1.4% in the conventionally managed group, 0.4% in the intensely managed group, and 0.5% in the control group. Thus, like the reduction of congenital anomalies in diabetic mothers by means of first-trimester euglycemia, strict glycemic control in the second and third trimesters may reduce the fetal macrosomia rate to near baseline.

### Fetal Hypoxic Stress

As previously noted, episodic maternal hyperglycemia promotes a fetal catabolic state in which oxygen depletion occurs. Several fetal metabolic adaptive responses to this episodic hypoxia occur. For example, the drop in fetal oxygen tension causes stimulation of erythropoietin, red cell hyperplasia, and elevation in fetal hematocrit. Polycythemia may lead to poor circulation and postnatal hyperbilirubinemia. Profound episodic hyperglycemia in the third trimester causing severe fetal hypoxic stress has been theorized as the cause of sudden intrauterine fetal demise in poorly controlled diabetic women.

## Classifying and Diagnosing Diabetes in Pregnancy

The classification system for diabetes in pregnancy recommended by White has been replaced by a scheme based on the pathophysiology of hyperglycemia and developed by the National Diabetes Data Group (NDDG) in 1979. The types are summarized in Table 9–2. This nomenclature is useful because it categorizes patients according to the underlying pathogenesis of their diabetes—insulin-deficient (type 1) and insulin-resistant (type 2 and gestational). One must remember that the diagnosis *gestational diabetes* applies to any woman who is found to have hyperglycemia

during pregnancy. A certain percentage of such women actually have type 2 diabetes, but the diagnosis cannot be confirmed until postpartum testing.

### Pregestational Diabetes

Patients with type 1 diabetes (formerly termed “juvenile-onset diabetes”) typically present with hyperglycemia, ketosis, and dehydration in childhood or adolescence. Often the diagnosis is made during a hospital admission for diabetic ketoacidosis and coma. Rarely the diagnosis is first made during pregnancy. It is not unusual for women tentatively diagnosed with gestational diabetes to be found to have overt diabetes after delivery. The diagnosis of type 2 diabetes in nonpregnant subjects is made using the 75-g, 2-hour glucose tolerance test (GTT). Diagnostic criteria are listed in Table 9–3.

### Gestational Diabetes

*Gestational diabetes* (GDM) is defined as glucose intolerance that begins or is first recognized during pregnancy (American Diabetes Association, 2002). Almost uniformly, GDM arises from significant maternal insulin resistance, a state similar to type 2 diabetes. Indeed, and in many cases, GDM is simply preclinical type 2 diabetes unmasked by the hormonal stress imposed by the pregnancy. Although GDM complicates no more than 2.5% of pregnancies in the United States (>135,000 cases annually) (Engelgau et al, 1995), the prevalence of GDM in specific populations varies from 1% to 14% (American Diabetes Association, 2002). Clinical recognition of GDM is important because therapy—including medical nutrition therapy, insulin when necessary, and antepartum fetal surveillance—can reduce the well-described perinatal morbidity and mortality associated with GDM.

Traditionally, universal screening for GDM has been recommended (Metzger, 1991). However, both the Fourth International Workshop-Conference on Gestational Diabetes and the American College of Obstetricians and Gynecologists have now indicated that either a risk-factor approach or universal screening can be considered (American College of Obstetricians and Gynecologists,

TABLE 9–2

#### Classification of Diabetes Mellitus

Type	Old Nomenclature	Clinical Features
Type I	Juvenile-onset diabetes	Insulin-deficient, ketosis-prone Virtually all patients with type I diabetes are insulin-dependent
Type II	Adult-onset diabetes	Insulin-resistant, not ketosis-prone Few patients with type II diabetes are truly insulin-dependent
Gestational		Occurs in and resolves after pregnancy Insulin-resistant, not ketosis-prone

TABLE 9–3

#### Criteria for the Diagnosis of Type II Diabetes with 75-g Glucose Tolerance Test\*

Diagnosis	Venous Plasma Glucose Level (mg/dL)	
	Fasting	2-Hour
Normal	<140	<200
Impaired glucose tolerance	<140	>140 and <200
Diabetes	≥140	≥140

\*Note: Diagnosis of non–insulin-dependent diabetes mellitus after pregnancy requires a 1-hour value of >200 mg/dL in addition to abnormal fasting and 2-hour values.

2001; Metzger and Coustan, 1998). This recommendation is based on the findings of Sermer and colleagues (1994), who reported the results of screening Canadian women at 26 weeks of gestation with the 100-g, 3-hour GTT. They identified several risk factors as significantly increasing the likelihood of GDM, among which were maternal age of 35 years or more, body mass index (BMI) higher than 22 kg/m<sup>2</sup>, and Asian or “other” ethnicity. Women with one or no risk factors had a 0.9% risk of GDM, whereas the risk for those with two to five factors who were diagnosed with GDM was 4% to 7%. By limiting screening for GDM to gravidas with more than one risk factor, these investigators were able to reduce testing by 34% while retaining a sensitivity rate of approximately 80% with a false-positive result rate of 13%. Thus, in patients meeting *all* of the criteria listed in Tables 9–4 and 9–5, it may be cost effective to avoid screening.

**TABLE 9–4**

### Oral Glucose Tolerance Test For Gestational Diabetes

#### Test Prerequisites

1-hr 50-g glucose challenge result >135 mg/dL  
 Overnight fast of 8-14 hours  
 Carbohydrate loading for 3 days including >150 g carbohydrate  
 Seated, not smoking during the test  
 Two or more values must be met or exceeded  
 Either a 2-hr (75-g glucose) or 3-hr (100-g glucose) test can be performed

#### Criteria for Gestational Diabetes: Venous Plasma Glucose Level

	With 100-g Glucose Load		With 75-g Glucose Load	
	mg/dL	mmol/L	mg/dL	mmol/L
Fasting value	95	5.3	95	5.3
1-hr value	180	10.0	180	10.0
2-hr value	155	8.6	155	8.6
3-hr value	140	7.8	—	—

**TABLE 9–5**

### Criteria For “Low Risk” of Gestational Diabetes (GDM)\*

Age <25 yr  
 Normal pre-pregnancy body weight  
 No first-degree relatives with diabetes  
 Not a member of an ethnic group at high risk for GDM  
 No history of GDM in prior pregnancy  
 No history of adverse pregnancy outcome

\*Note: Screening for GDM may be omitted only if *all* criteria are met.

Data from Metzger BE, Coustan DR: Summary and Recommendations of the Fourth International Workshop-Conference on Gestational Diabetes Mellitus. The Organizing Committee. Diabetes Care 21(Suppl 2):B161, 1998.

Notwithstanding these findings, multiple studies from more heterogeneous U.S. populations have demonstrated the inadequacy of GDM screening of patients with risk factors. Lavin and coworkers (1981) noted that if only those with risk factors were screened, the percentage of GDM cases detected was similar to the detection rate in those without risk factors (1.4%). A later study (Weeks et al, 1995), which assessed the effect of screening only patients with risk factors, reported that selective screening would have failed to detect 43% of cases of GDM. Moreover, 28% of the women with undiagnosed GDM would have required insulin and had a several-fold higher risk of cesarean section due to macrosomia.

Therefore, universal screening should be performed in members of ethnic groups recognized to be at higher risk for glucose intolerance during pregnancy, namely women of Hispanic, African, Native American, South or East Asian, Pacific Islands, or Indigenous Australian ancestry. For simplicity of administration, universal screening, with the possible exception of the very lowest risk category, is probably best. The universal screening method for GDM has been shown to result in earlier diagnosis and improved pregnancy outcomes, including lower rates of macrosomia and a decrease in neonatal admissions to NICUs (Griffin et al, 2000).

The timing of screening for GDM is important. Because maternal insulin resistance rises progressively during pregnancy, screening too early may miss some patients who will become glucose intolerant later. Screening too late in the third trimester may limit the time during which metabolic interventions can take place. Thus, risk factors for GDM should be assessed at the initial prenatal visit. Factors that should lead to a first-trimester glucose challenge test are listed in Table 9–6. In the remaining patients, screening should be performed with the use of 50 g of glucose at 26 to 28 weeks of gestation.

Various threshold levels for the 50-g glucose challenge are in use, including 140 mg/dL, 135 mg/dL, and 130 mg/dL. The sensitivity of the GDM testing regimen depends on the threshold value used. The most commonly utilized threshold, 140 mg/dL, detects only 80% of patients with GDM and results in requirement for a 3-hour oral GTT in approximately 10% to 15% of patients. Using a challenge threshold of 135 mg/dL improves sensitivity to more than 90% but increases the number of 3-hour oral GTTs by 42% (Ray et al, 1996). Thus, the clinician encountering a newborn with multiple stigmata of an IDM yet whose

**TABLE 9–6**

### Indications for the First-Trimester 50-g Glucose Challenge

Maternal age >25 yr  
 Previous infant >4 kg  
 Previous unexplained fetal demise  
 Previous pregnancy with gestational diabetes  
 Strong immediate family history of type II or gestational diabetes  
 Obesity (>90 kg)  
 Fasting glucose level >140 mg/dL (7.8 mmol) or random glucose reading >200 mg/dL (11.1 mmol)

mother had a “negative” diabetes screening test result during pregnancy does not rule out GDM. This is also why every patient who delivered a macrosomic infant in a prior pregnancy should be screened early in all subsequent pregnancies.

Definitive diagnosis of gestational diabetes is made with a GTT. Either 100 g of glucose and 3 hours of testing, or 75 g of glucose and 2 hours of testing can be utilized. The diagnostic criteria are shown in Table 9-3. Two or more values must be met or exceeded for the diagnosis of GDM to be made. A GTT should be performed after an overnight fast and with modest carbohydrate loading before the test.

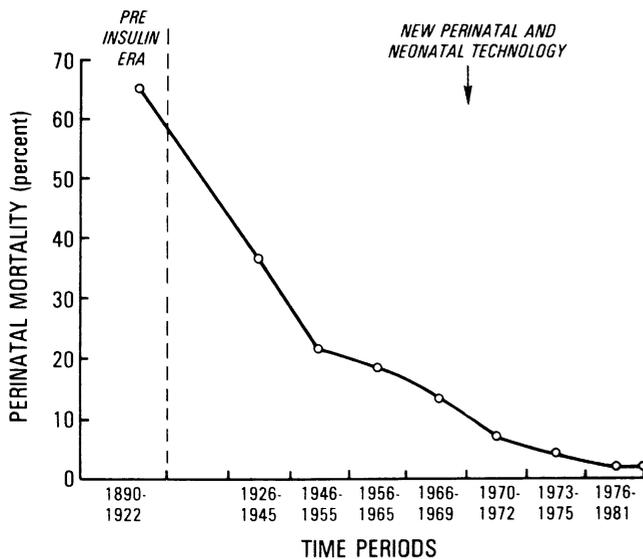

## Perinatal Complications of Diabetes During Pregnancy

### Fetal Morbidity and Mortality

#### Perinatal Mortality

Perinatal mortality in diabetic pregnancy has decreased 30-fold since the discovery of insulin in 1922 and the advent of intensive obstetric and infant care in the 1970s (Fig. 9-2). Improved techniques for maintaining maternal euglycemia have led to later timing of delivery and reduced incidence of iatrogenic respiratory distress syndrome (RDS).

Nevertheless, the currently reported perinatal mortality rates among diabetic women remain approximately twice those observed in nondiabetic women (Table 9-7). Congenital malformations, RDS, and extreme prematurity account for most perinatal deaths in contemporary diabetic pregnancy. Figure 9-3 show the different rates of RDS in diabetic and euglycemic pregnancies. In the past

**FIGURE 9-2.** Perinatal mortality rate (percentage) among infants of diabetic mothers from 1890 to 1981. Data plotted from reports of Craigin and Ryder (1916), DeLee (1920), Williams (1925), Pedersen (1977), Gabbe et al (1978), and Jorge et al (1981). (From Creasy RK, Resnik R [eds]: *Maternal-Fetal Medicine: Principles and Practice*, 2nd ed. Philadelphia, WB Saunders, 1989.)

**TABLE 9-7**

### Perinatal Mortality Rates (No. of Deaths per 100 Births) in Diabetic and Normal Pregnancies

	Mothers with Gestational Diabetes	Mothers with Pre-existing Diabetes	Normal Mothers*
Fetal mortality	4.7	10.4	5.7
Neonatal mortality	3.3	12.2	4.7
Perinatal mortality	8.0	11.6	10.4

\*California data for 1986, corrected for birth weight, sex, and race.

decade, fewer intrauterine deaths have been reported, probably reflecting more careful fetal monitoring. Nevertheless, intrapartum asphyxia and fetal demise remain persistent problems.

#### Birth Injury

Birth injury, including shoulder dystocia (Keller et al, 1991) and brachial plexus trauma, is more common among IDMs, and macrosomic fetuses are at the highest risk (Mimouni et al, 1992). *Shoulder dystocia*, defined as difficulty in delivering the fetal body after expulsion of the fetal head, is an obstetric emergency that places the fetus and mother at great risk. Shoulder dystocia occurs in 0.3% to 0.5% of vaginal deliveries among normal pregnant women; the incidence is twofold to fourfold higher in women with diabetes, probably because the hyperglycemia of diabetic pregnancy causes the fetal shoulder and abdominal widths to become massive (Nesbitt et al, 1998). Although half of shoulder dystocias occur in infants of normal birth weight (2500 to 4000 g), the incidence of shoulder dystocia is 10-fold higher (5% to 7%) among infants weighing 4000 g or more and rises to 31% for infants whose mothers are diabetic (Gilbert et al, 1999). (See also Chapter 15 for discussion of complicated deliveries and Chapter 64 for discussion of the neurologic consequences of birth injury.)

**FIGURE 9-3.** Rate of respiratory distress syndrome (RDS) versus gestational age. Improved management of maternal glycemic control permits delaying delivery until after 38 weeks of gestation, when the risk of RDS approaches that in nondiabetic pregnancy.

### Neonatal Morbidity and Mortality

(For complete discussion, see Chapter 93, on disorders of carbohydrate metabolism.)

#### **Polycythemia and Hyperviscosity**

Polycythemia (defined as central venous hemoglobin concentration >20 g/dL or hematocrit >65%) is not uncommon in IDMs and is apparently related to glycemic control. Widness and associates (1990) demonstrated that hyperglycemia is a powerful stimulus to fetal erythropoietin production, probably mediated by decreased fetal oxygen tension. Untreated, neonatal polycythemia may promote vascular sludging, ischemia, and infarction of vital tissues, including the kidneys and central nervous system.

#### **Neonatal Hypoglycemia**

The hyperinsulinemic IDM is at higher risk for low plasma glucose levels after birth. This complication is usually much milder and less common in the infant of the woman whose insulin-dependent diabetes is well controlled throughout the *entire* pregnancy and who is euglycemic during labor and delivery. Unrecognized postnatal hypoglycemia may lead to neonatal seizures, coma, and brain damage. Thus, it is imperative that the nursery receiving the IDM have a protocol for frequent monitoring of the infant's blood glucose level until metabolic stability is ensured.

#### **Hyperbilirubinemia**

The risk of hyperbilirubinemia is higher in IDMs than in normal infants. There are multiple causes of hyperbilirubinemia in IDMs, but prematurity and polycythemia are the primary contributing factors. Increased destruction of red blood cells contributes to the risks of jaundice and kernicterus. This complication is usually treated with phototherapy, but exchange transfusions may be necessary for marked bilirubin elevations.

#### **Hypertrophic and Congestive Cardiomyopathy**

In some macrosomic infants of mothers with poorly controlled diabetes, a thickened myocardium and significant septal hypertrophy have been described (Gutgesell et al, 1976). Although the prevalence of myocardial hypertrophy in IDMs may exceed 30% at birth, almost all cases have resolved by 1 year of age (Mace et al, 1979).

Hypertrophic cardiac dysfunction in a newborn IDM often leads to respiratory distress, which may be mistaken for hyaline membrane disease. IDMs with cardiomegaly may have either congestive or hypertrophic cardiomyopathy. Echocardiograms show a hypercontractile, thickened myocardium, often with septal hypertrophy disproportionate to the ventricular free walls. The ventricular chambers are often smaller than normal, and there may be anterior systolic motion of the mitral valve producing left ventricular outflow tract obstruction.

The pathogenesis of hypertrophic cardiomyopathy in IDMs is unclear, although it is recognized to be associated with poor maternal metabolic control. There is evidence that the fetal myocardium is particularly sensitive to insulin during gestation, and Susa and colleagues (1979) reported a doubling of cardiac mass in hyperinsulinemic fetal rhesus monkeys. The myocardium is known to be richly endowed with insulin receptors.

IDMs may also have *congestive* cardiomyopathy without hypertrophy. Echocardiography shows the myocardium to be overstretched and poorly contractile. This condition is often rapidly reversible with correction of neonatal hypoglycemia, hypocalcemia, and polycythemia; it responds to digoxin, diuretics, or both. In contrast, treatment of hypertrophic cardiomyopathy with an inotropic or diuretic agent tends to further decrease the size of the ventricular chambers and leads to obstruction of blood flow. Echocardiographic examination of IDMs with enlarged hearts is recommended to detect and treat clinically silent cardiomyopathy.

#### **Respiratory Distress Syndrome**

Since the 1970s, improved maternal management and better protocols for timing of delivery have resulted in a dramatic decline in the incidence of RDS from 31% to 3%. Nevertheless, respiratory dysfunction in the newborn IDM continues to be an all too common complication of diabetic pregnancy. It may be due to surfactant deficiency or to some other form of pulmonary distress. Surfactant production occurs late in diabetic pregnancies. Studies of fetal lung ion transport in the diabetic rat by Pinter and coworkers (1991) demonstrated decreased fluid clearance and lack of thinning of the lung's connective tissue in diabetics compared with controls. In humans, Kjos and associates (1990) noted *respiratory distress* in 18 of 526 infants delivered of diabetic gestations (3.4%). Surfactant-deficient airway disease accounted for less than one third of cases, with transient tachypnea, hypertrophic cardiomyopathy, and pneumonia responsible for the majority.

Thus, the near-term infant of a mother with poorly controlled diabetes is more likely to have neonatal RDS than the infant of a nondiabetic mother at the same gestational age. This circumstance further compounds the diabetic infant's metabolic and cardiovascular difficulties after birth. The nondiabetic fetus achieves pulmonary maturity at a mean gestational age of 34 to 35 weeks. By 37 weeks, more than 99% of normal newborn infants have mature lung profiles as assessed by phospholipid assays. In a diabetic pregnancy, however, it is unwise to assume that the risk of respiratory distress has passed until after 38.5 weeks of gestation (Moore, 2002). Any delivery contemplated before 38.5 weeks for other than the most urgent fetal and maternal indications should be preceded by documentation of pulmonary maturity through amniocentesis.

#### **Obstetric Complications**

Pregnancy complicated by diabetes is subject to a number of obstetric disorders, including ketoacidosis, preeclampsia, polyhydramnios, and abnormal labor, at higher rates than in nondiabetic pregnancy.

## Preeclampsia

Preeclampsia is an unpredictable multisystem disorder in which maternal neurologic, renal, and cardiovascular status can decline precipitously and that may threaten fetal health through placental ischemia and abruptio placentae. Preeclampsia is more common among women with diabetes, occurring two to three times more frequently in women with preeclampsia than in nondiabetic women (Moore et al, 1985; Sibai et al, 2000). However, the risk of developing preeclampsia is proportional to the duration of diabetes before pregnancy and the existence of nephropathy and hypertension; preeclampsia develops in more than one third of women who have had diabetes for more than 20 years. Patients with White's class B diabetes have a risk profile similar to that of nondiabetic patients, but the risk of hypertensive complications is 50% higher in women with evidence of renal or retinal vasculopathy (classes D, F, R) than in those with no hypertension. The rate of fetal death is higher in diabetic women with preeclampsia. In the diabetic patient with chronic hypertension, preeclampsia may be difficult to distinguish from near-term blood pressure elevations. The onset is typically insidious and not confidently recognized until severe.

When a patient with diabetes experiences preeclampsia, she should be evaluated for delivery. If signs of severe disease are present (e.g., blood pressure >160 mm Hg systolic/110 mm Hg diastolic, neurologic symptoms, or significant renal dysfunction), delivery should be performed promptly. In mild cases, the patient may be observed if the fetal lungs are immature. Preeclampsia after 38 weeks of gestation, however, is adequate grounds for initiating delivery.

## Polyhydramnios

*Polyhydramnios* is defined as excess amniotic fluid. The precise clinical definition varies, encompassing the recording of more than 2000 mL of amniotic fluid at delivery and various measures of amniotic fluid pocket depths as observed on ultrasonography. In practice, polyhydramnios is usually diagnosed when any single vertical pocket of amniotic fluid is deeper than 8 cm (equivalent to the 97th percentile) or when the sum of four pockets, one from each quadrant of the uterus (amniotic fluid index), exceeds approximately 24 cm (95th percentile) (Moore and Cayle, 1990). The principal causes of hydramnios in diabetic pregnancy are fetal gastrointestinal anomalies (e.g., esophageal atresia) and poor glycemic control. A rapid increase in fundal height should prompt a thorough ultrasound examination by a skilled examiner. The main clinical problems associated with hydramnios are fetal malposition and preterm labor.

Management of the patient with hydramnios is predominantly symptomatic, focused on improving glycemic control and preventing premature labor. Enhanced patient awareness of contractions and the signs and subtle sensations of preterm labor is essential.

## Management

### Preconception Management

Preconception counseling and a detailed medical risk assessment are recommended for all women with overt diabetes as well as for those with a history of gestational diabetes in a previous pregnancy. Significant impact on the maternal and neonatal complications of diabetic pregnancy cannot be realized until meticulous preconception metabolic control is achieved in all women contemplating pregnancy.

The important elements to be considered in preconception counseling of the diabetic patient are the patient's level of glycemic control; current status of the patient's retinal and renal health; and any medications being taken, especially antihypertensive or thyroid medications. A realistic assessment of the patient's risk of complications during pregnancy, including worsening of renal or ophthalmologic function, should be provided.

Preconception management should lead to a comprehensive program of glucose control. The major goals of the prepregnancy metabolic program are as follows:

- Establishing a regimen of frequent, regular monitoring of capillary blood glucose levels
- Adopting an insulin dosing regimen that results in smooth interprandial glucose profile (fasting blood glucose value 80 to 100 mg/dL, 2-hour postprandial glucose level <120 mg/dL, no reactions between meals or at night)
- Bringing HbA<sub>1c</sub> level into the normal range
- Developing family, financial, and personal resources to assist the patient if pregnancy complications require that she lose work time or assume total bed rest

This preconception care has been shown to decrease congenital anomalies and to result in fewer hospitalizations, fewer infants requiring intravenous glucose after delivery, and a substantial reduction in total costs (Herman et al, 1999).

### Prenatal Metabolic Management

The goals of glycemic monitoring, dietary regulation, and insulin therapy in diabetic pregnancy are to prevent the postnatal sequelae of diabetes in the newborn—macrosomia, shoulder dystocia, and postnatal metabolic instability. These measures must be instituted early and aggressively if they are to be effective.

### Principles of Dietary Therapy

Because women with diabetes have inadequate insulin action after feeding, the goal of dietary therapy is to avoid single, large meals and foods with a large proportion of simple carbohydrates. Three major meals and three snacks are prescribed. The use of *nonglycemic foods* that release calories into the gut slowly also improves metabolic control.

Nutritional therapy should be supervised by a trained professional who performs formal dietary assessment and counseling at several points during the pregnancy. The

dietary prescription should provide adequate quantity and distribution of calories and nutrients to meet the needs of the pregnancy and support achieving the plasma glucose targets that have been established. For obese women (BMI >30 kg/m<sup>2</sup>), a 30% to 33% restriction in caloric intake (to 25 kcal per kg actual weight per day or less) has been shown to reduce hyperglycemia and plasma triglycerides with no increase in ketonuria. Moderate restriction of dietary carbohydrate intake to 35% to 40% of calories has been shown to reduce maternal glucose levels and improve maternal and fetal outcomes (Major et al, 1998). In a non-randomized study, subjects with low carbohydrate intake (<42% of calories) led to lower requirements for insulin for glucose control as well as to significantly lower rates of macrosomia and cesarean deliveries for cephalopelvic disproportion and macrosomia.

### **Principles of Glucose Monitoring**

The availability of chemical test strips for capillary blood glucose measurements has revolutionized the management of diabetes, and their use should now be considered the standard of care for pregnancy monitoring. The discipline of measuring and recording blood glucose levels before and after meals may have the effect of improving glycemic control (Goldberg et al, 1986).

The frequency and timing of home glucose monitoring should be individualized, but *postprandial* values must be assessed because they have the strongest correlation with fetal growth (Jovanovic-Peterson et al, 1991). The Diabetes in Early Pregnancy Study found that *postprandial* glucose levels were strongly predictive of both birth weight and the overall percentage of macrosomic infants. With *postprandial* glucose values averaging 120 mg/dL, approximately 20% of infants were macrosomic; a 30% rise in *postprandial* levels to 160 mg/dL resulted in a predicted percentage of macrosomia of 35%.

Similar results were reported by de Veciana and associates (1995). Compared with the group who performed preprandial glucose monitoring, the group performing *postprandial* glucose monitoring demonstrated a greater mean change in the HbA<sub>1c</sub> value (3.0% vs. 0.6%;  $P < .001$ ), lower birth weights (3469 g vs. 3848 g;  $P = .01$ ), and lower rates of both neonatal hypoglycemia (3% vs. 21%,  $P = .05$ ), and macrosomia (12% vs. 42%;  $P = .01$ ).

A typical schedule involves performing blood glucose checks upon rising in the morning, 1 or 2 hours after breakfast, before and after lunch, before dinner, and before bedtime. The goal of *physiologic* glycemic control in pregnancy, however, is not met by simply avoiding hypoglycemia. The data summarized here regarding fetal macrosomia and postnatal morbidity emphasize the key role of excessive *postprandial* excursions in blood glucose values. Thus, close attention must be paid to both preprandial and *postprandial* glycemic profiles.

### **Principles of Insulin Therapy**

No available insulin delivery method approaches the precise secretion of the hormone from the human pancreas. The therapeutic goal of exogenous insulin therapy during

pregnancy is to achieve diurnal glucose excursions similar to those of nondiabetic pregnant women. Normal pregnant women maintain *postprandial* blood glucose excursions within a relatively narrow range (70 to 120 mg/dL). As pregnancy progresses, the fasting and between-meal blood glucose levels drop progressively lower as a result of the continual uptake of glucose from the maternal circulation by the growing fetus. Any insulin regimen for pregnant women must be designed to avoid excessive unopposed insulin action during the fasting state.

Insulin type and dosage frequency should be individualized. Use of regular insulin before each major meal helps limit *postprandial* hyperglycemia. To provide basal insulin levels between feedings, a longer-acting preparation is necessary, such as isoprotane insulin (NPH) or insulin zinc (Lente). Typical subcutaneous insulin dosing regimens are 2/3 of total insulin in the morning, of which 2/3 as intermediate-acting and 1/3 as regular insulin. The remaining 1/3 of the total insulin dose is given in the evening, with 50% as short-acting insulin prior to dinner and 50% as intermediate-acting given at bedtime.

The use of an insulin pump for type 1 diabetes mellitus during pregnancy has become more widespread (Gabbe et al, 2000). An advantage of this approach is the more physiologic insulin release pattern that may be achieved with the pump.

Ultrasonography has also been utilized to direct insulin management (Rossi et al, 2000). Kjos and coworkers (2001) showed that serial normal fetal abdominal circumference measurements may be used to avoid insulin therapy without increasing neonatal morbidity.

### **Oral Hypoglycemic Therapy**

Historically, insulin has been the mainstay of therapy for gestational diabetes because of early reports that oral hypoglycemic drugs are a potential cause of fetal anomalies and neonatal hypoglycemia. Sulfonylurea compounds have been considered contraindicated during pregnancy due to a high level of transplacental penetration and clinical reports of prolonged and severe neonatal hypoglycemia (Zucker and Simon, 1968). An increased rate of congenital malformations, particularly ear anomalies, has been reported from a small case-control study (Piacquadio et al, 1991). However, when Towner and coworkers (1995) evaluated the frequency of birth defects in patients who took oral hypoglycemic agents during the periconception period, they noted that first-trimester HbA<sub>1c</sub> level and duration of diabetes were strongly associated with fetal congenital anomalies but that use of oral hypoglycemic medications was not.

Glyburide, a second-generation sulfonylurea, has been shown to cross the placenta minimally in both laboratory studies (Elliott et al, 1994) and a large clinical trial. The prospective randomized trial, conducted by Langer and associates (2000), compared glyburide and insulin in 404 women with gestational diabetes and showed equivalently excellent maternal glycemic control and perinatal outcomes.

However, beyond this single, encouraging study, experience with glyburide during pregnancy is limited (Coetzee and Jackson, 1985; Lim et al, 1997). Chmait and Moore

(2002), reporting experience with 69 patients with gestational diabetes who were given glyburide, found a failure rate of 19% (>10% glucose values above target). Glyburide failure rate was higher in women diagnosed earlier in pregnancy (20 vs. 27 weeks;  $P < .003$ ) and whose average fasting glucose in the week prior to starting glyburide was higher (126 vs. 101 mg/dL). Until more studies of glyburide in pregnancy have been reported, the American College of Obstetricians and Gynecologists (2001) considers this agent to be experimental.

### Prenatal Obstetric Management

The overall strategy of the management of diabetic pregnancy in the third trimester involves preventing stillbirth and asphyxia and monitoring growth of the fetus to select the proper time and route of delivery to minimize maternal and infant morbidity. The first goal is accomplished by testing fetal well-being at frequent intervals, and the second through ultrasonographic monitoring of fetal size.

#### Periodic Biophysical Testing of the Fetus

A variety of biophysical tests of the fetus are available to the clinician, including fetal heart rate testing, fetal movement assessment, ultrasound biophysical scoring, and fetal umbilical Doppler studies. Most of these tests, if applied properly, can be used with confidence to provide assurance of fetal well-being while awaiting fetal maturity. They are summarized in Table 9–8.

Testing should be initiated early enough to avoid significant risk of stillbirth but not so early that the risk of a false-positive result is high. In patients with poor glycemic control or significant hypertension, testing should begin as early as 28 weeks of gestation. In lower-risk patients, most centers begin formal fetal testing by 34 weeks. Counting

of fetal movements is performed in all pregnancies from 28 weeks of gestation onward.

### Assessing Fetal Growth

Monitoring of fetal growth continues to be a challenging and highly inexact process. Although today's tools, consisting of serial plotting of fetal growth parameters, are superior to earlier clinical estimations, accuracy is still  $\pm 15\%$ . Both single and multiple longitudinal assessments of fetal size have been attempted.

#### Calculation of Estimated Fetal Weight

Several polynomial formulas using combinations of head, abdominal, and limb measurements have been proposed to predict the weight of the macrosomic fetus from ultrasonography parameters (Ferrero et al, 1994; Tongsong et al, 1994). Unfortunately, in such formulas, small errors in individual measurements of the head, abdomen, and femur are typically multiplied together. In the obese fetus, the inaccuracies are further magnified. Bernstein and Catalano (1992) observed that a significant correlation exists between the degree of error in the ultrasonographically estimated fetal weight and the percentage of body fat on the fetus ( $r = 0.28$ ;  $P < .05$ ). Perhaps this problem explains why no single formula has proved to be adequate in identifying the macrosomic fetus (Tamura et al, 1985).

Shamley and Landon (1994) reviewed the relative accuracy of the various available formulas. Approximately 75% of the fetal weight predictions were within 10% of actual birth weight, with sensitivity for detecting macrosomia varying greatly (11% to 76%). In another study, McLaren and colleagues (1995) found that 65% of weight estimates based on a simple abdominal circumference and femur length formula were within 10% of actual weight. A similar accuracy was achieved with more complex models (53% to 66% of estimates within the range).

TABLE 9–8

#### Tests of Fetal Well-Being

Test	How Often Performed	Reassuring Result	Comment
Counting of fetal movements	Every night from 28 wk	Ten movements in <60 min	Performed in all patients
Nonstress test	Twice weekly	Two heart rate accelerations in 20 min	Begin at: 28–34 wk in patients with insulin-dependent diabetes 36 wk in patients with diet-controlled gestational diabetes
Contraction stress test	Weekly	No heart rate decelerations in response to $\leq 3$ contractions in 10 min	Same as for nonstress test
Ultrasound biophysical profile	Weekly	Score of 8 in 30 min	The following findings are given 2 points each: 3 movements 1 flexion 30 sec breathing 2 cm amniotic fluid

The formula developed by Shepard and colleagues (1982), which uses biparietal diameter and abdominal circumference, is readily available in textbooks and is used most commonly in current ultrasonographic equipment software. It has accuracy levels similar to the statistics quoted.

### Serial Estimated Fetal Weight Assessments

Because prediction of fetal weight from a single set of measurements is inaccurate, serial estimates showing the trend of ultrasonographic parameters (typically made every 1.5 to 3 weeks) might theoretically offer a better estimate of actual weight percentile. A comparison of the efficacy of serial estimated fetal weight calculations to a single measurement, however, did not show better predictive accuracy. Larsen and associates (1995) reported that predictions based on the average of repeated weight estimates, on linear extrapolation from two estimates, or on extrapolation by a second-order equation fitted to four estimates were no better than the prediction from the last estimate before delivery. Similar findings (that a single estimate is as accurate as multiple assessments) were reported by Hedriana and Moore (1994).

### Choosing the Timing and Route of Delivery

Timing of delivery should be selected to minimize maternal and neonatal morbidity and mortality. Delaying delivery to as near as possible to the estimated date of confinement helps maximize cervical ripeness and improve the chances of spontaneous labor and vaginal delivery. Yet the risks of fetal macrosomia, birth injury, and fetal death rise as the due date approaches (Rasmussen et al, 1992). Although earlier delivery at 37 weeks of gestation might reduce the risk of shoulder dystocia, the higher rates of failed labor inductions and poor neonatal pulmonary status at this time must be considered. Thus, an optimal time for delivery of most diabetic pregnancies is between 38.5 and 40 weeks.

Delivery of a diabetic patient before 38.5 weeks of gestation without documentation of fetal lung maturity should be performed only for compelling maternal or fetal reasons. Fetal lung maturity should be verified in such cases from the presence of more than 3% phosphatidyl glycerol or the equivalent in amniotic fluid as ascertained from an amniocentesis specimen. After 38.5 weeks, the obstetrician can await spontaneous labor if the fetus is not macrosomic and results of biophysical testing are reassuring. In patients with gestational diabetes and superb glycemic control, continued fetal testing and expectant management can be considered until 41 weeks (Lurie et al, 1992).

Kjos and associates (1993) compared the outcomes of labor induction in gestational diabetics at 38 weeks and those of expectant management combined with fetal testing. Expectant management increased the gestational age at delivery by 1 week, but the cesarean delivery rate was not significantly different. The prevalence of macrosomic infants in the expectantly managed group (23%) was significantly greater than that in the active induction group (10%). This finding suggests that routine induction of

diabetic gravidas on or before 39 weeks of gestation does not raise the risk of cesarean section and may reduce the risk of macrosomia.

Given the previous data, the decision to attempt vaginal delivery or perform a cesarean section is inevitably based on limited data. The patient's obstetric history from previous pregnancies, the best estimation of fetal weight, the fetal adipose profile (abdomen larger than head), and results of clinical pelvimetry should all be considered. A policy of elective cesarean section for suspected fetal macrosomia (ultrasonographically estimated fetal weight of greater than 4500 g) would require 443 cesarean deliveries to avoid one permanent brachial plexus injury (Rouse et al, 1996). Most large series of diabetic pregnancies report a cesarean section rate of 30% to 50%. The best means by which this rate can be lowered is early and strict glycemic control in pregnancy. Conducting a long labor induction in the patient with a large fetus and marginal pelvis may increase rather than lower morbidity and costs.

### Intrapartum Glycemic Management

Maintenance of intrapartum metabolic homeostasis is essential to avoid fetal hypoxemia and promote a smooth postnatal transition. Strict maternal euglycemia during labor does not guarantee newborn euglycemia in infants with macrosomia and long-established islet cell hypertrophy. Nevertheless, the use of a combined insulin and glucose infusion during labor to maintain maternal blood glucose in a narrow range (80 to 110 mg/dL) during labor is common and reasonable practice. Typical infusion rates are 5% dextrose in lactated Ringer's solution at 100 mL/hr and regular insulin at 0.5 to 1.0 U/hr. Capillary blood glucose levels are monitored hourly in such patients.

For patients with diet-controlled gestational diabetes in labor, avoiding dextrose in all intravenous fluids normally maintains excellent blood glucose control. After 1 to 2 hours, no further assessments of capillary blood glucose are typically necessary.

### Neonatal Management

#### Neonatal Transitional Management

One of the metabolic problems common to IDMs is hypoglycemia, which is related to the level of maternal glycemic control over the 6 to 12 weeks before birth. Neonatal hypoglycemia is most likely to occur between 1 and 5 hours after birth, as the rich supply of maternal glucose stops with ligation of the umbilical cord and the infant's levels of circulating insulin remain elevated. These infants therefore require close monitoring for blood glucose concentration during the first hours after birth. IDMs also appear to have disorders of both catecholamine and glucagon metabolism as well as diminished capability to mount normal compensatory responses to hypoglycemia.

In the past, IDMs were treated with glucagon; however, this treatment frequently results in high blood glucose levels that trigger insulin secretion and repeated

cycles of hypoglycemia and hyperglycemia. Current recommendations, therefore, consist of early oral feeding, when possible, along with infusion of intravenous glucose.

Ordinarily, blood glucose levels can be controlled satisfactorily with an infusion of 10% glucose. If greater amounts of glucose are required, bolus administration of 5 mL/kg of 10% glucose is recommended, with gradually increasing concentrations of glucose administered every 30 to 60 minutes, if necessary. Close monitoring to correct hypoglycemia while avoiding hyperglycemia and consequent stimulation of insulin secretion is important.

### Breast-Feeding

Most authorities prefer to maintain strict monitoring of newborn IDM glucose levels for at least 4 to 6 hours, which frequently necessitates admission to a newborn special care unit. IDMs delivered atraumatically and well oxygenated, however, can be kept with their mothers while undergoing close glycemic monitoring for the first 1 to 2 hours of life. This approach permits early breast-feeding, which may reduce the need for intravenous glucose therapy.

### Summary

Intensive management of women with glucose intolerance during pregnancy has resulted in markedly improved outcomes. Despite these advances, care of the IDM continues to require vigilance and meticulous monitoring with a full understanding of the quality of the glycemic milieu in which the infant developed.

## DISORDERS OF THE THYROID

### Incidence

Thyroid disorders, in general, are more common in women than in men and represent a common endocrine abnormality during pregnancy. Both hyperthyroidism and hypothyroidism in the mother put the infant at risk and require careful management by the perinatal-neonatal team. Table 9-9 presents an overview of the approach to infants who are thought to be at risk for abnormal thyroid function because of maternal thyroid abnormalities. The most frequently described problem is the syndrome of postpartum thyroiditis, which has been reported to complicate as many as 5% of all pregnancies. The diagnosis of thyroid disease in pregnancy is complicated by the natural

TABLE 9-9

### Approaches for Infants Judged to be at Risk for Abnormal Thyroid Function

Possible Thyroid Abnormality	Cord Blood Analyses	Assessment at Birth	Assessment at 2-7 Days of Life
Congenital hyperthyroidism because mother has any of the following: Graves disease with hyperthyroidism and may have been treated with PTU, methimazole, <sup>131</sup> I, iodides, or surgery History of Graves disease History of Hashimoto disease	T <sub>4</sub> , RSH, TSAb	Physical examination for intrauterine growth restriction, goiter, exophthalmos, tachycardia, bradycardia, size of anterior fontanel, synostosis, congenital anomalies Determination of gestational age by dates, ultrasonography during pregnancy, or Dubovitz examination Neurologic examination Determination of bone age (knee) For selected cases: electrocardiogram, auditory and visual evoked potentials, motor conduction, velocity tests, skull radiographs	T <sub>4</sub> , TSH, TSAb (if available) determinations: If results normal, give no treatment; observe and repeat T <sub>4</sub> , T <sub>3</sub> , TSH determinations at 7-10 days* If results indicate hypothyroidism, repeat T <sub>4</sub> , TSH; if results abnormal, begin treatment at 7-10 days†
Congenital or early childhood hypothyroidism because mother has any of the following: Graves disease with excessive PTU therapy Hashimoto disease ?Acute (subacute) thyroiditis Familial genetic defect in thyroxine synthesis Treatment with iodides or lithium for nonthyroidal illness Exposure to <sup>131</sup> I while pregnant	T <sub>4</sub> , RSH, ThyAb	Same as for suspected hyperthyroidism	T <sub>4</sub> , TSH, ThyAb determinations: If results indicate hypothyroidism, perform ultrasound scan to define presence, size, location of thyroid tissue If hypothyroidism confirmed, begin treatment with levothyroxine sodium (Synthroid), 0.05 mg/day

\*Graves disease does not develop at 7-10 days in children whose mothers receive PTU.

<sup>131</sup>I, radioactive iodine; PTU, propylthiouracil; T<sub>3</sub>, triiodothyronine; T<sub>4</sub>, thyroxine; ThyAb, thyroid antibody; TSAb, thyroid-stimulating antibody; TSH, thyroid-stimulating hormone.

changes that occur in immunologic status of the mother and fetus and that variously affect the assessment of any of the autoimmune thyroid disorders.

## Maternal-Fetal Thyroid Function in Pregnancy

### Maternal Thyroid Function

Several pregnancy-related physiologic conditions affect maternal thyroid function, and the appropriate interpretation of thyroid function test results during pregnancy must take these normal physiologic factors into account. One important modification that occurs during pregnancy is the estrogen-dependent increase in thyroid-binding globulin. This results in an increase in total thyroxine (TT<sub>4</sub>) and total triiodothyronine (TT<sub>3</sub>) levels throughout pregnancy. The levels of unbound (free) thyroxine (FT<sub>4</sub>) and triiodothyronine (FT<sub>3</sub>), as well as levels of thyroid-stimulating hormone (TSH), in general remain unchanged. However, human chorionic gonadotropin (hCG), a second factor in pregnancy that may modify thyroid function, has a stimulatory effect on the thyroid and may transiently effect the FT<sub>4</sub>, FT<sub>3</sub>, and TSH levels in the first trimester and early in the second trimester. This stimulatory effect of hCG rarely causes aberrations of the thyroid function parameters into the thyrotoxic range (American College of Obstetricians and Gynecologists, 2001).

### Fetal Thyroid Function

The fetal thyroid actively concentrates iodide after 10 weeks, releases T<sub>4</sub> after 12 weeks, and becomes responsive to pituitary TSH at 20 weeks of gestation. Although maternal TSH does not cross the placenta, maternal thyroid hormones and thyrotropin-releasing hormone (TRH) are transferred to the fetus throughout gestation. In one study, cord blood thyroid function testing of neonates with congenital thyroid agenesis revealed hormone levels that were 30% of normal (Vulsma et al, 1989), suggesting a maternal source. Transplacental transfer of thyroid-stimulating immunoglobulin (TSI) may occur, causing fetal thyrotoxicosis. Other substances that may be transferred from the maternal compartment to the fetal compartment and affect fetal thyroid function are iodine, a radioactive isotope of iodine, propylthiouracil (PTU), and methimazole. The fetal effects of these agents are reviewed later.

### Hyperthyroidism

Hyperthyroidism occurs in approximately 0.2% of pregnancies and results in a significant increase in the prevalence of both low-birth-weight delivery and a trend toward higher neonatal mortality. The most common cause of thyrotoxicosis (85% of cases) in women of child-bearing age is Graves disease; other causes are acute (or subacute) thyroiditis (transient), Hashimoto disease, hydatidiform mole, choriocarcinoma, toxic nodular goiter, and toxic adenoma. Graves disease has a peak incidence during the reproductive years, but patients with the disorder may actually have remissions during pregnancy, followed by postpartum exacerbations. The unique feature of these

pregnancies is that the fetus may also be affected, regardless of the mother's concurrent medical condition. Thyroid function is difficult to evaluate in the fetus, and the status of the fetus may not correlate with that of the mother.

### Diagnosis

The differential diagnosis of thyrotoxicosis becomes more difficult during pregnancy because normal pregnant women may have a variety of hyperdynamic signs and symptoms—intolerance to heat, nervousness, irritability, emotional lability, and increased perspiration, along with tachycardia and anxiety. Laboratory data are also difficult to evaluate because total serum thyroxin values are normally elevated during pregnancy as a result of estrogen-induced increases in thyroxine-binding globulin. Thus, if thyroxine-binding globulin is increased, T<sub>3</sub> resin uptake may be in the euthyroid to slightly increased range in a patient who has true hyperthyroidism.

Hollingsworth (1989) has reviewed the assessment of thyroid function tests in nonpregnant and pregnant women, along with the differential diagnosis of hyperthyroidism during pregnancy.

### Pathogenesis of Graves Disease

The pathogenesis of Graves disease is not completely understood, but it probably represents an overlapping spectrum of disorders that are characterized by production of polyclonal antibodies. It has been appreciated since the 1960s (Sunshine et al, 1965) that abnormal TSIs, which appear to be immunoglobulin G (IgG), are present in pregnant women with Graves disease and cross the placenta easily to cause neonatal hyperthyroidism in some infants (McKenzie and Zakarija, 1978). The clinical spectrum of Graves disease in utero is quite broad and may result in stillbirth or preterm delivery. Some affected infants have widespread evidence of autoimmune disease, including thrombocytopenic purpura and generalized hypertrophy of the lymphatic tissues. Thyroid storm can occur shortly after birth, or the infant may have disease that is transient in nature, lasting from 1 to 5 months. Infants born to mothers who have been treated with thioamides may appear normal at birth but demonstrate signs of thyrotoxicosis at 7 to 10 days of age, when the effect of thioamide suppression of thyroxine synthesis is no longer present. The measurement of thyroid-stimulating antibodies (TSAbs) is useful in predicting whether the fetus will be affected.

### Management of the Mother

Because radioactive iodine therapy is contraindicated during pregnancy, treatment of the pregnant woman with thyrotoxicosis involves a choice between antithyroid drugs and surgery. The therapeutic goal is to achieve a euthyroid, or perhaps slightly hyperthyroid, state in the mother while preventing hypothyroidism and hyperthyroidism in the fetus. Either PTU or methimazole may be used to

treat thyrotoxicosis during pregnancy. Because methimazole therapy may be associated with aplasia cutis in the offspring of treated women and because PTU crosses the placenta more slowly than methimazole, PTU has become the drug of choice for use during pregnancy. Ordinarily, thyrotoxicosis can be controlled with doses of 300 mg per day. Once the disorder is under control, however, it is important to keep the dose as low as possible, preferably less than 100 mg daily, because this drug does cross the placenta and blocks fetal thyroid function, possibly producing hypothyroidism in the fetus.

In women with cardiovascular effects, the use of beta-blockers may be appropriate to achieve rapid control of thyrotoxicosis. Because administration of propranolol to pregnant women has been associated with intrauterine growth restriction and impaired responses of the fetus to anoxic stress as well as postnatal bradycardia and hypoglycemia, the dosages must be closely controlled. Iodides have also been used, particularly in combination with beta-blocking agents, to control thyrotoxicosis. Long-term iodide therapy, however, presents a risk to the fetus. Because of the inhibition of the incorporation of iodide into thyroglobulin, a large, obstructive goiter can develop in the fetus. Surgery during pregnancy is best reserved for cases in which the mother is hypersensitive to antithyroid drugs, compliance with medication is poor, or in rare cases in which drugs are ineffective in controlling the disease.

### Effects on the Newborn

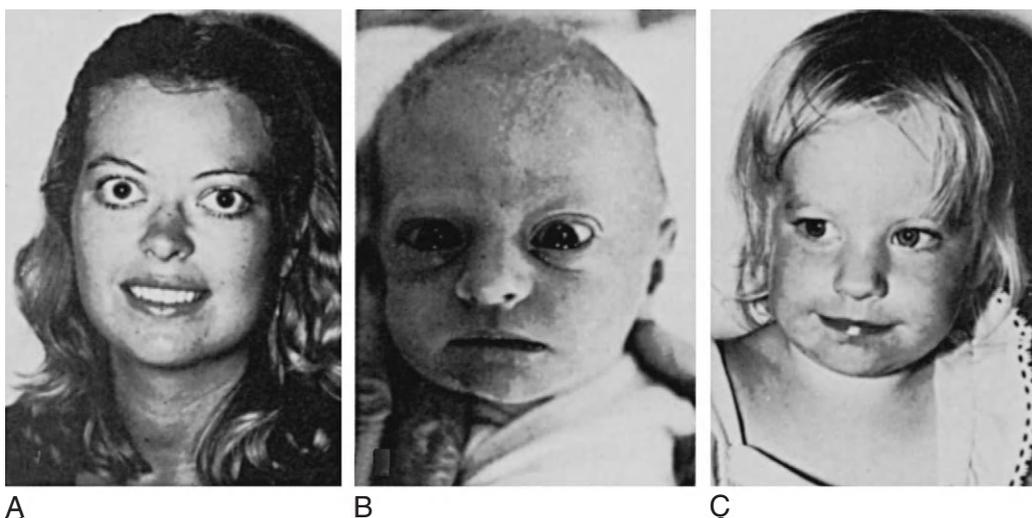

Approximately 1% of infants born to mothers with some level of thyrotoxicosis themselves have thyrotoxicosis

(Fig. 9-4). Assessment of fetal risk in utero includes measurement of TSIs, with expectation that if the titers are high, there is a higher risk of thyrotoxicosis. Additional assessment of the fetus should pay particular attention to elevated resting heart rate and poor fetal growth. Daneman and Howard (1980) reported on the outcome of nine infants with neonatal thyrotoxicosis and noted normal growth but a high incidence of craniosynostosis and intellectual impairment. It may, therefore, be necessary to treat the asymptomatic mother with thioamides and propranolol (and thyroid replacement) during pregnancy in order to treat the infant and prevent serious neonatal morbidity and long-term problems.

Mothers with thyrotoxicosis who are taking normal doses of thioamides may safely breast-feed their infants, although thioamides do appear in breast milk in low amounts. Currently, there does not appear to be any long-term adverse outcome for infants whose mothers have received PTU during pregnancy.

### Hypothyroidism

Treatment with replacement doses of thyroid hormone is usually well tolerated and easily titrated. The clinician must be aware of the fact that the increased TSI levels in maternal plasma may result in movement of thyroid hormone from the fetus to the mother, with a decrease in severity of her disease during the pregnancy. Hypothyroidism has occurred in fetuses whose mothers have inadvertently received radioactive iodine ( $^{132}\text{I}$ ) during pregnancy. There is currently no reliable method for diagnosing hypothyroidism in utero.

**FIGURE 9-4.** **A**, Hypothyroid 21-year-old mother who experienced Graves disease at age 7 and was treated by subtotal thyroidectomy. She was given maintenance therapy with daily levothyroxine sodium (Synthroid), 0.15 mg, throughout pregnancy. **B**, Her infant girl was born at term with severe Graves disease, goiter, and exophthalmos that persisted for 6 months. **C**, The child was normal at age 20 months. ## Maternal Medical Disorders of Fetal Significance: Seizure Disorders, Isoimmunization, Cancer, and Mental Disorders

Thomas F. Kelly and Thomas R. Moore

A significant spectrum of medical complications may complicate pregnancy. Some of these, very manageable in the nonpregnant patient, can be lethal to the gravid woman. Thus, two basic questions arise for the obstetrician dealing with the pregnant female who is experiencing a medical complication. First, is the condition affected by the patient's normal adaptations to pregnancy? And second, how does the medical problem affect the woman and her fetus? Although many medical conditions during pregnancy can be managed much like they would be in the nonpregnant woman, there are usually nuances in care during gestation to which the obstetrician must be attuned and that will potentially affect the fetus and neonate.

During pregnancy, any potential medical therapy should be carefully considered so that fetal risks are minimized. For example, thalidomide and diethylstilbestrol were prescribed in the past for morning sickness and recurrent miscarriages, respectively, on the basis of reasonable hypotheses that maternal sedation would decrease nausea and increased estrogens would "support" the placenta and reduce the likelihood of first-trimester loss. Unfortunately, use of both of these agents led to significant and tragic congenital anomalies in the offspring. In view of the profusion of new drugs available today, the importance of assessing the expected risk-to-benefit ratio for each medication prescribed to a pregnant woman is more important than ever. An example is phenytoin treatment for maternal seizures. If there is a less teratogenic alternative, it should be prescribed if effective. However, for most women taking phenytoin, other agents are unable to control their seizures, and the risks to the fetus must be accepted.

The altered pharmacokinetics of many agents during pregnancy must be considered, because the dosage of familiar medications may have to be adjusted if toxicity is to be avoided. Classic examples are thyroid hormone replacement (a higher level of thyroid-binding globulin in pregnancy increases total thyroxin [T<sub>4</sub>] but leaves the serum free thyroxin value unchanged) and aminoglycoside antibiotic therapy (increased glomerular filtration in pregnancy results in lower serum drug levels).

This chapter discusses four maternal conditions that may influence fetal growth, development, and outcome—seizure disorders, hypertensive states, and red blood cell isoimmunization. The basics of management, the potential effects of pregnancy on the condition, and the effects of the condition on the gravida and the fetus are considered.

### MATERNAL SEIZURE DISORDERS

Epilepsy is not uncommon, affecting more than 3 million people and approximately 1.1 million women of child-bearing age in the United States, with a prevalence in pregnancy approximating 0.5%. The pattern of maternal seizures ranges from complex partial to generalized tonic clonic seizures and generalized absence (*petit mal*). Physiologically, seizures arise from paroxysmal episodes of abnormal brain electrical discharges, and when associated with motor activity, they are termed *convulsive*.

The effect of pregnancy on the frequency and severity of the seizure disorder is highly variable from patient to patient. Although the condition worsens in 25% of patients (Wilhelm et al, 1990), and many patients experience improvement, the disease remains the same in the majority. Neither the type of epilepsy nor a prior pregnancy experience reliably influences the seizure frequency (Yerby, 2001). In patients in whom higher numbers of seizures occur during gestation, decreased plasma concentrations of antiepileptic medications have been hypothesized as causative. The fall in plasma drug levels during pregnancy may be in part due to increased protein binding, reduced absorption, and increased drug clearance. Adequacy of prepregnancy seizure control may influence a patient's course during gestation; the patient whose disease was poorly controlled tends to have more frequent seizures during pregnancy, and the patient who was seizure free for 2 years before pregnancy has only a 10% chance of experiencing seizures during gestation (Schmidt et al, 1983).

### Perinatal Risk

For reasons that are not immediately clear, women with seizures have more obstetrical complications during pregnancy and a higher rate of poor perinatal outcomes. Rates of preeclampsia, preterm delivery, small-for-gestational-age infants, congenital malformations, cerebral palsy, and perinatal mortality have all been reported as higher in women with an antecedent seizure disorder (Nelson and Ellenberg, 1982). Pregnancy outcome is also greatly influenced by the mother's socioeconomic status and age as well as by the prenatal care received.

The well-documented increased frequency of congenital malformations among women with seizure disorders is curious, because it is observed irrespective of fetal exposure to anticonvulsant medications (Bjerkedal, 1982). The malformation risk is, however, correlated with the severity of epilepsy and the number of medications used. Overall, the risk is increased over baseline by 3.5% to 4.4%. Specific malformations reported include a fivefold rise in rate of orofacial clefts (Friis et al, 1986), an increase in rate of congenital heart disease, particularly with trimethadione

(Friis and Hauge, 1985), and a 1% to 2% incidence of neural tube defects in fetuses exposed to valproic acid (Lammer et al, 1987). Facial abnormalities (e.g., mid-face hypoplasia) are not specific to any particular antiepileptic drug, being seen with phenytoin, carbamazepine, and trimethadione.

The classic features of the hydantoin syndrome are facial clefting, broad nasal ridge, hypertelorism, epicanthal folds, distal phalangeal hypoplasia, and growth and mental deficiencies; however, these are features of the use of other antiseizure medications as well (Table 10–1). The postulated cause of this syndrome is the action of a common epoxide intermediate of these medications on a teratogen. The hydantoin syndrome was found to develop in fetuses with inadequate epoxide hydrolase activity (Buehler et al, 1990). This enzymatic deficiency appears to be recessively inherited.

### Management

Management of the pregnant patient with epilepsy is based on keeping her seizure free. Theoretically, this goal reduces maternal physical risk and lowers the incidence of fetal complications. Preconception counseling is preferable and should entail (1) adjustment of medication dosages into the therapeutic range, (2) attempting to limit the patient to one drug if possible, and (3) choosing an agent with the least risk of teratogenesis. Frank discussion of the various risks of each agent should be conducted, particularly the risks associated with valproic acid and trimethadione. Usually, if the patient's disease is adequately controlled with one agent, it rarely needs to be changed, because the risks of increasing seizure activity are believed to outweigh the potential for reducing congenital malformations.

**TABLE 10-1**

#### Clinical Features of the Fetal Hydantoin Syndrome

Craniofacial abnormalities	Broad nasal ridge	
	Wide fontanel	
	Low-set hairline	
	Broad alveolar ridge	
	Metopic ridging	
	Short neck	
	Ocular hypertelorism	
	Microcephaly	
	Cleft lip and/or palate	
	Abnormal or low-set ears	
	Epicanthal folds	
	Ptosis of eyelids	
	Coloboma	
	Coarse scalp hair	
	Limb abnormalities	Smallness or absence of nails
		Hypoplasia of distal phalanges
		Altered palmar crease
Digital thumb		
	Dislocated hip	

Data from Briggs GC, Freeman RK, Yaffe SJ: *Drugs in Pregnancy and Lactation*, 5th ed. Baltimore, Williams & Wilkins, 1998.

Patients taking antiepileptic medications should also take folic acid supplements (800 to 1000 µg) before conception, because inhibition of folate absorption has been proposed as a teratogenic mechanism, particularly with phenytoin. During gestation, the anticonvulsant levels should be checked monthly, and the dose adjusted accordingly. Medications should not be changed unless they prove ineffective at the optimal serum level. If a patient reports greater seizure activity, the drug serum level should be checked immediately. A common source of increased seizures is that the patient is not taking her medication, usually because she fears its teratogenicity.

Mothers taking phenytoin, phenobarbital, or primidone may have a higher incidence of neonatal coagulopathy due to vitamin K–dependent clotting factor deficiency. Maternal vitamin K supplementation in the third trimester is reasonable; a single parenteral dose of 10 mg can be given at 34 to 36 weeks of gestation.

### ISOIMMUNIZATION

Hydrops fetalis, a condition associated with abnormal fluid collections in various body cavities of the fetus, was first described in 1892. The causes are many but can be conceptualized in two categories, immune causes and nonimmune causes. In immune-mediated hydrops, circulating immunoglobulins lead to the destruction of fetal red blood cells and hemolytic anemia. Landsteiner and Weiner first elucidated the Rhesus factor in 1940. Levine and associates showed pathogenesis of erythroblastosis to be due to maternal isoimmunization in 1941. Rh immune globulin (RhIG) was developed in the mid-1960s. Prophylaxis protocols utilizing Rh immune globulin significantly reduced the incidence of D isoimmunization, increasing the relative frequency of alloimmunization against atypical red blood cell antigens such as E, Duffy, and Kell. The pathophysiology of immune-mediated fetal hemolytic disease is similar, irrespective of the blood group antigen involved; therefore, the bulk of the discussion here is on the Rh system.

### Genetics

The Rh blood group actually represents a number of antigens, designated D, Cc, and Ee. The genes for these antigens, located on the short arm of chromosome 1, are inherited in a set of three from each parent. The presence of D determines whether the individual is Rh positive, and the absence of D (there is no recessive allele, so “d” does not exist) yields the Rh-negative type. Rarely, a patient exhibits a Du variant and should be considered D positive. The combinations of these various antigens occur with different frequencies. For example, prevalence of Cde (41%) is higher than that of CDE (0.08%) (Lewis et al, 1971). Although the Rh phenotype is the result of D status, the various genotype combinations help predict the zygosity of an individual. About 45% of Rh-positive individuals are homozygous and therefore will always produce an Rh-positive offspring, and 55% are heterozygous and will have an Rh-negative child if paired with an Rh-negative partner.

There are no sex differences in the frequency of Rh negativity. However racial variations are striking. Rh negativity is common in the Basque population (30% to 35%), but rare in Chinese persons, Japanese persons, and North American Indians (1% to 2%). The average incidence in white populations is about 15%. North American blacks have a higher incidence (8%) than African blacks (4%).

### Pathogenesis

Before modern blood banking, the Rh-negative patient became immunized from the transfusion of Rh-positive blood. In the case of atypical red blood cell antigens (Duffy, Kidd, etc.), blood transfusion is still a significant cause of isoimmunization. Today, fetal transplacental hemorrhage is currently the primary cause of Rh isoimmunization. Rh immune globulin prophylaxis protocols have reduced but not eliminated this problem. Transplacental hemorrhage of fetal cells into the maternal circulation is surprisingly common, with 75% of women showing evidence of this event at some time during gestation (Bowman et al, 1986). The amount of fetal blood is usually small, but approximately 1% of women have 5 mL, and in 0.25% of women, 30 mL or more of fetal cells are noted at Kleihauer-Betke testing. Obstetrical events increase the chance of transplacental hemorrhage (Table 10–2), as do the incidence and amount of hemorrhage with advancing gestational age (from 12% in the first trimester to 45% in the third trimester). As little as 0.3 mL of Rh-positive blood produces immunization, and the risk is dose dependent. ABO blood group incompatibility between fetus and mother affords some protection, reducing the risk from 16% to 2%.

The primary maternal immune response is slow and may take as long as 6 months to develop. First appearance of immunoglobulin (Ig) M class anti-D antibodies is weak; they do not cross the placenta but are soon followed by smaller IgG antibodies that are capable of traversing the placental barrier. Therefore, the initial event causing sensitization rarely results in fetal hemolysis. A second transplacental hemorrhage then leads to the more rapid and abundant amnestic IgG response that, in the presence of fetal D-positive cells, may cause significant hemolysis and fetal anemia.

The severity of hemolytic disease is related to the maternal antibody titer, the affinity for the red blood cell membrane, and the ability of the fetus to compensate for

**TABLE 10–2**

#### Clinical Conditions Associated with Increased Risk of Fetal-Maternal Hemorrhage

- Unexplained vaginal bleeding
- Abruptio placentae

#### Classification of the Severity of Hemolytic Disease

Severity	Description	Incidence (%)
Mild	Indirect bilirubin result 16-20 mg/dL No anemia No treatment needed	45-50
Moderate	Fetal hydrops does not develop Moderate anemia Severe jaundice with risk of kernicterus unless treated after birth	25-30
Severe	Fetal hydrops develops in utero Before 34 weeks of gestation After 34 weeks of gestation	20-25 10-12 10-12

Data from Bowman JM: Maternal blood group immunization. In Creasy R, Resnik R (eds): *Maternal-Fetal Medicine: Principles and Practice*. Philadelphia, WB Saunders, 1984, pp 561-602.

the red blood cell destruction. Table 10–3 summarizes the levels of fetal and neonatal disease and their incidence. Most cases are mild and result in normal outcomes; the cord blood is strongly Coombs positive, but the babies do not become significantly anemic or hyperbilirubinemic. Moderate disease results from the red blood cell destruction and the greater production of indirect bilirubin; although the mother is able to clear this product for the fetus in utero, the neonate is deficient in the liver glucuronyl transferase enzyme, leading to the buildup of this water-insoluble molecule. Albumin carries the indirect bilirubin, but if the binding capacity is exceeded, diffusion of the bilirubin into the fatty tissues occurs. Neural tissue is high in lipid content. Ultimate destruction of neurons can occur, resulting in kernicterus. Treatment depends on the recognition of the hyperbilirubinemia and usually entails phototherapy and exchange transfusion in the nursery. (See also Chapter 79.)

Severe disease occurs when the fetus is unable to produce enough red blood cells to compensate for the increased destruction of these cells. Extramedullary hematopoiesis, prominent in the liver, ultimately leads to enlargement, hepatocellular damage, and portal hypertension. This process is believed to be the etiology of placental edema and ascites. Albumin production diminishes due to hepatocellular damage and results in anasarca, giving rise to hydrops fetalis. The theory that hydrops is due to fetal heart failure no longer holds, as a result of observations that these infants are neither hypervolemic or in failure. The relationship between fetal anemia and hydrops is variable, but most hydropic fetuses have hemoglobin levels below 60 g/L.

### Management

Management of the sensitized patient, for both Rh and atypical red blood cell antigens, requires an understanding of the mechanism of disease and the skill and the experience to predict its severity. Although management schemes follow some very basic guidelines, successful

management requires access to a blood bank with expertise in antibody typing and individuals skilled in prenatal diagnostic procedures (e.g., cordocentesis). Referral to experienced high-risk centers for the management of this problem is common in the United States.

### Monitoring

At their first visit, all pregnant patients should undergo a blood type and antibody screen (indirect Coombs test), which identifies the Rh-negative woman and screens for the presence of anti-D antibody and other immunoglobulins associated with atypical red blood cell antigens and capable of causing fetal hemolytic disease (Table 10-4). Any positive result on antibody screening should be evaluated aggressively so as to identify the antibody and quantify its amount by titer. Consulting a blood bank pathologist may be necessary for atypical antibodies.

The amount of the anti-D antibody present according to indirect antibody titer is important. For a titer that is less than 1:16 and remains at that level throughout the pregnancy, most centers consider the fetus to be at negligible risk of hydrops or stillbirth. Each blood bank sets different standards for this critical titer, which depend on the assay used. At a titer of 1:16, the risk is 10%; at 1:128, it is 75%. For a woman with a previously affected fetus, no titer is predictive, and therefore management based on its result may underestimate the severity of fetal disease.

Once the patient has been identified as isoimmunized, her obstetrical history is important. All of her prior pregnancies and their outcomes must be documented to attempt to elucidate the timing and cause of the sensitization as well as to assess the risk in her current pregnancy. In general, the condition is worse with each pregnancy. In a first sensitized pregnancy, the risk of hydrops is approximately 10%. More than 90% of patients who have delivered one hydropic baby will deliver another one subsequently.

Paternal blood typing and Rh genotyping should be performed to calculate the fetal risk of Rh positivity. For atypical blood group immunization, history of prior outcomes plus transfusions (a significant cause of such

antibodies) and determination of the father's antigen status are of similar importance. For example, a woman with an anti-Kell antibody titer of 1:128 would be at moderate risk of hydrops—unless the father of the baby is found to be Kell-negative. No invasive procedures for isoimmunization should be performed until the father's antibody status is established, unless the fetus's paternity is in question or the partner is unavailable.

Ultrasonographic screening to identify the prehydropic fetus is notoriously unreliable, in that significantly anemic fetuses may not be grossly hydropic. However, clues that have been proposed to suggest impending hydrops are polyhydramnios, skin thickening, early ascites (particularly around the fetal bladder), and placental thickening. Ultrasonographic measurements of the liver and spleen have been suggested as aids in predicting anemia in nonhydropic fetuses but lack sensitivity and specificity (Bahado-Singh, 1998; Vintzileos, 1986).

Doppler blood flow measurements in the umbilical vein (Iskarios et al, 1998) and in the middle cerebral artery have shown promise. Using reference ranged middle cerebral artery peak systolic velocities, Mari (2000) was able to predict which nonhydropic fetuses had moderate or severe anemia. Currently, a multicenter trial is evaluating this promising noninvasive technology, which has already shown utility in reducing the number of invasive tests (amniocentesis) needed for surveillance of an otherwise lower risk patient.

Antibody titers should be followed monthly to predict which fetus is at risk (in the absence of a history of a prior hydropic infant). If the indirect antibody titer value is less than 1:16, the development of hydrops is unlikely. Most centers consider the critical value to be 1:16, because at and above this level, one cannot ensure the absence of hydrops. When a patient's antibody titer value is at or above 1:16, more invasive testing is needed. Such testing is usually accomplished with amniocentesis and, less commonly, through direct fetal blood sampling.

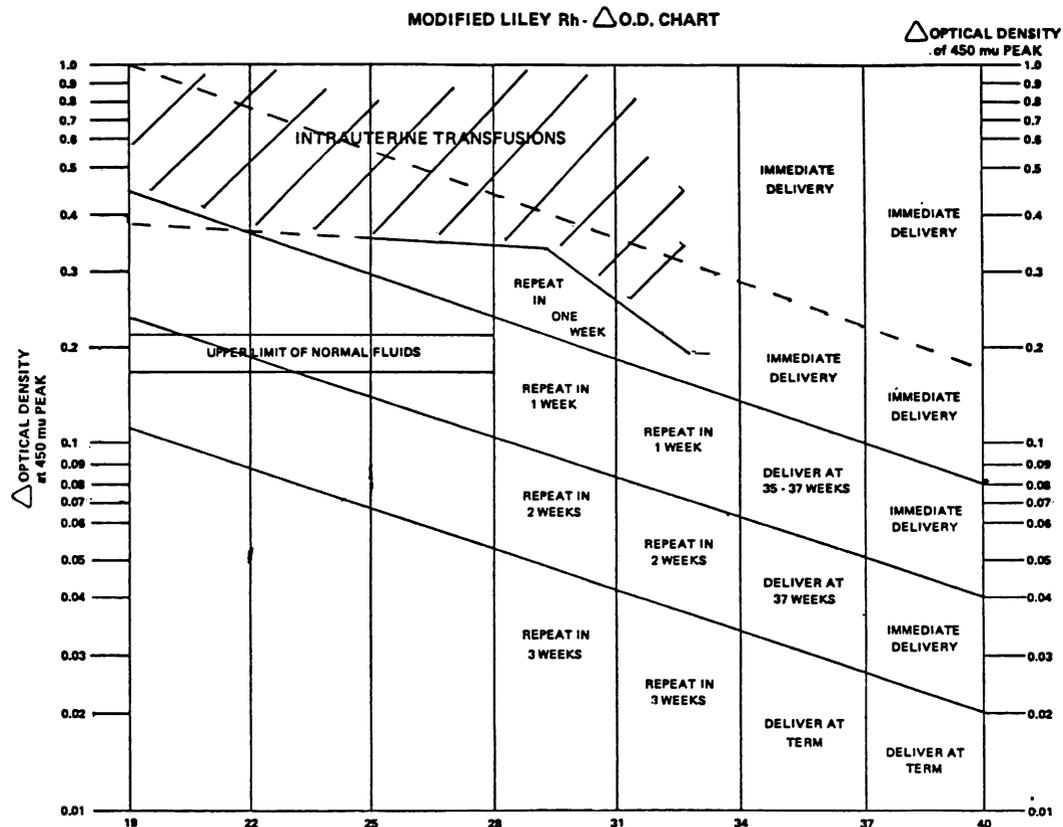

Amniocentesis remains the primary screening technique for fetal anemia because amniotic fluid contains hemolytic products excreted from the kidneys and lungs, including bilirubin. The unconjugated form of bilirubin is secreted across the respiratory tree and therefore into the amniotic fluid. The supernatant is analyzed with a spectrophotometer, and the bilirubin peak corresponding to the level of absorbance (or optical density [OD]) of these hemoglobin products (450 nm) is quantified. The magnitude of the peak is calculated after subtracting the mean baseline value surrounding the peak. The difference from baseline to peak is the  $\Delta OD_{450}$  value.

The amount of the increase in the  $\Delta OD_{450}$  value correlates reasonably well with severity of hemolysis. In 1961, Liley developed a graph that has been used to predict the severity of fetal hemolytic disease using the  $\Delta OD_{450}$  value. The graph is divided into three zones: Zone I represents the lowest risk and indicates an unaffected fetus, whereas zone III strongly suggests a severely affected fetus, in which fetal hydrops and death can ensue if disease is not treated within the next 7 to 10 days (Fig. 10-1). The Liley curve is authoritative in the third trimester, but its reliability before 26 weeks of gestation has been questioned (Queenan et al, 1993). At less than 20 weeks of gestation,

**TABLE 10-4**

#### Examples of Atypical Red Blood Cell Antigens Associated with Fetal Hemolytic Disease

Blood Group System	Antigen	Severity of Hemolytic Disease
Kell	K	Mild to severe
Duffy	Fya	Mild to severe
Kidd	JKa	Mild to severe
	JKb	Mild to severe
MNSs	M	Mild to severe
	N	Mild
	S	Mild to severe
	s	Mild to severe
	U	Mild to severe
P	PP	Mild to severe
Public antigens	Yta	Moderate to severe

**FIGURE 10-1.** Liley graph used to assess severity of fetal hemolysis. (From Liley AW: *Liquor amnii analysis in management of pregnancy complicated by rhesus immunization*. *Am J Obstet Gynecol* 82:1359, 1961.)

the  $\Delta OD_{450}$  value must be greater than 0.15 or less than 0.09 to be predictive of severe or mild disease, respectively, with a “gray zone” between the two values that is nonpredictive (Ananth and Queenan, 1989). Thus, the clinician must integrate clinical history and ultrasonography clues for possible impending hydrops or must consider fetal blood sampling in a fetus at risk between 18 and 25 weeks of gestation.

Amniocytes can be obtained at the amniocentesis, and through polymerase chain reaction (PCR) analysis, fetal D antigen typing can be obtained as early as 14 weeks (Dildy et al, 1996). This process allows the identification of the fetus at no risk for gestations in which the paternal status is heterozygous or unknown. Isoimmunization with atypical red blood cell antigens other than D can be detected similarly, reducing the amount of unnecessary invasive procedures on an otherwise unaffected fetus.

Direct ultrasound-guided fetal umbilical blood sampling provides valuable data for the fetus at risk, particularly after 18 weeks of gestation. Cordocentesis is used most often when the risk determined from history, indirect antibody titer values, Liley curve comparisons, or ultrasonographic clues are significant. It also provides vascular access if fetal transfusion becomes necessary. Although most obstetricians are skilled in amniocentesis, cordocentesis is usually performed in tertiary centers by perinatologists. The latter procedure carries a higher risk

of fetal loss and morbidity and is associated with a more significant chance of worsening maternal sensitization (Bowman and Pollock, 1994).

### Therapy

Fetal transfusion therapy is the mainstay of treatment for the severely affected but premature fetus. In most centers, for pregnancies beyond 33 weeks of gestation with suspected fetal anemia, administration of steroids and delivery are preferable to an invasive procedure with significant morbidity and mortality. Intraperitoneal transfusions, the primary therapy in the past, are still a useful treatment. O-negative, tightly packed, irradiated blood is percutaneously infused into the fetal peritoneal cavity via an amniocentesis needle with real-time ultrasound guidance. Approximately 10 mL is transfused for each week of gestation beyond 20 weeks. Red blood cell absorption occurs quite promptly through the subdiaphragmatic lymphatics, although it may be erratic in the hydropic fetus. Fetal survival rates approaching 100% for nonhydropic fetuses and 75% in hydropic fetuses have been reported (Harman et al, 1983). Problems associated with intraperitoneal transfusions include injury to vascular or intra-abdominal organs and the inability to obtain fetal blood type and blood count. This procedure should be avoided

if at all possible in the hydropic fetus, because the resulting higher abdominal pressure may precipitate venous compression and lead to circulatory collapse.

Direct intravascular transfusions are now the first line of treatment. The advantages of this procedure include assessing the severity of fetal anemia and documenting the fetal blood type. Ultimate success does not appear to be affected by the presence of hydrops (Ney et al, 1991). The overall success rate is about 85%. Limitations are usually procedure related. The most accessible site usually requires an anterior placenta, in which the cord root can be visualized; posterior placentation makes the technique more difficult. Also, risks include bleeding from the cord puncture site, fetal exsanguination, cord hematoma, rupture of membranes, and chorioamnionitis.

Further transfusions are required every 2 to 3 weeks to compensate for the falling hematocrit associated with fetal growth, the finite life of the transfused red blood cells, and ongoing hemolysis of the existing fetal erythrocytes. Ultimately, the entire fetal blood supply is replaced with Rh-negative blood by successive transfusions. A major neonatal side effect is bone marrow depression, which typically peaks at 3 to 6 weeks after birth.

As the pregnancy proceeds through the third trimester, frequent fetal testing is carried out either with nonstress tests and amniotic fluid index or with biophysical profiles. Delivery is planned for 3 to 6 weeks before term, usually after demonstration of a mature fetal lung profile. Preterm delivery may be indicated in the severely affected fetus, regardless of lung profile, if the risk of transfusion is deemed to exceed the morbidity of a delivery of a near-term yet premature baby.

## CANCER

### Principles

Cancer complicating pregnancy is rare, with an estimated frequency of 1 case per 1000 live births. The trend of delaying child-bearing to later maternal age may have influenced this rate. The sites or types of cancer in pregnancy, in descending order of frequency, are cervical, breast, ovarian, lymphoma, melanoma, brain, and leukemia (Haas, 1984; Jacob and Stringer, 1990) (Table 10-5). Finding a malig-

nancy during gestation poses a unique set of issues that must be addressed with care. Will the pregnancy accelerate the malignant process? Are the accepted therapies appropriate for the gravida, and are they safe for the unborn fetus? Will delay of therapy adversely affect the mother? Should the pregnancy be terminated, or should the child be delivered prematurely so as to maximize treatment of the mother with no resultant risk to the child?

Few conditions in pregnancy require as meticulous a multidisciplinary approach as cancer. Oncologists who are unaccustomed to interacting with a pregnant woman commonly wish to have the child delivered before giving definitive cancer therapy, for fear of the teratogenic risks to the fetus. Therefore, input regarding the situation must be acquired not only from an oncologist but also from the obstetrician, perinatologist, pediatrician, neonatologist, and dysmorphologist. The patient and her family must be involved in decision-making, being given information not only about the risks of the disease and its potential therapies but also about the limitations of current knowledge about cancer in pregnancy and the uncertainties of outcomes.

### Surgery in Pregnancy

Patients may undergo indicated surgery during pregnancy safely. The risk of fetal loss does not seem to rise with uncomplicated anesthesia and surgery. However, if there are any complications in either the anesthesia or the operation, the risk of not only fetal but also maternal mortality increases. For example, fetal loss is rarely related temporally to maternal appendectomy but is common when the mother's appendix has ruptured. The most comprehensive series of pregnant patients undergoing surgery was collected in Sweden (Mazze and Kallen, 1989). Although these researchers found a slight increase in rates of low birth weight and neonatal death by 7 days of life, the rates of stillbirth and congenital malformation were similar to the outcomes expected without surgery. Anesthetic agents are not believed to be teratogenic.

A few management guidelines help optimize outcome for the pregnant patient undergoing surgery. If general anesthesia is used, the maternal airway must be protected to avoid aspiration. Gastrointestinal motility is reduced during pregnancy, and even many after hours without eating, the stomach may contain significant residual contents. A left lateral decubitus position on the operating table is preferred in to maximize uteroplacental blood flow. If the fetus is viable, monitoring of the fetal heart rate should be performed to assist the anesthesia team in optimizing fetal status. Preoperative counseling of the patient is important to allow the surgical team to make appropriate choices with regard to any interventions for fetal distress.

### Chemotherapy

Administering agents that impair cell division in pregnancy is a concern for both the mother and the care team. Often the patient is more concerned about this issue than about the underlying cancer. Cytotoxic chemotherapy should be avoided in the first trimester due to the high incidence of spontaneous abortion and

**TABLE 10-5**

#### Cancers That Commonly Complicate Pregnancy

Site/Type	Cases per 1000 Pregnancies
Cervix	0.8
Breast	0.3
Melanoma	0.2
Ovary	0.05
Thyroid	<0.05
Colorectal	0.02
Leukemia	0.01
Lymphoma	0.01

Data from Jacob JH, Stringer AC: Diagnosis and management of cancer during pregnancy. *Semin Perinatol* 14:79-87, 1990.

the potential teratogenic effects on the fetus (Table 10–6). For a few agents with confirmed teratogenic effects, such as methotrexate, amethopterin, and chlorambucil, chemotherapy must be avoided during organogenesis. The use of folic acid antagonists in first-trimester cancer treatment raises the specific problem of possible induction of neural tube defects, because these lesions are known to be folate sensitive.

The literature regarding most other chemotherapeutic agents is limited, consisting of a few collected series. Therefore, use of these agents should be cautious, their potential harm to the fetus balanced against their benefit to the maternal condition. Little is also known regarding the long-term outcomes of fetuses exposed to chemotherapeutic agents in utero. The National Cancer Institute in Bethesda, Maryland, maintains a registry in hopes of determining the delayed effects. Small series of fetuses exposed to chemotherapeutic agents for acute leukemia revealed normal mental development with follow-up between 4 and 22 years (Aviles and Niz, 1988).

TABLE 10–6

**Common Chemotherapy Agents and Uses**

<b>Class/Drug</b>	<b>Risk Category</b>	<b>Common Uses</b>
<b>Alkylating Agents</b>		
Busulfan	D	Leukemias
Chlorambucil	D	Lymphomas, leukemias
Cyclophosphamide	D	Breast, ovary, lymphomas, leukemias
Melphalan	D	Ovary, leukemia, myeloma
Procarbazine	D	Lymphomas
<b>Antimetabolites</b>		
5-Fluorouracil	D	Breast, gastrointestinal
6-Mercaptopurine	D	Leukemias
Methotrexate	D	Trophoblastic disease, lymphomas, leukemias, breast
6-Thioguanine	D	Leukemias
<b>Antibiotics</b>		
Bleomycin	D	Cervix, lymphomas
Daunorubicin	D	Leukemias
Doxorubicin	D	Leukemias, lymphomas, breast
<b>Other Agents</b>

Vincristine	D	Leukemias, lymphomas

Data from Cunningham FG, MacDonald PC, Gant NF, et al: Neoplastic diseases. In Williams Obstetrics, 20th ed. Stamford, CT, Appleton & Lange, 1997, pp 1281-1296.

The risk of teratogenicity does not appear to be higher with combination chemotherapy than with single-agent therapy (Doll et al, 1989). Studies performed so far involve small numbers of patients, with power insufficient to show a statistic difference, but there seems not even to be a trend. Low birth weight is found in approximately 40% of babies whose mothers received cytotoxic drugs during pregnancy (Nicholson, 1968). Theoretical consequences, such as bone marrow suppression, immune suppression, and anemia, could occur in the fetus, and timing of chemotherapy should take the anticipated date of delivery into account. Data regarding safety for the breast-feeding neonate of a mother receiving cancer chemotherapy are limited, and for this reason, the majority of agents are contraindicated in the nursing mother.

**Radiation Therapy**

The deleterious effects of irradiation on the fetus have been both theorized and actual. Fortunately, the amount of concern about the former far exceeds the incidence of the latter. Irradiation promotes genetic damage and thus the potential for congenital malformations. The risk depends on both dose and time. Less than 5 rad is believed to be of little consequence (Brent, 1989). If radiation exposure occurs before implantation, the adverse outcomes are usually a small increase in miscarriage.

The major concern is high-dose radiation (>10 rad) received during the period of organogenesis (embryonic weeks 1 to 10). The central nervous system is the most radiation-sensitive organ, and the complications most often observed are microcephaly and mental retardation. Cataracts and retinal degeneration are also seen. After organogenesis is complete, there is still a risk of central nervous system abnormalities. However, the sequelae most often seen are skin changes and anemia. Because of the highly variable, yet potentially grave consequences of irradiation of greater than 10 rad, patients should be counseled accordingly and termination of pregnancy should be offered as an alternative if exposure has occurred in the previsible period (Orr and Shingleton, 1983).

There are several other considerations for a pregnant woman undergoing radiation therapy. First, the dose used in estimating risk should be the amount that the fetus actually receives. For example, axillary or neck irradiation for lymphoma involves a lower direct fetal exposure than direct pelvic irradiation for cervical cancer. The latter treatment, if given in the second trimester, will likely cause fetal demise. Second, the magnitude of radiation scatter to the pelvis must be considered. External shielding does not prevent internal reflection of the ion beam. Third, the advancing size of the uterus actually increases the amount of radiation exposure of the fetus because of the closer proximity of the nonpelvic irradiation. Therefore, an 8-week fetus may actually receive a smaller radiation dose from supraclavicular irradiation than a 30-week fetus. Fourth, will the fetus concentrate the radiation, and therefore increase its dosage? This is exemplified by the use of radioactive iodine (<sup>131</sup>I) for maternal thyroid conditions. The actual rad dosage is markedly higher in the fetus because the fetal thyroid concentrates the iodine.

TABLE 10-7

**Estimated Radiation Dose to the Pelvis From Common Radiologic Procedures**

Procedure	Pelvic Dose (millirads)
Chest x-ray	8
Abdominal series	289
Lumbar spine series	275
X-ray pelvimetry	40
Intravenous pyelogram	407
Barium enema (x-ray + fluoroscopy)	805
Upper gastrointestinal series (x-ray + fluoroscopy)	558

Data from Pentel RL, Brown ML: Genetically significant dose to the United States population from diagnostic medical roentgenology. *Radiology* 90:209-216, 1968.

Diagnostic tests such as radiography may also be associated with radiation exposure for the fetus (Table 10-7). The doses involved are usually much smaller than those used for cancer therapy. Nonetheless, the practitioner should limit the amount of radiographic testing if at all possible. Inadvertent imaging of a patient who is not known to be pregnant continues to occur despite sensitive pregnancy tests, creating significant concerns. Indicated radiographs should never be withheld because of pregnancy, but lead shielding of the maternal abdomen and careful selection of the type of study should be performed to minimize the pelvic dose. Usually the amount of fetal exposure is well less than 5 rad, with no significantly greater risk of malformations. There does appear to be a slightly higher incidence of childhood leukemia, even with low-dose irradiation.

### Cervical Cancer

Cervical cancer is the most common malignancy found in pregnancy. The incidence is approximately 1 in 2500 gestations. A Papanicolaou ("Pap") smear should be obtained in all patients at their first prenatal visit. However, about 30% of cervical cancers can be associated with negative cytologic smear results. Although the evaluation for an abnormal Pap

smear result should not be altered because of pregnancy, many physicians are reluctant for fear of cervical hemorrhage. Cervical biopsy remains the mainstay of diagnosis. The greater vascularity of the cervix during pregnancy predisposes to bleeding. An experienced colposcopist may be able to defer actual biopsy in cases of suspected visual findings of a noninvasive process. However, if cancerous invasion is suspected or the physician is uncertain of the visual findings, biopsy is necessary (Table 10-8). If microinvasive disease is confirmed by biopsy, cone biopsy is required to rule out frankly invasive disease. This procedure is undertaken with caution during pregnancy, because of the associated high rate of bleeding complications and miscarriage. Cervical conization may raise the risk of incompetence or preterm labor. The assistance of a gynecologic oncologist is preferred, given these unique sets of potential consequences. A shallow cone biopsy will reduce the risk of subsequent cervical weakness.

The therapy for invasive cervical cancer is based on the stage of disease and the gestational age of the fetus (Table 10-9). In most cases, delay of definitive therapy by 4 to 14 weeks may be acceptable. Pregnancy does not seem to accelerate the growth of the tumor. However, patient counseling is important. In the extremely previsible gestation, the likelihood of achieving a safe gestational age for the fetus without worsening the stage or spread of the cancer in the mother must be balanced against parental desires based on ethical or religious beliefs. Conversely, it appears reasonable to delay definitive therapy until a time in pregnancy when delivery would not likely result in a handicapped infant.

### Breast Cancer

Breast cancer is the most common malignancy of women, with approximately 1 of every 10 women affected in their lifetimes. The incidence of breast cancer in pregnancy is estimated to be 10 to 30 per 100,000 pregnancies (Isaacs, 1995). Pregnancy does not seem to influence the actual course of the disease. However, there appears to be a higher risk of delay in diagnosis and a trend towards more advanced stages at diagnosis in pregnant women than in nonpregnant controls.

The diagnostic procedures for breast cancer should not be altered during pregnancy. Any suspicious mass should

TABLE 10-9

## Treatment Options for Cervical Cancer in Pregnancy

Gestational Age	Stage I to IIa	Stage IIb to IIIb
<20 weeks	4500 cGy Wide pelvic irradiation If no abortion: modified radical hysterectomy If spontaneous abortion: brachytherapy <i>or</i> radical hysterectomy with lymphadenectomy	5000 cGy Wide pelvic irradiation If no abortion: type II radical hysterectomy If spontaneous abortion: brachytherapy <i>or</i> cesarean section at fetal viability Subsequent wide pelvic radiation ( $\pm 5000$ cGy) and brachytherapy ( $\pm 5000$ cGy)
>20 weeks	Cesarean section at fetal viability Subsequent wide pelvic radiation (5000 cGy) and brachytherapy (5000 cGy) <i>or</i> cesarean radical hysterectomy with lymphadenectomy	Cesarean section at fetal viability Subsequent wide pelvic radiation ( $\pm 5000$ cGy) and brachytherapy ( $\pm 5000$ cGy)

Data from Berman ML, Di Saia PJ, Brewster WR: Pelvic malignancies, gestational trophoblastic neoplasia and nonpelvic malignancies. In Creasy RK, Resnik R (eds): Maternal-Fetal Medicine, 4th ed. Philadelphia, WB Saunders, 1999, pp 1128-1150.

undergo biopsy. Mammography, although discouraged for routine screening in pregnancy, may be safely employed if indicated. The amount of radiation is negligible, approximately 0.01 cGy (Lieberman et al, 1994). Metastatic evaluation may be hampered somewhat because of a reluctance to use bone and liver scans during pregnancy. However, magnetic resonance imaging appears to be a reasonable alternative.

Surgical therapy for breast cancer should not be delayed because of pregnancy. The risks of mastectomy and axillary node dissection appear very low (Isaacs, 1995). Radiation therapy is usually not recommended during pregnancy because of the risk of scatter. If the pregnancy is to continue and the patient has "positive" lymph nodes, adjuvant chemotherapy is often given. The timing of delivery should take into account the following factors:

- When would the fetus have a reasonable chance for survival with a low risk of severe permanent morbidity?
- Can the number of cycles of chemotherapy be minimized with an earlier delivery? Also, avoiding delivery just before or just after administration of chemotherapy is important to reduce the risk of immunosuppression and infection.
- How long could radiotherapy be delayed without increasing the risk of metastatic spread of the tumor?

About 10% of women treated for breast cancer become pregnant, the majority within 5 years of diagnosis. Small series suggest that pregnancy does not influence the rate of recurrences or of distant metastasis (Dow et al, 1994). However, women should be encouraged to delay child-bearing for at least 2 to 3 years, the time of the highest rate of recurrence. Breast-feeding may be possible in women who have undergone conservative breast cancer surgery.

### Ovarian Cancer

Most ovarian cancer occurs in women older than 35 years. Because later child-bearing has been more widely accepted, it would not be surprising for the rate of ovarian cancer as

well as other cancers during pregnancy to increase. However, the current estimate of actual ovarian malignancies in pregnancy is quite low, estimated at 1 in 25,000 deliveries (Jacob and Stringer, 1990). Although most ovarian cancers are epithelial in origin, borderline epithelial and germ cell tumors are more common in pregnancy.

The widespread use of ultrasonography, particularly in the first two trimesters, has been helpful in identifying adnexal masses. Fortunately, most are benign functional cysts. Actual malignancy is rare, estimated at 5% of the ovarian masses found. In the nonpregnant female, the risk is higher, approaching 15% to 20%. Surgery for a suspected ovarian mass occurs in about 1 per 1000 pregnancies. Most procedures are performed not for suspected malignancy, but rather because of concern about torsion and rupture. The maximal times of risk of these events are at the end of the first trimester, when the uterus elevates beyond the true pelvis, and at the time of delivery. The characterization of an ovarian process can be aided by ultrasonography as well as magnetic resonance imaging, but these modalities are not definitive. Although the patient can gain some reassurance that an ovarian cyst, particularly if it is simple in nature, is very likely not malignant, she must be cautioned that histologic diagnosis is more definitive. Any complex mass or persistent simple cyst 6 cm or larger should undergo surgical exploration and removal. The optimal time for laparotomy is in the second trimester. At that time, there is minimal interference from the gravid uterus and less of a risk of fetal loss, and the theoretical concerns of teratogenic exposure to anesthetic agents are avoided. Some patients opt for more conservative management. They should be counseled that they have a 40% chance of needing urgent intervention with either surgery or percutaneous drainage (Platek et al, 1995).

If a malignancy is confirmed at the time of laparotomy, treatment and staging are no different from those in the nonpregnant woman. Frozen-section diagnosis, peritoneal washings, omentectomy, and subdiaphragmatic biopsy are performed. Depending on the cell type and the stage, treatment may range from removal of the affected adnexa to complete hysterectomy and bilateral oophorectomy. Chemotherapy may be given during pregnancy if necessary.

Fortunately, most cancers found in pregnant women are usually of a lower stage and a lesser malignant potential than those found in nonpregnant women.

## MENTAL DISORDERS

Pregnancy can be a stressful process. At times, it may induce a psychotic event. Women experiencing a mental disorder during pregnancy who have no history of a mood disorder usually present with a milder constellation of symptoms. Serious disorders such as mania and schizophrenia that are antecedent to pregnancy may not be so benign. In women with all types of mental illness as well as in previously nonaffected women, the postpartum state is a time of greater maternal risk. Ten percent to 15% of newly delivered women experience a depressive disorder (Weissman and Olfson, 1995). Women with preexisting mental illness have a higher recurrence risk in the puerperium. Patients presenting with suspected mental illness should be assessed for substance abuse and thyroid dysfunction. A multidisciplinary approach is advantageous. If the patient's mental competency is an issue, the caregiver should obtain legal assistance so as to be able to make medical decisions for the patient.

### Depression

One of every eight individuals suffers from a depressive disorder during his or her lifetime. Women appear to have an increased risk. However, less than one fourth of depressed women are appropriately treated (American College of Obstetricians and Gynecologists, 1993). The diagnosis of depression requires the presence of at least five of the following symptoms for a 2-week period:

- Depressed mood
- Diminished pleasure in most activities
- Weight loss or gain, or alterations of appetite
- Sleep abnormalities
- Psychomotor retardation or agitation
- Fatigue
- Feelings of worthlessness or guilt
- Diminished ability to concentrate
- Thoughts of suicide

These symptoms are associated with significant distress or impairment in all areas of functioning. They are symptoms of depression only if they are not related to a medical or substance abuse condition and are not associated with a recent (2 months) loss of a loved one (Mood disorders, 2000). If the onset is within 3 to 6 months after delivery, postpartum depression is diagnosed.

The predisposing risk factors for depression include early childhood loss, physical or sexual abuse, socioeconomic deprivation, genetic predisposition, and lifestyle stress due to multiple roles (McGrath et al, 1990). These factors may exaggerate or prolong symptoms and, if not addressed, can lengthen the duration of depression. The obstetrician must be aware that life events such as miscarriage, infertility, and complicated pregnancy in patients with risk factors are likely to precipitate depression, and must maintain a low threshold for diagnosis and treatment

of mood alterations in such patients. Alternatively, perinatal loss experienced by a woman without predisposing risk factors will probably lead to a grief reaction or adjustment disorder, which may be misdiagnosed as depression.

Chronic medical conditions that are associated with a high prevalence of depression and may occur in women of child-bearing age include renal failure, cancer, acquired immunodeficiency syndrome (AIDS), and chronic fatigue or pain. Antihypertensives, hormones, anticonvulsants, steroids, chemotherapeutics, and antibiotics can cause depression. Alcoholism and substance abuse may manifest as depression. Underlying personality disorders complicate the diagnosis of depression, not only by confusing the clinical situation but also secondary to many physicians' avoidance of patients suffering from the disorders.

Therapeutic interventions for depression include psychotherapy and medication. Electroconvulsive therapy has been shown to be an effective and relatively safe treatment in refractory cases (Rabheru, 2001). Treatment of depression is effective in about 70% of cases. Supportive treatment alone is rarely effective in major depressive episodes. Most antidepressant medications currently prescribed during pregnancy are serotonin reuptake inhibitors (SSRIs). Fluoxetine, paroxetine, and sertraline are class Bm according to the manufacturer (Briggs et al, 1998). SSRIs have the advantage over the tricyclic antidepressants in not causing orthostatic hypotension. Unfortunately, although limited series suggest that the SSRIs are relatively safe, little is known about long-term consequences for children exposed to them in utero (Altshuler et al, 1996; Chambers et al, 1996; Karasu et al, 2000). Currently, there is no consensus regarding use of SSRIs during breast-feeding. Although data suggests minimal passage of SSRI medications into the breast milk, the long-term side effects are currently listed as "unknown" (Briggs et al, 1998; Buist and Norman, 2000). The theoretical concerns are that such drugs may affect the developing central nervous system of the newborn and that abnormalities may not be readily apparent in the short term. Therefore, SSRIs should be prescribed for a nursing mother only if the benefit clearly exceeds the risk and after the patient has been counseled regarding the potential yet currently ill-defined risks. Given the current medical knowledge, bottle-feeding should be offered as an acceptable alternative if antidepressants must be used.

### Postpartum Psychosis

A severe disorder, postpartum psychosis is fortunately rare, occurring 1 to 4 per 1000 births (Weissman and Olfson, 1995). This condition is more worrisome than postpartum depression because of the patient's inability to discern reality and the periods of delirium. Patients at risk for postpartum psychosis may have underlying depression, mania, or schizophrenia. Other risks are younger age and family history. The recurrence rate is approximately 25%. The peak onset of symptoms is between 10 and 14 days after delivery. Recognition of this disorder is extremely important to the protection of the patient and her family.

## Schizophrenia

Schizophrenia is fairly common, with a prevalence of 1% (Myers et al, 1984). It is associated with delusions, hallucinations, and incoherence. Morbidity due to this mental illness is higher than that due to any other. There appears to be a genetic component to the etiology; schizophrenia develops in about 10% of offspring of an affected person. Concordance of schizophrenia in identical twins reaches 65%. There is some speculation and controversy as to whether low birth weight (Smith et al, 2001) and obstetric complications (Kendell et al, 2000) are associated with a higher rate of schizophrenia.

Because the peak age of incidence is around 20 years and females are more affected than males, it is unrealistic to assume that obstetricians will never encounter patients with schizophrenia. There appear to be higher rates of cesarean section and surgical vaginal delivery in affected patients (Bennedsen et al, 2001b). Children of women with schizophrenia may have a higher rate of sudden infant death syndrome and congenital malformations (Bennedsen et al, 2001a). However, it is difficult to ascertain whether these risks are independent of other factors, such as smoking, poor socioeconomic status, and use of certain medications.

Treatment is primarily achieved through the use of psychotropic medication. The potential for teratogenesis appears low with the older-generation medications in the phenothiazine class, but most data for this issue were derived from the use of lower doses given to patients with hyperemesis gravidarum. Antipsychotic medication does cross the placenta. Current recommendations include avoidance of their use in the first trimester if possible, the use of lower doses or higher-potency alternatives, and cessation of medication 5 to 10 days before delivery (Herz et al, 2000). The use of antipsychotics in breast-feeding is associated with an unknown risk (Briggs et al, 1998).

Lithium, used primarily in mania, is associated with a higher rate of Ebstein anomaly. Although the incidence of this consequence is low, either discontinuing the medication in the first trimester or continuing its use with careful counseling is a viable alternative. Fetal echocardiography should be performed in women who have used lithium in early pregnancy.

# Hypertensive Complications of Pregnancy

Andrew D. Hull and Thomas R. Moore

Hypertension is the most common medical problem in pregnancy, affecting 10% to 15% of all women. The second most common cause of maternal mortality after thromboembolic disease, hypertension accounts for almost 18% of maternal deaths in the United States (Koonin et al, 1997). Complications arising from hypertensive disorders have profound effects on the fetus and neonate and thus are a major source of perinatal mortality and morbidity. Preeclampsia is the primary cause of iatrogenic prematurity.

## CLASSIFICATION OF HYPERTENSIVE DISORDERS OF PREGNANCY

Any discussion of hypertension and pregnancy must begin with a set of definitions. Although many classifications are in use worldwide, perhaps one of the more useful is that of the National High Blood Pressure Education Program Working Group on High Blood Pressure in Pregnancy (Report, 2000) (Table 11–1). Although this classification scheme appears to be somewhat pedantic, it is of paramount importance because pregnancy outcome varies according to the type of hypertension involved. For practical purposes, hypertension in pregnancy may be divided into the following categories: chronic hypertension, gestational hypertension, and preeclampsia.

*Hypertension* is defined as a blood pressure of 140 mm Hg or higher systolic or 90 mm Hg or higher diastolic measured on two separate occasions. Korotkoff phase V (disappearance of sound) is used rather than Korotkoff phase IV (muffling of sound) to define *diastolic pressure*, because Korotkoff IV is poorly reproducible in pregnancy. *Severe hypertension* arising from any cause is defined as a blood pressure of 160 to 180 mm Hg or higher systolic or 110 mm Hg or higher diastolic.

### Chronic Hypertension

Up to 5% of pregnant women have *chronic hypertension*, which is diagnosed when hypertension is present before pregnancy or recorded before 20 weeks of gestation. Typically, the patient with chronic hypertension has an elevated first-trimester blood pressure or is known to have hypertensive disease before her pregnancy begins. However, when hypertension is first noted in a patient after 20 weeks of gestation, it may be difficult to distinguish chronic hypertension from pregnancy-induced hypertension or preeclampsia. In such cases, the precise diagnosis may

not be made until after delivery. Hypertension that is first diagnosed during the second half of pregnancy and persists more than 12 weeks postpartum is diagnosed as chronic hypertension.

Chronic hypertension has an adverse effect on pregnancy outcome. Women with the disorder are at higher risk for preterm delivery and placental abruption, and their fetuses for intrauterine growth restriction (IUGR) and demise (Ferrer et al, 2000). Superimposed preeclampsia complicates up to 50% of pregnancies in women with preexisting severe chronic hypertension (Sibai and Anderson, 1986) and may have a particularly early onset. The adverse effects on fetal and maternal perinatal outcomes are directly related to severity of the preexisting hypertension. When chronic hypertension is secondary to maternal renal disease, the risks of poor outcome are further increased, with up to a tenfold rise in fetal loss rate (Jungers et al, 1997). Women with untreated severe chronic hypertension are at increased risk of cardiovascular complications during pregnancy, including stroke (Brown and Whitworth, 1999).

The majority of cases of chronic hypertension seen in pregnancy are idiopathic (essential hypertension), but causes of secondary hypertension should always be sought because pregnancy outcome is worse in women with secondary hypertension. Renal disease (e.g., chronic renal failure, glomerulonephritis, renal artery stenosis), cardiovascular causes (coarctation of the aorta, Takayasu arteritis), and, rarely, Cushing disease, Conn syndrome, and pheochromocytoma should be excluded through physical examination, history, and more detailed testing if needed.

All patients with chronic hypertension should be evaluated periodically with serum urea, creatinine, and electrolyte measurements, urinalysis, and 24-hour urine collection for protein and creatinine clearance determinations. Typically, this assessment should be performed in each trimester and more frequently if the patient's condition deteriorates.

### Antihypertensive Treatment of Chronic Hypertension in Pregnancy

Except in cases of severe hypertension, randomized trials have shown that antihypertensive treatment of chronic hypertension in pregnancy does not improve fetal outcome (Sibai and Anderson, 1986). Rates of preterm delivery, abruption, IUGR, and perinatal death are similar in treated and untreated women. Thus, treatment is usually reserved for patients whose hypertension places them at significant risk of stroke (blood pressure of 180 mm Hg or higher systolic or 110 mm Hg or higher diastolic). Patients with less severe hypertension who were taking medications before conception may be able to discontinue therapy with close surveillance. The risk of superimposed preeclampsia is not changed by antihypertensive therapy, so its development should be watched for carefully.

The choice of antihypertensive agent for use in pregnancy is governed by a desire to adjust blood pressure without having ill effects on the fetus. Because excessive lowering of maternal blood pressure below 140 mm Hg systolic or 90 mm Hg diastolic (140/90 mm Hg) can compromise uterine perfusion, with consequent slowing of

TABLE 11-1

**National High Blood Pressure Education Program Working Group on High Blood Pressure in Pregnancy Classification of Hypertensive Disorders of Pregnancy\***

Chronic hypertension	Hypertension present before pregnancy, <i>or</i> diagnosed before 20 wks of gestation, <i>or</i> diagnosed for the first time during pregnancy that persists postpartum
Gestational hypertension	<i>Transient</i> if blood pressure returns to normal by 12 wks after delivery and preeclampsia was not diagnosed before delivery
Preeclampsia-eclampsia	<i>Chronic</i> if blood pressure does not resolve by 12 wks after delivery Usually occurs after 20 wks of gestation Hypertension accompanied by proteinuria in a woman normotensive prior to 20 wks of gestation Strongly suspected if nonproteinuric hypertension is accompanied by systemic symptoms such as headache, visual disturbance, abdominal pain, or laboratory abnormalities such as low platelet count and elevated liver enzyme values (HELLP [hemolysis, elevated liver enzymes, and low platelets] syndrome)
Preeclampsia superimposed on chronic hypertension	Preeclampsia occurring in a chronically hypertensive woman

\*Hypertension is defined as a blood pressure of  $\geq 140$  mm Hg systolic or  $\geq 90$  mm Hg diastolic.

Adapted from the Report of the National High Blood Pressure Education Program Working Group on High Blood Pressure in Pregnancy. Am J Obstet Gynecol 183:S1-S22, 2000.

fetal growth, fetal hypoxia, or both, the therapeutic goal is to maintain maternal pressures at 140 to 155 systolic and 90 to 105 diastolic. The drugs most commonly used in pregnancy are listed in Table 11-2.

Methyldopa is probably the most widely used drug in this setting. Obstetricians remain faithful to the use of this agent even though it has been largely abandoned by others, because of extensive clinical and research experience demonstrating its safety for both mother and fetus during pregnancy (Report, 2000). This agent does not impair uteroplacental perfusion and has a wide therapeutic margin before side effects are seen. However, methyldopa has the disadvantage of rather slow onset of action with prolonged time to therapeutic effect (days), and compliance with methyldopa therapy may be impeded by side effects such as sedation in some patients.

Labetalol is a mixed  $\alpha_1$ -adrenergic and  $\beta_1$ - and  $\beta_2$ -adrenergic blocking agent. It is often used as an alternative to methyldopa or added as the second agent. Some pure beta-blockers have been associated with a significant increase in the risk of IUGR (e.g., atenolol), and the mixed adrenergic blockade produced by labetalol is thought to mitigate this unwanted effect (Pickles et al, 1989).

Calcium channel blockers (e.g., nifedipine) are used mainly as second-line drugs, usually in long-acting (extended-release) forms. Calcium channel blockers appear to be as effective as methyldopa and labetalol with minimal fetal side effects (Levin et al, 1994).

TABLE 11-2

**Drugs Commonly Used to Treat Chronic Hypertension in Pregnancy and Their Modes of Action**

Methyldopa	Centrally acting antihypertensive
Labetalol	Mixed alpha- and beta-adrenergic blocker
Nifedipine	Calcium channel blocker
Hydralazine	Peripheral vasodilator
Prazosin	Alpha-blocker

A potent peripheral vasodilator, hydralazine is often used as a first-line parenteral drug to treat acute hypertensive emergencies in pregnancy (blood pressure of  $>160/110$  mm Hg). Its role as an oral agent in the management of chronic hypertension is limited to a second- or third-line choice. Long-term use of hydralazine may be associated with a lupus-like syndrome in some patients.

Prazosin has been used as a second- or third-line drug in pregnant women whose hypertension is difficult to control or is severe with an early onset. This agent appears to be similar in efficacy to nifedipine in such a setting (Hall et al, 2000).

Although diuretics are used extensively in hypertensive nonpregnant adults, there appears to be little role for them in the treatment of chronic hypertension. They have been alleged to reduce or prevent the normal plasma volume expansion seen in pregnancy (Sibai et al, 1984), an effect that theoretically might impede fetal growth, although the evidence for it is mixed. Most authorities restrict the use of diuretics to patients with a cardiac dysfunction or pulmonary edema.

Angiotensin-converting enzyme (ACE) inhibitors are not used in pregnancy. Their use in the second and third trimesters is associated with malformation of the fetal calvarium, fetal renal failure, oligohydramnios, pulmonary hypoplasia, and fetal and neonatal death (Buttar, 1997). These agents appear to be safe when taken in the first trimester (Steffensen et al, 1998), but a patient who conceives while taking an ACE inhibitor should be switched to a safer alternative as soon as possible. Similar precautions apply to the use of angiotensin receptor blockers in pregnancy.

**Antenatal Fetal Surveillance in Chronic Hypertension**

As the third trimester progresses, patients with chronic hypertension are at growing risk of a slowing of fetal growth as well as superimposed preeclampsia. Antenatal surveillance in women with chronic hypertension should include careful screening for signs and symptoms of superadded

preeclampsia, which constitutes the greatest perinatal risk. Fetal growth should be followed with serial ultrasonography evaluations (every 3 to 6 weeks). All patients should perform fetal kick counts from 28 weeks of gestation onward, and cases of suspected fetal growth impairment should be followed with nonstress tests as well as modified nonstress tests including an amniotic fluid index or biophysical profile determination. Although the optimum interval for these tests is controversial (every 3 to 7 days), and their role is unproven in the absence of fetal IUGR or other evidence of fetal compromise, most centers begin regular fetal biophysical testing at 32 to 34 weeks and continue until delivery.

Women with renal impairment and chronic hypertension have a markedly higher risk of poor perinatal outcome than normotensive women and women with hypertension without renal impairment. Additionally, moderate or severe renal disease (serum creatinine level  $\geq 1.4$  mg/dL) may accelerate the loss of renal function during pregnancy (Cunningham et al, 1990; Hou, 1999). Fetal growth is directly related to renal impairment, and women undergoing dialysis are at particular risk of fetal growth impairment, preterm delivery, and fetal death, even with optimal management. Those who start dialysis during pregnancy are at greatest risk, with only a 50% chance of a surviving infant (Hou, 1999).

## Gestational Hypertension

The diagnosis of gestational hypertension can be made with confidence only after delivery. It is defined as hypertension occurring in the second half of pregnancy in the absence of any other signs or symptoms of preeclampsia. Because a patient with what appears to be gestational hypertension at 36 weeks can finally evolve into full-blown preeclampsia at 39 weeks, the diagnosis of gestational hypertension should always evoke caution and vigilance. Only if the patient's blood pressure returns to normal postpartum without development of signs of preeclampsia should the final diagnosis of gestational hypertension be applied. During pregnancy, gestational hypertension is indistinguishable from preeclampsia-in-evolution. Thus, all patients with gestational hypertension should be regarded as being at risk for progression to preeclampsia.

The earlier gestational hypertension is evident, the greater the risk of preeclampsia. Of patients in whom the diagnosis is made before 30 weeks of gestation, more than one third will experience preeclampsia, whereas in those whose diagnosis is made after 38 weeks, the risk is less than 10%. Decisions to treat patients in this group with antihypertensives must be carefully considered, given the risk of subsequent preeclampsia and the lack of evidence supporting improved fetal outcome. Transient gestational hypertension tends to recur in subsequent pregnancies and predisposes women to hypertension in the future (Marin et al, 2000).

## Preeclampsia-Eclampsia

Preeclampsia is one of the most enigmatic diseases affecting human beings. It is unique to humans and has proved difficult to emulate in experimental animals. Despite years

of effort, we have a relatively poor understanding of the underlying cause of the disease, although much of the pathophysiology is known. Underlying the clinical manifestations of the disorder is a pattern of vascular endothelial dysfunction that may involve the central nervous system, the renal and hepatic systems, and the cardiovascular system and may produce a coagulopathy. Preeclampsia has an enormous variety of presentations with a wide range of severity and timing during the pregnancy or immediately postpartum.

The classic symptom triad that defines preeclampsia consists of hypertension, proteinuria, and edema. Most classifications of preeclampsia now dispense with edema because it affects around 80% of all pregnant women at term. Preeclampsia may be divided into mild and severe forms (Table 11-3). This distinction is important, because in the presence of severe disease at any gestational age, the only treatment option is delivery, whereas conservative management may be acceptable for a patient who has mild disease and whose pregnancy is remote from term.

Although the precise cause of preeclampsia remains uncertain, numerous factors raise the risk of the disease (Table 11-4). These factors may be additive, producing a well-defined group of patients at greatly increased risk. Up to 10% of primigravid patients have mild preeclampsia, and about 1% have severe disease.

## Preeclampsia

### Etiology

The most widely accepted theory for the pathophysiology of preeclampsia is based on a model of impaired placental implantation that results in placental hypoperfusion and hypoxia. The placenta then releases substances into the maternal circulation that adversely affect endothelial

**TABLE 11-3**

### Features of Mild and Severe Preeclampsia

Mild	Blood pressure $\geq 140$ mm Hg systolic or 90 mm Hg diastolic Proteinuria $\geq 300$ mg/24 hr
Severe*	Blood pressure $\geq 160$ mm Hg systolic or 100 mm Hg diastolic Proteinuria $\geq 5$ g/24 hr Elevated serum creatinine value Eclampsia Pulmonary edema Oliguria $< 500$ mL/hr HELLP (hemolysis, elevated liver enzymes, and low platelets) syndrome Intrauterine growth restriction Symptoms suggestive of end-organ involvement: headache, visual disturbance, epigastric or right upper quadrant pain

\*Any single feature in the severe definition satisfies the diagnosis of severe preeclampsia.

Modified from ACOG practice bulletin: Diagnosis and management of preeclampsia and eclampsia. Number 33, January 2002. American College of Obstetricians and Gynecologists. *Int J Gynaecol Obstet* 77:67-75, 2002.

TABLE 11-4

**Risk Factors for Development of Preeclampsia**

Factor	Relative Risk
Primigravida	3
Age >40 yrs	3
African-American race	1.5
Family history	5
Chronic hypertension	10
Chronic renal disease	20
Antiphospholipid syndrome	10
Insulin dependent diabetes mellitus	2
Multiple gestation	4

function, leading to the clinical syndrome of preeclampsia (Myers and Baker, 2002). Individual responses to this process vary in severity and timing in a manner that seems to have genetic, familial, and immunologic components. Thus, preeclampsia occurring in a first-degree relative confers a fourfold increase in risk of the disease (Chesley and Cooper, 1986), and women born to mothers with preeclampsia themselves have a higher risk. There is some evidence that the presence of certain genotypes, such as factor V Leiden and other thrombophilias (de Vries et al, 1997), or metabolic defects, such as hyperhomocystinemia secondary to methylenetetrahydrofolate reductase deficiency (Kupferminc et al, 1999), predispose women to preeclampsia, although a true “candidate gene” has yet to be established and will probably never be so. Population studies have suggested that women exposed to the antigenic effects of sperm before conception have a lower rate of preeclampsia than women who conceive with lesser degrees of exposure, although the evidence is inconclusive (Koelman et al, 2000).

The endothelial dysfunction that characterizes preeclampsia (Roberts, 1999) manifests as greater vascular reactivity to circulating vasoconstrictors such as angiotensin, reduced production of endogenous vasodilators such as prostacyclin and nitric oxide (Ashworth et al, 1997), and increases in both vascular permeability and a tendency toward platelet consumption and coagulopathy. The end result is hypertension, proteinuria secondary to glomerular injury, edema, and a tendency toward extravascular fluid overload with intravascular hemoconcentration.

### Predictors

Perhaps one of the most important contributions that prenatal care makes to maternal and fetal outcomes is the detection of preeclampsia and the prevention of eclampsia (Backe and Nakling, 1993; Karbhari et al, 1972). A wide variety of biochemical and physical tests has been proposed as screening tools for the early detection of preeclampsia (Dekker and Sibai, 1991). Most physical tests have been discredited, and even the most widely used biochemical tests have poor predictive values. Uric acid levels are elevated in many cases of preeclampsia, but the sensitivity of the measurement is low (Lim et al, 1998). Early detection of proteinuria is possible with the use of more sensitive tests, such as gel electrophoresis (Winkler et al,

1988), rather than conventional urinalysis but such tests do not lend themselves to routine use. Clinicians should be aware of the limitations of routine urine testing for detection of proteinuria, standard dipstick testing being notoriously inaccurate (Bell et al, 1999).

Doppler ultrasonographic assessment of the vascular dynamics in the uterine arteries during the second trimester has been proposed as a valuable screening tool in populations in which obstetric ultrasonography is routine (Kurdi et al, 1998). Up to 40% of women who go on to develop preeclampsia have abnormal waveforms, and this finding was reported to be associated with a six-fold rise in the risk of preeclampsia (Papageorghiou et al, 2002). Other researchers have obtained less impressive results (Goffinet et al, 2001). On balance, then, no effective screening test to predict preeclampsia currently exists, and clinicians are faced with the necessity of diagnosing the disease early and managing it as adroitly as possible.

### Prevention

If an accurate predictor of preeclampsia could be identified, the next logical step would be the application of a preventive or ameliorative treatment. Unfortunately, attempts to identify an effective treatment have proved equally difficult. Given the recognized association between vascular endothelial dysfunction and preeclampsia (in particular, vasoconstriction and excessive clotting in the maternal placental arteries), prostaglandin inhibitors have been viewed as a likely candidate for prophylaxis or treatment. Numerous trials have been conducted with low-dose aspirin, on the basis of the idea that aspirin's ability to irreversibly inhibit production of the vasoconstrictive prostaglandin thromboxane would promote greater activity of prostacyclin, a vasodilatory prostaglandin. This would help maintain patency in the maternal placental vascular bed and limit or prevent the evolution of preeclampsia. Unfortunately, although a modest reduction in the frequency of preeclampsia ( $\approx 15\%$ ) was documented, no improvement in key measures of perinatal outcome was demonstrable in a meta-analysis of the results of available studies (Duley et al, 2001).

Calcium supplementation was briefly in vogue as a preventive treatment in the 1990s, on the basis of the known vasodilatory effect of calcium and impressive results in early, small studies. However, its worth was not supported in a meta-analysis of studies (Atallah et al, 2000). Similarly, it has been suggested that antioxidants may have a role in preeclampsia prevention, but the only available trial to date showed mixed results, with improvements in biochemical indices in women receiving vitamins C and E, although perinatal outcomes were not different in treated and untreated groups (Chappell et al, 1999). Of concern was the finding that women in whom preeclampsia developed despite vitamin therapy had markedly worsened preeclampsia than controls in whom the disease developed. Thus, at present, an ideal preventive measure for preeclampsia does not exist.

### Antepartum Management

Given the current inability to predict or prevent preeclampsia, clinicians are left to deal with established disease and prevent maternal and fetal morbidity. The division of

established preeclampsia into mild and severe forms is of great worth in determining management and minimizing morbidity (see Table 11–3). Mild disease is generally managed conservatively (bed rest and frequent fetal and maternal biophysical assessments) until term is reached or there is evidence of maternal or fetal compromise. The appearance of severe preeclampsia mandates delivery in all but highly selected cases regardless of gestational age.

Patients with a diagnosis of mild preeclampsia should be evaluated for signs of maternal or fetal compromise, which would make their disease severe. Evaluation should include a 24-hour urine collection to evaluate for proteinuria, full blood count and platelet measurements, determination of serum uric acid, blood urea nitrogen, and creatinine levels, and evaluation of liver transaminases. Fetal size should be estimated with ultrasonography; the presence of IUGR (<10<sup>th</sup> percentile) is a sign of severe preeclampsia. Patients with mild disease at 37 weeks or more of gestation should be delivered, because prolongation of pregnancy has no material benefit to be gained from and increases the risks of maternal and fetal morbidity. Patients at earlier gestational stages should be closely monitored with sequential clinical and laboratory evaluations. Such monitoring often begins in the hospital and may be continued in an outpatient or home setting with appropriate supervision. If the clinical picture deteriorates or term is reached, delivery should be effected. There is no evidence that antihypertensive therapy influences progression of preeclampsia, and its use may actually be dangerous by masking worsening hypertension. Fetal well-being should be evaluated until delivery by means of kick counts and regular nonstress tests or modified biophysical profiles.

Patients with severe disease should be delivered. The only exception to this approach is the diagnosis of severe preeclampsia, in a patient remote from term (<28 weeks), on the basis of proteinuria and transiently (unsustained) severe hypertension *alone*. Such patients may be managed conservatively under close supervision while antenatal corticosteroids are administered without adversely affecting maternal or fetal outcome (Sibai et al, 1990). There is no place for conservative management in any other circumstance. The patient with severe preeclampsia at less than 24 weeks of gestation should be offered termination of the pregnancy; all others should be delivered by the most expedient means. Cesarean section should be reserved for obstetric indications.

Severe hypertension requires treatment with fast-acting antihypertensive agents if stroke and placental abruption are to be avoided. Intravenous hydralazine is well established as a first-line drug for this purpose, although there is a growing experience with other agents, including intravenous labetalol and oral nifedipine (Duley and Henderson-Smith, 2000a) (Table 11–5). The aim of treatment is to lower blood pressure into the mild preeclampsia range (140/90 mm Hg) to reduce the risk of stroke and other maternal cardiovascular complications. There is good evidence to support the use of parenteral magnesium sulfate to prevent eclampsia in all cases of severe disease (Duley et al, 2003).

Severe preeclampsia may manifest as classic disease with severe proteinuric hypertension or may cause atypical findings, such as pulmonary edema or severe central nervous

TABLE 11–5

### Drugs for Acute Treatment of Hypertension in Severe Preeclampsia

Drug	Dosage
Hydralazine	1-2 mg test dose 5-10 mg IV followed by 5-10 mg q 20 min as required, to a total of 30 mg
Labetalol	10-20 mg IV followed by 20-80 mg q 10 min to a total of 300 mg
Nifedipine	10 mg PO q 10-30 min up to three doses

system symptoms, including blindness. More commonly, patients show evidence of microangiopathy leading to the HELLP syndrome. The full-blown clinical syndrome of HELLP carries a significant maternal risk. Early reports suggested that the disease carries a grave prognosis (Weinstein, 1982). This suggestion remains true for florid clinical cases, but most patients now have “laboratory” HELLP and never experience major clinical features of the syndrome because they are delivered before deteriorating to that point.

### Preeclampsia and Fetal Risk

Because the only recourse in severe preeclampsia is delivery, the disease has a corresponding effect on prematurity and its attendant complications. IUGR is not uncommon in severe preeclampsia, and there may be evidence of progressive deterioration in fetal well-being with worsening disease. Infants delivered at less than 34 weeks of gestation will benefit from antenatal steroid therapy—even as little as 8 hours of therapy before delivery may have benefit. Many patients are able to deliver vaginally, but fetal compromise may preclude aggressive induction and mandate delivery by cesarean section. The incidence of respiratory distress syndrome is lower in infants of preeclamptic mothers delivered preterm than in those of age-matched controls without antenatal steroid exposure (Yoon et al, 1980). Nonetheless, the morbidity of such infants is greater because of hypoxic insults received in utero. Infants born to preeclamptic mothers may have thrombocytopenia or neutropenia, which further complicates their newborn course (Fraser and Tudehope, 1996).

### Intrapartum Management

All laboring women with a diagnosis of preeclampsia should receive magnesium sulfate as seizure prophylaxis (Table 11–6). Although the absolute risk of seizure is low, the occurrence of seizures is unpredictable and the margin of safety of magnesium sulfate therapy is fairly wide. Blood pressure should be maintained in the mild preeclampsia range. Epidural anesthesia is indicated for pain control and to aid in blood pressure management. Vaginal delivery should be possible in most cases. Delivery by cesarean section should be reserved for obstetric indications. Careful attention to fluid balance should be maintained. After delivery, the preeclamptic process should begin to resolve rapidly.

TABLE 11-6

### Magnesium Sulfate Therapy for Prevention of Eclampsia

1. Bolus 4-6 g IV over 20 min
2. Continuous infusion 1-2 g/hr
3. Follow up levels q 6-8 hr to target 4-6 mEq/L
4. Continue infusion 24 hr after delivery or 24 hr after seizure if seizure occurs despite magnesium therapy

## Eclampsia

*Eclampsia* is the occurrence of generalized tonic-clonic seizures in association with preeclampsia. It affects about 1 in 2500 deliveries in the United States and may be much more common in developing countries, affecting as many as 1% of parturients. Up to 10% of maternal deaths are due to eclampsia (Duley, 1992).

Most cases of eclampsia occur within 24 hours of delivery. Almost 50% of seizures occur before the patient's admission to labor and delivery, about 30% are intrapartum, and the remainder are postpartum. There is a considerable drop in the risk of eclampsia by 48 hours postpartum, seizures occurring in less than 3% of women beyond that time. Most patients have antecedent features suggestive of preeclampsia, although in some cases eclampsia may occur without warning. If eclampsia is left untreated, repetitive seizures become more frequent and of longer duration, and ultimately, status eclampticus develops. Maternal and fetal mortality may be as high as 50% in severe cases, especially if the seizures take place while the patient is far from medical care.

Randomized controlled trials have demonstrated the clear superiority of magnesium sulfate for the treatment of eclampsia over all other anticonvulsants (Duley and Gulmezoglu, 2002; Duley and Henderson-Smart, 2002b, 2002c). Intravenous magnesium sulfate is given as a 4-g bolus over 5 minutes followed by a maintenance infusion of 1 to 2 g/hr for 24 hours after delivery. Subsequent seizures may be treated by further bolus injections; in refractory cases, second-line treatment with other anticonvulsants may be required, or the patient may have to be paralyzed and ventilated.

Delivery after an eclamptic seizure should take place in a controlled, careful manner. There is little to be added by performing a "crash" cesarean section (Coppage and Polzin, 2002). The patient should be stabilized first. Vaginal delivery is possible in most cases, although cesarean delivery may be indicated if the status of the cervix is unfavorable or fetal compromise is ongoing despite control of seizures and maternal stabilization. Infants born to mothers after eclampsia require careful monitoring after birth.

## Perinatal Substance Abuse

Alma Martinez, J. Colin Partridge, and  
H. William Taesch

Substance abuse during pregnancy has been recognized for more than a century. Overall prevalence of cocaine or crack use has diminished since the epidemic of the late 1980s and early 1990s but has been followed by greater opiate use in pregnancy. Since the 1950s, awareness has also grown regarding the adverse effects of tobacco and ethanol on pregnancy.

Psychotropic substances, both legal (alcohol, cigarettes, and prescription drugs) and illegal (heroin, amphetamine, cocaine, and phencyclidine [PCP]), may cause obstetric complications and fetal injury. These substances have short-term and long-term consequences for the newborn infant. Although chronic or sporadic drug abuse can occur in a person in any socioeconomic class, several elements, such as lifestyle, health risks, poverty, and drug, tobacco, and alcohol abuse, often coexist. From this point of view, substance abuse, like many other health conditions, is a consequence of multiple societal, familial, psychological, medical, educational, and personal ills. Additionally, substance abuse often exacerbates disadvantageous medical and socioeconomic conditions (Table 12-1).

In general, the consequences of fetal exposure to drugs, alcohol, and tobacco smoking are poor intrauterine growth, prematurity, fetal distress, abortion, stillbirth, cerebral infarctions and other vascular accidents, malformations, and neurobehavioral dysfunction. It is often quite difficult to determine the effects of a single drug on the fetus and newborn, who are often exposed to multiple drugs during gestation. Multiple drug exposure, socioeconomic status of parents, and subsequent postnatal environmental factors typically confound studies of drug effects on the fetus and newborn. Nonetheless, established correlates of substance use during pregnancy are listed in Table 12-2.

Prevalence of drug use among pregnant women is less than among non-pregnant women, but about 3% of women use illicit drugs during pregnancy (HHS/Substance Abuse, 2001). Illicit drug use is estimated at nearly 13% among women aged 15 to 17 years, pregnant or not. Illicit drug use during pregnancy is more prevalent among black women (7%) than among white (3%) and Hispanic (2%) women. Additionally, as of 1999, 13% of pregnant women use alcohol, and nearly 3% report frequent or binge drinking, again substantially lower than nonpregnant women (53% and 12%, respectively) (Alcohol use, 2002). The largest gestational exposure rates are for smoking. About 19% of pregnant women between 15 and 44 years of age continue to smoke during pregnancy. Nationally, women

make up approximately 30% of drug treatment admissions and 25% of alcohol treatment admissions.

One of the most comprehensive geographically based studies on substance abuse by pregnant women was undertaken by the Perinatal Substance Exposure Study Group (Vega et al, 1993). In the study, urine was collected from more than 30,000 women at the time of delivery in California in 1992. The state of California has approximately 600,000 deliveries per year, representing about 15% of all deliveries in the United States. The major results of this study are shown in Table 12-3. These prevalence rates of maternal drug use (except for the higher rates of alcohol in California) are similar to those of earlier statewide surveys from South Carolina and Rhode Island, and lower than a statewide survey in Georgia that was based on newborn bloodspot screening (Surveillance, 1997). If these results are extrapolated to the United States at large, an estimated 450,000 infants per year (11% of 4 million live births) are exposed to alcohol or drugs (or both) in the days before delivery.

Table 12-4 shows the distribution of exposure of neonates to drugs, alcohol, and tobacco by ethnic group. Prevalence rates of alcohol, smoking, and drugs are highest among blacks and lowest among Asians and Pacific Islanders. While at lower risk for substance use, white, non-Hispanic babies account for roughly half the newborns exposed to drugs, smoking, and alcohol. Parents with substance use have lower educational achievement and are less likely to be employed full time, less likely to be married, and more likely to receive welfare support than nonusing parents. Substance exposure is twofold higher in groups identified as "poor" on the basis of eligibility for Medicaid health insurance, indicating the expected association between substance abuse and poverty. As documented by investigators, smoking serves as a major risk for illicit substance exposure, with a 22-fold higher risk for cocaine use among those who reported that they smoke (Vega et al, 1993). In the California prevalence study, polydrug use was not common. The rate reported, 0.5%, may underestimate polydrug use, however, because women may use drugs sequentially according to preference and availability rather than simultaneously. Studies that attempt to detail true dose and duration of exposures throughout gestation are not available.

Drug withdrawal and drug effects are seen in exposed infants, related to the specific drug as well as the timing, dose, and duration of exposure. Other emotional, medical, legal, familial, financial, and societal consequences play important roles in the outcome of drug-exposed newborn infants. Hospital costs average approximately \$7500 more for infants who have been exposed to drugs than for those who have not (Joyce et al, 1995). Frustrated by adverse consequences, some prosecutors have charged substance-abusing women with fetal or child abuse (Annas, 2001). For the most part, these efforts have been unsuccessful. The infant with a positive toxicology screen result has a 26% to 58% chance of being referred for foster care placement, compared with 1% to 2% for the infant with a negative result (U.S. General Accounting Office, 1990). Costs of foster care are roughly \$5000 per year for a normal infant and \$20,000 per year for an infant with special medical needs.

**TABLE 12-1**

**Associated Risks of Drug Use, Alcohol Use, and Smoking in Child-Bearing Women**

Suboptimal parenting
Physical, sexual, domestic violence
Poverty
Poor schooling, illiteracy, school dropout
Limited job skills, training
Limited jobs
Poor self-image, poor coping skills
Peer pressure
Ineffectuality of birth control and protection against sexually transmitted diseases (STDs)
Unplanned, unwanted pregnancy; teenage pregnancy
Poor nutrition and preconception health care
Poor access, receipt, and quality of prenatal care
Little family/father support
Stress
Psychological disorders, depression
Limited access to support services in community
Dependence/addiction
Pregnancy wastage
Increased risk of premature birth
Increased risk of fetal malformations
Fetal growth retardation
Fetal/neonatal death
Newborn assigned to foster care
Attempts at rehabilitation
Increased risk of human immunodeficiency virus, syphilis, hepatitis B or C, other STDs
Incarceration
Recapitulation in next generation

for abuse and addiction was documented in the mid-1800s, shortly after it began to be used extensively. Perinatal problems associated with opium were first reported in the late 1800s. Since the 1950s, heroin use has been endemic in most major American cities.

Specific opiate receptors ( $\mu$ ,  $\delta$ ,  $\kappa$ ) have been identified in the nervous system and the bowel that are activated by endogenous opiates, such as the naturally occurring endorphins and enkephalins (Vacarino and Kastin, 2000). Modulators of the sympathoadrenal system, endogenous opiates are important during periods of diverse forms of stress. Activation of these receptors by the endogenous opiates has physiologic effects, including analgesia, drowsiness, respiratory depression, decreased gastrointestinal motility, nausea, and vomiting as well as alterations in the endocrine and autonomic nervous systems. Activation of these same endogenous opiate receptors by exogenous opioid drugs has similar clinical effects.

The use of opioid drugs can result in the development of tolerance, physiologic dependence, and addiction. Tolerance leads to a shortened duration of the action of opioids and a decrease in the intensity of the drug action, followed by the need for a higher dose of drug to obtain the same clinical effect. Tolerance is believed to result from continued occupancy of the opioid receptor. Continuous administration of opioids, therefore, leads to more rapid onset of tolerance (Anand and Arnold, 1994; Suresh and Anand, 2001). With physiologic dependence, there is a need for further drug administration to prevent withdrawal symptoms (agitation, dysphoria, temperature instability). Addiction is a more severe form of dependence that involves a complex pattern of drug-seeking behavior.

**OPIATES**

Opium derivatives have been used as analgesics for centuries and remain the most effective analgesics available. Opioids of clinical interest are morphine, heroin, methadone, meperidine, and codeine. Morphine's potential

**Epidemiology**

Prevalence of opiate use among pregnant women is reported to range from 1% to 2% (Vega et al, 1993; Yawn et al, 1994) to as much as 21% in a highly selected group of women (Behnke and Eyler, 1993; Nair et al, 1994; Ostrea et al, 1992b). One multicenter study found that the

PCP (phencyclidine)	0.0
Alcohol	6.7
Illicit drugs	3.5
Drugs and/or alcohol <sup>+</sup>	11.3
Tobacco <sup>‡</sup>	8.8

\*Percentages represent the positive urine test results obtained from 29,494 women delivering infants from March through October 1992.

<sup>+</sup>Includes alcohol and/or any drug; excludes tobacco.

<sup>‡</sup>Tobacco was self-reported and not based on urine testing.

Data from Vega W, Kolody B, Hwang J, Noble A: Prevalence and magnitude of prenatal substance exposures in California. *N Engl J Med* 329:850, 1993.

prevalence of opiate use varied by center and ranged from 1.6% to 4.5% at the different sites (Lester et al, 2001). Additionally, these centers reported higher rates of opiate use with low-birth-weight and very low-birth-weight infants. Rates for heroin use are higher in metropolitan areas and cities and are more concentrated in Northeast and West Coast cities. Opiate abuse is more common in groups of lower socioeconomic status. Studies of the distribution of opiate abuse among ethnic groups in the United States have shown inconsistencies and apparent contradictions. Reports showing blacks and Hispanics to be disproportionately represented (Hartnoll, 1994) can be contrasted with those showing a higher incidence among white women (Gillogley et al, 1990). In a population-based study

in California, the prevalence of opiate use during pregnancy was highest in black women, followed by white women, and then Asian and Hispanic women (Vega et al, 1993).

Women using opiates during pregnancy are more likely to use other drugs (Bauer, 1999; Brown et al, 1998; van Baar et al, 1994a, 1994b). Investigators have also reported that 93% of women identified as using opiates and cocaine during pregnancy had also used a combination of alcohol, nicotine, or marijuana (Bauer, 1999). Women who smoke during pregnancy are more likely to use opiates, alcohol, cocaine, amphetamines, and cannabis during pregnancy than women who do not smoke (Vega et al, 1993). In a study from Amsterdam, only 7% of heroin-using and methadone-using women did not smoke during pregnancy (Boer et al, 1994).

Of the opiate drugs known to be abused during pregnancy, heroin has been the most extensively studied. Heroin can be ingested through smoking or by the intranasal or intravenous route. Intranasal use is common among women, especially in the western United States, whereas the intravenous route is more popular among users on the eastern seaboard. Reports from European countries suggest a trend away from intravenous injection of opiates (Hartnoll, 1994). The use of noninjectable heroin may reduce the risk of transmission of human immunodeficiency virus (HIV); however, its wider use ensures the emergence of new groups of heroin users for whom the risk of intravenous use is a major deterrent.

## Clinical Aspects

### Maternal Health

Many heroin-addicted pregnant women have poor general health with multiple medical problems associated with the drug abuse lifestyle. Intravenous drug use places the woman at risk for multiple infectious complications, including cellulitis, thrombophlebitis, hepatitis, endocarditis, syphilis, gonorrhea, and acquired immunodeficiency syndrome (AIDS). In a prospective study undertaken in

**TABLE 12-4****Race/Ethnicity and Substance Exposure at Term in California, 1992\***

Canada, a 5-year incidence of HIV seroconversion was 13.4%; the rate of conversion associated with injection of heroin or cocaine was 40% higher in women than in men (Spittal et al, 2002). Opiate abusers are also less likely to receive prenatal care or to obtain late prenatal care (Bauer, 1999). Heroin-addicted mothers are often poorly nourished, and iron-deficiency anemia is more common in pregnant opiate users than nonusers. In studies throughout the world, women who use heroin have higher rates of maternal complications of pregnancy, such as prematurity, small-for-gestational-age infants, and antepartum hemorrhage, as well as a higher incidence of sexually transmitted diseases (Bauer, 1999; Lam et al, 1992; Little et al, 1990). Bauer (1999) found that maternal hepatitis infections were five times higher in opiate-using women than in a control group of non-users.

The rates of maternal complications of pregnancy are further increased when drug use is added to infection with HIV. Women infected with HIV who also use opiates (methadone) have higher rates of miscarriage, preterm deliveries, and small-for-gestational-age infants, and more vaginal and urinary tract infections than women who are HIV-positive but are not using drugs (Mauri et al, 1995). Domestic violence is also identified as a significant factor complicating perinatal outcomes for women using opiates (Bauer, 1999).

### **Maternal Methadone Maintenance**

The potential benefits of maternal methadone maintenance are numerous (Kandall and Doberczak, 1999; Ward et al, 1999). They include the prevention of opiate withdrawal symptoms in the mother, better medical and prenatal care, improved health and growth of the fetus, maintenance of opiate levels in the mother to decrease both the use of illicit drugs and the potential for perinatal infections. Methadone maintenance programs associated with comprehensive medical and psychosocial services for the pregnant woman are of additional benefit. Methadone maintenance has been shown to be associated with higher birth weight in some but not all studies (Brown et al, 1998; Kandall and Doberczak, 1999). Because maternal drug withdrawal is believed to be associated with subsequent fetal withdrawal, fetal asphyxia, and spontaneous abortions, detoxification of a pregnant heroin user is infrequently attempted (Barr and Jones, 1994). Dashe and colleagues (1998) reported on a small study of opiate-using pregnant women undergoing safe maternal detoxification. Close to 60% of the women completed detoxification, but almost 30% resumed opiate use. McCarthy and associates (1999) showed that women who reduced their methadone dose during pregnancy had infants with higher birth weights than a control group who continued on the same (or increased) methadone dose throughout pregnancy. In the United States, most pregnant women are treated with daily methadone. Some authorities, however, have urged reappraisal and reevaluation of the benefits of methadone maintenance in pregnancy (Brown et al, 1998; Hulse and O'Neil, 2001).

In the Netherlands, women enrolled in a methadone program had higher rates of prenatal care. In this study, higher rates of prenatal care were associated with higher

birth weights and less prematurity in the offspring (Soepatmi, 1994). When women in a methadone maintenance program were enrolled in an enhanced prenatal care program, their infants' birth weights were significantly larger than those in the control group of women receiving regular methadone maintenance during pregnancy (Chang et al, 1992). Others have shown that higher methadone doses are associated with improved head circumference and increased gestational age at delivery (Hagopian et al, 1996). Using meta-analysis design, Hulse and coworkers (1997) found that infant birth weight was associated with heroin use and that birth weights were better with methadone treatment during pregnancy. These favorable outcomes are believed to be due to a stable intrauterine environment uncomplicated by periods of intoxication and withdrawal as well as less stress and better nutrition in the mother.

Several investigators have found that neonatal withdrawal symptoms, birth weight, length of pregnancy, and number of days infants require treatment for abstinence do not correlate with maternal methadone dosage (Brown et al, 1998; Finnegan, 1991; Madden et al, 1977; Rosen and Pippenger, 1976). In contrast, others have reported correlation between the severity of neonatal withdrawal and maternal methadone dose (Harper et al, 1977; Maas et al, 1990; Malpas et al, 1995). Studying maternal and neonatal serum levels of methadone does not help clarify this dilemma. Investigators have found no correlation between neonatal serum levels of methadone and the maternal methadone dose at delivery, the maternal serum levels, or the severity of withdrawal symptoms in the neonates (Harper et al, 1977; Mack et al, 1991). Other researchers have reported that neonatal signs of withdrawal correlate with the rate of decline of the neonatal plasma level during the first few days of life (Doberczak et al, 1993). Still others have suggested that neonatal withdrawal occurs after plasma methadone levels fall below a threshold level (Rosen and Pippenger, 1976).

There are no guidelines for methadone dosages during pregnancy. Controversy continues over the most appropriate dose of methadone maintenance during pregnancy. The divergent findings noted previously have been used to argue either for weaning a pregnant woman to a low methadone maintenance dose or for attempting complete maternal detoxification during pregnancy. Some authorities believe in maintaining high methadone doses to keep the mother from "chipping" with additional street drugs, which would put her at risk not only for greater complications of pregnancy but also for higher risk of infections transmitted by intravenous use of drugs (HIV, hepatitis) or of sexually transmitted disease. High-dose methadone maintenance ranges between 60 and 150 mg/day. Despite reports of the safe detoxification of pregnant women, there are still concerns that the fetus is placed at risk during maternal detoxification. The medical management of pregnant women who are addicted to opiates remains controversial.

### **Fetal and Neonatal Health**

Obstetric complications reported in the literature to be associated with use of opiates include higher incidences of spontaneous abortions, premature delivery and preterm

labor, abruptio placentae, chorioamnionitis, increased risk of cesarean section associated with breech presentation, impaired fetal growth, and fetal distress. In women who use opiates during pregnancy, the incidence of preterm labor and premature delivery ranges between 25% and 41% (Chiriboga, 1993; Lam et al, 1992; Little et al, 1990). Infants exposed to opiates have a higher incidence of intrauterine growth restriction (IUGR) (Lam et al, 1992) and smaller head circumference (Bauer, 1999; Boer et al, 1994). Maternal opiate use is associated with higher rates of meconium staining, lower Apgar scores, and longer duration of membrane rupture (Gillogley et al, 1990). Others have also reported increased incidences of syphilis and HIV infection at birth (Bauer, 1999).

The higher risks for fetal loss, IUGR, prematurity, and low birth weight are multifactorial. Maternal lifestyle, malnutrition, and infections as well as polydrug affects are likely to result in poor perinatal outcomes, including poor intrauterine growth and prematurity. Finally, because the drug supply is often episodic, the pregnant addict is subject to episodes of withdrawal and overdose, thereby subjecting the fetus to intermittent episodes of hypoxia in utero, hindering growth and raise the risk of spontaneous abortion, stillbirth, fetal distress, and prematurity. Infants born to opiate addicts are more likely to be of low birth weight, to be premature, and to suffer from infection and perinatal asphyxia. The incidence of respiratory distress syndrome is reportedly lower in infants exposed to heroin in utero than in nonexposed infants. This difference may represent a direct effect of heroin on lung maturation, stress-induced accelerated lung maturation, or both (Tausch et al, 1973).

### Neonatal Withdrawal Syndrome

The classic neonatal withdrawal or abstinence syndrome consists of a wide variety of central nervous system (CNS) signs of irritability, gastrointestinal and feeding problems (diarrhea, hyperphagia), autonomic signs of dysfunction, and respiratory symptoms (Table 12-5). The incidence of neonatal withdrawal syndrome in the

infants of women using heroin or methadone is quite high, with wide ranges reported between 16% and 90% (Agarwal, et al, 1999; Boer et al, 1994; Maas et al, 1990; van Baar et al, 1994a).

The mortality rate for withdrawal infants was estimated as high as 10% for the years 1969 through 1979 in Amsterdam. Current estimates, however, show marked improvement, with perinatal mortality rates of less than 1% (Boer et al, 1994). Death is rarely associated with withdrawal alone but occurs as a consequence of prematurity, infection, and severe perinatal asphyxia.

A number of evaluation tools is used to assess the severity of opiate withdrawal after birth. The Neonatal Abstinence Score is a scale based on nursing observations of the severity of signs of withdrawal (Finnegan et al, 1975). Green and Suffet (1981) introduced the Neonatal Narcotic Withdrawal Index as a rapid physician-based evaluation for neonatal signs of withdrawal. Use of these scoring systems enables one to quantify the severity of the infant's withdrawal. The scores are used to guide the clinician's treatment of the withdrawing infant. It is important to not rely simply on an absolute score to either institute pharmacologic interventions or to wean the infant from such medications. Rather, a daily evaluation of the abnormal clinical elements observed in the scoring system is also critical. These methods have shown good interobserver reliability and can improve clinicians' ability to treat the withdrawing infant appropriately (Anand and Arnold, 1994; Franck and Vilardi, 1995). The goal of medical management of opiate withdrawal is to maintain infant comfort while enabling the infant to feed, sleep, and gain weight in an appropriate manner. Standard medical practice is to combine both developmental and behavioral methods with pharmacologic interventions as necessary to soothe the infant.

### Treatment

Treatment for opiate withdrawal consists of soothing (swaddling, rocking, decreased environmental stimulation) and pharmacologic management when necessary. Medications most commonly used for opiate withdrawal are dilute tincture of opium, benzodiazepines, and phenobarbital (Levy and Sino, 1993; Neonatal drug withdrawal, 1998). The mainstay of treatment for opiate withdrawal is the use of opiates, either alone or in combination with other medications. The medication is titrated according to the severity of the signs of withdrawal for each infant.

A usual standard starting dose of diluted tincture of opium (0.4 mg/mL of morphine equivalent) is 0.1 mL/kg given orally every 3 to 4 hours. This dose can be increased in increments of 0.05 to 0.1 mL until the symptoms are controlled. The usual dose for infants withdrawing at birth ranges from 0.2 to 0.5 mL every 3 to 4 hours (Anand and Arnold, 1994; Levy and Sino, 1993; Neonatal drug withdrawal, 1998). Higher doses may often be needed to control significant physiologic signs of withdrawal such as diarrhea, pyrexia, hypertension, and significant hypertonicity. Investigators suggest that the use of shorter dosing intervals and lower peak doses of tincture of opiate solution are associated with shorter hospital stays for infants withdrawing from opiates (Jones, 1999).

**TABLE 12-5**

#### Clinical Signs of Neonatal Withdrawal Syndrome

Central nervous system dysfunction	Irritability, excessive crying Jitteriness, tremulousness Hyperactive reflexes Increased tone Sleep disturbance Seizures
Autonomic dysfunction	Excessive sweating Mottling Hyperthermia Hypertension
Respiratory symptoms	Tachypnea Nasal stuffiness
Gastrointestinal and feeding disturbances	Diarrhea Excessive sucking Hyperphagia

Phenobarbital has been used for signs of acute opiate withdrawal. Phenobarbital does not, however, reduce significant physiologic signs of withdrawal such as diarrhea and seizures. Studies comparing phenobarbital with paregoric (morphine equivalent) showed that 11% of infants treated with phenobarbital had clinical seizures, whereas none of the infants treated with paregoric had this complication (Kandall et al, 1983). At higher doses, phenobarbital has also been shown to impair infant sucking and cause excessive sedation. The therapeutic blood level of phenobarbital for control of opiate withdrawal signs is not known. In addition to the limitations just noted, phenobarbital levels must be monitored when this medication is used for treatment of withdrawal. Coyle and associates (2002) showed that combining deodorized tincture of opium (DTO) and phenobarbital was associated with decreases in hospitalization days, hospital costs, and severity of withdrawal signs in opiate-exposed term infants. In this study, however, the infants were discharged home on phenobarbital therapy, from which they were slowly weaned throughout infancy. Some of these infants received phenobarbital for prolonged times.

Diazepam can also be used as an additional or adjuvant drug for infants withdrawing from opiates. This agent helps relieve irritability and improve infant comfort and should be used on a discretionary basis. Diazepam should not be used as the sole medication for the treatment of withdrawal. The usual starting dose is 0.1 mg/kg, given as an oral dose for intermittent use in treating withdrawal signs (Anand and Arnold, 1994; Levy and Sino, 1993).

Adverse effects have been reported with the use of paregoric in preterm infants. Paregoric has been associated with acidosis, CNS depression, respiratory distress, hypotension, renal failure, seizures, and death (Anand and Arnold, 1994). Because of these significant limitations, this medication may have limited usefulness in patients with opiate withdrawal.

Although methadone has not been studied in neonates, and certainly not in premature infants, it has been used in the treatment of opiate withdrawal in older infants and children (Tobias, 2000; Tobias et al, 1990). Methadone has a long duration of action and can be administered by either the oral or the parenteral route. The initial methadone dose recommended for older infants and children is 0.05 to 0.1 mg/kg given every 6 to 12 hours, with increases of 0.05 mg/kg until symptoms are controlled. Tobias and colleagues (1990) showed that methadone could be given every 12 to 24 hours because of its longer half-life.

Once medications have been titrated to a level that controls the severity of opiate withdrawal, a judicious tapering of the dosage should be begun. A common method is to decrease the opiate dose by 10%, with continued surveillance of the infant for tolerance of this decrease. It is not unusual to note increased signs of opiate withdrawal during the medication tapering. The goal of tapering is to allow the infant to acclimate to a new and lower dose of medication while ensuring that he or she is comfortable and consolable, and is able to sleep, eat, and gain weight appropriately. Objective measurements using established withdrawal scoring systems should be used to determine the rate and efficacy of medication tapering.

### **Sudden Infant Death Syndrome and Opiates**

Numerous small studies and reports have suggested a link between maternal opiate use during pregnancy and an increased risk for sudden infant death syndrome (SIDS). A large 10-year study from New York showed, after data were controlled for known associated high-risk factors, that the risk ratio for SIDS was two to four times greater among opiate-exposed infants than among infants not exposed to any perinatal drugs (Kandall et al, 1993). Others, in a case-control study of SIDS in California, found that after adjustment of data for maternal smoking during pregnancy, there was no apparent association between maternal drug use and the occurrence of SIDS (Klonoff-Cohen et al, 2001; Ostrea et al, 1997). Using a meta-analysis of neonatal mortality rates in relation to opiate exposure, Hulse and colleagues (1998) found no support for a higher mortality rate among heroin- or methadone-exposed infants.

Interestingly, investigators have shown an increase in the rate of infant death (1 to 2 years after birth) in low-birth-weight infants (<2501 g) who had been exposed in utero to cocaine or cocaine plus opiates (Ostrea et al, 1997). It is unclear from this report how many of these infants represented cases of SIDS and how many were immature rather than growth-retarded at birth. To date, it is unclear whether there is an additional risk for SIDS for preterm infants who were exposed to opiates during gestation. A number of confounding maternal risk factors may be associated with both opiate use and SIDS. Reports point to the stronger association between maternal smoking and SIDS (Taylor and Sanderson, 1995).

### **Prognosis**

Because the typical opiate drug abuser uses multiple drugs, including cigarettes, alcohol, cocaine, PCP, and amphetamines, it is impossible to ascribe all adverse developmental effects in the infant of an opiate abuser to opiates alone. A woman's socioeconomic status has significant effects on her children's performances on intelligence measures and social adaptive behaviors. Because of multiple confounding factors in neurodevelopmental studies of opiate-exposed infants, controversy remains regarding the long-term effects of opiates on normal child development.

A number of studies suggests that exposure to exogenous opiates during fetal development may influence lifelong alterations in the developing brain. Infants who have been exposed to opiates in utero have a higher risk for fetal growth retardation and smaller head circumference than those who have not (Bauer, 1999). Also, significant developmental and learning deficits have been described in both methadone-exposed and heroin-exposed children (Soepatmi, 1994; van Baar and de Graaf, 1994; van Baar et al, 1994). Bunikowski and associates (1998) have reported a higher incidence of abnormalities in intellectual performance, developmental retardation, and neurologic abnormalities in a group of opiate-exposed infants compared with a control group of infants. However, the treated infants in the study had an unusually high incidence of seizures during withdrawal treatment (with phenobarbital alone) as well as a higher incidence of prematurity than the control infants. These important considerations temper the findings of the study.

Other investigators have shown normal development for opiate-exposed infants during the first 2 years of life after data have been controlled for socioeconomic status and birth weight (Bauer, 1999). Using regression analysis, researchers have shown that the amount of prenatal care obtained by the mother and the postnatal home environment were more predictive of the infant's future intellectual performance. Conversely, the amount of maternal opiate use during pregnancy was not found to be predictive. Others have pointed to the adverse environmental effects of poverty and poor learning environment on the development of methadone-exposed children. A multifactorial model has been proposed that encompasses both prenatal and postnatal influences on childhood development in drug-exposed infants (Zuckerman and Bresnahan, 1991). Ornoy and colleagues (2001) have shown that children exposed to heroin but adopted at an early age performed better on intelligence testing than opiate-exposed infants who were raised in their biologic homes. The same investigators found a higher rate of attention deficit disorders in children exposed to opiates regardless of home environment, with the highest incidence in children who were raised in their biological homes. Thus, numerous studies point to the importance of the home environment in optimizing child development.

## COCAINE

Cocaine is a highly psychoactive stimulant with a long history of abuse. A naturally occurring anesthetic of the tropane family of alkaloids, cocaine is obtained from the *Erythroxylon coca* plant, which is indigenous to the mountain slopes of Central and South America. The coca leaf has been chewed or made into a stimulant tea for centuries by the natives of these areas to decrease fatigue and hunger. Introduced to Europe in the 16th century, cocaine was isolated in 1860. Cocaine's euphoria-producing effect was exploited extensively in the United States in the late 19th and early 20th centuries, when the agent was an active ingredient in a number of widely used over-the-counter elixirs and tonics. Easy access became a major medical problem. Cocaine use markedly decreased after the Harrison Narcotic Act of 1914, which regulated the distribution of narcotics and cocaine, and the supervening Comprehensive Drug Abuse Prevention and Control Act of 1970, which classified cocaine as a Schedule II drug (i.e., one of "high abuse potential with restricted medical use," similar to opiates, barbiturates, and amphetamines). Until the mid-1980s, cocaine held the status of an expensive and exotic drug used primarily by the affluent as well as a performance enhancer by people in sports and entertainment. Its reputation as a glamour drug, the widely held misconception that cocaine is nonaddicting, and the development and marketing of crack, a cheap version of cocaine, were major factors in the resurgence of drug use. Cocaine and other stimulants have become the drugs of choice for women in the United States (Berger et al, 1990), with estimates that up to 13% of women 18 to 25 years old use cocaine regularly. Studies based on urine toxicology screening report a prevalence ranging from 5% of parturients in New York City, to 1.1% of those in a

geographic sample in California, and to less than 0.5% of those in private hospitals in Denver, Colorado (Burke and Roth, 1993). Prevalence increases to 18% when both self-report and urine testing are used, and the highest prevalence rates are reported from studies using meconium testing. In these studies, up to 31% of women delivering in a high-risk urban setting and 3.4% of women randomly tested in more representative urban samples tested positive for cocaine use (Ostrea et al, 1992a, 1992b).

The pharmacologic actions of cocaine include inhibition of postsynaptic re-uptake of norepinephrine, dopamine, and serotonin neurotransmitters by sympathetic nerve terminals. Cocaine allows higher concentrations of neurotransmitters to interact with receptors. Higher levels of epinephrine and norepinephrine produce vasoconstriction, hypertension, and tachycardia. In adults, cocaine binds strongly to neuronal dopamine re-uptake transporters, thereby increasing postsynaptic dopamine at the mesolimbic and mesocortical levels and producing the addictive cycle of euphoria and dysphoria (Malanga and Kosofsky, 1999). Tryptophan uptake is similarly inhibited, altering serotonin pathways with resultant effects on sleep. Sodium ion permeability is blocked, producing the anesthetic effect of cocaine. The metabolites of cocaine are pharmacologically active and may produce neurotoxicity in the pregnant woman or her fetus. Two forms of cocaine are commonly used, cocaine hydrochloride and cocaine base (either extracted by organic solvents or precipitated as "crack" through the use of ammonia and baking soda). Cocaine hydrochloride is a water-soluble white powder that is used orally, intranasally ("snorting"), or intravenously ("running"). Intravenous users are more likely to have a history of heroin abuse and often use the drug in combination with heroin ("speedballing"). Cocaine hydrochloride decomposes on heating and is, therefore, cocaine converted to the free base for inhalation. "Freebasing" involves extraction of cocaine from aqueous solution into an organic solvent such as ether. "Crack," the most widely available form of freebase, is almost pure cocaine, and when it is smoked, it readily enters the blood stream to produce levels similar to those occurring with intravenous use. Crack cocaine is popular in urban minority communities, where it may be smoked in combination with PCP ("spacebasing"). Crack smoking appears to be particularly reinforcing and is associated with compulsive use, binges, and acceleration of the addictive process.

Many adverse perinatal outcomes associated with cocaine use are due to the effects of cocaine on uterine blood supply (Woods et al, 1987). An increase in maternal mean arterial blood pressure, a decrease in uterine blood flow, and a transient rise in fetal systemic blood pressure after an intravenous cocaine infusion have been described in fetal sheep (Moore et al, 1986). Animal studies demonstrated significant fetal hypoxemia associated with changes in uterine blood flow after cocaine infusion (Woods et al, 1987). Maternal hypertension and intermittent fetal hypoxia contribute to the higher risks for abruptio placentae and IUGR seen in cocaine-exposed infants.

Cocaine and some of its metabolites readily cross the placenta and achieve pharmacologic levels in the fetus (Schenker et al, 1993). Amniotic fluid may serve as a reservoir for cocaine and its metabolites and prolong exposure

to vasoactive compounds. The extent to which cocaine or its metabolites are responsible for aberrant fetal growth, neurodevelopmental sequelae in exposed infants, and the range of congenital malformations reported in the literature may be less than suggested by uncontrolled case reports early in the cocaine-epidemic era. The confounding effects of increased use of multiple drugs, tobacco, or alcohol, nutritional deficits, and decreased use of prenatal care among cocaine-using women make interpretation of the causal relationships between gestational cocaine exposure and intrauterine growth and subsequent neurobehavioral development difficult (Chiriboga, 1993). These identified confounders may explain much or all of the reported effects attributed to cocaine in clinical series (Dempsey et al, 1996).

### Maternal Effects of Cocaine

Cocaine use leads to a sense of well-being, increased energy, increased sexual achievement, and an intense euphoria, or “high.” The sympathomimetic action can have potentially devastating physiologic effects on the cardiovascular system. In adults, cocaine has been associated with cerebral hemorrhage, cardiac arrest, cardiac arrhythmias, myocardial infarction, intestinal ischemia, and seizures. Chronic use is associated with anorexia, nutritional problems, and paranoid psychosis. Chronic use of cocaine ultimately results in neurotransmitter depletion and a “crash,” characterized by lethargy, depression, anxiety, severe insomnia, hyperphagia, and cocaine craving.

Women who use cocaine during pregnancy are at higher risk for stillbirths, spontaneous abortions, abruptio placentae, intrauterine growth restriction (IUGR), anemia and malnutrition, and maternal death from intracerebral hemorrhage (Table 12–6). Cocaine directly stimulates uterine contractions because of its alpha-adrenergic, prostaglandin, or dopaminergic effects, with resulting greater risks for fetal distress and premature deliveries. Abruptio placentae appears to be related to cocaine only when the drug is used shortly before delivery (Ostrea et al, 1992b). Other problems are evidence of fetal distress associated with abnormal fetal heart rate tracing and meconium staining (but not aspiration syndrome). Such women are at high risk for premature labor, low-birth-weight infants, premature rupture of the membranes, and perinatal infections. The higher prevalence of sexually transmitted disease in cocaine-using women has been associated with the trading of sex for drugs. In a high-risk, inner city population of New York City, Greenberg and colleagues (1991) found fourfold higher odds of cocaine exposure among infants with congenital syphilis. Both intravenous injection and noninjection use of cocaine increase the risks for acquisition of HIV, with a 3.5-fold higher risk among women who trade sex for crack cocaine (Lindsay et al, 1992).

### Fetal Growth

Multiple studies early in the cocaine epidemic documented diminished intrauterine growth as the most common fetal effect of gestational cocaine exposure, with weight, height,

TABLE 12–6

### Associated Clinical Features in the Mother and Infant with Cocaine Use During Pregnancy

Pregnancy	Spontaneous abortions Abruptio placentae Stillbirths
Growth	Premature delivery Low birth weight Intrauterine growth restriction Small head
Infections	Perinatal human immunodeficiency virus Congenital syphilis
Malformations	Urogenital Brain Midline defects (agenesis of the corpus callosum, septo-optic dysplasia) Skull defects, encephaloceles Ocular Vascular disruption (limb reduction, intestinal atresia) Cardiac
Neurodevelopmental findings	Neonates Impaired organizational state Hypertonia, tremor Strokes, porencephaly Seizures Brainstem conduction delays Sudden infant death syndrome Infants and children Hypertonia in infancy Abnormal behaviors(?)

and head circumference affected at birth (Table 12–7). Investigators have demonstrated asymmetric IUGR (head circumference affected) among newborns exposed to high levels of exposure, but not in infants with low levels or no exposure to cocaine (Bateman and Chiriboga, 2000). Zuckerman and colleagues (1989) reported that abstinence after the first trimester reduces the intrauterine growth-retarding process but may not prevent diminished head growth or neurobehavioral abnormalities. Their large prospective study suggested direct cocaine effects on intrauterine growth as well as indirect effects of cocaine-associated undernutrition. The effects of suboptimal intrauterine growth on subsequent neurodevelopmental outcome abnormalities have not been distinguished from those of cocaine or its metabolites.

### Congenital Malformations

Cocaine has been reported to be associated with a variety of congenital anomalies in animals. A fourfold rise in genitourinary anomalies has been reported (Martin et al, 1992). Some of the malformations reported in cocaine-exposed

TABLE 12-7

**Neonatal Neurobehavioral Symptoms After Fetal Drug Exposure**

Drug	Onset (days)	Peak (days)	Duration	Relative Severity
Alcohol	0-1	1-2	1-2 days	Mild
Cocaine	0-3	1-4	? mos	Mild–moderate
Amphetamine	0-3		2-8 wks	Mild–moderate
Phencyclidine	0-2	5-7	2-6 mos	Moderate–severe
Heroin	0-3	3-7	2-4 wks	Mild–moderate
Methadone	3-7	10-21	2-6 wks	Mild–severe

infants may be explained by effects of norepinephrine-mediated vasoconstriction (e.g., limb reduction deformities, intestinal atresia or infarction, and other vascular disruption sequences) during organogenesis (Mahalik and Hitner, 1994). CNS ischemic and hemorrhagic lesions have been inconsistently reported (Dusick et al, 1993; Konkol et al, 1994) in both term and premature infants. Cardiac malformations, including cardiomegaly, atrial septal defects, and ventricular septal defects, have also been reported (Lipschultz et al, 1991). Ocular abnormalities in infants that have been attributed to cocaine exposure include retinopathy, persistent hyperplastic vitreous, dilated and tortuous iris blood vessels, delayed visual maturation, palpebral edema, and structural anomalies of the eye (Dominguez et al, 1991). To date, no well-defined cocaine-associated syndrome has been identified, and the teratogenic potential of cocaine remains controversial. The association between fetal cocaine exposure and malformations may be confounded by higher rates of maternal tobacco, marijuana, or alcohol use among the cocaine-exposed groups. Overall, the preponderance of data from multiple studies fails to demonstrate higher rates of other congenital anomalies among cocaine-exposed infants (Behnke et al, 2001).

### Cocaine and Premature Delivery

Of all the problems attributed to cocaine use in the pregnant woman, the most common problem is premature delivery (Bateman et al, 1993). Infants born to women who use cocaine may experience sequelae of prematurity, including cerebral palsy, developmental delay, diminished intellectual capacity, and behavioral impairment. Most studies with sample sizes large enough to assess independent effects of cocaine on prematurity demonstrated this association (Gillooley et al, 1990; Handler et al, 1991). One study showed no such association in woman receiving prenatal care, suggesting that in the absence of prenatal care, cocaine may bear an independent association with prematurity (Zuckerman et al, 1989). A number of studies shows that prematurity and IUGR due to cocaine appear to be closely related to maternal lifestyle. In populations studied in which the mother receives good prenatal care in association with drug treatment, the incidence of prematurity and IUGR is low (Shiono et al, 1995). In the presence of poor prenatal care and no documented drug treatment, the rates of premature birth and IUGR are high. These findings have obvious implications for the development of

effective treatment strategies to minimize adverse perinatal outcome in substance-abusing women, as has been suggested by cohort studies demonstrating lower rates of prematurity in women with adequate prenatal care. Overall, because of the higher risks of premature delivery, the frequency of respiratory distress syndrome is greater in cocaine-exposed infants. Cocaine-exposed infants less frequently require surfactant administration and intubation for respiratory distress syndrome; however, the risks of bronchopulmonary dysplasia are similar in infants who have and those who have not been exposed to cocaine during gestation (Hand et al, 2001).

### Neurobehavioral Abnormalities

Cocaine-exposed infants manifest a range of neurobehavioral abnormalities that were initially described as drug withdrawal but are more likely due to acute intoxication (Dempsey et al, 1996). Signs are present at birth or a few days thereafter and wane as cocaine and the metabolite, benzoylecgonine, are cleared from plasma. The infants are hypertonic, irritable, and tremulous (Chiriboga, 1993) and may have abnormal crying, sleep, and feeding patterns, although controlled, blinded studies have demonstrated cocaine withdrawal signs in a lower proportion of cocaine-exposed infants than in unblinded studies. Tachycardia, tachypnea, and apnea have been noted in two blinded, controlled studies, with significant elevations in cardiac output, stroke volume, mean arterial blood pressure, and cerebral artery flow velocity resolving by day 2, consistent with an intoxicant effect of cocaine (van de Bor et al, 1990a, 1990b). Other early and late patterns of neurobehavioral abnormalities are a depressed state occurring immediately after birth and lasting 3 to 4 days (resembling the adult cocaine crash) and a later hyperirritable phase with onset from 3 to 30 days (Mott et al, 1994). Cocaine-exposed infants may have abnormal electroencephalograms or clinical seizures, perhaps the result of toxicity from the metabolite, benzoylecgonine (Konkol et al, 1994). Although up to 50% of exposed infants in one series had seizures (Doberczak et al, 1989), this finding was not confirmed by another study (Legido et al, 1992), and in our experience, neonatal seizures stemming directly from maternal use of cocaine are rare. Seizures may occur because of complications associated with maternal cocaine use. Prospective studies have demonstrated increased rates of hypertonia, peaking at 6 months after birth and resolving

in most children over the next 2 to 3 years (Chiriboga et al, 1995; Hurt et al, 1995).

Persisting behavioral, neurologic, and rearing problems are reported in children exposed to cocaine (Chasnoff et al, 1989a, 1992). Significant impairment of orientation, motor, and state regulation among infants with documented cocaine exposure during only the first trimester has been reported (Chasnoff et al, 1989a). In contrast, Chasnoff and colleagues (1992) noted no significant differences in mean developmental scores between a group of children exposed to cocaine plus polydrugs and a group without drug exposure. Other investigators report no differences between infants who have and those who have not been exposed to cocaine in mean cognitive, psychomotor, or language quotients at age 36 months (Kilbride et al, 2000). Compromised motor performance in late infancy has been reported in exposed infants in a controlled longitudinal study (Feters and Tronick, 1996). These motor abnormalities did not persist at 15 months, and both the exposed infants and the control group had motor scores significantly below norms for age. Variable outcomes of these studies may depend on amounts and style of drug use, which vary with geographic area, or on other covariates, such as nutritional status, poverty, and parental educational level.

The neurodevelopmental problems among children exposed to cocaine may occur either from a direct encephalopathic drug effect during gestation or from the effects of the social environment in which the developing infant is reared. Singer and colleagues (2002) reported that cocaine-exposed infants are twice as likely to have significant cognitive but not motor delays at 2 years of age and raised the concern that exposed infants demonstrate a downward trend in mean developmental scores by age 2 consistent with a deleterious effect of the environment, parental stimulation, socioeconomic status, or possibly other, indirect effects of drugs on the developing CNS. Other studies have not consistently demonstrated this association (Frank et al, 2001). To date, little is known about subsequent effects on adult behavior and learning.

### Postnatal Growth

Growth-retarded infants exposed to cocaine generally exhibit catch-up growth. Their height at 18 months does not differ from that of control subjects not exposed to cocaine. By 2 years, the mean height of cocaine-exposed infants does not differ significantly from that of alcohol-exposed or marijuana-exposed infants. At all ages, infants exposed to drugs (cocaine, ethanol, or marijuana) have lower mean head circumferences than unexposed infants. Some studies, however, have questioned the belief that growth aberrations result from gestational cocaine exposure (Shankaran et al, 1998).

## AMPHETAMINES

Amphetamine (methylphenethylamine) was synthesized in 1887 and introduced in the United States in 1931, being marketed as Benzedrine. A number of other isomers soon followed, the D-isomer dextroamphetamine (marketed as Dexedrine) having four times greater CNS effects than the

L-isomer. The N-methylated form, methamphetamine ("crystal"), is increasingly abused because it readily dissolves in water for injection and it "sublimes" (goes directly from a solid to gas) when smoked. The amphetamine isomers have similar clinical effects and can be distinguished only in the laboratory. Amphetamines were initially marketed for the treatment of obesity and narcolepsy and continue to be used for treatment of attention deficit disorders in children. Amphetamines are classified as Schedule II drugs, like cocaine and narcotics.

The clinical effects of amphetamines resemble those of cocaine. Like cocaine, amphetamines are sympathomimetics, and they potentiate the actions of norepinephrine, dopamine, and serotonin. In contrast to cocaine, amphetamines appear to exert their CNS effects primarily by enhancing the release of neurotransmitters from presynaptic neurons. Amphetamines may block re-uptake of released neurotransmitters. They may also exert a weaker direct stimulatory action on postsynaptic catecholamine receptors.

Amphetamines are taken orally, inhaled, or injected. The clinical effects and toxicity of these agents are often indistinguishable from those of cocaine. The primary difference is in the duration of action. The psychotropic effects of cocaine are of short duration, 5 to 45 minutes. The effects of amphetamines may last from 2 to 12 hours. Amphetamines have usurped cocaine as the primary illicit drugs used by pregnant women in many areas of California and other states. Methamphetamine ("crystal") has been the primary form abused. The appearance of a new smokable form of methamphetamine, ("ice"), has made methamphetamine the principal abused drug in several parts of the United States, especially Hawaii and California. Both crystal and ice can be produced locally and fairly cheaply. Greater restrictions on the importation of cocaine has also contributed to a resurgence in amphetamine use. Amphetamines have always been popular among adolescents, especially females, and accordingly, women of child-bearing age are at high risk for perinatal abuse. A California study of drug-exposed infants in the social welfare system documented a higher prevalence of amphetamine use among white pregnant women than in women of other ethnicities (Sagatun-Edwards et al, 1995).

The medical and obstetric complications of amphetamine use are similar to those described for cocaine use. Amphetamine toxicity has been described as more intense and prolonged than cocaine toxicity. Visual, auditory, and tactile hallucinations are common, and microvascular damage has been seen in the brains of chronic users. Amphetamine withdrawal is characterized by prolonged periods of hypersomnia, depression, and intense, often violent paranoid psychosis. Obstetric complications include a higher incidence of stillbirth. Like the pregnancies of cocaine-using women, the pregnancies of amphetamine users are characterized by poor prenatal care, sexually transmitted diseases, and cardiovascular problems including abruptio placentae and postpartum hemorrhage. The risk of cerebrovascular accidents is lower in pregnant amphetamine users than in pregnant cocaine users, but the mechanism for this difference is not understood.

Neonatal problems associated with amphetamine use during pregnancy include prematurity and IUGR. Fetal

growth restriction, leading to smaller head circumference and lower birth weight, may result from the vasoconstrictive effects of norepinephrine or other vasoactive amines, or from diminished maternal nutrient delivery as a consequence of the anorectic effect of amphetamine. Systemic effects from altered norepinephrine metabolism explain the transient bradycardia and tachycardia reported in exposed infants. Studies have failed to show consistent patterns of malformations in amphetamine-exposed infants, although several studies report cleft lip and palate in association with amphetamine and methamphetamine exposure during early gestation (Plessinger, 1998). Neurodevelopmental abnormalities have been described during the neonatal period and appear to persist, as documented by follow-up studies, as late as 14 years (Cernerud et al, 1996). Intellectual capacity does not appear to be diminished among exposed infants. These children are described as exhibiting disturbed behavior, including hyperactivity, aggressiveness, and sleep disturbances. Eriksson and colleagues (2000) report that neurobehavioral abnormalities appear to be associated with the extent and the duration of fetal exposure and with the severity of head growth restriction. In this study, children with the most severe problems were those born to mothers who abused amphetamines throughout pregnancy and were reared in homes with an addicted parent. Alterations in growth have been reported after prenatal exposure, with striking gender differences (Cernerud et al, 1996). Drug-exposed boys in Sweden were taller and heavier, and girls smaller and lighter, than national standards. This finding suggests that fetal amphetamine exposure accelerates onset of puberty in boys and delays it in girls. There may be an added mechanism by which amphetamines interfere with neurodevelopment of the adenohypophysis. Children of amphetamine abusers appear to be at high risk for social problems, including abandonment, abuse, and neglect. In two Swedish studies, only 22% of 10-year-old children who had been exposed to amphetamine in utero remained in the care of their biologic mothers, whereas 70% were in foster care (Cernerud et al, 1996; Eriksson and Zetterstrom, 1994).

Substitution of aryloxy groups on the benzene ring of amphetamines produces “designer drugs,” which are chemically similar to mescaline, the active ingredient in peyote cactus. These drugs have potent psychostimulant effects in addition to the serotonergic effects demonstrated in animals. Methylenedioxyamphetamine (MDMA, “Ecstasy”) and methylenedioxyethamphetamine (MDEA, “Eve”) are increasingly used as recreational drugs. Their use during pregnancy has been reported in association with an overall higher incidence of a wide variety of congenital defects, including limb anomalies and cardiac septal defects (McElhatton et al, 1999), although the data from the case series are insufficient to establish a causal relationship between MDMA (in the absence of other drug use) and any specific anomaly. Other investigators have not found a consistent association between MDMA use during pregnancy and congenital anomalies (van Tonningen-van Driel et al, 1999). Because MDMA is often used in conjunction with other drugs, vigorous exercise, and poor diets, it is not clear whether reported fetal effects of its use during pregnancy are due to MDMA alone or to confounding factors.

## PHENCYCLIDINE

Phencyclidine hydrochloride (1-phenyl cyclohexyl piperidine) is an arylcyclohexamine developed in 1956 and marketed for the first time in 1963 as an anesthetic (Sernyl) and in the early 1970s as a veterinary drug (Sernylan). PCP was withdrawn from the market after reports of delirium and hallucinations and the recognition of its potential for abuse. No longer legally manufactured, PCP is still included in the Comprehensive Drug Abuse Prevention and Control Act of 1970. The first reports of the illicit use of PCP came in 1967 from the Haight-Ashbury district of San Francisco. Epidemic use of PCP began in the mid-1970s and peaked in 1983, when it was the most frequently used hallucinogen among young adults in the United States. Since it developed a reputation as a dangerous drug, its popularity has been episodic and often geographically and demographically concentrated. Use of PCP is common among polysubstance users, particularly in combination with marijuana, heroin, and alcohol, but not in combination with cocaine (Mvula et al, 1999).

PCP, also known as “angel dust,” is a white crystalline powder that is soluble in water and alcohol. It can be inhaled, taken orally, or injected intravenously. Its popularity among young adults, especially women, however, relates to its low cost and the fact that it can be smoked. PCP is usually smoked by being sprinkled (dusted) on cigarettes (“lovely”) or marijuana (“sherm”). PCP increases epinephrine release, but its exact mechanism of action is not clearly understood. PCP receptors have been identified in the brain, but their physiologic function and how they interact with PCP are unclear. The effects of the drug are dose-related and differ according to the duration of exposure. Low doses primarily cause euphoria associated with disturbances in body image. Moderate doses result in confusion, disorientation, and impaired sensory perception (analgesic and anesthetic effects). High doses are followed by hypertension, seizures, hyperpyrexia, an acute toxic paranoid psychosis, coma, and death. Chronic, continuing use of PCP results in violent behaviors, depressive anxiety, an organic brain syndrome, and, rarely, schizophrenia-like reactions. The toxic psychosis is treated with sensory isolation and diazepam, whereas the prolonged PCP psychosis requires antipsychotic medications.

PCP readily crosses the placenta to the fetus and is secreted in breast milk. Although animal studies demonstrate alterations in septohippocampal cholinergic innervations with later behavioral consequences (Yanai et al, 1992), data on the effects of PCP on pregnancy and the newborn are limited. From 1981 to 1984, PCP was the primary drug of abuse among parturients in some urban areas of the United States. In 1985, crack cocaine replaced PCP as the drug of choice for substance-abusing women. Subsequently, use of PCP has decreased in this country. Its use was more prevalent among pregnant Latinas in one study in California (Sagatun-Edwards et al, 1995).

The effects of PCP on the outcome of pregnancy appear to be dose related. In low doses, PCP has few side effects, although the anesthetic nature of the drug increases the frequency of precipitous deliveries at home, in ambulances, and in emergency departments. Although some studies have shown that up to 40% of PCP-exposed

infants are small for gestational age, PCP is not necessarily associated with higher risk of prematurity or low birth weight (Mvula et al, 1999). Other obstetric complications are not known, but associated polydrug use, syphilis, and diabetes mellitus increase perinatal risks among infants exposed to phencyclidine (Mvula et al, 1999).

A severe syndrome associated with PCP exposure in utero has been reported, with onset shortly after birth (Rahbar et al, 1993). The timing and severity of the symptoms, often present at birth, raise the question whether the neurologic findings represent drug intoxication rather than drug withdrawal effects, because PCP persists in the body, and especially in the fetal brain, for prolonged periods (Ahmad et al, 1987). The neurologic findings in PCP-exposed infants include severe hypertonicity and hyperreflexia, often associated with spontaneous clonus and persisting for several weeks. Sudden episodes of agitation and fluctuating levels of consciousness have been described. Gastrointestinal symptoms, including abdominal distension, vomiting, and diarrhea, are also present in about 20% of the infants. The morbidity of significant PCP withdrawal can be attributed to gastrointestinal complications and the prolonged duration of symptoms. The mean duration of hospitalization in the authors' population was 14 days (range 10 to 21 days) (Ahmad et al, 1987). The withdrawal syndrome seen in infants exposed to PCP in combination with other drugs appears to be less intense, most likely in relation to a lower dose exposure or to inadvertent or erratic exposure when other drugs, such as cocaine, are "cut" with PCP.

Congenital anomalies have been inconsistently reported in association with PCP use during pregnancy. A clear causal association with PCP has not been verified. The reported somatic growth of PCP-exposed infants appears similar to that of polydrug-exposed infants. Isolated microcephaly, usually less severe than that seen in cocaine-exposed infants, has also been described and may be dose related (Rahbar et al, 1993).

Early alterations in state lability and consolability more severe than in all other drug-exposed groups have been documented in infants exposed in utero to PCP but do not appear to persist later in infancy. Neurobehavioral abnormalities, temperament problems, sleep disturbances, and aberrant attachment have been reported in infants with gestational exposure to PCP. Some long-term outcome studies of chronically PCP-exposed infants show a higher prevalence of severe developmental and behavioral problems.

## ALCOHOL

First described in Europe in 1968 and subsequently in the United States, fetal alcohol syndrome (FAS) is an extensively documented teratogenic syndrome. The incidence of FAS in the United States has been estimated to vary from 1.95 to 5 cases per 1000 live births (Abel, 1995; American Academy of Pediatrics [AAP], 2000; Sampson et al, 1997; Surveillance, 1997). Fetal alcohol syndrome is recognized more frequently in the United States than in other countries and is most common (4.3%) among women who report "heavy" drinking (Abel, 1995). Accurate incidence

and prevalence rates of FAS are difficult to obtain because of wide variations in methodologies used for estimation of rates and because the clinical diagnosis is often missed in the neonatal period. In fact, most cases (up to 89%) are not diagnosed until after a child is 6 years old (Surveillance, 1997).

It is unclear how much alcohol exposure is necessary to cause fetal teratogenicity, and even high consumption levels do not always result in the birth of a child with FAS (Abel and Hannigan, 1995). However, a woman with a previous affected child is at increased risk for having a child with FAS if she consumes alcohol during a subsequent pregnancy. The adverse effects of alcohol on the fetus are related to gestational age at exposure, the amount of alcohol consumed and the pattern of consumption (binge drinking), maternal peak blood alcohol concentrations, maternal alcohol metabolism, and the individual susceptibility of the fetus. Studies show that maternal peak blood alcohol levels are affected by maternal nutrition, age, body size, and genetic disposition (Eckardt et al, 1998; Maier and West, 2001). Additionally, various risk factors increase susceptibility to FAS, including advanced maternal age and confounding factors such as nonwhite race, poverty, and socioeconomic status (Abel, 1995; Bagheri et al, 1998; May and Gossage, 2001). In the United States, the incidence of FAS is ten times higher for African-Americans living in poverty than for white middle class people (Abel, 1995). Indeed, despite the differences in incidence of FAS worldwide, reports consistently point to poverty (or socioeconomic status) as a major determinant of FAS (Abel 1995; May et al, 2000).

Accurate data quantifying fetal exposure are difficult to amass because of unreliable maternal history, the numerous methods of estimating alcohol exposure, and the lack of an objective measurement tool. Women with higher rates of alcohol intake are at the highest risk for fetal effects, but whether there is a dose-dependent response to fetal alcohol exposure or a threshold for fetal effects is unclear (Abel, 1999; Jones and Chambers, 1999). Our understanding of the effects of alcohol on the developing fetus, the importance of timing of exposure, and the effects of other agents (nutrition, smoking) in raising the incidence of FAS is incomplete (Abel, 1995). Because of these limitations, there is no absolutely safe level of alcohol ingestion during pregnancy (AAP, 2000).

The three major components of FAS are prenatal and postnatal growth deficiencies, characteristic facial features, and microcephaly associated with mental retardation (AAP, 2000; Jones and Smith, 1973; Stratton et al, 1996). The facial features consist of short palpebral fissures, mid-face hypoplasia, broad flat nasal bridge, a broad and indistinct philtrum, and thin upper vermilion. Other facial abnormalities have also been described, including ptosis, strabismus, and low-set or dysplastic ears. The CNS is the organ system most affected by fetal alcohol exposure. Microcephaly is the most serious finding with FAS. Investigators have also reported dysgenesis of the corpus callosum as well as hypoplasia of the basal ganglia and cerebellum in children with FAS (Archibald et al, 2001; Riley et al, 1995; Roebuck et al, 1998). A finding of FAS associated with facial dysmorphology is a hearing deficit with neurosensory hearing loss (AAP, 2000; Hannigan and

Armant, 2000). Children with FAS have poor coordination, hypotonia, and feeding impairment as infants. Attention deficit–hyperactivity disorder and speech and behavioral problems contribute to learning disabilities characteristic of these children (AAP, 2000). IUGR is one of the most consistent findings of prenatal exposure to alcohol (Hannigan and Armant, 2000). Growth deficit begins in utero and continues throughout childhood (AAP, 2000). The facial features and the growth restriction become less noticeable during adolescence and puberty (Streissguth, 1991, 1993). Skeletal anomalies, abnormal hand creases, and renal and cardiac anomalies have been described in children with FAS.

Children do not always exhibit the full FAS, but may have “partial FAS,” manifesting a few malformations or neurodevelopmental disabilities believed to be secondary to fetal alcohol exposure (AAP, 2000; Stratton et al, 1996). Other terms developed to describe the spectrum of fetal alcohol effects include alcohol-related neurodevelopmental disorder (ARND) and alcohol-related birth defects (ARBDs). Children with a history of significant fetal alcohol exposure and subsequent behavioral, cognitive, or developmental disabilities are classified as having ARND; children with alcohol exposure and malformations are classified as having ARBDs. These clinical conditions have been reproduced in animal models and represent plausible consequences of fetal alcohol exposure (Abel and Hannigan, 1995). Although these terms are used to describe incomplete FAS, the clinical manifestations can be quite severe and disabling and should not be regarded as “mild” consequences of alcohol exposure (Abel, 1999). Indeed, children with heavy alcohol exposure during pregnancy but without the physical stigmata of FAS have been shown to have lower IQ scores, significant cognitive impairment, and abnormalities on testing of verbal learning and memory skills (Mattson et al, 1997, 1998).

Fetal alcohol syndrome is diagnosed from the history and physical findings. No laboratory tests are available for clinical use to quantify the extent of alcohol exposure during fetal life. There also are no clinical methods for validating maternal self-reporting of alcohol use, quantifying the level of fetal exposure, or predicting future disability after fetal exposure (Jones and Chambers, 1999). Koren and associates (2002) have proposed meconium fatty acid ethyl ester levels as a potential biologic marker for fetal alcohol exposure. Whether this finding is shown to correlate with childhood outcomes remains to be seen. The development of a screening tool for recognition of fetal alcohol exposure may help diagnose children at an earlier age than is currently seen. Investigators have shown that pediatricians fail to recognize FAS in the newborn and do not always inquire about alcohol exposure during pregnancy (Stoler and Holmes, 1999).

FAS is not a problem just for pediatricians. Patients with FAS continue to have serious disabilities into adulthood (Streissguth, 1991, 1993). Although the facial features and growth restriction are no longer as distinctive as during childhood, mental retardation continues to have a significant effect. Adults with FAS have behavior, socialization, and communication dysfunction, and on average, they function at the second or third grade level. A significant number of patients does not achieve fully independent

living. Earlier recognition and intervention for children with FAS (and its variants) may help minimize eventual adulthood disabilities and help prepare adolescents and young adults with the disorder for independent living.

The approach to a newborn with suspected FAS is to establish the diagnosis by ruling out other causes of malformations, determining the extent of malformation, and establishing long-term care for both the mother and her infant. A reasonable postnatal assessment consists of head, renal, and cardiac ultrasonography as well as consultations with genetics, neurology, ophthalmology, and social services professionals.

## CIGARETTES AND NICOTINE

Cigarettes and nicotine are the drugs most often used during pregnancy. Although smoking in the United States has decreased over the last 2 decades, 26% of reproductive-aged women smoke, and 15% to 20% of women smoke during their pregnancies (Andres and Day, 2000). Cigarette smoking has been associated with numerous perinatal complications, often in a dose-dependent fashion. Smoking has been shown to raise the risk of spontaneous abortion, stillbirth, fetal growth retardation, prematurity, perinatal mortality, and SIDS (Andres and Day, 2000; Kallen, 2001; Lambers and Clark, 1996; Tuthill et al, 1999). Cigarette smoking represents the most influential and most common factor adversely affecting perinatal outcomes.

Nicotine crosses the placenta and concentrates in fetal blood, amniotic fluid, and breast milk (Haustein, 1999). Nicotine can be detected in the fetal circulation and in amniotic fluid at levels that significantly exceed maternal concentrations. The serum concentration of cotinine, the primary metabolite of nicotine, is used to quantitate the level of smoking and fetal exposure. Cotinine has a half-life of 15 to 20 hours, and because its serum levels are 10-fold higher than those of nicotine, this substance may represent a better marker for exposure (Lambers and Clark, 1996).

Although the exact mechanism of the adverse effect on pregnancy is unknown, cigarettes contain numerous potentially toxic compounds that presumably affect fetal health in a number of ways. In animal models, nicotine has been shown to raise maternal blood pressure and to be associated with a decrease in uterine blood flow. Additionally, with cigarette smoking, increased levels of carbon monoxide cross the placenta and form carboxyhemoglobin in the fetus (Lambers and Clark, 1996). Erythropoietin levels are also higher in smoking exposed infants at delivery, a finding presumed to reflect fetal hypoxia (Beratis et al, 1999; Jazayeri et al, 1998). Investigators have shown an association between the number of cigarettes a woman smokes and umbilical cord plasma erythropoietin levels (Jazayeri et al, 1998). Most theories of the adverse effects of smoking on fetal health involve the induction of fetal hypoxia from carbon monoxide production, nicotine-induced vasospasm, or both. A direct cytotoxic effect is also possible. Investigators have shown decreased levels of amino acids in umbilical cord blood samples for infants exposed to maternal smoking during pregnancy, suggesting a disturbance of protein metabolism during gestation (Jauniaux et al, 2001).

The effect of smoking on fetal growth is significant. Smoking affects fetal growth in a dose-dependent manner (Kyrklund-Blomberg and Cnattingius, 1998; Nordentoft et al, 1996). Investigators report that lower birth weights are associated with levels of exposure as measured by cotinine levels (Eskenazi et al, 1995; Perkins et al, 1997; Savitz et al, 2001). A 1-g reduction in birth weight has been observed for every  $\mu\text{g/mL}$  increase in maternal serum cotinine level (Eskenazi et al, 1995; Perkins et al, 1997). IUGR is also related to the number of cigarettes smoked. Investigators have shown a dose-dependent relationship between amount of smoking and extent of fetal growth restriction and birth weight reduction (Horta et al, 1997; Jaakkola et al, 2001; Savitz et al, 2001; Sprauve et al, 1999). The risk ratio for fetal growth restriction in heavy smokers ( $>20$  cigarettes/day) was reported as 2.4 (95% confidence intervals, 1.4, 4.0) (Savitz et al, 2001). Smoking has also been shown to affect the length of gestation in a dose-dependent manner, a higher risk of preterm delivery being associated with higher maternal cotinine levels (Jaakkola et al, 2001; Savitz et al, 2001). Investigators also report a twofold increase in the incidence of placental abruption in women who smoke (Ananth et al, 1996). Perinatal mortality is increased in pregnant smokers, likely reflecting the increases in rates of prematurity, growth retardation, placental abruption, and placenta previa in women who smoke. Mothers who smoke during pregnancy commonly continue to smoke during their infants' childhood. Asthma as well as recurrent otitis media are more common in infants exposed to passive smoking (Ey et al, 1995; Martinez et al, 1995).

Potential mechanisms for the effects of smoking on fetal growth have included direct effects of nicotine on placental vasoconstriction, decreased uterine blood flow, increased levels of fetal carboxyhemoglobin, fetal hypoxia, adverse maternal nutritional intake, and altered maternal and placental metabolism (Andres and Day, 2000; Pastrakuljic et al, 1999).

Both reducing and ceasing cigarette smoking during pregnancy have been shown to be beneficial and to improve fetal growth. Lieberman and colleagues (1994) have shown that if women stop smoking during the third trimester, their infants' weights are indistinguishable from those of a nonsmoking population. Other investigators report even a reduction in smoking is associated with improved fetal growth (Li et al, 1993; Walsh et al, 2001).

### **Sudden Infant Death Syndrome (SIDS) and Cigarette Smoking**

Numerous reports have shown a strong association between smoking and SIDS (Mitchell et al, 1997; Taylor and Sanderson, 1995; Tuthill et al, 1999). Among the numerous risk factors associated with the syndrome, maternal smoking was found to be independently associated with SIDS (Taylor and Sanderson, 1995). Prenatal, postnatal, and passive smoking exposures have all been shown to be associated with increased risk for SIDS (Blair et al, 1996; Mitchell et al, 1993; Schoendorf et al, 1992). Additionally, a dose-response relationship has been reported, consisting of an increased incidence of SIDS in association with a

higher amount of maternal smoking (MacDorman et al, 1997; Mitchell et al, 1993). Investigators have found cotinine levels in pericardial fluid to be significantly higher in infants dying from SIDS than in infants with infectious causes of death (Milerad et al, 1998). Researchers in Germany have shown that in a population of heavy smokers during pregnancy, IUGR (lower birth weight, lower body mass index) was more common in infants dying from SIDS than in a population of surviving infants born to heavy smokers. The growth restriction effects were even more pronounced in preterm infants exposed to heavy smoking during pregnancy (Schellscheidt et al, 1998). This study suggests that preterm infants who are born to heavy smokers and have IUGR are at a high risk for crib death.

The direct physiologic link between smoking and SIDS has not been identified. Theories are proposed that cigarette smoking may alter lung function or may alter CNS control of respiration, arousal, or both (Andres and Day, 2000). Slotkin and colleagues (1995), documenting loss of neonatal hypoxia tolerance after prenatal nicotine exposure, suggest this finding as a causative factor in the increased risk of SIDS among offspring of mothers who smoke.

### **MARIJUANA**

Marijuana is probably the illegal drug most frequently used during pregnancy. It is derived from the hemp plant *Cannabis*, and its most active ingredient being delta-9-tetrahydrocannabinol. Use of marijuana during pregnancy is associated with growth retardation. Neurologic abnormalities similar to a mild withdrawal syndrome, consisting of hypertonicity, irritability, and jitteriness, have been seen in the newborn but without documented evidence of long-term sequelae. Marijuana is often used in combination with other drugs and may potentiate risks for prematurity, low birth weight, or the teratogenic effects of other drugs (Cornelius et al, 1995).

### **CAFFEINE**

Fetal exposure to caffeine may occur in 75% of pregnancies in the United States (Eskenazi, 1993). Caffeine is contained in coffee, tea, colas, and chocolate (100 mg/cup of coffee). Most studies detect an increased risk of IUGR with caffeine intake in excess of 300 mg/day—that is to say, a detectable and significant increase of growth retardation occurs (relative risk about 1.5). Many studies also report a higher risk of spontaneous abortion with higher amount of caffeine exposure (e.g., risk of abortion increases by 1.017 for each cup of coffee per day in the first trimester [Armstrong et al, 1992]). Most studies of caffeine, like those of other licit and illicit drugs, share problems of ascertainment, dose, duration, response, and confounding factors. For example, genetic differences may affect susceptibility to caffeine. Caffeine may have fetotoxic additive effects when combined with smoking, and drinks such as coffee may contain ingredients with effects on pregnancy that are independent of the effects of caffeine. Granted these considerations, and to a greater degree than with other drugs discussed in this chapter, it

is usually not possible to attribute growth retardation or spontaneous abortion in a specific case to caffeine. It is prudent to advise women to limit maximum caffeine intake to less than 100 mg/day both when pregnant and when anticipating pregnancy (Infante-Rinard et al, 1993).

## **MANAGEMENT OF GESTATIONAL SUBSTANCE USE**

### **Intrapartum Management**

The pregnant woman with suspected or admitted gestational or intrapartum substance use should undergo urine toxicology screening after informed consent; clinicians should recognize, however, that both self-report and urine screening are neither sensitive nor specific tools for identifying intrapartum complications, neonatal morbidity, long-term outcome, or families at risk of child neglect or abuse. Identification of gestational substance use offers the potential benefits of screening for sexually transmitted diseases, closer obstetric monitoring of maternal and fetal well-being, drug counseling, support and referrals for rehabilitation, and social service needs assessment. Use of prenatal care should be encouraged on the basis of the benefits to the mother and fetus rather than enforced by incarceration or prosecution. Obstetric care should be given in a nonjudgmental manner, and the givers of such care should avoid being codependent or punitive. Recommendations for intrapartum medications in substance users do not differ from those for drug-free women; however, drug-using women may require treatment for hypertension, agitation, or low tolerance of pain.

We recommend using standardized criteria for perinatal toxicology screening to avoid the risks of differential screening and reporting. Routine prenatal laboratory tests, including third-trimester (or intrapartum) syphilis serology, should be performed. We also strongly encourage HIV antibody testing for drug-using women, in keeping with current obstetric recommendations for routine perinatal care. Postpartum education should stress general health, routine postpartum teaching, breast-feeding risks, neonatal care, parenting skills, and the need for obstetric and neonatal follow-up. Referrals for drug treatment and counseling should be facilitated before discharge, with the recognition that resources available to substance-using women with children are scarce. Follow-up by a public health nurse is recommended.

### **Neonatal Care**

Although at higher risk for medical complications, the majority of infants of drug-using women do not require intensive neonatal care. Symptomatic infants often need more nursing care. Admission physical examination should document a maturational age assessment, birth weight, head circumference, and length. Infants should be examined for any evidence of malformations or complications of prematurity. Hypertonic, tremulous infants usually respond to swaddling, being held, decreases in ambient environmental stimuli (light and noise), pacifiers, and more frequent feedings. Studies such as electroencephalography, brain imaging, and renal ultrasonography may add diagnostic

or prognostic information when physical or neurologic abnormalities are noted, but these procedures are not indicated for all drug-exposed infants. Neurologic or ophthalmologic evaluation may document tone and ocular abnormalities in some infants, but it is not clear that all drug-exposed infants should be referred for such examination. Feedings in premature infants with cocaine exposure should be started with diluted formula in lower than usual volume increments, because premature infants exposed to cocaine have been found to be at increased risk for both early-onset and late-onset necrotizing enterocolitis. Maternal cocaine use exposes infants to a higher than expected risk of problems with postasphyxial syndrome, and organ malfunction from this cause should be sought and treated.

Toxicology testing should be performed on neonatal urine (or meconium, as a potential substitute method) as soon as possible. Infants should undergo screening for anemia, polycythemia, hypoglycemia, congenital syphilis, and perinatal HIV exposure. Discharge planning should identify a continuity provider as well as support services for the mother and infant (e.g., nutritional, social/familial, parenting) and a plan for neurodevelopmental follow-up.

### **Mother-Infant Care**

Breast-feeding has the benefits of improved bonding, but the risks of HIV and continued drug exposure may outweigh these benefits. Women who wish to breast-feed despite these potential risks should undergo drug monitoring of breast milk and sequential HIV antibody testing. Close observation of mother-infant interaction should be documented in the infant's chart. Parenting and child-care skills should be stressed as part of the discharge education for the mother. All physician interactions with the family should be documented in detail.

## **BREAST-FEEDING AND DRUG EXPOSURE**

Psychotropic drugs, which are of low molecular weight and lipophilic, are readily excreted in breast milk. Breast-feeding by women using methadone is not recommended by the American Academy of Pediatrics (American Academy of Pediatrics Committee on Drugs, 1994). Methadone is excreted in small quantities in breast milk regardless of the daily maternal methadone dose and is probably safe for infants (Geraghty et al, 1997; McCarthy and Posey, 2000). Seizures and symptoms of overdose have been reported in an infant whose mother used cocaine. Amphetamines appear in large quantities in breast milk. PCP has also been found to cross into breast milk readily. Because of the risk of toxicity, breast-feeding should be discouraged for known abusers of these drugs. An exception is made for mothers enrolled in drug treatment programs in which the methadone use is monitored closely. Judicious evaluation of other safety considerations must be made on a case-by-case basis before allowing the infant to breast-feed, although we recommend caution if the mother is using a high methadone dose, and we actively discourage breast-feeding when mothers are not compliant with their maintenance programs or are infected with or at high risk for HIV. Alcohol use while breast-feeding is not listed as a contraindication by the

American Academy of Pediatrics, but excessive maternal alcohol intake during breast-feeding may be deleterious for the infant and should be avoided (see Chapter 33). Smoking in the postnatal period as well as during breast-feeding also has deleterious effects on the newborn. Smoking is associated with measurable levels of nicotine and cotinine in maternal breast milk.

### **SUDDEN INFANT DEATH SYNDROME IN DRUG-EXPOSED INFANTS**

The incidence of SIDS is greater in drug-exposed infants, although the increase appears less significant for cocaine-exposed infants (Chasnoff et al, 1989b; Kandall et al, 1993) than for methadone-exposed or heroin-exposed infants (Bauchner and Zuckerman, 1990). A meta-analysis of 10 studies demonstrated a 4.1 odds ratio for SIDS among cocaine-exposed infants (Fares et al, 1997) in comparison with infants not exposed to perinatal drugs. However, after data were controlled for concurrent use of other drugs, the increased risk for SIDS could not be attributed to intrauterine cocaine alone, but was believed to be due to exposure to illicit drugs in general. Additionally, a higher risk for SIDS in infants exposed to maternal smoking appears to be present whether the exposure is antenatal or postnatal (Blair et al, 1996; Mitchell et al, 1993; Schoendorf and Kiely, 1992). Despite the increased risks of SIDS among drug-exposed infants, neither polysomnography nor home apnea monitoring are indicated in the absence of other risk factors for SIDS.

### **HUMAN IMMUNODEFICIENCY VIRUS INFECTION**

Nationwide, intravenous drug abusers are the second largest risk group for HIV infection. Drug abusers also may be the primary source of infection for non-using heterosexuals as well as for children (Chamberland and Dondero, 1987). Nationwide, 75% of cases of acquired immunodeficiency syndrome in children are perinatally acquired. The seropositivity rate varies across the country; the rate among female intravenous drug users in New York City and northern New Jersey is estimated at 50% to 70%, compared with 5% to 20% in California. Heroin and cocaine addicts often resort to prostitution to support their habits. Amphetamine and methamphetamine users often inject drugs several times daily. Alcohol decreases sexual inhibition, impairs judgment, and increases the incidence of unsafe sexual activity. Every infant born to a substance abuser should be evaluated for HIV infection, and universal precautions should be observed.

### **DISPOSITION OF COCAINE-EXPOSED INFANTS**

Many states include maternal substance abuse among reasons for mandated reporting of an infant to child protective services for evaluation of potential foster care placement. Cocaine exposure increases the risk for foster care placement from a general background rate of 1% to 2% among nonexposed infants to 26% to 58% in exposed infants (U.S. General Accounting Office, 1990). Cocaine

use has become the dominant characteristic of child welfare caseloads in 22 states and the District of Columbia (Besharov, 1989). Variations in screening and reporting protocols lead to inconsistent reporting practices. In a Florida study, for example, referrals to child protective services were more frequent for black women using crack cocaine (Chasnoff et al, 1990). In California, cases involving maternal cocaine use are more apt to reach court adjudication for foster care placement than are cases involving maternal use of amphetamines (Chasnoff et al, 1990; Sagatun-Edwards et al, 1995).

The number of children in foster care rose by 81% in the first 4 years of the crack cocaine epidemic (County Welfare Directors Association of California, 1990). This increase was attributed to the cocaine epidemic and was associated with a decrease in the average age of children in foster care and with rapidly increased numbers of out-of-home placements (Halfon et al, 1990). Maltreatment of infants of cocaine-using women has been described in a controlled cohort study (Wasserman and Leventhal, 1993). However, the neurobehavioral abnormalities seen in foster children suggest that the separation of mother and infant should occur only in high-risk cases.

Costs of care for cocaine-exposed infants are significantly higher than for nonexposed infants and outweigh the costs of providing prenatal care (Joyce et al, 1995). The added costs of gestational cocaine exposure include those of perinatal care for the substance-using woman, of neonatal intensive care, and of boarding infants awaiting release to foster care, in addition to the costs of later specialized services to infants with the anatomic or neurodevelopmental sequelae of cocaine exposure.

### **IDENTIFICATION AND GOALS OF INTERVENTION**

The abuse of a variety of drugs during pregnancy has adverse consequences for the mother, fetus, and newborn. Clearly, it is important to ascertain and distinguish the causes of fetal and neonatal consequences of IUGR, vascular problems, and acute neurobehavioral symptoms. It is often less clear why one should identify infants who have been exposed to drugs in utero if they are asymptomatic. Reasons offered are that a positive toxicology screen result (sometimes backed by the potential loss of her newborn to foster care) may break through the mother's denial of drug abuse and enable her to accept treatment. In addition, courts are more apt to accept hard evidence such as a positive toxicology test result than historical data of drug abuse that may be denied by the mother.

History of drug and alcohol use should be routinely included in the initial contact with every pregnant patient. To be effective, the history-taking must be nonjudgmental and must occur in the context of other lifestyle questions. When a positive history of use is obtained, intervention should begin immediately. The person taking the history should be prepared to offer preliminary counseling on risk reduction and concrete referrals for treatment programs, although access to drug programs is often restricted, inadequate, or delayed.

A more controversial method of identification is using drug screening of mothers and infants in cases in which

drug abuse is suspected. Rapid reliable drug testing using urine or blood is readily available in most clinical laboratories. Drug screening has proved reliable in both high-prevalence urban and in low-prevalence rural settings (O'Connor et al, 1997). Drug screening should be combined with a history and should be a part of a well-delineated protocol that clearly defines which infants and mothers should be screened. Screening protocols should be based on well-defined, high-risk behavior documented to be associated with perinatal drug abuse. High-risk behavior during the prenatal period consists of a history of drug abuse, physical evidence of drug use (track marks or altered mental status), noncompliance with medical treatment and appointments, history of child abuse or removal of children from the home, and history of a partner who uses drugs or excessive alcohol. Homelessness, prostitution, and recent incarceration are also risk factors. A large percentage of drug abusers has no prenatal care or inadequate prenatal care (beginning in the last trimester or consisting of only a few visits), and this group has a high rate of complicated deliveries. In addition, screening may include patients being admitted to the hospital with the complications associated with drug abuse, such as hemorrhage, untreated sexually transmitted diseases, and premature labor. Infants born to mothers who received no prenatal care and those born precipitously or prematurely should also be included in a toxicology screening protocol. Screening should always be done in a manner to ensure as much as possible the right of privacy of the mother while allowing physicians to provide optimal medical care to both mother and infant. Also, the infant should never be screened unless the mother is informed of the testing and the reasons for it.

In the absence of intervention, infants discharged to mothers who abuse alcohol or illegal drugs are at high risk for subsequent physical abuse and neglect, but the extent of risk is unknown. Most states require some form of reporting of such cases to a child protective service agency. States differ in the aggressiveness with which they deal with this issue. In some states, the child's drug exposure may be considered *prima facie* evidence of abuse. In general, however, the mother's addiction is evaluated in the context of its effect on her ability to care for her child. The primary focus of physicians caring for the mother and infant should be to ensure that all interventions are therapeutic and designed to foster the health of both patients.

# ISSUES IN LABOR AND DELIVERY

Editor: ROBERTA A. BALLARD

## CHAPTER 13

### Antepartum Fetal Assessment

Andrew D. Hull and Thomas R. Moore

Fetal death in utero is a tragedy that patients and obstetricians wish to avoid. Figure 13-1A is a graph showing the incidence of fetal death in utero from 1959 through 1996. In the 1950s, approximately 1 in every 50 pregnancies ended in fetal death before delivery. Among women of African heritage, the rate was almost double that figure. Thanks to changes in obstetric practice and the institution of progressively more widely applied antepartum tests of fetal well-being beginning in the 1970s, the current risk of fetal death is approximately 1 in 150 pregnancies. However, as can be seen in Fig. 13-1A, substantial progress is needed, because no change has been noted in the rates for white or African-American women in the last decade.

In an ideal world, astute clinicians would be able to correct any inadequacies of the intrauterine environment so as to optimize fetal growth, development, and well-being. With such corrections, fetal outcome would be uniformly excellent. Because this is, as yet, an unattainable goal, clinicians must carefully observe fetal status and effect delivery when extrauterine life seems safer or more desirable than continuing the pregnancy. To that end, obstetricians have developed a set of tests that can assist in determining the timing of delivery so as to minimize unexpected fetal morbidity (American College of Obstetricians and Gynecologists [ACOG], 1999).

Although the primary aim of antenatal fetal surveillance is the prevention of stillbirth, a secondary, although no less important, aim is minimizing fetal and neonatal morbidity. A comparison of the efficacy of various surveillance methods reveals that reduction in fetal mortality is a convenient outcome measure. The best tests, however, result in the birth of healthier newborns. The various current methods of assessing fetal status are listed in Table 13-1, and the details of each are discussed subsequently.

#### GENERAL PRINCIPLES OF FETAL BIOPHYSICAL ASSESSMENT

The ideal test of fetal well-being would be simple, cheap, and accurate and would generate clear, reproducible results not subject to variable interpretation. Equally, the test would be easy to apply to an entire patient population and thus to identify all patients at significant risk of poor fetal outcome. Unfortunately, such a test does not yet exist. Given the problems with designing the perfect test, clinicians have, over time, begun testing more and more pregnancies in order to minimize poor fetal outcome.

Platt and colleagues (1987) studied the impact of the increasing use of antepartum fetal testing in the period from 1971 through 1986. The results are shown in Table 13-2. Clearly, although the outcomes for the small tested population improved, the largest number of fetal deaths occurred in the larger untested population, in spite of a marked rise in the percentage of patients undergoing expensive antepartum testing.

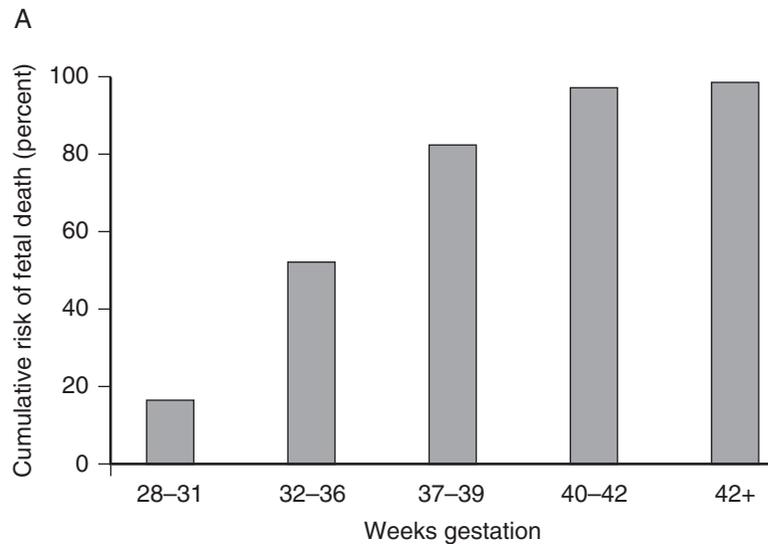

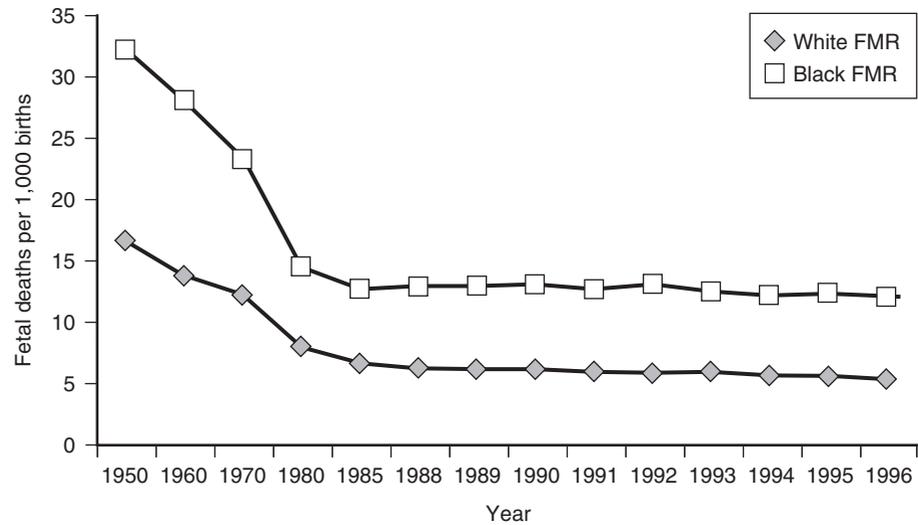

The financial impact of this trend can be roughly calculated. Using estimated charges of approximately \$125 per test, one can calculate that the cost of fetal testing in a cohort of 1000 pregnant patients would be \$37,500, discounting the expense to the patient associated with child care or absence from a job to visit the testing center. If, as Platt and colleagues (1987) showed, such testing reduces fetal mortality rate by 2 per 1000 births, the cost per fetal life saved equals \$18,750.

In reviewing the data, Platt and colleagues (1987) suggested that better means of identifying the at-risk fetus should be devised so that antepartum testing could be applied to the population most likely to experience benefit. On the basis of the accumulated experience with traditional biophysical testing, further increasing the indications for nonstress or biophysical profile testing is not likely to be economical or effective in reducing the fetal mortality rate.

#### Indications for Fetal Testing

As noted previously, 30% or more of stillbirths occur in patients without identifiable risk factors (Hovatta et al, 1983). Thus, simply screening or testing high-risk patients is not enough. Nevertheless, conditions in which fetal surveillance is traditionally considered mandatory are listed in Table 13-3. This list can almost be expanded indefinitely. Optimally, fetal testing should involve use of an inexpensive, widely applied test, with further specific testing limited to those pregnancies identified as being at risk.

**FIGURE 13-1. A,** The incidence of fetal death in utero in the United States from 1959 to 1996. **B,** Cumulative likelihood of fetal death versus gestational age. (A adapted from *National Vital Statistics Reports, vol 49, no 8. Hyattsville, MD, National Center for Health Statistics, 2001; B adapted from McIlwaine, GM, Dunn FH, Howat RC, et al: A routine system for monitoring perinatal deaths in Scotland. Br J Obstet Gynaecol 92: 9-13, 1985.*)

### When to Begin Fetal Testing

Given that testing is indicated in an individual pregnancy, the next question is when to begin testing. Because there is little to be gained in identifying a fetus in distress before viability, testing typically begins after 24 to 26 weeks. As shown in Fig. 13-1B, the incidence of fetal death during pregnancy rises somewhat linearly in the third trimester. More than half of fetal deaths occur before 37 weeks. If performance of fetal testing is restricted to the estimated delivery date

and beyond, the testing regimen will fail to detect more than 90% of fetuses at risk of death. Thus, the best test regimen includes all pregnancies after 32 weeks (83% sensitivity). Gestational age at entry into a surveillance program for specific diagnostic groups is most commonly based on risk assessment. For example, in insulin-dependent diabetic women, routine testing is typically begun at 32 to 34 weeks of gestation, because the risk of stillbirth rises at that time. For women otherwise without complications, in whom the cost of universal testing could be substantial, testing is initiated after 41.5 weeks of gestation, when the risk of fetal death is fivefold higher than before the estimated delivery date.

**TABLE 13-1**

#### Fetal Biophysical Assessment Modalities

Maternal assessment of fetal movement	Biophysical profile
Cardiotocography	Doppler flow studies
Nonstress testing	Amniocentesis
Contraction stress testing	Cordocentesis
Assessment of amniotic fluid volume	

### Frequency of Fetal Testing

Fetal assessment clearly lends itself to the use of algorithms both for selecting patients and for designing a cascade of testing methods. Such a sequential approach is commonly used (Devoe et al, 1990) and potentially nullifies some of the subjective shortcomings of fetal testing.

Clearly, if clinicians are willing to use methods of fetal surveillance, they must be willing to act on the results.

TABLE 13-2

**Antepartum Fetal Deaths in Tested and Untested Pregnancies over 15 Years**

	1971-1975	1976-1980	1981-1985
No. pregnancies tested	1233	4163	11,263
Death rate (per 1000)	10.5	6.3	4.4
Percentage of all deaths	1.9	3.4	6.7
No. pregnancies untested	51,254	61,963	69,677
Death rate (per 1000)	13.3	11.9	10.0
Percentage of all deaths	98	96	93

TABLE 13-3

**Indications for Fetal Surveillance**

Threatened preterm delivery	Chronic maternal illness:
Post-term pregnancy	Diabetes
Hypertensive disorders	Anemia
Intrauterine growth restriction	Hemoglobinopathies
Previous stillbirth	Cyanotic heart disease
Decreased fetal movement	Collagen vascular disease
Multiple gestation	Renal impairment

Given that for the most part the action required is delivery, it is imperative that the testing method chosen yields few false-positive results and even fewer false-negative results. This topic is addressed after the descriptions of each testing modality.

**ULTRASONOGRAPHY**

Ultrasonography has become an increasingly important tool in the evaluation of high-risk obstetric patients. In many obstetric practices, all pregnant women are offered an ultrasonographic evaluation of the fetus at some point in pregnancy. Although this practice is controversial, there are several well-recognized indications for ultrasonography.

**Determination of Gestational Age**

Accurate determination of pregnancy duration is a central goal of prenatal care. Although precise dating is valuable in even uncomplicated pregnancies, this information is critical in situations of marginal fetal viability and salvageability. A typical scenario involves the problem of performing or avoiding cesarean delivery in a pregnancy with fetal distress at 23 (<5% survival) to 26 (50% survival) weeks of gestation. Typical dating criteria and their accuracy are listed in Table 13-4. Although a crown-rump length measurement obtained between 7 and 10 weeks of gestation provides the smallest error ( $\pm 3$  days), a single ultrasonographic study performed between 16 and 22 weeks affords acceptable dating accuracy ( $\pm 10$  days) while allowing visualization of most of the fetal organs.

**Diagnosis of Fetal Anomalies**

A major additional benefit of routine ultrasonographic scanning of pregnancies is the diagnosis of unexpected fetal anomalies. The following secondary benefits are associated with antenatal identification of the anomalous fetus:

1. Selection of appropriate level of obstetric and neonatal care. *Antenatal counseling by pediatric and neonatal specialists provides a smoother transition for both parents and the newborn.* Typical anomalies in which antenatal counseling improves postnatal care are congenital diaphragmatic hernia and cyanotic heart disease.
2. *Identification of lethal anomalies, avoiding unnecessary cesarean delivery and futile neonatal intervention.* Examples are anencephaly, holoprosencephaly, thanatophoric dwarfism, and bilateral renal agenesis, all of which have a

TABLE 13-4

**Accuracy of Gestational Age Estimation**

Parameter	Accuracy	Comment
<b>Clinical</b>		
Last menstrual period	$\pm 2$ wks	Depends on cycle length and maternal recollection
First-trimester uterine size	$\pm 2$ wks	Depends on operator skill
Auscultation of fetal heart tones	$\pm 2$ wks	Typically at 20 wks (fetoscope); 12 wks with Doppler scope
Fundal height measurements	$\pm 3$ wks	Varies with maternal body habitus
<b>Ultrasonographic</b>		
Gestational sac diameter	$\pm 5$ days	Variable shape distorts measurements Performed from 4.5 to 5.5 wks
Embryonic crown-rump length	$\pm 3$ days	Performed from 6.0 to 12 wks
Biparietal diameter, femur length, cerebellar transverse diameter	$\pm 10$ days; $\pm 14$ -20 days	If performed from 15 to 22 wks; if performed after 22 wks

high incidence of distress during labor that often leads to emergency cesarean delivery. Antenatal recognition of these lethal conditions permits families to make rational choices about the route of delivery.

3. Identification of chromosome anomalies *in otherwise low-risk women*. Most major chromosome anomalies have typical ultrasonographic features, which may suggest further diagnostic procedures, such as amniocentesis and umbilical cord blood sampling. Up to 50% to 60% of chromosome anomalies may be identified from the presence of structural abnormalities evident on midtrimester ultrasonogram.
4. Identification of nonlethal but significantly debilitating fetal anomalies *before viability permits the option of pregnancy termination or in utero fetal therapy*. Examples are large meningomyelocele, multiple amputations associated with the amniotic band syndrome, and fetal hydrops arising from perinatal viral infections such as cytomegalovirus. Conditions that may be amenable to in utero therapy include congenital hydrothorax and posterior urethral valves.

Factors that may adversely affect the accuracy and sensitivity of ultrasonographic screening for fetal anomalies include fetal position, maternal obesity, and decreased amniotic fluid volume. Further, accurate evaluation of fetal anatomy requires a skilled team of experienced ultrasonographers and perinatologists using equipment with optimal image resolution. Counseling of the affected family and formulation of the management plan should involve neonatologists, pediatric subspecialists, and geneticists. Even with optimal equipment and personnel, up to 25% of significant structural defects may be missed.

### ASSESSMENT OF FETAL MOVEMENT

The use of maternally perceived fetal activity to identify fetuses at risk for distress or death has been proposed because of its relatively low cost, convenience, and applicability to a large population. The optimal technique, frequency, and duration of fetal movement monitoring have not been clarified. Factors such as fetal waking and quiet cycles, maternal attention span, compliance, and motivation must be considered. The roles of maternal body habitus, placental position, and amniotic fluid volume may also be important. An understanding of the biology of fetal movement may provide important clues that will be helpful to the development of an effective program of fetal testing.

### Maturation and Circadian Influences

Patrick and colleagues (1982) monitored fetal body movements in third-trimester human pregnancy from 30 to 40 weeks of gestation using continuous 24-hour ultrasonographic observation. The results of their study are shown in Table 13-5. They observed no statistically significant change in the number of movements per hour as gestational age advanced. This finding was confirmed by three other studies (Manning et al, 1979; Rayburn, 1982; Valentin and Marsal, 1986). Valentin and Marsal (1986) documented a mean of 85 fetal movements in a 45-minute period, with a 95% confidence interval of 14 to 232 movements.

**TABLE 13-5**

### Frequency of Fetal Body Movements (FBMs) in the Human Fetus

	30-31 Wks Gestation	34-35 Wks Gestation	38-39 Wks Gestation
No FBMs per hour*	33 ± 2	28 ± 2	32 ± 2
Percentage of time spent in FBMs*	9.3 ± 0.9	98 ± 0.7	11.2 ± 0.9

\*Expressed as mean ± SD.

Adapted from Patrick J, Campbell K, Carmichael L, et al: Patterns of gross fetal body movements over 24 hour observation intervals during the last 10 weeks of pregnancy. *Am J Obstet Gynecol* 142:363, 1982.

### Effect of Fetal Oxygenation on Body Movements

The thesis that fetal movements decrease with hypoxia is central to understanding of the nonstress test (NST) and biophysical profile. Bekedam and Visser (1985) monitored fetal body movements in growth-retarded fetuses before, during, and after uterine contractions. During contractions associated with late decelerations, the frequency of fetal body movements was 85% lower than the frequency before such contractions. In contractions associated with normal fetal heart rate, no change in fetal body movements occurred. The exquisite sensitivity of fetal movement frequency to reductions in oxygenation is similar to that reported by Natale and associates (1981).

Valentin and Marsal (1986) found that the 97.5th percentile for absence of fetal activity was 28 minutes, suggesting an ideal observation interval of approximately 1 hour. Moore and Piacquadio (1989) reported that the mean time to perceive 10 fetal movements was 18 ± 12 (standard deviation) minutes. A 1-hour observation period lacking 10 movements represented 3.5 standard deviations (99th percentile).

On the basis of these observations, various methods of "kick counting" have been proposed. Perhaps the simplest of proven worth is that of Moore and Piacquadio (1989), in which the patient records the time taken for 10 fetal movements to occur between 7 and 11 PM (the period of peak fetal activity). If the requisite 10 movements are not obtained after 1 hour of recording, further fetal evaluation is performed. An example of the card used for patient recording of fetal movement times is shown in Figure 13-2.

Other investigators have confirmed the utility of fetal movement counting in normal and high-risk patients (Neldham, 1980). The results of general population screenings are mixed, ranging from no benefit in a British multicenter randomized trial (Grant et al, 1989) to a significant reduction in stillbirth rate in a case-control study of patients in a military population (Moore and Piacquadio, 1989). Despite the varied results, it is difficult to formulate a good argument against maternal kick counting, and thus this method should probably be widely used as an initial screen from 28 weeks of gestation onward.

Fetal movement assessment thus is a simple screening test that enables the pregnant patient to participate in her

late decelerations in the fetal heart rate; such a test result is shown in Figure 13–3. Although the CST remains a useful test, its disadvantages include significant time investment (45 to 60 minutes), the high frequency of uterine contraction hyperstimulation, and the need for close supervision. Furthermore, the CST is contraindicated in the following high-risk groups:

- Threatened preterm delivery
- Premature ruptured membranes
- Previous classic cesarean section
- Placenta previa

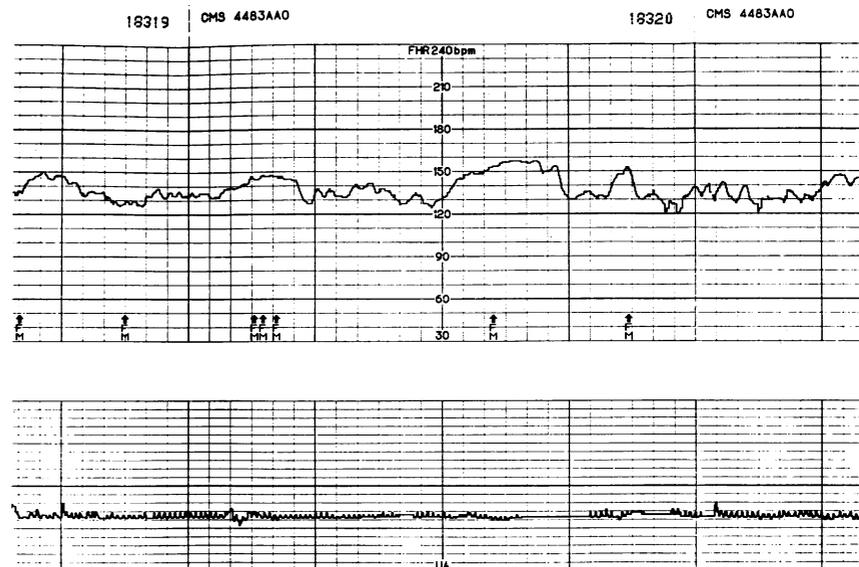

The criteria for a satisfactory result are a minimum of three contractions in 10 minutes and a continuous fetal heart rate signal. Test results are categorized as negative (reassuring), equivocal, positive, and unsatisfactory. A negative CST result requires the absence of late decelerations after all contractions. The diagnostic categories of the CST are summarized in Table 13–6. If more than three contractions occur in 10 minutes and late decelerations are noted, the CST result is classified as hyperstimulatory or unsatisfactory, requiring further testing. In a woman with a reassuring CST result, testing can be repeated weekly. The risk of fetal death with a negative CST result is less than 1 per 1000 (Freeman et al, 1982).

### Nonstress Test

Several observers noted that CST results were rarely abnormal when fetal heart rate accelerations were present in association with movement. This clinical observation led to omission of the contractions, with simple monitoring for fetal heart rate accelerations (Lee et al, 1976; Rochard et al, 1976). Because of its ease of use, universal applicability, and lack of contraindications, the NST has replaced the CST as a first-line surveillance tool.

The NST is carried out with the patient supine with a lateral tilt. The fetal heart rate and uterine activity are recorded with an external transducer for up to 40 minutes. Usually, uterine activity is monitored simultaneously,

**FIGURE 13–4.** A reassuring nonstress test. Note two fetal heart rate (FHR) accelerations exceeding 15 beats/min and lasting at least 15 seconds during the monitoring period.

**TABLE 13–6**

### Diagnostic Categories of the Contraction Stress Test Result

Result	Criteria	Comment
Negative (reassuring)	No late FHR decelerations after a minimum of 3 contractions in 10 min	Retest weekly
Positive	Late FHR decelerations after >50% of contractions	Further testing or delivery indicated
Equivocal	Late FHR decelerations noted, but after <50% of contractions	Retest in <24 hrs
Unsatisfactory	Hyperstimulation noted (>3 contractions/10 min with FHR decelerations or inadequate FHR tracing)	Retest immediately

FHR, fetal heart rate.

and the patient records perceived fetal movement with an event marker. A normal (reactive) NST result is shown in Figure 13–4.

Criteria for a reassuring NST result are as follows:

- Observation period of 20 minutes
- Baseline fetal heart rate between 110 and 160 beats/min
- Short-term variability of <5 beats/min
- Two or more fetal heart rate accelerations of at least 15 beats/min lasting at least 15 seconds
- No nonreassuring features (decelerations, tachycardia, bradycardia)

Although the risk of fetal death with a nonreactive NST result is approximately 40/1000, a reactive result has a risk of 1 to 5 per 1000.

### Factors Influencing the Nonstress Test Result

Fetal heart rate is modified by autonomic activity and may show reduction or absence of reactivity in the presence of hypoxia, neurologic depression, maternal drug ingestion, or acidosis. Fetal behavioral state influences the cardiac reactivity. The human fetus commonly exhibits periods of lowered activity referred to as “sleep cycles.” These periods may produce a decrease or absence of reactivity on an NST. The sleep cycles rarely last more than 20 minutes and may be discounted by observing the fetus for up to 40 minutes.

Adjustments must be made for monitoring of the fetus remote from term (Lagrew, 1987). Between 24 and 32 weeks, the fetus may show accelerations of lesser amplitude that are of shorter duration, reduced reactivity (Druzin et al, 1985; Lavin et al, 1984), and spontaneous low-amplitude decelerations with movement (Sorokin et al, 1982), which do not carry the same ominous portent as in later gestations.

### Indications for and Frequency of Nonstress Testing

The typical indications for the NST are as follows:

- Multiple gestation
- Post-term pregnancy
- Intrauterine growth restriction (IUGR)
- History of previous stillbirth
- Maternal chronic illness (e.g., hypertension, renal or cardiac disease)
- Decreased fetal movement
- Maternal collagen vascular disorders
- Maternal diabetes mellitus

Although NSTs were originally performed weekly, studies suggest that the fetal death rate with weekly testing is excessive, especially compared with the CST (Freeman et al, 1982). Twice-weekly NST, often coupled with simultaneous measurement of amniotic fluid volume, is the mainstay of fetal monitoring for most complicated pregnancies today (Boehm et al, 1986).

It has been suggested that diabetes mellitus and post-term pregnancy increase the risk of fetal mortality and morbidity and thus are ideally suited to the application of fetal monitoring (Slavenssen et al, 1993). Several studies have convincingly shown that waiting for spontaneous labor to occur as late as 42 weeks of gestation in women for whom fetal testing results are reassuring leads to healthy newborns and lower cesarean section rates than when a more aggressive labor induction policy is followed. Nonetheless, the growing risk to the fetus with pregnancy extending beyond 42 completed weeks leads many obstetricians to terminate pregnancy arbitrarily by induction at that point.

Sequential NSTs performed in fetuses with IUGR provide an ideal way of following fetal well-being and aid significantly in timing delivery for optimal outcome, especially when combined with assessment of amniotic fluid volume.

## ASSESSMENT OF AMNIOTIC FLUID VOLUME

Abnormalities of amniotic fluid volume are associated with suboptimal pregnancy outcome. *Oligohydramnios* (inadequate fluid volume) is associated with increased frequency of fetal urinary obstruction, placental insufficiency, umbilical cord compression, fetal distress, meconium passage, and fetal asphyxia (Hill et al, 1984). Prolonged oligohydramnios interferes with normal lung growth, resulting in potentially lethal pulmonary hypoplasia (Nimrod et al, 1984). *Hydramnios* (excessive amniotic fluid volume) is associated with maternal diabetes, fetal esophageal obstruction, and duodenal atresia. Pregnancies complicated by hydramnios have higher rates of abnormal fetal lie, cesarean delivery, and abruptio placentae (Hill et al, 1987). The major diagnostic entities associated with abnormal amniotic fluid volume are listed in Tables 13–7 through 13–9.

### Normal Amniotic Fluid Volume

Twelve studies devoted to the direct quantitation of human amniotic fluid volume have been published since 1965. Brace and Wolf (1989) summarized the changes in amniotic fluid volume during gestation derived from 705 observational studies of normal pregnancies as follows:

- Amniotic fluid volume rises progressively during gestation until approximately 32 weeks.
- From 22 to 39 weeks, the mean volume remains relatively constant, ranging from 630 to 817 mL.
- After 40 weeks, amniotic fluid volume declines at a rate of 8% per week, averaging only 400 mL at 42 weeks. Although amniotic fluid volume varies significantly during pregnancy, the lower 5th percentile in the third trimester (oligohydramnios) is approximately 300 mL. Hydramnios (>95th percentile) is greater than approximately 2000 mL.

### Ultrasonographic Assessment of Amniotic Fluid Volume

Although the increase in perinatal complications associated with abnormal amniotic fluid volume has been recognized for many decades, only the availability of ultra-

	Parvovirus infection
<b>Central nervous system abnormalities</b>	Twin-twin transfusion syndrome
Structural	Maternal diabetes
Chromosomal	Constitutional macrosomia

sonography has enabled the estimation of amniotic fluid volume. Because of the complex shape of the fetus within the uterus, however, direct calculation of the volume of amniotic fluid surrounding the fetus is not currently feasible. Current techniques to estimate with ultrasonography the relative amount of fluid include subjective estimates (Moore et al, 1989), measurement of the largest pocket of amniotic fluid (Chamberlain et al, 1984), and sampling of pocket depths in several areas of the uterus (Rutherford et al, 1987). The amniotic fluid index (AFI) appears to offer better reproducibility and predictive value.

Measuring the AFI involves imaging the amniotic fluid pockets in each of four uterine quadrants and adding the deepest measurements (in mm). Longitudinal measurements of the AFI in normal pregnancies have shown that the AFI varies significantly during gestation (Moore and Cayle, 1990). The normal and boundary values for the AFI are depicted in Figure 13-5.

Although the percentile lines of Figure 13-5 define the limits of normal AFI, the values of AFI that constitute *action* points are less clear. Currently accepted values are shown in Table 13-7, although they have not necessarily been rigorously established. Typically, AFIs greater than 70 mm are regarded as normal, values between 50 and 70 mm require further evaluation, and values less than 50 mm mandate further, more complex testing or delivery.

**FIGURE 13-5.** Amniotic fluid index (AFI; in mm) plotted against gestational age. The *darker line* represents the 50th percentile, and the *thinner lines* represent the 10th and 90th percentiles.

**BIOPHYSICAL PROFILE**

Theoretically, identification of the compromised fetus could be improved by assessing several biophysical variables by means of real-time ultrasonography rather than simple monitoring of the fetal heart rate, as is done in cardiotocography. Manning and associates (1980) recognized the limitations of existing means of fetal heart rate monitoring and developed the biophysical profile (BPP), which encompasses observations of fetal behavioral activity on ultrasonography in addition to fetal heart rate reactivity. Prospective clinical studies have demonstrated generally good but varying predictive accuracies for each variable, but a combination of these measures improves the predictive accuracy substantially (Manning et al, 1987). The components of this BPP are listed in Table 13-10.

TABLE 13-10

**Elements of the Biophysical Profile Score**

Parameter	Criterion Earning 2 Points*
Nonstress test	Reactive test
Fetal breathing movements	At least one episode of fetal breathing of 60 sec duration
Gross fetal body movements	At least three discrete episodes of fetal movement
Fetal tone	At least one episode of extension and return to flexion of extremities or spine or hand open/close
Amniotic fluid volume	At least one pocket of amniotic fluid $\geq 1$ cm in depth

\*Total of 10 points available.

A positive finding in each of the BPP parameters is awarded a value of 2 to give a total BPP score of 10. Outcomes in the initial study were collected prospectively, and scores of 8 to 10 were found to correlate with good outcome. Scores of 2 and 4 are associated with high perinatal mortality and warrant intervention. A summary of possible scores and recommended actions is given in Table 13–11. The risk of fetal death with a BPP score of 8 is less than 1 per 1000.

Although a number of studies have demonstrated the efficacy of the BPP, its performance is time-consuming and expensive in resources. Many centers now use the so-called *modified BPP*, in which the NST provides the estimate of short-term fetal acid-base status and the AFI assesses comparatively longer-term alterations in placental function and fetal well-being (Clark et al, 1989; Vintzileos and Knuppel, 1994). Adding AFI measurements to the NST reduces the risk of fetal death from approximately 2 per 1000 to less than 1 per 1000.

### DOPPLER FLOW STUDIES

Reports of the use of Doppler ultrasonography for the evaluation of maternal and fetal conditions have increased in frequency in the obstetric literature. Despite the increasing number of publications reporting a variety of applications of Doppler ultrasonography in obstetrics, however, there is still considerable question as to the reliability of and the indications for its use.

It is possible to study flow in many fetal vessels using Doppler ultrasonography. The umbilical artery has been widely studied, but considerable interest has been generated by studies of cerebral blood flow and other regional circulations. Despite the enthusiasm of the proponents of Doppler ultrasonography, it remains an investigational tool only and is never required in any given situation, although it may aid decision-making.

### Physiology of Doppler Velocimetry

In fetal hypoxia or other forms of stress, abnormalities of the fetal velocity waveforms develop. Although the systolic component reflects the vigor of fetal cardiac function, the *diastolic component* of the fetal velocity waveforms is of greatest value in assessing fetal status because it reflects the amount of peripheral resistance that the downstream vascular bed presents to the heart. As peripheral resistance increases, blood flow velocity decreases during cardiac diastole. Therefore, the fetus with an infarcted placenta and associated increase in intraplacental resistance demonstrates rising systolic-to-diastolic ratios over time. If resistance rises high enough, flow in diastole may cease completely. In extreme cases, reversed diastolic flow may be seen. The association of absence of end-diastolic velocities (AEDV) in the umbilical artery with IUGR, meconium aspiration, intrauterine fetal death, and birth asphyxia has been reported by many investigators.

**TABLE 13–11**

#### Interpretation and Management of Biophysical Profile (BPP) Score

Score (of 10)	Comment	Perinatal Mortality Within 1 Wk Without Intervention (per 1000)	Management
10	Risk of fetal asphyxia extremely rare	<1	Intervention only for obstetric and maternal factors
8: Normal fluid	No indication for intervention for fetal disease	—	—
Nonstress test (NST) not performed	Equivalent to BPP score of 10 with NST	—	—
Abnormal fluid	Probable chronic fetal compromise	89	Determine whether there is functioning renal tissue and membranes are intact; if so, deliver for fetal indications
6: Normal fluid	Equivocal test, possible asphyxia	Variable	If the fetus is mature, deliver In the immature fetus, repeat test within 24 hrs; if BPP score is <6, deliver
Abnormal fluid	Probable fetal asphyxia	89	Deliver for fetal indications
4	High probability of fetal asphyxia	91	Deliver for fetal indications
2	Fetal asphyxia almost certain	125	Deliver for fetal indications
0	Fetal asphyxia certain	600	Deliver for fetal indications

Adapted from Manning FA, Morrison I, Harman CR, et al: Fetal assessment based on fetal biophysical profile scoring: Experience in 19,221 referred high-risk pregnancies. *Am J Obstet Gynecol* 157:880, 1987.

In pregnancies complicated by IUGR, between two thirds and three quarters of fetuses exhibit an excessively high index of placental resistance (systolic-to-diastolic ratio or resistance index) (Trudinger et al, 1991). Fetuses with abnormal flow-velocity waveforms have a higher incidence of neonatal morbidity than those with normal study findings.

Histologically, the high placental resistance evidenced by the abnormal umbilical Doppler flow velocity waveform is associated with reduced numbers of small (diameter <90  $\mu\text{m}$ ) arteries in the tertiary villi of the placenta (the resistance vessels) (Giles et al, 1985) and obliterative changes in the remaining vessels.

Abnormalities of blood flow velocity may occur in other vascular beds in the fetus experiencing hypoxemia. As the oxygen level in the umbilical venous blood drops, the cerebral circulation compensates by increasing flow in the carotid arteries. Accordingly, with progressive hypoxia, intracerebral vascular resistance typically falls, and diastolic velocity increases. Flow velocity in the descending aorta, supplying the majority of the fetus's visceral organs, may be adversely affected. The level of intrauterine hypoxemia at any given time may be best expressed as the sum of effects on umbilical, cerebral, and aortic circulations.

Because the relationship of the fetal heart to the placental, cerebral, and visceral circulations is in a dynamic state of flux during pregnancy, the fetal velocity waveform indices must be corrected for gestational age. *Normative tables* for the pulsatility index and systolic-to-diastolic ratio have been published by Schulman and coworkers (1984).

Abnormalities in the fetal velocity waveform (particularly the diastolic changes) generally become evident 1 to 3 weeks before the onset of abnormalities in other clinical parameters, such as fetal heart rate, amniotic fluid volume, and fetal BPP. During pregnancy, uterine blood flow is markedly increased with minimal resistance secondary to the effects of estrogen on the uterine circulation. From reasonably early in gestation, the fetal velocity waveforms of the uteroplacental circulation can be documented, and in certain maternal diseases, such as chronic hypertension and pregnancy-induced hypertension, abnormalities in the uteroplacental fetal velocity waveforms can be documented. In fact, Campbell and associates (1986) noted abnormalities in uteroplacental circulation from approximately 20 weeks onward in pregnancies in which either severe IUGR or pregnancy-induced hypertension developed.

## Applications of Doppler Waveform Analysis in Fetal Management

### Rule Out Chronic Fetal Hypoxia

Despite the flurry of papers concerning the use of Doppler ultrasonography throughout pregnancy, its most common indication is as an advisory adjunct in the evaluation of fetal status. As an example, in pregnancies remote from term with no evidence of IUGR, decreased amniotic fluid volume, or abnormal fetal heart rate changes, it is unlikely that one would deliver the fetus on the basis of a grossly abnormal Doppler blood flow unless the BPP score also was less than 4. The controversy surrounding

use of Doppler ultrasonography in fetal testing has been well characterized by Low (1991).

Later investigators have used pulsed Doppler ultrasonography to examine blood flow in the carotid artery or descending aorta. They have found that under normal conditions, diastolic blood flow in the carotid arteries is decreased. With the development of IUGR or hypoxia, there is a dilation of the cerebral blood flow during diastole. These findings are consistent with the known increase in cerebral blood flow with hypoxia in laboratory animals.

Overall, the decision to intervene in a pregnancy at risk for IUGR is strengthened by knowing the trend in Doppler flow velocity ratios. Most experts believe that Doppler velocimetric findings alone are not adequate evidence of urgent fetal compromise unless diastolic flow is actually reversed. Doppler velocimetry should be used to guide the use of more traditional biophysical tests (e.g., NST, CST).

However, two findings (AEDV and reversed end-diastolic velocity [REDV]) should be viewed with concern. These two entities, marked by absence or reverse of umbilical artery flow during cardiac diastole, are associated with significantly increased placental resistance and fetal cardiac failure. The incidence of meconium staining, admission to a neonatal intensive care unit, and fetal growth restriction is several times higher with AEDV than if some diastolic flow is present. If fetal blood flow to the placenta reverses during the resting part of the cardiac cycle, cardiac pump function and placental resistance are at end stage; more than 60% of fetuses die within 48 hours of this finding.

### Investigate Discordant Growth in Twins

In a twin gestation, finding one large, possibly hydramniotic twin and the other twin smaller by 4 to 6 weeks of gestation in a sac with markedly diminished amniotic fluid can present a difficult diagnostic challenge, especially if the genders are concordant. The entity of severe growth discordance can be due to twin-twin transfusion syndrome (TTS) or associated with placental discordance and IUGR. Use of serial Doppler velocimetry measurements can help differentiate TTS from IUGR: in TTS, the systolic-to-diastolic ratio in umbilical fetal velocity waveforms of the small twin is usually normal or decreased, whereas the Doppler studies in a growth-restricted twin with small or infarcted placenta displays absence of diastolic velocity. Following such pregnancies with Doppler velocimetry studies can help identify the starting point for biophysical testing (when systolic-to-diastolic ratios rise or end-diastolic velocity disappears) and may provide an early signal of the need for urgent delivery.

Doppler ultrasonography is a helpful tool in the evaluation of fetal status. In some cases, the results can be predictive of abnormal future fetal or maternal outcomes, but the method is neither sensitive nor specific enough at this time to be completely reliable unless extremes of flow velocity are present.

## AMNIOCENTESIS

Examination of amniotic fluid in late pregnancy for biochemical evidence of lung maturity may precede elective delivery or aid in timing of delivery in a compromised pregnancy. The following tests are available:

- Lecithin-sphingomyelin ratio
- Phosphatidyl glycerol
- TDx-FLM (TDx–fetal lung maturity) fluorescence polarization assay

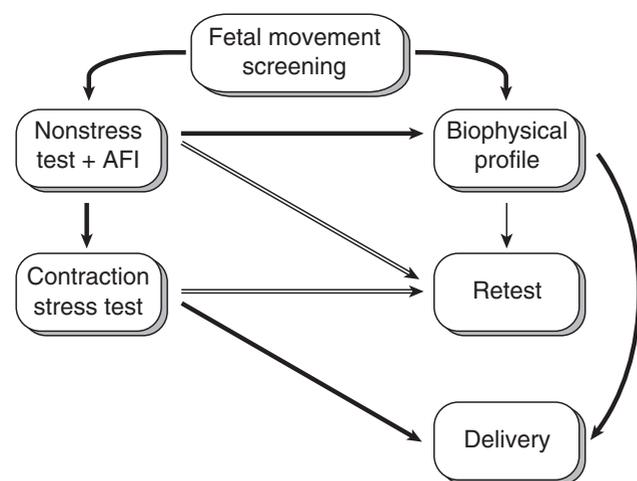

In certain cases of apparent fetal compromise, it may be necessary to exclude potentially lethal chromosome anomalies before intervention and delivery. Amniocentesis for karyotyping or the more rapid fluorescent *in situ* hybridization for identification of trisomies 13, 18, and 21 may thus be indicated.

## CORDOCENTESIS

Access to fetal blood provides the ultimate means of assessing fetal status—although not without significant procedural risk, carrying a fetal loss rate of 1%. Acid-base status and blood gas levels may be determined (Soothill et al, 1992), although critical values for intervention have not been firmly established (Sonek and Nicolaides, 1994).

## SUMMARY

Clearly, fetal surveillance encompasses a wide range of modalities, each with advantages and disadvantages. A suggested cascade of complexity is shown in Figure 13–6. There is no agreement among authorities as to the ideal tests for fetal well-being. Because there are no large randomized, prospective studies comparing the various methods available, none may be considered superior to others. The key is to identify the fetus potentially at risk and then to ensure that a reassuring test result is obtained at each scheduled encounter. Avoidable mortality occurs

**FIGURE 13–6.** Fetal testing cascade. *Filled lines* indicate abnormal, or nonreassuring, test result. *Open lines* indicate normal, or reassuring, test result. AFI, amniotic fluid index.

most often when the practitioner does not act on concerning test results.

# Prematurity: Causes and Prevention

George A. Macones

## TRENDS IN RATES OF PRETERM BIRTH

Preterm birth continues to be one of the major challenges in perinatal medicine. Despite years of research, the rate of preterm birth has remained constant over the past 20 years (Goldenberg and Rouse, 1998). If anything, the incidence of preterm birth may be rising somewhat, due in part to the increasing rates of multiple gestations resulting from advanced reproductive technologies. Fortunately, advances in neonatal medicine have led to drastic improvements in survival as well as reductions in morbidity among infants born preterm. These advances are well-described in other sections of this book.

In this chapter, we focus on the etiology, prediction, and prevention of preterm birth. We describe a current approach to prevention of preterm birth from the perspective of the obstetrician.

## Etiology of Preterm Birth

A *preterm birth*, defined as one occurring before 37 completed weeks of gestation, can occur for a variety of reasons. This diversity of etiologies is one reason why the prevention of preterm birth has been so problematic. In general, preterm births are categorized as either spontaneous or indicated (Meis et al, 1995). *Spontaneous* preterm births occur secondary to either preterm labor or preterm premature rupture of the amniotic membranes (PPROM). *Indicated* preterm births are those that occur because of a medical or obstetric problem that places either the mother or the fetus at risk; delivery is undertaken to preserve or improve the maternal or fetal status. Notably, spontaneous preterm births account for more than two thirds of all preterm births in the United States, and indicated preterm births account for the remaining third (Goldenberg and Rouse, 1998).

There are a variety of reasons for an indicated preterm birth, and they may be divided into maternal and fetal indications (Meis et al, 1995). The maternal indications for preterm delivery are as follows:

- Preeclampsia
- Placental abruption
- Placenta previa
- Any maternal medical condition requiring delivery (e.g., cancer)

Fetal indications for preterm delivery are:

- Severe fetal growth retardation
- Nonreassuring fetal status

As one can see from the preceding lists, the etiology of indicated preterm births is very heterogeneous, and it should not be surprising that spontaneous and indicated preterm births differ in epidemiology. For this reason, most preventive strategies for reducing preterm birth are focused on spontaneous, rather than indicated, preterm births. The remainder of the chapter focuses on spontaneous preterm births.

## RISK FACTORS FOR SPONTANEOUS PRETERM BIRTHS

Spontaneous preterm births occur because the labor process begins early (without any other identifiable maternal or fetal conditions). Preterm births resulting from preterm labor or PPRM account for a majority of preterm deliveries in the United States (Goldenberg and Rouse, 1998). There is considerable but not complete overlap in the risk factors for these two conditions. *Spontaneous preterm labor* is defined as the onset of uterine contractions with cervical change before 37 weeks of gestation. PPRM is rupture of the amniotic membranes before 37 weeks of gestation. The variety of risk factors for these spontaneous preterm deliveries is described in this discussion.

## Multiple Gestation

Multiple gestation is one of the strongest risk factors for either a spontaneous or indicated preterm birth. With advances in the treatment of infertility by means of ovulation induction and in vitro fertilization, the rate of multiple gestations both in the United States and in other developed countries is rising. It is generally believed that the risk of preterm labor and PPRM is increased with multiple gestation because of excessive uterine distension (because the same higher risk is observed with polyhydramnios). In addition, the more fetuses present, the higher the rate of preterm birth. The mean gestational age at delivery is approximately 37 weeks for twins, approximately 33 weeks for triplets, and approximately 28 weeks for quadruplets. Rates of preterm birth are higher for monochorionic than for dichorionic multiple gestations.

Because of the concerns with high-order multiple gestations (triplets or higher), patients are often offered fetal reduction. Fetal reductions are performed in the late first trimester. Under ultrasonographic guidance, potassium chloride is injected into the thorax of one or more of the fetuses. This procedure carries a small procedure-related loss rate, approximately 4%. Patients whose multiple gestations are reduced to twins seem to have perinatal outcomes similar to those of women with nonreduced twin gestations. The only exception to this is that there may be a higher rate of growth retardation in pregnancies that have been reduced to twins. Most physicians are comfortable with offering a fetal reduction to a patient with triplet or greater gestations, although there is controversy about the role of fetal reduction in triplet pregnancies (Macones et al, 1993; Melgar et al, 1991; Porreco et al, 1991; Yaron et al, 1999).

### Maternal Uterine Abnormalities

Maternal uterine abnormalities are also associated with spontaneous preterm birth, accounting for approximately 5% of all preterm births. Such anomalies include bicornuate uterus, uterus didelphys, and unicornuate uterus. The usual obstetric history of someone with a uterine abnormality would be the occurrence of multiple preterm births, with advancing gestational ages in subsequent pregnancies. At the University of Pennsylvania, any patient with a spontaneous preterm birth is counseled to undergo a postpartum evaluation for uterine abnormalities. This evaluation can be done via either hystero-graphy or a hysterosalpingogram. Such an evaluation is essential, because some abnormalities are amenable to surgical correction, which in theory could lessen the chances of a subsequent preterm delivery.

### Fetal Abnormalities

Some fetal abnormalities also raise the risk of a spontaneous preterm birth. They include anomalies that might increase the volume of amniotic fluid, which through overdistension of the uterus can lead to preterm delivery—such as bowel obstruction and tracheoesophageal fistula. Because of the relationship between fetal abnormalities and preterm birth, it is essential to review findings of prior scans or to perform a targeted ultrasonogram for any woman presenting with preterm labor.

### Maternal Infection

Maternal infections are risk factors for preterm birth as well. Infections such as pneumonia and pyelonephritis have been linked to preterm birth. Genital tract infections, including *Chlamydia* and gonorrhea, have also been related to preterm birth. Attention has now turned to the relationship between maternal bacterial vaginosis and preterm birth. A number of observational studies both in the United States and around the world link bacterial vaginosis to spontaneous preterm birth (Hillier et al, 1995; Kurki et al, 1992; Riduan et al, 1995). The mechanism of this association is unclear, though some researchers have theorized that the bacterial vaginosis-associated organisms can ascend and cause a subclinical infection in the decidua. In theory, this smoldering infection could lead to activation of the inflammatory cascade, which in turn could lead to the activation of proteases and matrix metalloproteinases, weakening the amniotic membranes and causing preterm birth. Interestingly, the association between infection and preterm birth is strongest at earlier gestational ages.

### Maternal Cervical Abnormalities

Maternal cervical abnormalities can be associated with preterm birth. Traditionally, obstetricians have believed that cervical abnormalities lead to an incompetent cervix. Incompetent cervix has been associated with midtrimester cervical dilation and delivery. Substantial research has now been conducted on the relationship between the length of the cervix and preterm birth. On the basis of this work, it is now believed that the shorter the cervix, the

higher the rate of preterm birth. Thus, the traditional teaching of an incompetent versus a competent cervix is being reconsidered (Iams et al, 1995, 1996).

### History of Spontaneous Preterm Birth

A history of a spontaneous preterm birth is among the strongest risk factors for a subsequent preterm birth. For example, in the United States, the baseline rate of preterm birth is approximately 8%. In women who had experienced a previous preterm birth, the rate rises to almost 16%. Table 14–1 demonstrates results from a landmark study describing rates of preterm birth based on pregnancy history. If an individual has a single preterm birth, the rate in the subsequent pregnancy rises to 17.2%. With two consecutive preterm births, the rate rises to more than 28% in the next pregnancy (Bakketeig and Hoffman, 1981).

### Ethnicity

Ethnicity is also a risk factor for preterm delivery. Specifically, rates of preterm birth in those of African-American descent are nearly twice as high as those in whites (Meis et al, 2000; Mercer et al, 1996). There are probably many reasons, but one commonly cited is the association between African-American race and bacterial vaginosis (Meis et al, 2000).

### Genetic Susceptibility

There is a great deal of ongoing work on whether or not there is a genetic susceptibility to preterm birth. The following lines of evidence support such a susceptibility:

- A history of a prior preterm birth is a strong risk factor for its subsequent occurrence (Bakketeig and Hoffman, 1981; Goldenberg et al, 1998).
- There appears to be an intergenerational risk of preterm birth (Klebanoff et al, 1989).
- Twin studies support a higher concordance of preterm birth in monozygotic twins than in dizygotic twins (Treolar et al, 2000).

Because of this work as well as the advances in genetic research, many investigators are looking for candidate genes

TABLE 14–1

#### Risk of Preterm Birth in Subsequent Births

First Birth	Second Birth	Subsequent Preterm Birth (%)
Not preterm		4.4
Preterm		17.2
Not preterm	Not preterm	2.6
Preterm	Not preterm	5.7
Not preterm	Preterm	11.1
Preterm	Preterm	28.4

From Bakketeig LS, Hoffman HJ: Epidemiology of preterm birth: Results from longitudinal study of births in Norway. In Elder MG, Hendricks CH (eds): Preterm Labor. London, Butterworths, 1981, p 17.

that might increase or decrease the risk of preterm birth. Interestingly, consideration is being given to both maternal and fetal candidates. Much of this current work is focused on polymorphisms that relate to the host inflammatory response to infection.

### SCREENING FOR PRETERM BIRTH

Conditions for screening for a given condition have been well described. Following are some of the tenets for a successful screening program:

- The screening test must be acceptable.
- The disease must be prevalent.
- The disease must have serious consequences.
- The screening test must have acceptable discriminatory ability (i.e., high sensitivity and specificity).
- There must be interventions to reduce disease burden in those with positive screening results.

Preterm birth meets many, though not all, of these requirements. Certainly, from an individual and societal perspective, a screening strategy that could reduce preterm births would be welcome. However, screening for preterm birth is limited because of the lack of interventions that could reduce preterm birth in women with positive results. Thus, most screening tests currently available have little, if any, clinical application. Rather, they are often used in research studies of new interventions. Despite these limitations, there are three methods of screening for preterm birth.

First, there are well-described *risk scoring indices* for preterm birth (Creasy et al, 1980; Mercer et al, 1996). Several of these indices have been published, and they are based on large epidemiologic studies of risk factors for preterm birth. The sensitivity of these indices approximates 50%, suggesting that at least half of preterm births would be missed by evaluations based on these clinical grounds alone.

Second, *biochemical markers* have been assessed as screening tests for preterm birth. Fetal fibronectin has undergone an extensive evaluation in this setting (Bartnicki et al, 1996; Goldenberg et al, 1996, 1997; Jones and Poston, 1998; Leitich et al, 1999; Lockwood et al, 1991). Fibronectin is a glycoprotein that is released when the extracellular matrix degrades. It is believed that fibronectin may be released when subclinical infections develop. These subclinical infections (such as bacterial vaginosis) can lead to activation of the cytokine cascade, which in turn leads to release of proteases and collagenases. The action of these enzymes on the extracellular matrix can then lead to the release of fetal fibronectin. Fetal fibronectin is measured in the cervix and vagina, and rapid tests are available (and have been approved by the U.S. Food and Drug Administration). The presence of fetal fibronectin at 16 to 22 weeks of gestation has been associated with a higher risk of spontaneous preterm birth (Goldenberg et al, 2000). Unfortunately, no interventions are available to reduce the risk of preterm birth in women with positive results. In fact, one large, multicenter study (Andrews et al, 2003) tested whether administration of antibiotics to women who test positive for fetal fibronectin could reduce preterm birth. Unfortunately, this study did not demonstrate any benefit in women who were treated with antibiotics compared with

those who received placebo. For this reason, screening for risk of preterm birth using fibronectin is rarely performed in clinical practice.

Lastly, there are *physical screening tests* for preterm birth. They are digital and transvaginal ultrasonographic assessments of the cervix (Iams et al, 1995, 1996). Although a short cervix, as detected either digitally or ultrasonographically, is associated with preterm birth, as is testing positive for fibronectin, no interventions have been demonstrated to improve perinatal outcomes.

### CURRENT TREATMENTS TO REDUCE PRETERM BIRTHS

Although screening strategies have been disappointing, mainly because of the lack of efficacy of interventions, a number of treatments are commonly employed in those at risk of preterm birth.

#### Screening for Bacterial Vaginosis

As has been mentioned earlier, maternal bacterial vaginosis has been associated with spontaneous preterm birth (Hillier et al, 1995; Kurki et al, 1992; Riduan et al, 1995). Given this association, it was hoped that screening and treating bacterial vaginosis in pregnancy could reduce the occurrence of preterm birth. Results of studies in women with a history of a prior preterm birth were conflicting, with some suggesting that screening and treatment could reduce the occurrence of preterm birth in high risk subjects, and others showing no benefit (Hauth et al, 1995; Morales et al, 1994). Still, these studies led to optimism that screening and treating all pregnant women could reduce the burden of preterm births in the United States. A large clinical trial performed within the Maternal-Fetal Medicine Units Network of screening and treating bacterial vaginosis in low-risk women did not demonstrate any benefit of treatment (Carey et al, 2000). Thus, screening for bacterial vaginosis in low-risk women is not currently recommended. On the basis of results of small clinical trials, some authorities still advocate screening and treating bacterial vaginosis in women with a previous spontaneous preterm birth.

#### Avoidance of High-Order Multiple Gestations

The occurrence of preterm birth has been well documented to increase with increasing fetal number. Thus, limiting high-order multiple gestations that are achieved with advanced reproductive technologies is paramount. In addition, women with high-order multiple gestations should be counseled about the option of fetal reduction.

#### Tocolysis for Preterm Labor

Neonatologists are very familiar with the treatment of an acute episode of preterm labor. *Preterm labor* is defined as the occurrence of regular uterine contractions accompanied by a change in the cervix (dilation or effacement). Depending on the gestational age, the arrest of preterm labor with

various medications can be attempted. The oldest class of medications used for tocolysis are the beta-agonists, such as ritodrine and terbutaline. Ritodrine, in fact, is the only drug approved by the U.S. Food and Drug Administration for tocolysis (though no one manufactures it in the United States). Although these medications seem to be effective for a short-term delay in delivery (i.e., 48 hours), they do not reduce the rate of preterm birth (Barden et al, 1980; Downey and Martin, 1983; Larsen et al, 1986; Leveno et al, 1986). Nevertheless, a 48-hour delay allows for the administration of steroids, which can reduce the rate of various neonatal complications. The use of beta-agonists is limited by the occurrence of maternal side effects. Beta-agonist infusion has been associated with the following maternal complications (Alper and Cohen, 1983; Armson et al, 1992; Ferguson et al, 1989; Goyert et al, 1987; Ron-El et al, 1983):

- Hyperglycemia (and diabetic ketoacidosis in women with diabetes mellitus)
- Tachycardia
- Pulmonary edema
- Anxiety and restlessness
- Myocardial ischemia

Because of these complications, most centers in the United States do not use beta-agonists as a first line treatment for preterm labor.

Magnesium sulfate is commonly used for the arrest of preterm labor (Chau et al, 1992; Elliott, 1983; Macones et al, 1997; Madden et al, 1990; Miller et al, 1982; Smith et al, 1992; Tchilinguirian et al, 1984; Wilkins et al, 1988). Magnesium sulfate is usually administered intravenously—first as a loading dose and then as a constant infusion. The mechanism of action of magnesium sulfate is largely unknown, although it is believed to be related to calcium influx or efflux in smooth muscle. Magnesium sulfate is believed to be safe to use in pregnancy, although it has maternal side effects, such as lethargy, anxiety, chest heaviness, and pulmonary edema. Importantly, at very high levels of magnesium sulfate, maternal respiratory depression or cardiac arrest can occur.

There has been some concern about the fetal or neonatal safety of magnesium sulfate when used for preterm labor (Mittendorf et al, 1997). The MagNet Study was designed to evaluate whether the administration of magnesium sulfate to women at high risk of preterm delivery could reduce the occurrence of cerebral palsy. This clinical trial was stopped early because of an excess of pediatric deaths in the group receiving magnesium sulfate. However, many of the pediatric deaths reported in this study would be difficult, if not impossible, to ascribe to magnesium sulfate (e.g., accidents, congenital abnormalities). Thus, many maternal-fetal medicine specialists are skeptical of these findings. A large multicenter clinical trial is currently underway to assess whether the administration of magnesium sulfate to women at risk of preterm birth (e.g., those in preterm labor or with ruptured amniotic membranes) reduces the risk of cerebral palsy and neurodevelopmental disability.

Prostaglandin synthetase inhibitors, such as indomethacin, have also been tested and used to arrest an acute episode of preterm labor (Blake et al, 1980; Carlan et al, 1992; Keirse, 1995; Morales et al, 1989; Nieby et al, 1980; Zuckerman et al, 1974, 1984). These medications

can be administered either orally or as vaginal or rectal suppositories. Although these agents are believed to have few serious maternal side effects, there has been concern about their safety for the fetus and neonate. Specifically, indomethacin freely crosses the placenta and has an extremely long half-life in preterm fetuses. Indomethacin has the following actions on the fetus:

- Reduction of renal blood flow
- Alteration of regional gastrointestinal blood flow
- Interference with platelet aggregation
- Closure of the ductus arteriosus

Because of these well-described physiologic changes associated with indomethacin, a number of observational studies have assessed the occurrence of necrotizing enterocolitis and intraventricular hemorrhage in infants who received antenatal indomethacin and in those who did not (Dudley and Hardie, 1985; Eronen et al, 1994; Goldenberg et al, 1989; Major et al, 1994; Norton et al, 1993). These studies have had conflicting results, with some showing higher rates of both disorders in infants who were exposed to indomethacin, and others demonstrating no relationship between indomethacin and adverse neonatal outcome (Gardner et al, 1996). Thus, at this point it is unclear whether the benefits of delaying delivery with indomethacin are outweighed by the neonatal or fetal risks of therapy (Macones and Robinson, 1997; Macones et al, 2001; Merrill et al, 1994). Most authorities agree that if indomethacin is to be used, it should be for a short course only (48 hours or less) and that this agent not be used beyond 34 weeks of gestation (when the fetal ductus arteriosus is more responsive to closure with indomethacin).

### **Conservative Management of Preterm Premature Rupture of the Amniotic Membranes**

Conservative management has become the standard method of managing PPRM at most centers around the country. Basically, when PPRM is confirmed at a gestational age of 30 weeks or less, the patient is admitted to the hospital and observed for signs of infection (chorioamnionitis) and for signs of labor. During this period, the following therapies are undertaken and the following procedures performed:

- Administration of corticosteroids
- Administration of antibiotics
- Fetal assessment via nonstress testing or biophysical profile
- Monitoring of maternal vital signs

The role of antenatal steroids in the setting of PPRM has been a topic of debate for many years. The concern had been that the administration of steroids in this setting could increase the rate of both maternal and fetal infections. However, a National Institute of Child Health and Human Development (NICHD) consensus panel has advocated the use of steroids in PPRM at less than 30 to 32 weeks of gestation. Beyond that gestational age, the risk-to-benefit ratio is less clear.

Administration of maternal antibiotics, irrespective of group B beta-hemolytic streptococci status, has been

demonstrated to have benefits for the neonate (Mercer and Arheart, 1995; Mercer et al, 1997). Mercer and Arheart performed a meta-analysis to assess the role of maternal administration of antibiotics in patients with PPRM. This meta-analysis demonstrated that antibiotics improved outcomes as follows:

- Reduced occurrence of chorioamnionitis and postpartum maternal infection
- Reduced risk of neonatal sepsis (Table 14–2)
- Reduced risk of neonatal pneumonia
- Greater proportion of women undelivered after 7 days (Table 14–3)

**TABLE 14–2****Neonatal Sepsis and Antimicrobial Therapy in PPRM**

There are some unanswered questions regarding the use of antibiotics in the setting of PPRM. Specifically, a variety of antibiotics appears to be effective, but it is unclear which regimen, including duration of treatment, is most effective (Cox and Leveno, 1995). Another controversy in the management of PPRM is at what gestational age elective delivery should be considered. This decision should be made jointly by the neonatal group and obstetric group. At the Hospital of the University of Pennsylvania, we generally deliver patients electively with PPRM at 34 weeks of gestation.

## SUMMARY

Preterm birth remains one of the great challenges in perinatal medicine. Currently, there is active research on developing additional screening tests for preterm birth. More importantly, interventional studies on those who screen positive are ongoing.

## Complicated Deliveries: Overview

Sameer Gopalani and Thomas J. Benedetti

In the past, childbirth was often regarded as a perilous undertaking. However, over the last century in the United States, perinatal and maternal mortality rates have dramatically fallen with advances in modern obstetric care, such as the widespread use of antibiotics, easy access to expedient cesarean delivery, and a better understanding of the proper use of instruments such as forceps and vacuum extraction (National Vital Statistics System, 2001). Indeed, adverse outcomes are in general uncommon in modern obstetrics, and unlike in the past, labor and delivery sessions conclude in most cases with a healthy mother and neonate. Nevertheless, complicated deliveries still occur, and knowledge of their conduct and sequelae are still required for the administration of proper maternal and infant care.

In this chapter we first address the complicated vaginal delivery, with particular attention to neonatal outcomes. We then discuss cesarean delivery and vaginal birth after a prior cesarean delivery (VBAC), and what neonatal implications they may have. However, prior to discussing complicated labor and its neonatal impact, we briefly consider the conduct of normal labor and delivery. A comprehensive discussion of labor and delivery is beyond the scope of this chapter; the interested reader is directed to any standard obstetric textbook chapter on normal labor (Fig. 15–1).

The *first stage of labor* begins with the onset of regular uterine contractions with concomitant cervical dilation and effacement, and ends with complete cervical dilation. The first stage is further subdivided into a *latent phase*, the length of which is quite variable and can last for several hours. The second part of the first stage of labor is the *active phase*, which usually begins when the cervix has dilated to 3 to 4 cm; this phase is marked by further rapid, progressive cervical dilation and effacement. Often the diagnosis of the transition from latent phase to active phase labor is retrospective, because the time of onset of active labor varies from patient to patient. The *second stage of labor* begins with complete cervical dilation and terminates with the expulsion of the fetus from the birth canal. The *third stage of labor* concludes with the delivery of the placenta.

Disorders of the conduct of labor are either of *protraction*, in which cervical dilation or fetal descent occurs but at a rate much less than expected, or *arrest*. Both disorders, if unresponsive to active medical management, are addressed by operative delivery. This delivery can be performed abdominally through cesarean section or vaginally with obstetric forceps or vacuum extraction if the cervix is

fully dilated and specific criteria are fulfilled (see later). All these modalities can have neonatal and maternal effects, and the choice of instrument or mode of delivery must always take these potential morbidities into account.

### CESAREAN SECTION

Neonatal mortality within 7 days of birth was 20.5 per 1000 live births in 1950; this figure has fallen to 4.5 per 1000 (National Vital Statistics System, 2003). Certainly much of the improvement in neonatal survival stems from advances in neonatal intensive care and resuscitative techniques. Along with improved technology available to the pediatricians, however, is the fact that the last 50 years have also seen a dramatic increase in the universal access to safe cesarean section, which affords quick and timely fetal delivery. The National Center for Health Statistics (NCHS) records that in 1999, 20.8% of all infants born were delivered by cesarean section; in the 1950s and 1960s, the operative delivery rate was closer to 5% (NCHS, on line).

Cesarean section is usually performed through either a Pfannenstiel or vertical skin incision. The uterine incision is often made transversely in the lower uterine segment, as this approach minimizes intraoperative blood loss and future rupture risk during subsequent labor compared with a vertical or *classic* incision. The rupture risk in future labor is thought to be 0.5% to 1% for a low transverse incision, compared with 4% to 9% for a classic incision (American College of Obstetricians and Gynecologists [ACOG], 1999).

The accepted obstetric indications for operative delivery are as follows:

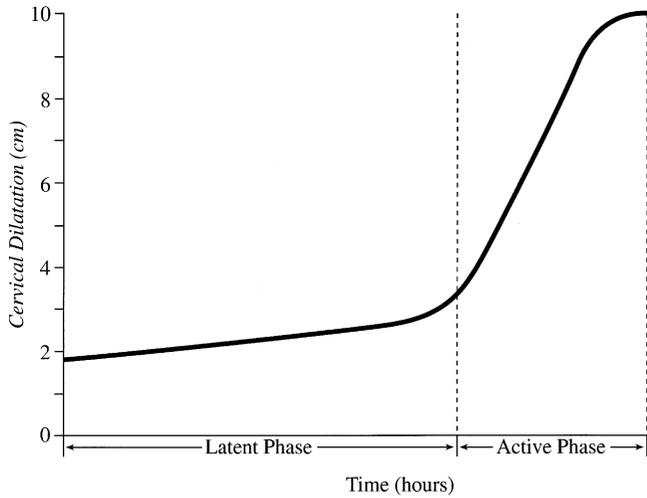

- Fetal malpresentation (e.g., shoulder or breech)
- Placenta previa
- Prior classic uterine incision
- Nonreassuring fetal status, remote from vaginal delivery
- Higher-order multiple gestation (triplets or more fetuses)
- Fetal contraindications to labor (alloimmune thrombocytopenia, neural tube defect)
- Maternal contraindication to labor (e.g., history of rectal or perineal fistulas from inflammatory bowel disease; large lower-uterine segment or cervical leiomyoma preventing vaginal delivery)

Cesarean section is also performed for disorders of protraction or arrest in the first stage of labor when conservative measures, such as oxytocin and amniotomy, fail to augment delivery or in the second stage, when assisted or operative vaginal delivery is deemed to be not feasible or not safe.

### THE COMPLICATED VAGINAL DELIVERY: OBSTETRIC FORCEPS AND VACUUM EXTRACTION

#### Obstetric Forceps

Obstetric forceps have been employed for thousands of years to terminate difficult labors. However, many of these instruments were furnished with hooks and other accessories of destruction, being intended to save the mother but certainly not the fetus. It is only over the last

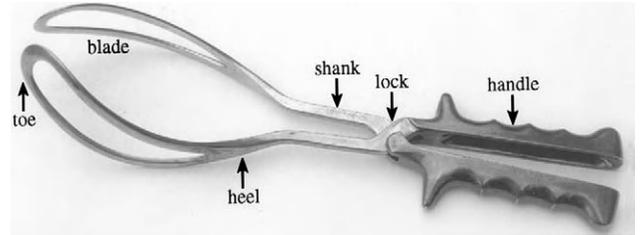

**FIGURE 15-1.** A graphic representation of normal labor, showing the variable time of onset to the active phase (3 to 4 cm), with a subsequent increase in the slope of cervical dilation.

400 years that ancestors of the modern instruments employed today came into existence, with the hope of delivering an intact, living baby.

Current obstetric forceps were first devised for practical use in the 17th and 18th centuries. They have been perfected over the past 200 years into the models that we currently use. There are many variations on the standard blueprint, depending on the indication for its use, but all obstetric forceps have a similar anatomy.

Forceps are devised of stainless steel and all have a *handle*, whereby the instrument is grasped by the obstetrician. There are long *shanks*, which are either parallel, divergent, or convergent, depending on the type of instrument, and a *lock*, which allows the two separate halves of the forceps to articulate. The two most common types of lock are the *sliding lock*, which can articulate anywhere along the shanks of the blade, and the *English lock*, which is fixed. The part of the forceps which grasps the fetal head is the *blade*. The blade can either be fenestrated, meaning that the body of the blade is hollow, or solid. Obstetric forceps also possess a rounded *cephalic curve*, which accommodates the fetal vertex, and a *pelvic curve*, which mirrors the curve of the mother's pelvis (Fig. 15-2).

**FIGURE 15-2.** Simpson forceps: a standard obstetric forceps with features common to all such instruments.

More than 60 different types of obstetric forceps have been described in the literature, but most of these are not employed in current practice. The forceps most commonly used today are described in Table 15-1, along with the variations in anatomy that distinguish one from the other and their indications for use.

**Indications for and Use of the Obstetric Forceps**

To an individual without obstetric training, the employment of forceps seems a dangerous and difficult undertaking, fraught with potential trauma for both the mother and fetus. It is certainly true that this instrument, if not handled carefully or appropriately, can have serious consequences. Nevertheless, in properly trained hands and with a proper appreciation of its use, forceps can be life-saving for both mother and fetus.

The criteria for safe application of obstetric forceps are as follows:

1. The cervix must be fully dilated.
2. The position of the fetal vertex must be known. *Forceps should not be applied when the fetal presentation is in doubt.*
3. The fetal vertex must be engaged. Often in difficult or challenging labors, significant edema of the fetal scalp can lead to the false impression that fetal station is lower than it actually is. For this reason, the obstetrician must be confident that the actual biparietal diameter has passed the pelvic inlet and that the leading part of the fetal skull is beyond the level of the ischial spines. In addition, when the presentation is occiput

**TABLE 15-1**

**Types of Obstetric Forceps in Most Common Use**

Obstetric Forceps Type	Anatomic Modification	General Use
Simpson	Parallel shanks	Molded vertex or significant caput
Elliot	Convergent shanks	Nonmolded vertex
Tucker-McClane	Solid blade	Nonmolded vertex
Laufe	Pseudofenestrated blade; divergent shanks	For infants who are preterm or with estimated fetal weight <2500 g
Kielland	English lock; no pelvic curve	For rotation of fetal vertex >45 degrees

posterior, the leading point of the fetal skull may appear to be lower in the pelvis even though the biparietal diameter has not yet passed through the pelvic inlet; this situation can also lead to an erroneous conclusion about fetal station.

4. When the forceps are properly applied, the sagittal suture must be exactly midway between the blades, and the lambdoidal sutures should be equidistant (usually a fingerbreadth) from the edge of the blade.

If the preceding conditions are not met, application of the forceps should be reconsidered. Furthermore, in 1988, the ACOG revised its classification of the type of forceps delivery according to the station of the fetal vertex before forceps application, as follows (ACOG, 2000b):

- *Outlet forceps:* The fetal vertex is visible at the labia without manually separating them, and the fetal skull has reached the pelvic floor.
- *Low forceps:* The leading point of the fetal skull is more than 2 cm beyond the ischial spines.
- *Mid-forceps:* The fetal head is engaged and is beyond the level of the ischial spines; *the forceps should be applied only if (1) cesarean delivery cannot be performed quickly or imminently and the fetus is in distress or (2) there is a high likelihood that the forceps operation will be successful.*
- *High forceps:* The vertex is not engaged (i.e., not at the level of the ischial spines or beyond); *under these circumstances, the forceps must never be applied.*

Obstetric forcep deliveries are further divided according to whether they are *rotational* (sagittal suture is more than 45 degrees from the midline) or *nonrotational* (sagittal suture less than 45 degrees from the midline).

The indications for use of the obstetric forceps are as follows:

- Maternal exhaustion or inability to push (endotracheal intubation with sedation or paralysis; neuromuscular disease)
- Nonreassuring fetal heart tracing or “fetal distress”
- Maternal contraindications to pushing (cardiopulmonary disease, cerebrovascular aneurysm)
- Aftercoming head in a vaginal breech delivery
- Facilitation of difficult extraction of the fetal vertex during cesarean delivery

### Forceps and Potential Neonatal Morbidity

As stated previously, forceps were employed for hundreds of years without thought for fetal survival, being needed primarily to terminate difficult labors for maternal benefit. Today with the widespread availability of cesarean delivery, considerations turn to providing the best neonatal outcome possible. Thus, the difficult forceps deliveries of the past have been abandoned. Nevertheless, forceps still play a crucial role in modern obstetrics and, if judiciously used, can provide a safer alternative to cesarean delivery for both mother and baby.

The difficulty in interpreting the obstetric literature with regard to neonatal morbidity incurred by forceps use is that the classification for type of forceps was revised by ACOG in 1988, and thus, studies performed before then

did not use the same clinical criteria employed today in modern practice to select appropriate candidates for the use of forceps. Furthermore, residency training in operative vaginal delivery has dramatically decreased over the past 30 years, potentially increasing fetal risk (Hankins and Rowe, 1996). Consequently, for proper interpretation of adverse outcomes, one must look to studies performed after the ACOG revised its classification.

The prevalence of forceps use varies widely by region and accounts for approximately 5% to 10% of all vaginal deliveries (Duchon et al, 1988). National statistics show that of the 3,063,870 deliveries in 1999, 3.2% were forceps-assisted and 6.2% were vacuum-assisted, for a total national operative vaginal delivery rate of 9.4% (NCHS, on line). Unfortunately, the national prevalence of low forceps, outlet forceps, and mid-forceps deliveries is not known, nor is the rate of use of rotational and nonrotational forceps. Neonatal outcome according to type of forceps application is also not generally known, and collection of data on this issue is hindered by the fact that even with the universal ACOG classification scheme, the determination of fetal station and type of forceps can be quite subjective as well as dependent on the experience and examining skill of the obstetrician. Moreover, the indication for forceps use varies widely by clinical situation, and the neonatal morbidity that can result from a “difficult pull” in a patient with a transverse arrest and marked fetal asynclitism may well be different from the quick delivery of a 2600-g fetus whose mother is unable to push, even if both are low-forceps deliveries.

Nevertheless, what large studies exist show that long-term or even short-term neonatal morbidity from outlet or low forceps delivery is uncommon. Towner and colleagues (1999) analyzed 583,340 live-born singleton infants of nulliparous women born between 1992 and 1994 and weighing between 2500 and 4000 g for neonatal intracranial injury according to mode of delivery. These investigators found that risks of subdural and intraventricular hemorrhage as well as nerve injury are higher with operative than with spontaneous vaginal delivery; however, the rates of morbidity from operative vaginal delivery were not different from those for cesarean delivery with labor (Towner et al, 1999). The rate of birth injury was lowest in patients with non-labored cesarean delivery, a finding that illuminates an important fact that has heretofore not been clearly evaluated: It is the process of labor itself, and not necessarily the operative delivery, that can lead to adverse neonatal outcome. This provocative conclusion bears further investigation. Furthermore, the overall risk of intracranial injury was very low for all modalities, as listed in Table 15–2.

Few randomized prospective trials have specifically addressed the issue of neonatal morbidity arising from forceps operations, yet those that have been published suggest no significantly higher risk from operative vaginal delivery than from spontaneous birth. Yancey and colleagues (1991) randomly assigned 364 women giving birth at term whose deliveries were at +2 station to either elective outlet forceps delivery or unassisted birth. Women with suspected fetal macrosomia or chorioamnionitis were excluded from the study. Neonates were examined at birth and at 72 hours of age, and cranial ultrasonography was performed by neonatologists 24 to 72 hours after

TABLE 15-2

**Risk of Intracranial Injury According to Type of Delivery**

Mode of Delivery	Incidence of Intracranial Injury
Vacuum	1/860
Forceps	1/664
Combined vacuum-forceps	1/256
Cesarean	
In labor	1/907
Without labor	1/2750
Spontaneous vaginal delivery	1/1900

birth. The spontaneous and forceps-assisted births showed no statistically significant differences in the incidence of scalp abrasions, facial bruising, cephalhematoma, subconjunctival hemorrhage, or abnormal cranial ultrasonograms (Yancey et al, 1991).

Carmona and associates (1995) conducted a prospective, randomized, controlled trial to evaluate neonatal morbidity arising from low forceps procedures. They selected nulliparous women giving birth at 38 to 42 weeks gestation, excluding pregnancies with suspected fetal macrosomia or growth restriction, and randomly assigned them at 0 to +1 station to either a low forceps-assisted delivery or spontaneous birth once the fetal vertex had reached +2 station. These investigators found no clinically significant differences in Apgar scores, rates of admission to neonatal intensive care units (NICU), or umbilical artery pH between the groups (Carmona et al, 1995).

Several retrospective, population-based studies have further examined the issue of potential adverse neonatal sequelae arising from forceps procedures. Robertson and coworkers (1990) reclassified forceps operations in accordance with the 1988 revised ACOG guidelines and examined neonatal outcomes according to type of forceps operation, matching them to cesarean sections with a second stage of at least 30 minutes from a similar station. These researchers found that mid-forceps operations resulted in greater neonatal resuscitation requirements, lower umbilical artery pH, greater/higher "birth trauma," defined as nerve injuries or fractures, than cesarean section from comparable station. There was no greater risk of trauma from low forceps procedures compared with cesarean section, although the prevalence of arterial cord pH less than 7.10 was increased with forceps deliveries (Robertson et al, 1990). It must be remembered, however, that this study was not randomized as to treatment and that women undergoing abdominal delivery do not necessarily make an appropriate control group for operative vaginal delivery. Nevertheless, this large population-based study (from a database of 20,831) emphasizes the relative safety of outlet and low forceps procedures, casting some doubt on the safety of mid-forceps operations.

The role of mid-forceps delivery in modern obstetrics, specifically with regard to rotation greater than 45 degrees,

has incited much controversy. The difficulty lies in the fact that no randomized trials comparing mid-forceps operations with other modes of delivery have been performed, and it is unlikely that any will be done in the near future because training in this type of delivery has declined among obstetric residents in the United States (Hale and Dennen, 2002; Lafe, 1992). Our evaluation of the potential neonatal morbidity arising from these procedures is mainly from retrospective, population-based studies, and we must interpret them with an appreciation for their inherent biases.

Hankins and associates (1999) reported a case-controlled study of 113 rotational forceps deliveries with rotation of 90 degrees or more matched to 167 controls with rotation of 45 degrees or less. They found no significant differences in major injuries, defined as skull fracture, brachial plexus, facial or sixth nerve palsy, and subdural hemorrhage. There were also no differences in the prevalence of cephalhematoma, clavicular fracture, or superficial laceration. All deliveries were performed with Kielland forceps by resident staff, with supervision by attending physicians as required. The prevalence of nerve injury in these forceps operations ranged from 2% to 3%; there were no skull fractures.

A retrospective study comparing 104 rotational deliveries with 163 low or outlet forceps deliveries found similar results, although a higher rate of NICU admissions (9.3% vs. 2.5%, respectively;  $P = .015$ ) was seen in the rotation group (Feldman et al, 1999). Another study comparing 55 deliveries involving Kielland forceps rotations with 213 nonrotational forceps deliveries found no significant differences in neonatal morbidity between the groups, save for a 1-minute Apgar score in the Kielland focus group of less than 6 (Krivak et al, 1999).

In conclusion, the available literature supports the fact that neonatal morbidity from outlet or low forceps delivery is exceedingly low and is comparable with that of spontaneous vaginal delivery. This conclusion comes from both prospective data and large population-based investigations. The evidence concerning neonatal safety from more advanced forceps operations (mid-forceps and rotations) shows that morbidity is slightly increased with these procedures, although whether the increase arises from the operative vaginal delivery itself or from difficult labor is at present impossible to discern (Bashore et al, 1989; Dierker et al, 1985). The benefit of appropriately selected candidates for mid-forceps or rotational forceps delivery in well-trained hands, may be justifiable, although the numbers of residents in the United States who are adept at these procedures are steadily declining.

## Vacuum Delivery

Operative vaginal delivery for the indications listed previously can also be alternatively performed with the vacuum extractor. The situations that call for the use of this device and the requirements that must be fulfilled for its correct use are identical to those for obstetric forceps. The vacuum extractor usually has a metal or plastic cup (flexible or semirigid) that is applied to the fetal vertex. Care is taken in its application to ensure that an adequate seal has been created and that no maternal soft tissue is trapped

between the suction device and the fetus. Traction is then applied to the fetal head in the line of the birth canal, in an effort to assist delivery. Also, rocking movements and torque should not be applied to the cup. Prematurity of the fetus is a relative contraindication to vacuum application. It is also generally advised that no more than two “pop-offs” (unintended release of the vacuum from the fetal head) occur before attempts at vacuum extraction are abandoned, although this recommendation stems from an era in which the metal cup, and not the softer polymeric silicone (Silastic) cups currently employed, were more widely used (Hankins et al, 1999).

In a laboratory experiment, Duchon and colleagues (1988) compared the maximum force at suggested vacuum pressures (550 to 600 mm Hg) prior with “pop-offs” for different types of vacuum devices. They found that the average force of traction exerted before “pop-offs” ranged from 18 to 20 kg. This finding is of interest when one considers the older report by Wylie (1935), who estimated the average tractive force required for delivery of 15.95 kg for a primigravida and 11.33 kg for a multiparous woman (Fig. 15-3).

The vacuum extractor is widely used in the United States but can still be associated with neonatal injury. In addition to superficial scalp lacerations or abrasions, which usually heal without incident, and local soft tissue swelling or bruising, use of the vacuum extractor has been associated with cephalhematoma and subgaleal hemorrhages.

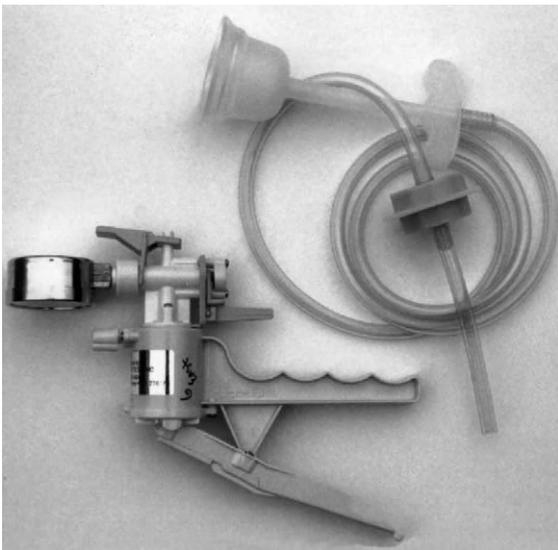

*Cephalhematoma* results when the force created by the vacuum results in ruptures of *diploic or emissary vessels* between the periosteum and outer table of the skull. The potential space between the two fills with blood. Luckily, although cephalhematomas are often cosmetically alarming, they are limited to traveling along one cranial bone, because the firm periosteal attachments limit further extravasation of blood across suture lines. Thus, large amounts of blood cannot usually collect in this space, and serious neonatal compromise from this bleeding is rare. Bofill and associates (1997), in a randomized trial of con-

tinuous or intermittent vacuum application, examined factors associated with raising the risk of cephalhematoma. They found that only asynclitism and traction time were independently related to this complication. There was a clear relationship between longer time of vacuum application (up to 6 minutes) and cephalhematoma. Interestingly, these researchers did not find a significant independent association of neonatal injury with continuous or intermittent vacuum, nor with decreasing gestational age or increasing birth weight. Furthermore, the number of “pop-offs” was not correlated with cephalhematoma. These results were corroborated by Teng and Sayre (1997), who conducted a prospective observational study of 134 vacuum extractions and found that only increasing total duration of vacuum application was associated with neonatal injury (Fig. 15-4).

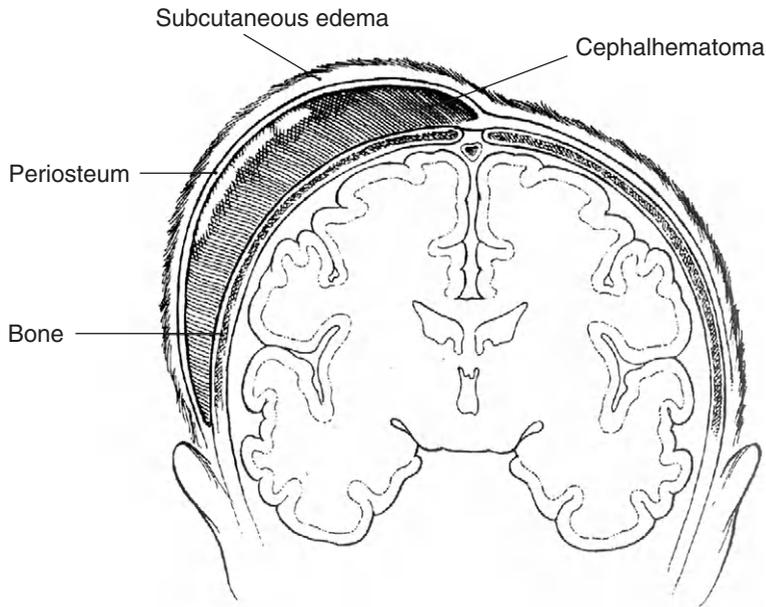

*Subgaleal hemorrhage* poses much more of a potential risk for the neonate. It occurs when emissary veins above the skull and periosteum rupture, and blood dissects through the loose tissue underlying the cranial aponeurosis, unimpeded by suture lines. A tremendous amount of blood, potentially the entire neonatal blood volume (approximately 250 mL), can fill this space; thus, this complication can significantly compromise the neonate (Plauche, 1980). Much of the literature about this unusual complication of vacuum extraction was published in the 1970s and early 1980s, with few later studies to detail associated risk factors. Plauche (1979), in his classic paper on vacuum extraction–related neonatal injury, identified only 18 cases of subgaleal hematomas among 14,276 cases of vacuum-assisted births, in contrast to a mean incidence of cephalhematoma of 6%. These morbidity estimates are derived from data that is nearly 30 to 40 years old; nevertheless, in a later investigation, Teng and colleagues (1997) noted an incidence of 8% for cephalhematoma and 0.7% for subgaleal hemorrhage, which agree well with Plauche’s estimates.

Australian investigators evaluated 37 cases of subgaleal hemorrhage at a single tertiary care center accrued over a period of 23 years, with an estimated prevalence of 1.54 per 10,000 total births. They found that this complication occurred most often in primigravidas and that a large proportion of the cases (89.1% compared with 9.8% in the general control population) was associated with attempted vacuum extraction (Chadwick et al, 1996) (Fig. 15-5).

It must be kept in mind that the overall neonatal morbidity of the vacuum extractor is low, as ascertained from the large population-based study by Towner and coworkers (1999), which showed that the risk of intracranial injury is only 1 in 664. Yet as outlined previously, there are definite neonatal risks associated with the use of vacuum extraction. In 1998, the U.S. Food and Drug Administration (FDA) issued a statement warning obstetric care providers to use the vacuum device with caution and only for definite indications. This recommendation was made in response to the fact that from 1994 to 1998, there were 12 neonatal deaths and 9 serious injuries attributable to the vacuum, a five-fold increase in comparison with previous years. One must remember that during this period, the overall number of vacuum extractions in the United States nearly doubled, a development that could potentially account for the increase in adverse outcomes (NCHS, on line).

**FIGURE 15-3.** A soft-cup polymeric silicone (Silastic) vacuum extractor (MityVac device), along with a device used to generate negative pressure.

**FIGURE 15-4.** A cephalhematoma is a hemorrhage that occurs under the periosteum of the skull and is thus confined to a defined space with limited capacity for expansion. (Adapted from Gilstrap LC, Cunningham FG, Hankins GDV, et al: *Operative Obstetrics*, 2nd ed. Appleton & Lange Publishers, 2002.)

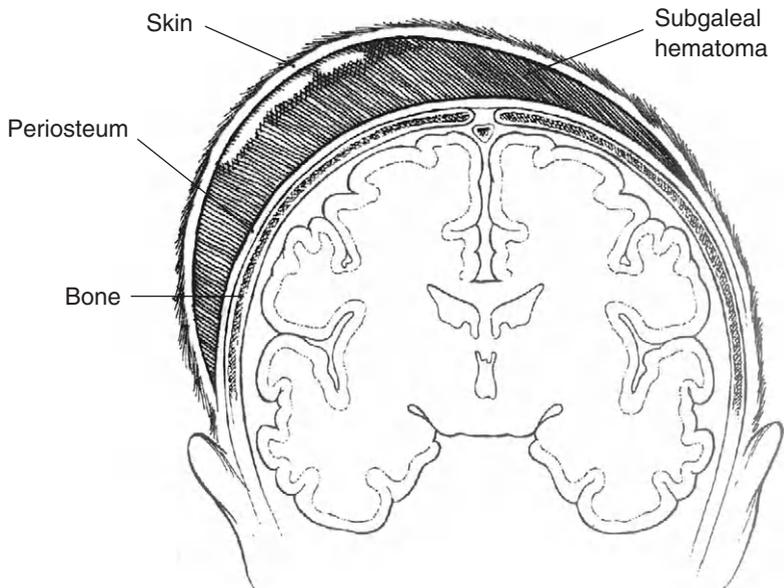

The FDA further suggested that infants delivered with the vacuum undergo close monitoring for subgaleal or subaponeurotic hematoma and that a high index of suspicion be maintained for this rare complication.

We emphasize here that the overall risk of adverse events attributable to the vacuum is extremely low, in that the FDA estimated only 5 serious complications per year of use during a time when 228,354 vacuum deliveries were performed. However, there is a definite possibility that sequelae related to vacuum extraction are often under-reported.

The choice of instrument, forceps or vacuum, is usually determined by the skill level and experience of the obstetric care provider with the two methods. Several randomized trials have explored this issue (Bofill et al, 1996; Broekhuizen et al, 1987; Johanson, 1997; Williams et al, 1991).

The Cochrane Library has pooled the results from 10 randomized trials comparing these two devices in terms of neonatal morbidity and successful vaginal delivery (Johanson and Menon, 2001). This analysis found that the vacuum was more likely to fail than the forceps (odds ratio [OR] 1.69; 95% confidence interval [CI] 1.31 to 2.19) and was associated with a greater likelihood of Apgar scores less than 7 at 5 minutes (OR 1.67; 95% CI .99 to 2.81), cephalhematoma (OR 2.38; 95% CI 1.68 to 3.37), and retinal hemorrhage (OR 1.99; 95% CI 1.35 to 2.98). However, the overall rate of serious complications was low, and there was no difference in long-term morbidity between the two devices.

The largest danger in the use of either vacuum or forceps comes from the combined use of the two instruments together. Towner and colleagues (1999) showed that the

**FIGURE 15-5.** A subgaleal hematoma spreads along subcutaneous soft tissue planes and has no immediate barrier to expansion, creating the potential for significant neonatal hemodynamic compromise. (Adapted from Gilstrap LC, Cunningham FG, Hankins GDV, et al: *Operative Obstetrics*, 2nd ed. Appleton & Lange Publishers, 2002.)

use of one instrument after the other had failed carries a 1 in 256 risk of neonatal intracranial injury, significantly greater than that for either modality alone. This finding was further supported by the work of Gardella and associates (2001), who matched 11,223 women—one third of whom underwent combined forceps and vacuum instrumentation, one third vacuum alone, and one third forceps alone) to an equivalent number of women having spontaneous vaginal deliveries. These investigators found no statistically significant difference in risk of intracranial hemorrhage between use of either single instrument and vaginal delivery; however, use of both instruments markedly increased the risk not only of intracranial hemorrhage but also of seizures and low 5-minute Apgar scores (Gardella et al, 2001). The overall risk of nerve injury and scalp injury was greater for single-instrument delivery than for spontaneous delivery, but the overall incidence of each complication is rare.

Thus, the vacuum extractor is an acceptable instrument if used judiciously and in the proper circumstances, carrying an overall minimal risk of serious neonatal complications. Its safety is comparable with that of the obstetric forceps, although the vacuum extractor is associated with a higher incidence of cephalhematoma and a lower potential for facial nerve injury. The chance of failure is greater with the vacuum, which could then potentially tempt the care provider to employ the forceps. *The use of forceps or vacuum extractor after the other instrument has failed carries a higher risk of adverse outcomes and should be undertaken only with an understanding of this higher likelihood of neonatal morbidity.*

## SHOULDER DYSTOCIA

Shoulder dystocia is arguably the most dreaded complication in obstetrics. The problem it poses is that although much anticipated, shoulder dystocia is quite unpredictable and can appear despite the most cautious measures taken to prevent its occurrence. *Shoulder dystocia* is defined as the delivery of the fetal head with an impaction of the fetal shoulder girdle or trunk against the pubic symphysis, making subsequent delivery of the body either difficult or impossible without the performance of auxiliary delivery maneuvers.

Once shoulder dystocia occurs, a series of maneuvers (which, because of the sporadic and unpredictable nature of this complication, has never been tested in a prospective fashion) is employed to resolve it. The first step is the *McRoberts maneuver*, which consists of hyperflexing the maternal thighs onto the abdomen in hopes of increasing the anteroposterior dimensions of the pelvis to facilitate delivery. If unsuccessful, this step is usually followed by *suprapubic pressure* to disimpact the anterior shoulder from behind the pubic symphysis. The *Woods screw maneuver* or the Rubin rotational maneuver may also be used to attempt to rotate the infant's shoulders and thereby relieve the impaction of the shoulder against the pubic bone. If these measures fail, *delivery of the posterior arm* can be attempted: The operator inserts a hand in the vagina, grasps the posterior fetal arm, and extracts the arm across the fetal chest and through the vaginal introi-

tus. It is often necessary to perform an episiotomy to have sufficient room in the vagina to accomplish this maneuver. If the dystocia continues, the *Zavanelli maneuver* or *cephalic replacement* is performed. After the fetal head is rotated from occiput transverse to occiput anterior, it is flexed and pushed back in the birth canal, and the child is delivered by emergency cesarean section. The McRoberts maneuver or suprapubic pressure will relieve more than 50% of shoulder dystocias. Cephalic replacement should be necessary in less than 5% of cases.

The prevalence of shoulder dystocia varies according to the population studied and to the presence of various risk factors known to predispose women to this obstetric emergency. Estimates range from 0.2% to 1% in a low-risk population to 20% in higher-risk groups (ACOG, 1997, 2000b; Gross et al, 1987; Lipscomb et al, 1995; Nesbitt et al, 1998). Maternal obesity, fetal macrosomia, history of shoulder dystocia in previous birth, and maternal diabetes mellitus are the most common associated variables, but they are not of sufficient prognostic power to be clinically useful in predicting shoulder dystocia (ACOG, 1997, 2000b; Nesbitt et al, 1998).

Because shoulder dystocia has the potential to cause significant neonatal morbidity and mortality, efforts have been made to predict its occurrence; unfortunately, no clinical guidelines have been clinically tested or proven. Ultrasonography is commonly used in patients with suspected fetal macrosomia or maternal diabetes mellitus to detect high-birth-weight infants who might be more likely to experience shoulder dystocia. Third-trimester ultrasonographic examination has an accuracy of 10% to 15% in the prediction of fetal weight and is thus not completely reliable (Delpapa and Mueller-Huebach, 1991; Gross et al, 1987; Rouse et al, 1996). In addition, even if ultrasonography was completely reliable, what fetal weight cutoff would prompt an elective cesarean section in an effort to avoid shoulder dystocia? These questions have been the subject of much debate in the obstetric literature.

Lipscomb and associates (1995), evaluating the deliveries of 227 mother-infant pairs at their institution with birth weights greater than 4500 g, found a shoulder dystocia rate of 18.5%; thus, the majority of women delivering vaginally did so without any adverse event. Of the infants who experienced shoulder dystocia, 51.7% suffered a neurologic injury, but at 2 months, all of the affected infants had normal neurologic findings. Thus, even the occurrence of shoulder dystocia does not necessarily guarantee permanent neurologic morbidity.

This conclusion has been reinforced by several other studies. Gherman and coworkers (1998) reviewed 285 cases of shoulder dystocia. They found that 77 of the infants (24.9%) suffered fetal injury, most commonly brachial plexus injury (16.8%) or fracture of the clavicle (9.5%) or humerus (4.2%). Nearly half of the shoulder dystocias resolved with the McRoberts maneuver alone; the rest required the Woods maneuver, posterior arm extraction, or the Zavanelli maneuver. The requirement of additional fetal manipulative procedures raised the risk of humeral fracture only and not of clavicular fracture or brachial plexus injury. As with previous studies, the incidence of permanent musculoskeletal injury was only 1.4% (Gherman et al, 1998).

A prospective investigation evaluated the natural history of recovery after a birth-related brachial plexus injury in infants referred to a tertiary care multidisciplinary neurologic center. Enrollment required identification of injury in the newborn period, initial evaluation at the center between 1 and 2 months of age, and persistence of lack of antigravity movement in the shoulder or elbow until 2 weeks of age. Even in this group of children subject to ascertainment bias (because injuries that resolved before 2 weeks of age would not have been included in the results), complete neurologic recovery was documented in 66%, and only 14% had persistent, severe weakness (Noetzel et al, 2001).

Rouse and colleagues (1996) performed a decision analysis showing that if one chose to perform an elective cesarean section for all nondiabetic women with ultrasonographically predicted macrosomia (estimated fetal weight >4000 g), 2345 cesarean sections would have to be performed to prevent one permanent brachial plexus injury. Even in the diabetic mother, if one chose a cutoff of 4500 g, 443 cesareans would be needed to prevent one permanent injury. The conclusions from this decision analysis have been borne out by several other investigators, who have established that the risk of nerve injury certainly increases with rising birth weight but that the large number of macrosomic infants who undergo normal, spontaneous vaginal delivery without sequelae does not justify a policy of elective cesarean delivery for macrosomia alone, especially in a nondiabetic population (Ecker et al, 1997; Gilbert et al, 1999; Gordon et al, 1973; Gregory et al, 1998; McFarland et al, 1986; Ouzounian et al, 1998; Roberts et al, 1995).

Therefore there is at present no universally accepted method to prevent shoulder dystocia. Studies have shown that operative vaginal delivery of a fetus suspected to have macrosomia on either clinical or ultrasonographic grounds could increase the risk of shoulder dystocia (Benedetti et al, 1978). It seems wise to avoid difficult forceps or vacuum delivery in a patient who is thought to have an infant larger than 4000 g, especially if she has diabetes or a history of shoulder dystocia. In addition, the ACOG (ACOG Bulletin, Shoulder Dystocia, 1997; ACOG Bulletin, Fetal Macrosomia, 2000a) states that “for pregnant women with diabetes who are suspected of carrying macrosomic fetuses, a planned cesarean delivery may be a reasonable course of action, depending on the incidence of shoulder dystocia, the accuracy of predicting macrosomia, and the cesarean delivery rate within a specific population.”

## VAGINAL BREECH DELIVERY

Three percent to 4% of all full-term infants are in breech presentation at the time of delivery. There are three main types of breech presentations. In the *footling breech*, either one (single footling) or both (double footling) lower extremities are presenting. In the *frank breech*, both thighs are flexed but the legs are extended. An infant in *complete breech* has both thighs and legs flexed. Because the vaginal delivery of a singleton footling breech carries attendant risks of cord prolapse and head entrapment, the consensus among obstetricians is that the infant with this

presentation should be delivered operatively (unless the fetus is a second twin, as discussed later). The baby in frank breech with buttocks presenting has a lower risk of these adverse events and thus could potentially be delivered vaginally. The complete breech presentation converts to frank or footling breech during labor, and the appropriate management scheme for delivery depends on which leading fetal part descends.

The feasibility of vaginal breech delivery and its safety have been the subject of much debate throughout the past half-century. With the advent of safe, expedient cesarean delivery in the United States, many obstetricians have favored the operative approach as the method of choice for management of the breech presentation at term. The literature to support this point of view has produced conflicting conclusions, and its interpretation is consequently quite difficult. The delivery of the vaginal breech is also an emotional issue; physicians trained in the art of the vaginal breech delivery maintain that for an appropriately selected candidate, vaginal breech delivery has acceptable neonatal risk as well as the advantage of sparing the mother significant operative morbidity. Proponents of cesarean delivery further state that the level of resident training in the art of the singleton vaginal breech delivery has markedly diminished, with most graduating senior residents having performed only a few such deliveries.

There has been an extensive body of literature over the previous half-century examining this issue. Unfortunately, only two randomized trials have explored the question of which delivery route is best for the term singleton frank breech fetus, but there are several large retrospective series describing neonatal outcomes with the vaginal approach, most of which suggest that vaginal delivery in carefully selected patients carries a low risk of long-term neonatal morbidity and mortality. Diro and colleagues (1999) evaluated 1021 term singleton breech deliveries occurring at their institution over a 4-year period. Women with clinically adequate pelvic dimensions and frank breech presentation whose infants weighed less than 3750 g were allowed a trial of labor. These researchers found an overall cesarean delivery rate of 85.6%; however, for women allowed to deliver vaginally, the “success” rate, defined as vaginal delivery, was 50% (19/38 patients) for nulliparous women and 75.8% (116/153 patients) for multiparous women. The need for admission to the NICU was higher for the group delivered vaginally (17.4% vs. 12.1%;  $P = .036$ ), but major morbidities between operative and vaginal deliveries were not significantly different. Long-term outcome was not evaluated. It is notable that evaluation of the pelvic dimensions of the women in this cohort was clinical rather than radiographic or by computed tomography (CT) pelvimetry, as has been done in other studies.

Norwegian investigators examined their similar policy of vaginal breech delivery and evaluated maternal and neonatal outcomes in a large cohort of women (Albrechtsen et al, 1997). Patients were allowed a trial of vaginal delivery if radiographic pelvimetry showed adequate pelvic dimensions and were excluded for an estimated fetal weight greater than 4500 g or a footling presentation. Each vaginal breech birth was matched to a term vaginal vertex birth; each cesarean birth was matched to the appropriate vertex control. The researchers evaluated 1212 breech

deliveries, 639 (52.7%) of which were vaginal, 172 (11.4%) intrapartum cesarean section, and 138 (11.4%) planned cesarean section. Once major or lethal anomalies and fetal disorders not related to delivery were excluded from the data, no perinatal deaths were attributable to mode of delivery. When births planned vaginally were compared with operative deliveries, there was a higher risk of 1-minute Apgar score of less than 7 and “traumatic morbidity” in the vaginal group but no significant differences in the rates of NICU admissions, 5-minute Apgar scores, or “uneventful course.” The researchers concluded that short-term morbidity was worse in the group delivered vaginally but long-term outcomes were similar in the groups. It must be remembered, however, that this study was not randomized, and the infants selected for vaginal delivery or cesarean section were intrinsically different. Also, all deliveries occurred in a tertiary care institution.

The truly interesting point raised by these investigators is that aside from the issue of cesarean delivery versus a trial of labor, singleton breech infants regardless of mode of delivery have a higher risk of morbidity than their vertex counterparts. Breech infants had higher incidences of NICU admissions, “eventful courses,” hip dislocation, and traumatic morbidity (soft tissue trauma, fracture, facial nerve paralysis, and brachial plexus palsy). Thus, both the obstetrician and the pediatrician must be aware of these potential factors at the birth of a breech infant.

Christian and associates (1990) evaluated their policy of offering a trial of vaginal breech delivery to women in whom estimated fetal weight was between 2000 and 4000 g and CT pelvimetry documented adequate pelvic dimensions. Of 122 women evaluated, 85 were judged appropriate by these standards for vaginal delivery, of whom 81.2% had a successful vaginal delivery. The only indices of neonatal outcome evaluated were the Apgar score, which was not different between groups; and neonatal cord pH, which was lower in a statistically but not clinically significant manner in the vaginal delivery group.

The greatest difficulty in interpreting the large number of retrospective studies examining the issue of vaginal breech delivery in the obstetric literature is that even the best-designed reports have relatively small numbers of patients, and the possibility of a type II or beta error is quite high; in addition, the groups being compared (those undergoing planned cesarean section and vaginal deliveries) are different because the patients are not randomly assigned to the two treatments (Christian et al, 1990; Westgren et al, 1985). Often the women chosen to undergo cesarean section tend to have factors that would place their neonates at higher risk than those of women allowed a trial of labor. A meta-analysis evaluating seven cohort studies and two randomized trials compared 1825 patients given trials of labor with 1231 patients undergoing elective cesarean section and found a statistically significant (but clinically questionable) higher risk with vaginal breech delivery of 1.10% (Gifford et al, 1995).

This controversy has been clarified by a large, multi-centered, multinational trial that randomly assigned 2088 women at 121 centers in 26 countries to either planned vaginal birth or planned elective cesarean section (Hannah et al, 2000). Criteria for enrollment were frank or complete term singleton breech with no evidence of fetal macrosomia. The investigation was halted when preliminary

results showed that there was significantly higher neonatal mortality and severe morbidity in the vaginal breech arm than in the cesarean arm of the study (5.0% vs. 1.6%, respectively). This conclusion was not altered by experience of the delivering obstetrician or maternal demographic factors such as parity and race. Maternal morbidities of the two groups were comparable. The difference in outcome for vaginal breech versus cesarean section was even more striking in countries with low national perinatal mortality rates, such as the United States (5.7% vs. 0.4%).

Criticisms of this study include the fact that patients enrolled did not undergo CT pelvimetry, which in some institutions is standard practice before a vaginal breech delivery is considered. Furthermore, intermittent fetal auscultation every 15 minutes was performed rather than continuous fetal monitoring. In addition, the capabilities of various centers to perform emergency cesarean section differ markedly, with potential effects on neonatal morbidity and mortality rates. Nevertheless, it is unlikely that another large study will ever be performed to examine this issue, and the ultimate results are difficult to dispute given the excellent study design and adequate sample size. Indeed, the ACOG (2001) has issued a statement that “planned vaginal delivery of a term singleton breech may no longer be appropriate . . . . Patients with a persistent breech presentation at term in a singleton gestation should undergo a planned cesarean delivery.” As is discussed further, this statement does not apply to the vaginal delivery of a nonvertex second twin.

## MULTIPLE-FETUS DELIVERY

With the advent of in vitro fertilization (IVF) and the sophisticated assisted reproductive technologies and techniques (ARTs), the incidence of multiple-fetus pregnancies is steadily rising, in particular higher-order multiples. The mode of delivery for twins is well delineated by several studies, and the issues surrounding the choice of vaginal birth versus cesarean is outlined here.

### Twin Delivery

#### Vertex-Vertex Twins

It is almost universally accepted that the appropriate method of delivery if both twins are vertex is vaginal. The first infant is delivered like a singleton infant. The second infant is delivered in a similar fashion, but care must be taken not to rupture membranes before the head is well engaged, so as not to increase the risk of cord accident. It is notable that the delivery of the second twin does not necessarily occur immediately after the first.

#### Vertex-Nonvertex Twins

The first twin of a vertex-nonvertex pair is usually delivered vaginally. The options for delivery of the second twin are cesarean section, breech extraction, or attempts at external cephalic version and, if they are successful, vertex delivery. The optimal delivery choice for the second twin has been a subject of much controversy. Many obstetricians claim that

cesarean section is the safest approach to the nonvertex twin, whereas others claim that vaginal delivery affords equivalent neonatal outcome while sparing the mother an unnecessary surgical procedure. Fortunately, there is a large body of evidence in the literature addressing these issues.

If the vaginal approach is chosen for the second, nonvertex twin, the obstetrician inserts a hand into the uterine cavity and, under ultrasonographic guidance if necessary, finds the feet of the second twin. Once the feet are firmly grasped, they are brought down into the vagina, and the membranes are ruptured. Traction is applied to the fetus along the pelvic curve; once the body has been delivered through the introitus, delivery of the arms, shoulders, and aftercoming head proceeds in a fashion similar to that of a singleton breech delivery (see earlier discussion).

Several large cohort studies have examined the issue of the feasibility and safety of total breech extraction of the nonvertex second twin. These have almost unanimously come to the conclusion that the neonatal outcome for nonvertex second twins delivered vaginally not only is similar to that for the vertex first twin but also is not statistically different from that of second twins delivered by cesarean section, regardless of birth weight or gestational age (Adam et al, 1991; Berglund and Axelsson, 1989; Chervenak et al, 1985; Davison et al, 1992; Fishman et al, 1989; Gocke et al, 1989; Winn et al, 2001).

Although several retrospective studies have evaluated the outcomes of vaginally born nonvertex second twins, there is only one randomized trial. Rabinovici and colleagues (1987) allocated 60 women with vertex-nonvertex twins to either operative or vaginal delivery. Maternal morbidity and hospital stay were higher in the surgical group, but there were no differences in neonatal outcome.

Thus, the available body of evidence supports attempts at vaginal delivery of the nonvertex second twin. Of course, the responsible obstetrician must choose a management plan most compatible with his or her experience and training, and for an obstetrician not versed in techniques of successful vaginal breech extraction, cesarean delivery might be a more prudent plan.

The third option for a nonvertex twin is *external cephalic version* (attempting to turn a nonvertex fetus to vertex by abdominal manipulation). Studies have shown that this option is associated with a higher failure rate for vaginal delivery and with other complications (such as cord accidents and malpresentations unamenable to vaginal delivery) compared with primary breech extraction and cesarean section (Chauhan et al, 1995; Gocke et al, 1989).

### Nonvertex-Nonvertex Twins

Due to the theoretic risk of “interlocking twins” as well as data showing greater morbidity for the singleton vaginal breech (see preceding discussion), cesarean section is the recommended choice for delivery of this presentation.

### Monochorionic, Monoamniotic Twins

Monochorionic, monoamniotic twins share a single intra-amniotic space and thus have a higher risk of cord and extremity entanglement during the course of delivery. It is

thus commonly accepted that the optimal mode of delivery is a planned cesarean section before labor ensues.

### Higher-Order Multiple Gestations

Most perinatologists suggest cesarean section for triplets and higher-order multiple gestations (ACOG, 1998). Although this is a common practice, data mandating operative delivery are far from conclusive. At present, quadruplets and higher-order multiples are usually delivered by cesarean section.

### VAGINAL BIRTH AFTER CESAREAN: NEONATAL ISSUES

Cesarean section accounts nationally for one quarter of all deliveries (NCHS, on line). Surgery, of course, carries maternal risks for increased blood loss, prolonged hospital stay, and longer recovery period compared with vaginal delivery. Thus, in the 1980s and 1990s, efforts were made to encourage women to attempt vaginal birth after a previous cesarean (VBAC), success rates for which vary from 60% to 80%, depending on the indications for the previous cesarean (ACOG, 1999). Unfortunately, VBAC can result in uterine dehiscence, in which the scar from the cesarean separates asymptotically, or, more seriously, uterine rupture. A full discussion of VBAC, studies supporting its safety, and controversies surrounding its feasibility are beyond the scope of this chapter; the interested reader is urged to consult an obstetric textbook for further details. We instead focus on neonatal risks of VBAC, particularly from its most dreaded complication, uterine rupture.

Studies have uniformly shown a risk of uterine rupture with VBAC on the order of 0.5% to 1% (ACOG, 1999; Lydon-Rochelle et al, 2001). In a large, retrospective study, Lydon-Rochelle and colleagues (2001) evaluated 20,095 women with a history of previous cesarean section and found that rupture risk was 0.16% if the woman elected a second operative delivery; 0.52% if VBAC occurred as a result of spontaneous labor; 0.77% if labor was induced without prostaglandins, and 2.5% if labor was induced with prostaglandins. Thus, VBAC carries the lowest risk if labor is spontaneous and non-augmented.

There are few large, well-designed studies specifically evaluating neonatal rather than maternal outcomes in VBAC. Socol and Peaceman (1999) compared 1677 successful with 920 unsuccessful VBACs, and further compared these neonatal outcomes with those in 22,863 spontaneous vaginal births without a history of prior cesarean section as well as in 2432 patients undergoing primary cesarean section during labor. These researchers found that neonates born of successful VBAC had a higher likelihood of a 5-minute Apgar score of less than 7 (but not less than 4), and an umbilical artery pH of less than 7.10 (but not less than 7.00) compared with those from spontaneous vaginal births. However, long-term outcome was not evaluated in this study, and the generally good outcome of all infants with a cord blood pH higher than 7.00 does not necessarily support a clinically significant greater neonatal risk with VBAC (Socol and Peaceman, 1999).

Yap and associates (2001) retrospectively evaluated 38,027 deliveries occurring at a single tertiary care institution

and found 21 cases of uterine rupture; 17 had occurred in women with prior cesarean deliveries. Two neonatal deaths occurred, one the result of prematurity (23-week fetus) and the other of multiple congenital anomalies; all live-born infants were discharged from the hospital without neurologic sequelae. Thus, the ultimate neonatal outcome despite uterine rupture was favorable. However, all deliveries occurred in a tertiary care institution with rapidly available obstetric anesthesiologists, neonatologists, and obstetricians. Most deliveries after diagnosis of rupture occurred within 26 minutes.

A second group of investigators retrospectively identified 99 cases of uterine rupture occurring during a period in which 159,456 births occurred (Leung et al, 1993). Thirteen of the ruptures occurred before the onset of labor. There were six neonatal deaths, but four of them occurred in women who presented at admission with uterine rupture (and thus were never given a “trial of labor”). There were five cases of perinatal asphyxia; however, the study does not mention whether they occurred in women allowed a trial of labor or in women with uterine rupture on presentation to the hospital. Moreover, many of these women had an undocumented prior scar, which in some institutions would warrant an elective repeat cesarean section. The study by Lydon-Rochelle and colleagues (2001) evaluating 20,095 women with previous cesarean delivery and the subsequent risk of rupture found a neonatal mortality of 5.5%. However, this population-based study did not specify whether these deliveries occurred in tertiary care institutions with the capability of performing emergency operative rescue procedures in the event of uterine rupture. Thus, the true neonatal risk of VBAC, especially in the event of uterine rupture, cannot be precisely estimated at present. There are no studies adequately evaluating long-term outcomes of infants surviving after uterine rupture.

In conclusion, it appears that the risk of uterine rupture after a previous cesarean is low but rises when labor is augmented with oxytocin or prostaglandins. It is appropriate to offer women VBAC but they must carefully be counseled about the potential risk of uterine rupture. Moreover, VBAC should ideally occur in a tertiary care institution or in facilities capable of rapidly performing an emergency cesarean section, to improve the likelihood of minimizing adverse neonatal sequelae.

### CORD ACCIDENTS

*Cord accident* usually refers to adverse events affecting the fetus that occur as a result of some problem with the umbilical cord. This heterogeneous term encompasses umbilical cord prolapse, in which the cord delivers through the cervix and compression of the cord by a fetal part results in a significantly higher risk of asphyxia. It also includes such entities as cord entanglements and “true knots,” which can lead to fetal compromise as well.

The incidence of such an event is not clearly known, as the diagnosis is often one of exclusion. One large population-based study compared 709 cases of cord prolapse occurring in 313,000 deliveries with matched controls and found that low birth weight, male sex, multiple gestation, breech presentation, and congenital anomalies all increased

the risk of umbilical cord prolapse (Critchlow et al, 1994). Not surprisingly, cord prolapse was associated with a high mortality rate (10%), which was reduced if cesarean rather than vaginal delivery was performed.

The standard of care in cases of cord prolapse is to proceed immediately with cesarean section while an assistant elevates the presenting fetal part with a hand in the vagina to prevent compression of the umbilical cord. It is also of paramount importance to have appropriate pediatric support available at the time of delivery, because the newborn is likely to be depressed and to require resuscitation.

Cord accident or in utero compromise secondary to entanglement of the umbilical cord as a clinical entity is difficult to understand. Often in cases of in utero fetal demise (IUFD), a diagnosis or cause of fetal death is never found. It is tempting to attribute the demise to the occurrence of some event that compromises umbilical blood flow to the developing pregnancy. The literature on this subject is quite scarce. Hershkovitz and colleagues (2001) identified 841 cases of true knots from a population of 69,139 deliveries (for a prevalence of 1.2%) and, in a case-controlled study, found that grand multiparity (>10 deliveries), maternal chronic hypertension, history of genetic amniocentesis, male gender of the fetus, and umbilical cord prolapse were all independently associated with true knots of the umbilical cord. The presence of a true knot was associated with both IUFD and greater likelihood of cesarean delivery (Hershkovitz et al, 2001) (Fig. 15–6).

**FIGURE 15–6.** (See also Color Plate 15–6.) A 28-year-old woman presented to the labor and delivery department with an intrauterine demise. Examination of the fetus shows the cord wrapped tightly around the torso, leg, and ankle, suggesting cord accident as a cause of death. No other pathologic abnormalities were found on autopsy. ## Maternal and Fetal Anesthesia and Analgesia

Mark A. Rosen and Samuel C. Hughes

Modern obstetric anesthesia was born in Scotland on January 19, 1847, when James Young Simpson used diethyl ether to anesthetize a woman with a contracted pelvis. Morton's historic demonstration of the anesthetic properties of ether at the Massachusetts General Hospital in Boston had occurred only 3 months earlier. Fanny Longfellow, wife of Henry Wadsworth Longfellow, was the first American woman to receive anesthesia for childbirth, publicly proclaiming in 1847, "This is certainly the greatest blessing of this age."

Although anesthesia for surgery was immediately accepted, Simpson's contemporaries in obstetrics in the United States, France, and England were opposed to the use of anesthesia in obstetrics, presenting both medical and religious arguments—for example, that the Bible (Genesis 3:16) states, ". . . in sorrow, thou shalt bring forth children." However, this reading was likely based on a poor translation of the ancient Hebrew word meaning "labor." Certainly, the public outcry in 1853 was vehement; the reaction from Thomas Wolsley, editor of *The Lancet*, after John Snow administered ether for Queen Victoria's eighth child, Leopold, was so strong that court physicians denied that anesthesia had been used. The great debate was largely settled when Victoria delivered her ninth and last child, Beatrice, 4 years later and the use of a royal anesthetic was acknowledged.

Patients' demand for pain relief had won the argument as Simpson had predicted. Still, it was not until 1957 that Pope Pius XII felt the need for a special encyclical about the spiritual value of childbirth pain, in which it was explained that there was no prohibition of the use of labor analgesia in the tradition of the Catholic Church. The church had finally caught up with the public's opinion.

During the second half of the 20th century, anesthesiologists made significant advances in techniques and advances in the safety of delivering analgesia. The continuous caudal catheter developed by Hingson and Edwards (1943) was followed by the epidural catheter. Virginia Apgar (1953) proposed a simple scoring system for neonatal evaluation as a guide for neonatal resuscitation. Other early pioneers in the emerging specialty of obstetric anesthesia were Gertie Marx (Marx and Orkin, 1958), John Bonica (1967), and Sol Shnider (1963). They helped characterize the normal changes in maternal physiology related to pregnancy, confirm the safety and efficacy of obstetric analgesia, determine the effects of these techniques on uterine blood flow as well as the placental transfer of anesthetic agents, and evaluate the effects of these techniques and agents on newborn well-being.

The purposes of this chapter are to introduce the neonatal practitioner to the scientific background and clinical techniques of modern obstetric anesthesia and to discuss the consequences of these techniques for the fetus and neonate. Obstetric analgesia may benefit the parturient in painful labor, facilitate safe and painless use of forceps or vacuum devices for vaginal delivery, and facilitate safe vaginal delivery of twins or a fetus in a breech presentation, and is certainly required to permit delivery by cesarean section. Although the effects of modern obstetric anesthesia on the fetus and newborn are ordinarily benign, they can rarely have an adverse effect that the neonatal practitioner should learn to recognize, comprehend, and manage. Simpson observed that the umbilical cords of babies born to mothers given ether smelled of the agent.

### ANATOMY OF LABOR PAIN

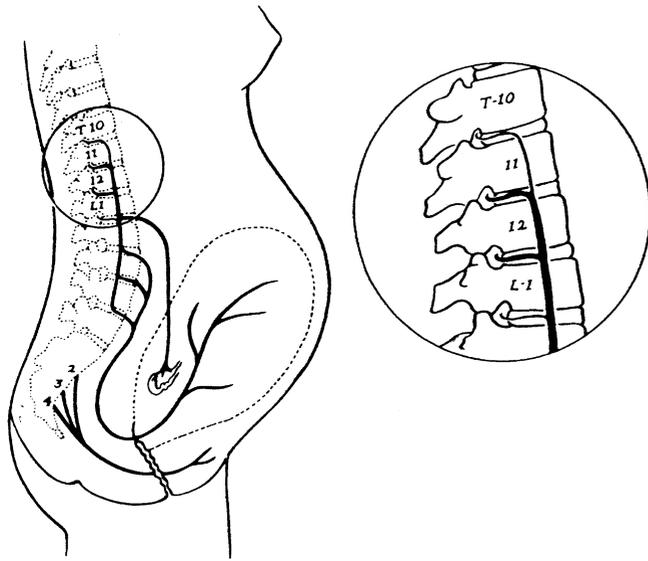

Pain during labor and delivery is caused by uterine contractions, dilatation of the cervix, and distention of the perineum. Somatic and visceral afferent sensory fibers from the uterus and cervix travel with sympathetic nerve fibers to the spinal cord (Fig. 16–1). These fibers pass through the paracervical tissue, with the uterine artery, and then through the inferior, middle, and superior hypogastric plexuses to the sympathetic chain. Nerve impulses from the uterus and cervix enter the spinal cord through the 10th, 11th, and 12th thoracic nerves (T10 to T12) and the 1st lumbar nerve (L1). Somatic perineal pain impulses travel to the 2nd, 3rd, and 4th sacral nerves primarily via the pudendal nerve (S2 to S4). Pain in the perineum, caused by distention of the vagina, perineum, and pelvic floor muscles, is associated with descent of the fetus into the pelvis during the second stage of labor, and with delivery.

Somatic pain and visceral pain are very different types of pain sensation. *Somatic pain* (e.g., incision pain, second-stage labor pain) is well localized and typically described as "sharp." *Visceral pain* (e.g., uterine contractions in the first stage of labor) is poorly localized and usually described as "dull but intense aching." Along with the subjective sensation of pain, nerve impulses of labor pain lead to stimulation of the autonomic nervous system and create reflex cardiovascular, respiratory, endocrine, and musculoskeletal effects, such as maternal tachycardia, hypertension, hypotension, elevation in catecholamines, and reduced uterine blood flow.

### CHANGES IN MATERNAL PHYSIOLOGY AND THE IMPLICATIONS FOR ANESTHESIA

During pregnancy, labor, and delivery, women undergo fundamental changes in anatomy and physiology due to altered hormonal activity, biochemical changes associated with increasing metabolic demands of a growing fetus, placenta, and uterus, and mechanical displacement by an enlarging uterus (Cheek and Gutsche, 2002; Parer et al, 2002).

Hypotension may occur when a pregnant woman assumes the supine position, because of aortocaval compression by the gravid uterus: Significant aortoiliac artery

**FIGURE 16-1.** Parturition pain pathways. Nerves that accompany sympathetic fibers and enter the neuraxis at the T10, T11, T12, and L1 spinal levels carry afferent pain impulses from the cervix and uterus. Pain pathways from the perineum travel to S2, S3, and S4 via the pudendal nerve. (From Bonica JJ: *The nature of pain of parturition. Clin Obstet Gynaecol* 2:511, 1975.)

compression occurs in 15% to 20% of parturients and vena caval compression in all. Vena caval compression may contribute to lower extremity venous stasis, resulting in ankle edema and varices.

Physiologic (dilution) anemia of pregnancy occurs as a result of a greater increase in plasma volume than in red blood cell (RBC) mass. Average blood loss at delivery—300 to 500 mL for vaginal delivery and 600 to 1000 mL for cesarean section—is well tolerated because of this expanded blood volume.

Venous compression by the gravid uterus diverts some blood returning from the lower extremities through the internal vertebral venous plexus, the azygos and epidural veins, increasing the likelihood of epidural venous puncture with epidural or spinal techniques of anesthesia. Supine positioning is avoided in pregnant women during anesthetic administration in the second and third trimesters. Anesthetic techniques that interfere with increased sympathetic tone will further compromise compensatory mechanisms for vena caval compression induced by supine positioning, potentially causing profound hypotension.

The stomach is displaced cephalad and anterior, and the pylorus cephalad and posterior, by the gravid uterus. Gastric pressure is increased by the gravid uterus and by the lithotomy position. Plasma gastrin levels rise, probably by placental production of the hormone, increasing gastric acidity. Higher progesterone and estrogen levels reduce esophageal sphincter tone, and progesterone inhibits plasma motilin. Gastric reflux is common during gestation. Labor or opioids considerably slow gut motility and gastric emptying.

Beyond mid-gestation, women are at increased risk for pulmonary aspiration of acidic gastric contents because of decreased competence of the lower esophageal sphincter as well as delayed gastric emptying with onset of labor or

administration of opioids. This risk has important consequences for both the method of induction of general anesthesia and airway management by the anesthesiologist.

### Uterine Blood Flow

Uterine weight rises, and blood flow increases to about 700 mL/min (about 10% of cardiac output) at term, with about 80% of the uterine blood flow perfusing the intervillous space (placenta) and 20% going to the myometrium. Uterine vasculature is not autoregulated, and remains (essentially) maximally dilated under normal conditions during pregnancy. Although the uterus is capable of marked vasoconstriction in response to  $\alpha$ -adrenergic agents, pregnancy is associated with reduced uterine artery response and sensitivity to vasoconstrictors.

Uterine blood flow (UBF) decreases because of decreased uterine arterial blood pressure, which results from systemic hypotension (shock or general, epidural, or spinal anesthesia). UBF also decreases with aortocaval compression or increased uterine venous pressure, which results from vena caval compression (e.g., supine position) or uterine contractions (particularly uterine hyperstimulation, for instance by oxytocin hyperstimulation, or placental abruption).

### ANALGESIC TECHNIQUES FOR LABOR AND VAGINAL DELIVERY

The pain of labor is highly variable, described by many women as severe. Analgesia for labor and childbirth reduces the psychological or subjective component of pain. Factors that may influence a woman's perception of labor pain include duration of labor, maternal pelvic anatomy in relation to fetal size, use of oxytocin, parity, participation in childbirth preparation classes, fear and anxiety about childbirth, attitudes about and experience of pain, and coping mechanisms. Labor analgesia may prevent reflex effects that can be deleterious for certain high-risk patients or their fetuses (e.g., patients with severe preeclampsia, valvular heart disease, myasthenia gravis). However, a maternal request for pain relief is sufficient justification for administration of analgesics during labor. According to the 4th edition of the *Guidelines for Perinatal Care*, published by the American Academy of Pediatrics and the American College of Obstetricians and Gynecologists, "Of the various pharmacologic methods used for pain relief during labor and delivery, lumbar epidural block is the most flexible, effective, and least depressing to the central nervous system, allowing for an alert, participating mother" (Guidelines, 1997).

The choice of analgesic technique resides primarily with the parturient. The medical condition of the parturient, stage of labor, condition of the fetus, and availability of qualified personnel also are factors. Many different techniques are used to alleviate labor and delivery pain. *Analgesia* refers to pain relief without loss of consciousness; *regional analgesia* denotes partial sensory blockade in a specific area of the body, with or without partial motor blockade. *Regional anesthesia* is the loss of all sensation, motor function, and reflex activity in a specific area

of the body. *General anesthesia* results in the loss of consciousness; goals for providing general anesthesia typically include hypnosis, amnesia, analgesia, and skeletal muscle relaxation. (It is of interest that agents that produce general anesthesia are not necessarily analgesic when administered in low concentrations.)

Techniques for labor analgesia must be safe for mother and fetus and individualized to satisfy the analgesic requirement and desires of the parturient; they also must accommodate the changing nature of labor pain as well as the evolving, varied course of labor and delivery (e.g., spontaneous vaginal delivery, instrumental vaginal delivery, and cesarean delivery). The current approaches to pain relief are outlined in Table 16–1.

### Nonpharmacologic Analgesia: Psychological and Alternative Techniques

Psychological and alternative techniques of obstetric analgesia include hypnosis, “natural childbirth” as described by Dick-Read, the breathing techniques described by Lamaze, acupuncture, acupressure, the LeBoyer technique (LeBoyer, 1975), transcutaneous nerve stimulation, hydrotherapy, and biofeedback. Psychoanalgesic techniques require a high level of personal concentration and are not entirely reliable or applicable to all deliveries.

### Systemic Medications

Systemic medications for labor and delivery are widely utilized but are administered in limited doses because they readily cross the placenta and can depress the fetus in a dose-dependent fashion. The use of sedative-hypnotics (barbiturates, phenothiazine derivatives and hydroxyzine, benzodiazepines), and dissociative agents (ketamine, scopolamine) is uncommon, but the use of opioid analgesics is very widespread. Opioids are the most effective systemic medications for relief of pain. However, excessive maternal sedation, maternal respiratory depression, loss of maternal

protective airway reflexes, and the risk of neonatal depression limit the amount that can be administered for labor analgesia. The most commonly utilized opioid analgesics in obstetrics are the opiate morphine and the synthetic opioids fentanyl, butorphanol, nalbuphine, and meperidine.

Systemic administration of opioids at doses safe for mother and newborn provides some analgesia but cannot substitute for the analgesia provided by regional anesthetic techniques. Systemic opioids are recommended for administration in the smallest doses possible with minimization of repeated dosing to reduce the accumulation of drug and metabolites in the fetus. Opioids are most useful in primiparas in early labor, as adjuncts to major regional anesthetics, and in multiparas who have relatively short, predictable labors with minimal pain.

### Sedatives and Tranquilizers

Sedatives and tranquilizers are administered to parturients to diminish the adverse motivational-affective component of labor pain. Examples of such drugs are barbiturates, phenothiazines, and benzodiazepines.

Secobarbital and pentobarbital have been used in obstetrics. Due to the prolonged effects of these agents, their use is confined principally to facilitate maternal sleep in the early latent stage of labor, when delivery is not likely to occur for 12 to 24 hours. Barbiturates have been described as having an “antianalgesic effect” and may convert a minimally uncomfortable, controlled patient into a hyperventilating, confused, and unmanageable one. For this reason, they are used rarely today.

Promethazine and propiomazine are phenothiazines. Hydroxyzine, although not a phenothiazine, has similar properties. These drugs are useful for relieving anxiety, modifying the response to painful stimulation, and potentiating the actions of opioid analgesics. In addition, they are useful in controlling nausea and vomiting, which may be severe enough to produce maternal dehydration during labor. In recommended dosages, these drugs appear to have minimal depressant effects on both mother and fetus, although they rapidly cross the placenta and have been noted to cause a decrease in fetal beat-to-beat heart rate variability (Powe et al, 1962).

Diazepam and midazolam are used as anxiolytic agents in obstetrics. They rapidly cross the placenta, yielding approximately equal maternal and fetal blood levels within minutes of intravenous (IV) administration (Cree et al, 1973). In addition, the neonate has a limited ability to excrete diazepam, so the drug and its active metabolite may persist in significant amounts in the neonate for a week (Scher and Hailey, 1972). The use of benzodiazepines remains somewhat controversial, but these agents can reduce maternal anxiety, can decrease opioid dosage, and are useful for treatment of convulsions associated with local anesthetic toxicity or eclampsia. Benzodiazepines may produce hypotonia, lethargy, and hypothermia when used in large maternal doses (30 mg) (Cohen et al, 1993); however, when it is used in small doses (2.5 to 10 mg IV), minimal sedation and hypotonia have been observed (McAllister, 1980).

### Dissociative Analgesia

The intramuscular or IV administration of low-dose ketamine (0.25 mg/kg) produces a state called *dissociative analgesia*, which is characterized by good analgesia and amnesia without loss of consciousness or protective airway reflexes (Galloon, 1976). This state is accompanied by a dreaming phenomenon, which may be unpleasant but can be minimized by co-administration of benzodiazepines. Used in divided doses totaling less than 1 mg/kg, ketamine can provide adequate analgesia for vaginal delivery and episiotomy repair. As the dose administered increases, however, airway protection cannot be guaranteed, so aspiration may occur. This agent is best reserved for use as a supplement (in low doses) to other techniques or for situations in which (1) more reliable and safer agents or techniques are contraindicated or (2) rapid control is required because the mother's pain is compromising the fetus (e.g., mother thrashing in pain, unable to push cooperatively with contractions, while the fetal head is crowning with a prolonged deceleration of the fetal heart rate).

### Opioid Analgesics

The opioid analgesics act by stimulating opiate receptors found in many locations throughout the central nervous system (CNS). The majority of opiate receptors in the brain and spinal cord that produce analgesia are the  $\mu$  receptors (Yaksh, 1981). These receptors are also responsible for respiratory depression and may affect thermoregulation. Binding of opiate agonist agents, probably at synaptic junctions, alters neural transmission. Another class of opioid drugs binds to the receptor with high affinity but does not produce analgesia. These drugs are capable of displacing the agonist drugs from the receptor and reversing their effects; they are known as *opioid antagonists* (e.g., naloxone, naltrexone). A third class of agents interacts with the receptors and results in both agonist and antagonist activity. Unlike the pure antagonists, these drugs, with high receptor affinity, are capable of having some analgesic effect (e.g., levallorphan, pentazocine, nalbuphine, and butorphanol). It is possible that the receptor specificity is the explanation for the peculiar actions of the agonist-antagonist agents (Bullingham et al, 1983).

In general, all opioids, at equipotent doses, have similar effects on the fetus and newborn, crossing the placental barrier through passive diffusion. Although systemic opioids can alleviate labor pain, large doses would be necessary, risking excessive maternal sedation, maternal respiratory depression, loss of protective airway reflexes, newborn respiratory depression, impairment of early breastfeeding and neurobehavior. In clinical use, large doses of opioids are avoided, and the doses used to relieve labor pain should not have adverse effects on either the mother or baby. All opioids readily cross the placental barrier and exert neonatal effects in normal doses, including decreased fetal heart rate variability. Normal doses also have maternal side effects, including nausea, vomiting, pruritus, and decreased motility of the gastrointestinal system (with delayed gastric emptying).

Intramuscular administration of opioids is technically easy but leads to uneven analgesia, the possibility of late

respiratory depression, and profound neonatal effects if not properly timed (Shnider and Moya, 1960). For many parturients, opioids do not provide adequate analgesia during labor and delivery (Olofsson et al, 1996; Bricker and Lavender, 2002). For these reasons, many centers have abandoned this method of analgesia (Douglas and Levinson, 2002).

Intravenous administration is the most widely used technique to give opioids to a woman in labor, with effects that are more predictable and doses more easily timed. However, achievement of a steady blood level of opiate sufficient to provide analgesia is difficult, with the parturient frequently suffering underdosage (rarely overdosage). Continuous IV infusion of short-acting opiates (e.g., alfentanil, remifentanil) or self-administration of IV opiates may overcome this limitation.

Patient-controlled analgesia (PCA) is becoming a popular method of IV administration of these drugs, because the patient usually titrates her dose to the minimum required for analgesia with the lowest blood levels of opiates and, hence, considerably less placental transfer (McIntosh and Rayburn, 1991). With the introduction of remifentanil, which is rapidly metabolized by nonspecific serum esterases, it is possible that PCA with remifentanil will prove an effective method for continuous intravenous opiate analgesia, presuming that the drug does not accumulate in the fetus. It has been demonstrated that remifentanil rapidly crosses the placenta but appears to be rapidly metabolized and redistributed (Kan et al, 1998). PCA with remifentanil has been successful but it appears difficult to achieve satisfactory analgesia without the real potential of maternal respiratory depression (Olufolabi et al, 2000; Thurlow and Waterhouse, 2000; Volikas and Male, 2001).

Overall, the epidural injection of opiates alone has proven to be of limited utility for labor analgesia. Intraspinal opiates were demonstrated in 1979 to be capable of producing profound analgesia in humans (Behar et al, 1979; Wang et al, 1979). Shortly thereafter, several researchers attempted to apply this technique for the relief of labor pain. In one study, high doses of epidural morphine (7.5 mg) provided satisfactory but not excellent analgesia for 6 hours in the first stage of labor, whereas 2 mg or 5 mg produced barely satisfactory analgesia in less than half the patients (Hughes et al, 1984). Besides the inadequate analgesia, and the long time of onset (about 1 hour), the side effect of pruritus was significant. When rapidly acting, lipid-soluble opioids are administered alone into the epidural space, analgesia achieved is equivalent to that of systemic administration (Camann et al, 1992), inferior to that of dilute concentrations of local anesthetics, and less effective for somatic pain associated with the second stage of labor.

Subarachnoid (i.e., spinal) injections of fentanyl, meperidine, and sufentanil have been more promising, having analgesic effects that are more potent than that with epidural or systemic administration but are of short duration (2 hours) and less effective than dilute solutions of local anesthetics for analgesia in the second stage (Honet et al, 1989). This method is commonly performed with a combined spinal-epidural (CSE) technique. Reports of fetal heart rate changes after intrathecal administration of fentanyl or sufentanil (Cohen et al, 1993) may be due to

rapid onset of analgesia and rapid decrease in circulating catecholamines, epinephrine faster than norepinephrine, resulting in unopposed oxytocic effect on the uterus, which increases uterine tone and decreases uterine blood flow. This mechanism is speculative but is suggested by observed cases and case reports (Friedlander et al, 1997). However, prospective, randomized studies have suggested no difference in incidence of fetal bradycardia between epidural administration of local anesthetics and intrathecal opioids administered with the CSE technique (Fogel et al, 1999; Nageotte et al, 1997).

When administered into the epidural or intrathecal spaces, these agents can be useful primarily in the first stage of labor but do not provide adequate analgesia for the second stage of labor or for obstetric surgical procedures. They have been most useful when co-administered into the epidural (or intrathecal) space with local anesthetics.

After maternal administration, the lipid-soluble, poorly ionized opioid analgesics rapidly enter the fetal circulation, where they cause a dose-related respiratory depression, as evidenced by a rightward shift in the carbon dioxide response curve. The severity of depression is a function of the amount of drug administered, the timing, and the route of administration. Intramuscular administration is associated with a high incidence of neonatal depression 2 to 4 hours after injection. Intravenous or epidural injection produces peak neonatal depression at 30 to 60 minutes. In addition, some opioids, most notably meperidine, have active metabolites that prolong their fetal effects far longer than the action of the parent drug.

### Inhalation Analgesia

Some birthing centers use nitrous oxide, which is usually administered by a device that delivers 50% oxygen and 50% nitrous oxide, a concentration that alone (without co-administration of opioids, etc.) is insufficient to cause unconsciousness or loss of protective airway reflexes. Appropriate equipment and fully trained personnel are essential to ensure safety (limiting the nitrous oxide concentration, avoiding administration of a hypoxic mixture, avoiding co-administration of other agents, minimizing risk of maternal loss of protective airway reflexes).

Nitrous oxide can provide satisfactory pain relief for some parturients and can be utilized during the first, second, or third stage of labor and either alone or to supplement a block or local infiltration. Use of 50% nitrous oxide in a supervised fashion is safe and rapid acting, causes minimal maternal cardiovascular or respiratory depression, and does not affect uterine contractility; its effects are rapidly reversed, and it does not cause neonatal depression regardless of duration of administration (Rosen, 2002). However, 50% nitrous oxide is a weak analgesic.

### REGIONAL ANALGESIA

Regional analgesia, including epidural, spinal, and CSE techniques, has become the most widely used regional block for labor analgesia. Lumbar sympathetic blocks and paracervical blocks are rarely performed for labor analgesia, but pudendal blocks are utilized for delivery. Regional

blocks usually involve local anesthetic administration, and some include co-administration of opioid analgesics; the future will see administration of other agents that modulate interneuronal communication (Bouaziz et al, 1995; Eisenach et al, 1996).

### Local Anesthetics

The clinically useful compounds consist of amine moieties linked by an intermediate chain containing an ester or amides. Local anesthetics reversibly block impulse conduction in sensory and motor nerves; their chemical structures are of secondary or tertiary amines, which are weak bases, marketed as the hydrochloride salts to achieve aqueous solubility.

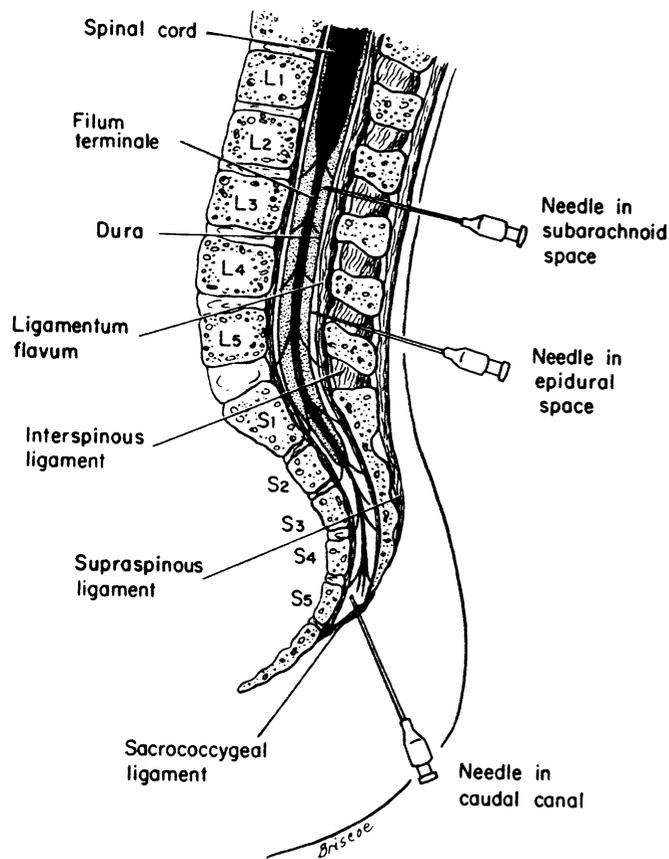

The ester-linked local anesthetics (procaine, chlorprocaine, tetracaine) are rapidly metabolized by plasma cholinesterase, limiting the risk of maternal toxicity and placental drug transfer (O'Brien et al, 1979). The amide-linked local anesthetics (lidocaine, bupivacaine, ropivacaine, levobupivacaine) are slowly degraded by the liver and bind to plasma protein. Ropivacaine and levobupivacaine, the newest local anesthetics, are *S*-enantiomers, amino amide-type local anesthetic agents with a chemical formula similar to that of bupivacaine. The significant difference from the other two congener local anesthetic agents is that ropivacaine is an *S*-isomer rather than a racemic mixture. Vascular absorption of local anesthetics limits the safe dose that can be administered; toxic plasma concentrations produce neurologic toxicity (seizures) or cardiovascular toxicity (myocardial depression, ventricular arrhythmia). Accidental intravascular injection of bupivacaine has resulted in maternal death.

Effects of mild overdoses of local anesthetic are exhibited by the neonate as decreases in neuromuscular tone similar to those seen with magnesium. If a direct intravascular or intrafetal injection of local anesthetics occurs, significant depression can develop, signified by bradycardia, ventricular arrhythmia, and severe cardiac depression with acidosis.

### Epidural Analgesia and Combined Spinal-Epidural Analgesia

In many centers, epidural analgesia for labor and delivery is the technique of choice. The parturient remains awake and alert without sedative side effects, maternal catecholamine concentrations are reduced (Shnider et al, 1983), hyperventilation is avoided (Levinson et al, 1974), cooperation and capacity to participate actively during labor are facilitated, and excellent, predictable analgesia can be achieved, superior to the analgesia provided by all other techniques.

The technique involves insertion of a specialized needle between vertebral spinous processes in the back, through the ligamentum flavum, and into the (potential) epidural space (but not through the dura, which forms the perimeter of the intrathecal or subarachnoid space) using a tactile technique of "loss of resistance" with an air- or saline-filled syringe (Fig. 16–2). Once the needle is properly placed, a catheter is inserted through the needle and left in place, and the needle removed. The catheter is secured in place (with

**FIGURE 16-2.** Schematic diagram of lumbosacral anatomy showing needle placement for subarachnoid, lumbar epidural, and caudal blocks. (From Rosen MA, Hughes SC, Levinson G: *Regional anesthesia for labor and delivery*. In Hughes SC, Levinson G, Rosen MA [eds]: *Shnider and Levinson's Anesthesia for Obstetrics*, 4th ed. Baltimore, Lippincott Williams & Wilkins, 2002, p 125.)

tape and adhesives) for intermittent or continuous injections. Most commonly, the needle is inserted at the lumbar epidural level (L1-L2, L2-L3, or L3-L4); caudal anesthesia is a similar technique, with placement of needle, catheter, and medication in the caudal epidural space rather than the lumbar epidural space.

Careful monitoring of the fetus and uterus is important after administration of regional analgesia. Fetal bradycardia from uterine hyperactivity causing decreased uteroplacental perfusion can occur, although rarely, most likely from the rapid decrease in maternal catecholamines after administration of analgesia (Friedlander et al, 1997). When resolution does not occur spontaneously and promptly, administration of nitroglycerin is an effective method to achieve fast onset and brief duration of uterine relaxation (Segal et al, 1998).

Epidural block can be performed early in labor, as soon as satisfactory progress of labor is established and the patient requests analgesia (i.e., usually 3 to 4 cm of cervical dilation in nulliparas, less in multiparas). During early labor, many anesthesiologists strive to provide a segmental block, to provide analgesia for the pain of uterine contractions and cervical dilation (T10 to L1). Later, a larger volume can be administered to provide perineal analgesia for spontaneous vaginal delivery, if necessary or desired, or for an instrumental vaginal delivery. Once the catheter is placed, analgesia

may be attained and continued throughout the active stage of labor and delivery or for operative anesthesia (cesarean delivery) as well as postoperative analgesia, when necessary.

Local anesthetics are typically infused continuously after incremental bolus doses, to produce reliable pain relief with similar or lower blood levels of local anesthetics than repetitive, intermittent boluses of these drugs (Hicks et al, 1988; Rosenblatt et al, 1983). Most important, the possibility of disastrous complications of total spinal anesthesia or massive intravascular injections with cardiovascular collapse secondary to large doses of local anesthetics is decreased. If an epidural catheter enters an epidural vein during continuous infusion, the analgesia merely ceases without producing neurologic or cardiovascular toxicity (Dathis et al, 1988). If the catheter enters the subarachnoid space instead, the level of sensory and motor blockade increases slowly without the sudden onset of complete subarachnoid blockade that may occur with bolus techniques (Li et al, 1985).

The choice of drug for continuous epidural infusion includes dilute solutions of lidocaine, bupivacaine, ropivacaine or chloroprocaine (Lee et al, 2002). The concentration and volume of the loading dose, which is administered before initiation of the continuous infusion, and the volume and concentration of the infusion are quite variable. With higher concentrations of local anesthetics, the density of the motor blockade increases. With larger volumes, a greater dermatomal spread of analgesia is achieved. Most practitioners routinely use reduced concentrations of local anesthetics and co-administer an opioid with both the bolus and the infusion. Dilute solutions of local anesthetics minimize the motor blockade and preserve the perception of pelvic pressure with descent of the fetus. The administration of both agents, local anesthetics and opioids, results in an additive (perhaps synergistic) effect (Chestnut et al, 1988). Some practitioners use extremely dilute concentrations of local anesthetics combined with an opioid and allow the parturient to ambulate (after careful neurologic testing) (Rosen et al, 2002).

One variation of the lumbar epidural technique is CSE. After placement of the epidural needle but before insertion of the epidural catheter, a long spinal needle is passed through the indwelling epidural needle to puncture the dura, and a small dose of either local anesthetic or opioid or both is administered. If opioid alone is administered and the epidural catheter is not activated, analgesia without motor blockade or sympathectomy is achieved. This method allows the parturient to ambulate safely. The side effects pruritus, nausea, and vomiting are usually not substantial with lipid-soluble opioids such as fentanyl or sufentanil, but the analgesia is limited (about 2 hours in the early active stage) and is rarely effective for the second stage of labor.

If small doses of local anesthetics are administered through the spinal needle, a segmental analgesia results more rapidly than with epidural administration of local anesthetics. The epidural placement of the catheter allows continuation of the segmental analgesia initiated by the spinal technique. Although some practitioners use this technique routinely and allow the patient to walk after careful evaluation, most use the more straightforward epidural technique.

## Contraindications to and Complications of Regional Anesthesia

Certain conditions contraindicate regional anesthesia, such as patient refusal, infection at the needle insertion site, coagulopathy, and hypovolemic shock. Human immunodeficiency virus (HIV) infection is not a contraindication to regional technique in the parturient (Hughes et al, 1995).

Infrequent but occasionally life-threatening complications can result from administration of regional anesthesia. The most serious complications are from accidental intravenous or intrathecal injections of local anesthetics. After careful test dosing, administration of the therapeutic dose as incremental fractionation of doses is an important method of ensuring safety.

Hypotension secondary to sympathetic blockade is the most common complication of major regional block for parturition (Rosenblatt et al, 1983). Prophylactic measures include adequate hydration, avoidance of the supine position, and displacement of the uterus off the abdominal great vessels. Treatment consists of further uterine displacement, IV fluids, and vasopressor administration (e.g., ephedrine, 10 to 20 mg, which has primarily  $\beta$ -adrenergic effects, restoring uterine blood flow to normal values as well as correcting hypotension, unlike primarily  $\alpha$ -adrenergic drugs, which increase uterine vascular tone, resulting in restoration of maternal pressure but not uterine blood flow). If treated promptly, maternal hypotension does not lead to fetal depression or neonatal morbidity. Other relatively common complications of epidural analgesia include headache from cerebrospinal fluid leak after accidental dural puncture. Resuscitation and support of the mother will reestablish uterine blood flow and allow adequate fetal oxygenation and excretion of local anesthetic (Morishima and Adamsons, 1967). Unless the mother cannot be resuscitated, delivery of the fetus should be delayed, because the neonate has an extremely limited ability to excrete local anesthetics and may have prolonged convulsions (Ralston and Shnider, 1978). Measures that minimize the likelihood of accidental intravascular injection include careful aspiration before injection, test dosing, and incremental administration of therapeutic doses.

An excessive level of neural blockade (high or total spinal) may develop during initiation of a spinal, epidural, or caudal block or during an infusion, leading to blockade of the motor nerves to the respiratory muscles (Yentis, 2001). Treatment consists of endotracheal intubation, ventilation with oxygen, and avoidance of aortocaval obstruction. Maternal circulation must be supported by avoidance of aortocaval compression and administration of additional fluids and vasopressors (e.g., ephedrine), if needed. If these measures are not promptly effective, epinephrine (0.5 to 1.0 mg) should be administered.

In any situation of maternal cardiac arrest with unsuccessful resuscitation, consideration must be given to urgent delivery of the fetus. If the fetus is delivered within 5 minutes of the arrest, the chances for survival are maximized, and evacuation of the uterus relieves aortocaval compression, improving the chances of maternal resuscitation (American Heart Association, 1997; Lee et al, 1986).

A rise in core maternal body temperature has been associated with epidural analgesic infusions during labor and may be influenced by several factors, including duration, ambient temperature, administration of systemic opioids, and, possibly most important, the presence of shivering. During the first 5 hours of epidural analgesia, there is no significant rise in body temperature (Mercier and Benhamou, 1997). If labor is prolonged, temperature increases at about 0.10 degrees C/hour, and may reach 38° C in as many as 15% of cases by 12 hours (Lieberman et al, 1997). Lieberman and colleagues (1997) suggested a significant increase in newborn sepsis work-up (SWU) rate with epidural analgesia, but 67.3% of the SWUs were ordered in infants born to mothers without fever. Kaul and associates (2001) found no association between epidural analgesia and SWU. However, patients who received epidural analgesia and their neonates had an increased body temperature at delivery and about 6% of women had temperatures equal to or exceeding 38° C. Although maternal temperature had no predictive value for SWU, Kaul and colleagues found other risk factors associated with SWU, including low birth weight, gestational age, meconium or respiratory distress requiring intubation at birth, hypothermia at birth, group-B  $\beta$ -hemolytic streptococcus colonization, and maternal preeclampsia or hypertension. Although the etiology of the maternal temperature rise remains uncertain, it need not affect neonatal SWU. Labor epidural analgesia does not increase the incidence of neonatal sepsis. Although some suggest that the fever may be associated with noninfectious inflammatory activation or altered thermoregulation, it is not associated with a change in white blood cell (WBC) count or with an infectious process, and treatment is not necessary.

## Spinal Analgesia

When utilized, spinal anesthesia is administered immediately before delivery. A small dose of a local anesthetic dissolved in a hypertonic dextrose solution is injected into the subarachnoid space, typically with the patient in the sitting position. Injection produces immediate analgesia of the lumbosacral nerve roots and provides excellent anesthesia for episiotomy, forceps application, and delivery.

## Paracervical and Lumbar Sympathetic Blocks

Paracervical block is occasionally used by obstetricians to provide pain relief in the first stage of labor. The technique consists of submucosal administration of local anesthetics immediately lateral and posterior to the uterocervical junction, which blocks transmission of pain impulses at the paracervical ganglion. Analgesia is not as profound as with epidural or spinal regional block, and the duration of analgesia is short (45 to 60 minutes), but the complications and side effects of epidural analgesia, such as hypotension, hypoventilation, and motor blockade, are avoided. Convulsions, however, may occur as a result of systemic absorption of local anesthetic.

The obstetrician performing a paracervical block should closely monitor the fetus, should inject just beneath the vaginal mucosa after aspiration for blood in the needle is

negative, and should allow a 5-minute interval between injections on the two sides. 2-Chloroprocaine is often used for this block because it undergoes rapid intravascular hydrolysis and has a very short intravascular half-life if accidentally injected intravascularly or into the fetus. Lidocaine is also used, but bupivacaine is contraindicated.

Paracervical block is associated with a relatively high incidence of fetal bradycardia. The mechanism of this phenomenon is unclear but probably involves decreased uterine blood flow secondary to the vasoconstrictor properties of local anesthetics. The bradycardia is usually limited to less than 15 minutes, and treatment is supportive, consisting of lateral positioning and administration of oxygen. Because the fetal bradycardia is associated with increased neonatal morbidity and mortality, this block is rarely performed and should be avoided in patients with evidence of uteroplacental insufficiency or nonreassuring fetal heart rate patterns (Thiery and Vroman, 1972).

### **Pudendal Block**

The obstetrician performs a pudendal block with a transvaginal technique, guiding a sheathed needle to the vaginal mucosa and sacrospinous ligament just medial and posterior to the ischial spine. Although the technique provides analgesia for vaginal delivery or uncomplicated instrumental vaginal delivery, the rate of failure is high, and the block achieved is often inadequate for mid-forceps application, examination of the cervix and upper vagina, or manual exploration of the uterus after delivery. In many centers, this technique is used when epidural or spinal blocks are unavailable. Complications in addition to failure include vaginal lacerations, systemic local anesthetic toxicity, ischiorectal or vaginal hematoma, and, rarely, fetal injection of local anesthetic.

### **Perineal Infiltration**

Infiltration of the perineum is commonly performed by obstetricians to provide anesthesia for episiotomy and its repair. Care is taken to avoid both injection into the fetal scalp and excessive (total) doses of local anesthetic agents. This is a common and useful technique when used either alone or in conjunction with other regional blocks.

### **Anesthesia For Cesarean Delivery**

Although the majority of cesarean deliveries are performed with regional anesthesia, the use of general anesthesia is sometimes required by the severity of the fetal condition (e.g., severe fetal heart rate deceleration) or when regional anesthesia is contraindicated. Regardless, in preparation for cesarean delivery, all women should receive an oral antacid (nonparticulate, such as sodium citrate) to reduce gastric content pH; some anesthesiologists routinely co-administer an agent to accelerate gastric emptying—metoclopramide, an histamine<sub>2</sub> receptor antagonist (e.g., ranitidine) or both—to reduce production of gastric acid.

### **Epidural Anesthesia**

Epidural anesthesia is an excellent choice for surgical anesthesia when an indwelling, functioning epidural catheter had been placed for labor analgesia. It is also ideal for patients who cannot tolerate the sudden onset of a sympathectomy, such as some patients with cardiac disease. The volume and concentration of local anesthetic agents used for surgical anesthesia are larger than those used for labor analgesia; however, the technique of catheter placement, test dosing, and potential complications are similar. Typically, the anesthesiologist attempts to provide a dense block from the T4 level to the sacrum. This technique may not always alleviate the visceral pain associated with peritoneal manipulation, and adjuvant drugs may be necessary.

### **Spinal Anesthesia**

For the patient without an epidural catheter (e.g., a patient undergoing elective cesarean delivery or a laboring patient who has not been given an epidural block), spinal anesthesia is the most common regional anesthetic technique used for cesarean delivery. The block is technically easier than epidural blockade, more rapid in onset, and more reliable in providing surgical anesthesia from the mid-thoracic level to the sacrum (Riley et al, 1995). The incidence of post-dural puncture headache has fallen with the introduction of noncutting, “pencil point” spinal needles. However, the risk of hypotension is much higher and the hypotension more profound with spinal anesthesia than with epidural anesthesia, because the onset of the sympathectomy is more rapid. Prehydration, avoidance of aortocaval compression, and aggressive use of ephedrine (even as a prophylactic) results in very favorable conditions and outcome. Data also suggest that spinal anesthesia can be safely used for patients with preeclampsia (Wallace et al, 1995; Hood and Curry, 1999).

### **Local Anesthesia**

Although cesarean delivery can be performed with local infiltration, it is accompanied with considerable discomfort to the woman and risks the possibility of local anesthetic overdose; also, most obstetricians have not been trained to perform the technique. However, in rare circumstances, such as acute fetal distress, inadequacy of a regional block, and in patients for whom induction of general anesthesia is considered dangerous (e.g., morbid obesity), local infiltration can be helpful to at least deliver the baby. Then general anesthesia can be induced after the patient’s airway has been secured while she is awake (using fiberoptic or other techniques).

### **GENERAL ANESTHESIA**

General anesthesia is used in obstetric practice for cesarean section typically when regional anesthesia is contraindicated (e.g., coagulopathy, certain cardiac lesions, hemorrhage) or for emergencies because of its rapid and predictable action (e.g., placental abruption, uterine rupture, fetal bradycardia, prolapsed umbilical cord). General anesthesia should be administered after placement of a cuffed endotracheal tube,

due to the risks of pulmonary aspiration of acidic gastric contents as previously described.

After induction of anesthesia by “rapid sequence,” anesthesia is maintained by administration of a combination of inhaled nitrous oxide, an inhaled potent halogenated agent (e.g., isoflurane), sedative-hypnotics, and opioid analgesics, and intravenous skeletal muscle relaxants are administered to decrease muscle tone and facilitate surgery.

### Induction Agents

A number of different agents are used by anesthesiologists to rapidly induce unconsciousness. Among the most common are thiopental, ketamine, and, to a lesser extent, etomidate and propofol. Each agent represents a different biochemical class, and each has specific advantages and cardiovascular effects.

Sodium thiopental is a highly lipid-soluble, protein-bound barbiturate that rapidly crosses the placenta and produces a dose-related global depression in the neonate. It is the most commonly used agent for induction of general anesthesia in obstetrics. Intravenous administration of an appropriate dose (4 to 6 mg/kg) renders the patient unconscious within 30 seconds and has no significant clinical effect on neonatal well-being. Although the drug undergoes hepatic oxidation to inactive, water-soluble metabolites, patients awaken within 15 minutes of initial administration because of rapid redistribution of the drug from vessel-rich organs (including the brain) to muscle and fat. Neonatal depression is found with higher dosages of barbiturates, however, which must be treated by cardiorespiratory supportive techniques until the neonate can excrete the drug; this process may take up to 2 days (Fox et al, 1979).

Ketamine, a structural analogue to phencyclidine, is more lipid soluble and less protein bound than thiopental. These characteristics lead to rapid brain uptake and subsequent redistribution, with awakening due to redistribution to peripheral tissue rather than metabolism. Ketamine is biotransformed in the liver to active metabolites, such as norketamine. In contrast to thiopental, ketamine increases arterial pressure, heart rate, and cardiac output through central stimulation of the sympathetic nervous system. Doses above those appropriate for induction of unconsciousness can increase uterine tone, reducing uterine arterial perfusion. In low doses (0.25 mg/kg), ketamine has profound analgesic effects, unlike barbiturates, but has been associated with undesirable psychotomimetic side effects (e.g., illusions, bad dreams), which can be lessened by co-administration of benzodiazepines. Many authorities consider this agent a more appropriate choice for the parturient who is actively hemorrhaging, for whom blood volume is uncertain and there is risk of profound hypotension in response to intravenous thiopental.

Etomidate contains a carboxylated imidazole ring, which provides water solubility in acidic solutions and lipid solubility at physiologic pH. Like thiopental, etomidate has a rapid onset of action because of its high lipid solubility, and redistribution results in a relatively short duration of action. Unlike thiopental and ketamine, etomidate has minimal effects on the cardiovascular system, but it is painful on injection and induces extrapyramidal motor activity and so is rarely used in obstetrics.

Propofol is a diisopropylphenol, available as a 1% aqueous solution in an oil-in-water emulsion containing soybean oil, glycerol, and egg lecithin. Because this preparation is preservative free, it does not lend itself to use in many labor and delivery units, where it is crucial to have syringes of induction agents ready to administer for rapid response to urgent situations requiring induction of general anesthesia (e.g., fetal distress). For an elective cesarean section, this highly lipid-soluble drug results in a rapid onset of action (about that of thiopental) and a very short initial distribution half-life, with less “hangover” effect than thiopental. However, propofol has not been demonstrated to be superior to thiopental in maternal or neonatal outcome. Further, it has been associated with maternal bradycardia when administered with succinylcholine for induction of general anesthesia for cesarean section.

### Nitrous Oxide

See previous discussion of this agent under “Inhalation Analgesia.”

### Halogenated Hydrocarbons

Halothane, enflurane, isoflurane, sevoflurane, and desflurane are all halogenated hydrocarbons that differ in chemical composition, physical properties, biotransformation, potencies, and rates of uptake and elimination. In clinical use, specialized vaporizers deliver these volatile liquid agents, so the inhaled concentrations can be carefully titrated by anesthesiologists due to their relatively profound cardiovascular effects and potential for uterine muscle relaxation. These agents are important components of general anesthesia for cesarean section but readily cross the placenta. Without use of these agents, the incidence of maternal recall of intraoperative events is unacceptably high (Schultetus et al, 1986; Tunstall, 1979).

Placental transfer of inhalation agents is rapid because these are non-ionized, highly lipid-soluble substances of low molecular weight. The concentrations of these agents in the fetus depend directly on the concentration and duration of anesthetic in the mother. If excessive concentrations of anesthetic are given for inordinately long times, neonatal anesthesia, evidenced by flaccidity, cardiorespiratory depression, and decreased tone, can be anticipated (Moya, 1966). It cannot be overemphasized that if the neonatal depression is due to transfer of anesthetic drugs, the infant is merely lightly anesthetized and should respond easily to simple treatment measures. Treatment should include effective ventilation; cardiopulmonary resuscitation is rarely necessary. Ventilation will allow excretion of the inhalation anesthetic by the infant’s lungs. Rapid improvement of the infant should be expected; if not, a search for other causes of depression is imperative.

Clinicians often confuse the use of general anesthesia, “fetal distress,” and the depressed neonate. A “depressed” fetus will likely become a depressed neonate, and general anesthesia may be employed because it is the most rapidly acting anesthetic to allow cesarean delivery. However, for a healthy fetus, the use of general anesthesia is not contraindicated; the induction–delivery interval is not as important in

neonatal outcome as the uterine incision–delivery interval, during which uterine blood flow may be compromised and fetal asphyxia may occur. A long induction–delivery time may result in a neonate who is lightly anesthetized but not asphyxiated.

The opioid analgesics have already been described. During typical general anesthesia for cesarean delivery, opioids are administered after the baby is delivered, to avoid placental transfer of these agents to the neonate.

### Neuromuscular Blocking Agents

Succinylcholine remains the skeletal muscle relaxant of choice for obstetric anesthesia because of its rapid onset and short duration of action. This depolarizing neuromuscular blocking agent is normally hydrolyzed in maternal blood by the enzyme pseudocholinesterase and usually does not interfere with fetal neuromuscular activity. If the hydrolytic enzyme is present either in low concentrations (Shnider, 1965) or in a genetically determined atypical form (Brada et al, 1975), prolonged maternal or neonatal respiratory depression secondary to muscular paralysis can occur.

Nondepolarizing neuromuscular blocking agents are titrated to the response shown by neuromuscular stimulation monitoring for continued neuromuscular blockade. Under normal circumstances, the poorly lipid-soluble, highly ionized, nondepolarizing neuromuscular blockers (e.g., D-tubocurarine, pancuronium, atracurium, vecuronium) do not cross the placenta in amounts significant enough to cause neonatal muscle weakness (Kivalo and Saaroski, 1972). This placental impermeability is only relative, however, and when large doses are given over long periods, as in the treatment of maternal tetanus or status epilepticus, neonatal neuromuscular blockade can occur (Older and Harris, 1968).

The diagnosis of neonatal depression secondary to neuromuscular blockade may be made on the basis of the maternal history (e.g., prolonged administration of neuromuscular blockers, history of atypical pseudocholinesterase), the response of the mother to neuromuscular blocking drugs, and the physical examination of the newborn. The paralyzed neonate has normal cardiovascular function and good color but lacks spontaneous ventilatory movements, has muscle flaccidity, and shows no reflex responses. The anesthesiologist can place a nerve stimulator on the neonate and demonstrate the classic signs of neuromuscular blockade (Ali and Savarese, 1976). Treatment consists of respiratory support until the neonate excretes the drug, up to 48 hours. Reversal of nondepolarizing relaxants with cholinesterase inhibitors may be attempted (e.g., neostigmine, 0.06 mg/kg), but adequate respiratory support is the mainstay of treatment.

### Adjuvant Medications

In addition to opioids, anesthesiologists may administer benzodiazepines, antiemetic agents, and other agents, but they typically do so only after the baby is delivered and the cord has been clamped. These drugs are rarely administered before delivery in doses large enough that placental transfer has a clinically important neonatal effect.

### SUMMARY

Maternal anesthetics may affect the fetus and neonate through diffusion from the maternal circulation to the fetal circulation, causing direct drug effects. However, these drugs are the same as those used for neonatal surgery in which they are directly administered to the neonate. Properly managed, these drugs are not toxic to the neonate. Serial dilutions, protein-tissue binding, and maternal administration of restricted doses usually protect the fetus from the effects of anesthetic drugs administered to the mother.

An anesthetic drug or technique may affect the fetus indirectly, producing the signs and symptoms of fetal distress and asphyxia; treatment is based on restoring placental exchange, perfusion, and gas exchange. Any technique that results in maternal hypotension, hypoxia, or both will decrease maternal-fetal oxygen exchange and produce fetal distress. Examples are overdose with opioid or inhalation analgesia, total spinal anesthesia, and maternal aspiration of gastric contents.

Uteroplacental blood flow depends on an adequate maternal cardiac output and perfusion pressure. Anesthetic techniques that interfere with maternal cardiovascular integrity can produce fetal depression by (1) increasing uterine arterial tone (e.g., use of drugs with primarily  $\alpha$ -adrenergic activity), (2) decreasing cardiac output (e.g., decreased venous return caused by vena caval compression by the gravid uterus; venodilation and bradycardia secondary to the sympathectomy accompanying spinal or epidural block; myocardial depression due to overdose of potent inhalation anesthetic or local anesthetic drug) or (3) decreasing systemic blood pressure (e.g., sympathectomy due to high spinal or epidural anesthesia).

An increase in uterine muscular tone can reduce uteroplacental perfusion by impeding venous outflow from the intervillous space (Vasicka and Kretchmer, 1961). High levels of local anesthetics (e.g., after intravascular injection) or of  $\alpha$ -adrenergic vasopressors may produce increased myometrial tone and fetal distress, particularly when combined with oxytocin stimulation.

In general, modern techniques of obstetric analgesia for labor and anesthesia for instrumental vaginal delivery or cesarean delivery are safe and effective for the mother and safe for the fetus and neonate. The analgesics and anesthetics, however, must be administered by skilled clinicians who observe appropriate precautions and understand the physiologic changes in pregnancy. Skillful labor analgesia coupled with emotional support for the parturient may not only reduce maternal stress but decrease intrapartum stress for the fetus as well (Jouppila et al, 1978; Morishima et al, 1978).

## GENETICS

Editor: H. WILLIAM TAEUSCH

CHAPTER  
17Impact of the Human  
Genome Project on  
Neonatal Care

DeWayne M. Pursley and Gary A. Silverman

**OVERVIEW AND HISTORY OF THE INTERNATIONAL  
HUMAN GENOME PROJECT**

Since the 1970s, nearly all avenues of biomedical research have led to the gene, for genes contain the basic information about how the human body carries out its duties from conception until birth.

*Francis S. Collins, 1999*

Almost 50 years after Watson and Crick (1953) described the crystal structure of DNA, the International Human Genome Project (IHGP) completed sequencing the human genome. Inaugurated in October of 1990, this herculean task was achieved ahead of schedule (2 years shy of the 15-year goal) and under budget (0.3 billion dollars less than the 3 billion dollars allocated) and will radically change our understanding of human development, the pathogenesis of disease, and the diagnosis and treatment of constitutional and somatically acquired disorders. Although the impact of this new knowledge on clinical decision-making may be subtle at first, there is no doubt that the paradigms for clinical education and practice have been transformed.

The next major challenge for physicians and scientists is to unravel the complex links between genes and physiology (Duyk, 2003). Consider, for example, the complexity of a Boeing 747 jet. Imagine how difficult it might be to provide routine maintenance of this aircraft with only a rudimentary understanding of the location of its assembled parts, such as the engines, wings, and fuselage, and a limited knowledge of how these parts work together to achieve flight. In contrast, maintenance practices would be dramatically enhanced if a complete list of the aircraft's 6 million parts and an exact

blueprint of how they are assembled were provided. Historically, physicians have cared for patients with a limited knowledge of their parts (gross anatomy) and how they function (physiology). Although the last 50 years have provided significant insight into the genetic basis of human development, anatomy, physiology, and disease, only a fraction of the molecular components that compose our body mass has been catalogued. Decoding the approximately 3 billion nucleotides that constitute our genome is a sentinel event in our quest to understand the complexity of human life. In essence, the IHGP has provided medicine with a "parts list" for creating a human. The daunting challenge ahead will be to synthesize the "blueprint" by determining how, when, and where the parts fit together during the human journey from conception to death.

The first concepts of a genome project were formulated at the Alta, Utah, conference in 1984 and the Santa Cruz, California, conference in 1985 (Watson, 1990). The concept was promulgated further by the U.S. Department of Energy (DOE). The DOE's interest stemmed from its Congressional mandate to track the heritable effects of radiation-induced DNA mutations. After vigorous scientific debate on the merits and costs of undertaking such a monumental task, a subcommittee of the National Research Council (NRC) in 1988 proposed that the United States, in collaboration with the international scientific community, undertake the task of sequencing the human genome. However, the subcommittee urged that the first 5 years of the project be focused on the generation of molecular and genetic maps as well as on improving the technology for mapping, DNA sequencing, and data handling (the birth of bio-informatics). Moreover, there was considerable interest in performing DNA mapping and sequencing projects for organisms that were the mainstays of biologic experimentation. As a consequence, the IGHP also included the analysis of model organisms such as bacteria (*Escherichia coli*), yeast (*Saccharomyces cerevisiae*), the roundworm (*Caenorhabditis elegans*), the fruit fly (*Drosophila melanogaster*), and the laboratory mouse (*Mus musculus*).

The inclusion of model organisms in the analysis was critical to the overall success of the program, for several reasons. First, by analyzing smaller genomes before more complex genomes (Table 17-1), scientists were able to develop more sophisticated sequencing, automation, and data management technologies. This "ramp-up" in technology was essential before an assault on the mega-sized, highly repetitive human sequence could even be considered. Second, by providing the sequence of model organisms, sequencing centers became integrated into the mainstream of experimental biology. Much as the 5' end of RNA is processed while the 3' end is still being synthesized,

**TABLE 17-1****Comparison of Genome Sizes**

Organism	Haploid Genome Size (kilobases)	Approximate Number of Genes
Small DNA virus (SV40)	5	6
Bacteria ( <i>Escherichia coli</i> K-12)	4600	4400
Yeast ( <i>Saccharomyces cerevisiae</i> )	12,000	6000
Roundworm ( <i>Caenorhabditis elegans</i> )	100,000	19,000
Fruit fly ( <i>Drosophila melanogaster</i> )	160,000	13,700
Mouse ( <i>Mus musculus</i> )	3,000,000	30,000-40,000
Human ( <i>Homo sapiens</i> )	3,000,000	30,000-40,000

biologists were analyzing data well before the complete sequences were available. As the genomes of prokaryotes, single-cell eukaryotes, and more complex multicellular organisms were unraveled (Table 17-2), the landscape for conducting science was shifting rapidly to a more global perspective in terms of how genes function within cellular systems and how they have been modified throughout evolution. Instead of thinking about single genes or mole-

cules, scientists began to contemplate systems that were orders of magnitude more complex than could have been appreciated before complete genomic DNA sequences from multiple organisms were available. Third, the sequence of model organisms, with their increasing complexity, provided a reference point from which to compare the human sequence. Comparative genomic analysis is a powerful tool used to identify elements conserved throughout

**TABLE 17-2****International Human Genome Project (IHGP) Timeline**

Year	Event
1953	Watson and Crick report on structure of DNA
1966	Genetic code revealed by Nirenberg, Khorana, and Holley
1972	Cohen and Boyer develop recombinant DNA technology
1977	DNA sequencing described by Sanger, Gilbert, and Maxam
1982	GenBank established
1983	First disease-related gene mapped (Huntington disease)
1985	Polymerase chain reaction (PCR) developed by Mullis
1986	First disease-related gene cloned by position (dystrophin)
1987	U.S. Department of Energy (DOE) recommends that the nation commit to a large, multidisciplinary, scientific, and technologic undertaking to map and sequence the human genome
1988	National Research Council (NRC) and U.S. Office of Technology Assessment (OTA) recommend that the United States map and sequence the human genome with National Institutes of Health (NIH) and DOE support
1989	Cystic fibrosis transmembrane conductance regulator (CFTR) cloned
1988	DOE establishes three genome centers
1989	NIH Director James Wyngaarden establishes National Center for Human Genome Research, with James Watson as director; Francis Collins becomes director in 1993, and Center becomes an Institute (NHGRI) in 1997
1990	IHGP begins at an estimated cost of \$200 million/year $\times$ 15 years (\$3 billion)
1991	First NIH-funded genome centers established
1995	<i>Haemophilus influenzae</i> genome completed (first prokaryotic genome sequenced)
1996	<i>Saccharomyces cerevisiae</i> (yeast) genome completed (first unicellular eukaryotic genome sequenced)
1997	<i>Escherichia coli</i> genome completed
1998	<i>Caenorhabditis elegans</i> (roundworm) genome completed (first multicellular eukaryote sequenced)
1999	Large-scale sequencing of the human genome begins
1999	Human chromosome 22 completed
2000	Human genome draft sequence completed
2000	<i>Drosophila melanogaster</i> (fruit fly) genome completed
2000	<i>Arabidopsis thaliana</i> (plant) genome completed
2001	Human genome draft published
2002	Mouse genome draft published
2002	Rat genome draft completed
2003	Human genome completed

evolution or those unique to individual lines of descent. In general, the conservation of genes between humans and other organisms provides insight into human gene function by facilitating the study of their homologues (related by local duplication events) or orthologues (related by direct descent) in more tractable experimental systems. These model systems (see later) have been crucial in elucidating fundamental biologic and disease-related processes (Table 17–3).

The DOE in 1987 and the National Institutes of Health (NIH) in 1988 began to allocate funds for genomic research. With a more substantial fiscal appropriation in 1989, the NIH Office of Genome Research became the National Center for Human Genome Research. A joint NIH-DOE subcommittee further defined the program's first 5-year goals, and the IHGP began officially on October 1, 1990 (Collins, 1999). The United Kingdom, Canada, France, Germany, Italy, Australia, Japan, and China also joined the effort. The first draft sequence of the human genome was reported in 2001 (Lander et al, 2001; Venter et al, 2001). Although obtaining the complete human genomic DNA sequence (99%) with 99.99% accuracy (and no gaps) was the primary goal of the project, the program also yielded a series of accomplishments and technological advances, which are outlined in Table 17–2. In addition, the project provided scientists with a treasure trove of cloned resources (genomic DNA clones and complementary DNA [cDNA]) that could be used for functional and diagnostic studies.

A rough scorecard shows that the human genome contains between 30,000 and 40,000 genes. This number does not, however, take into account all of the genes encoding nontranslated RNAs—for example, transfer RNAs (tRNAs), ribosomal RNAs (rRNAs), rRNA-processing small nucleolar RNAs (snoRNAs), splicing-associated small nuclear RNAs (snRNAs), telomerase RNA, signal recognition particle 7SL RNA, and Xist RNA. Many of these RNAs are likely to mediate important regulatory roles and possibly epigenetic alterations of the genome in a cell-specific fashion. Only 2% of the genome encodes for proteins, whereas more than 50% of the genome con-

tains various types of repetitive elements (e.g., short interspersed elements [SINEs], long interspersed elements [LINEs]). Of the protein-coding genes, approximately 60% are alternatively spliced. Alternative splicing combined with a myriad of post-translational modifications (e.g., glycosylation, prenylation, phosphorylation) add to the diversity of protein function.

A more important set of instruction books will never be found by human beings.

James Watson (1990)

## IMPACT ON CLINICAL PRACTICE

### Identification and Molecular Diagnosis of Disease-Related Genes

#### Individual Gene Assessments and Antecedents to Adult Disease

Diseases primarily attributable to single genes are termed *monogenic* or *mendelian disorders*, because their heritability follows the heritability of the classic autosomal dominant, autosomal recessive, and sex-linked modes of inheritance (Guttmacher and Collins, 2002). Mutations in regulatory regions of genes may have profound effects on the rates of RNA synthesis, splicing, and stability. All of these factors can result in an abnormal phenotype through a quantitative effect on gene activity. Mutations in coding regions may be due to single-nucleotide changes or to small insertions and deletions (*indels*). Single-nucleotide changes may result in silent (no change in the amino acid encoded), missense (conservative or nonconservative amino acid change), or nonsense (stop codon) mutations. Although most silent mutations appear to be benign, single-nucleotide variants may effect codon usage or activate cryptic splice sites, leading to alternative splicing or *frame-shifts*. Similar events can occur with indels, even if they appear within introns. Other modes of monogenic inheritance associated with disease are mitochondrial inheritance, tri-nucleotide repeat expansion with successive generations (anticipation), genomic imprinting, and uniparental disomy.

The target genes have now been identified for well over 100 monogenic disorders. Many of these disorders manifest in the newborn period (Table 17–4). Although the locations of some of these genes were pinpointed at the breakpoints of chromosomal aberrations—for example, the cloning of dystrophin was facilitated by the identification of rare females with Duchenne muscular dystrophy and constitutional translocations involving Xp21 (Ray et al, 1985)—most were isolated by positional cloning. *Positional cloning* is a multiple-step technique whereby a disease-related gene is identified from its location in the genome and without any prior knowledge of its function (Collins, 1992). For example, a disease phenotype is segregating within an extended family (*pedigree*) with an apparent autosomal recessive mode of inheritance. DNA is collected from both affected and unaffected family members and scored for the presence of highly polymorphic genetic markers that map to precise locations throughout the genome. Linkage analysis is used

**TABLE 17–3**

#### Fundamental Biologic Processes Studied in Model Organisms

Organism	Process
Bacteria	Gene regulation
Yeast	Cell cycle control, mitosis, proteasome function
Nematodes	Apoptosis, aging, stress response, chemoreception, neural development, axonal guidance, ion channels, receptor tyrosine kinase signaling
Fruit flies	Innate immunity, development
Zebrafish	Hematopoiesis and cardiac, retinal, and vertebrate development
Mice and rats	Models for many human diseases including hypertension and cancer, genomic imprinting

TABLE 17-4

## Monogenic Disorders Presenting in Newborns

Disorder	Gene	Location	OMIM Number
$\alpha$ 1-Antitrypsin deficiency	<i>SERPINA1</i>	14q32.1	107400
Achondroplasia	<i>FGFR3</i>	4p16.3	134934, #100800
Adrenoleukodystrophy	<i>ABCD2</i>	12q11	601081, #300100
Alport syndrome	<i>COL4A5</i>	Xq22.3	303630
Angelman syndrome	<i>UBE3A</i>	15q11.2	601623, #105830
Cockayne syndrome	<i>CKN1</i>	5q12	216400,

OMIM, Online database of Mendelian Inheritance in Man.

\*Modified from Genes and Disease. Available online at [www.ncbi.nlm.nih.gov/books/bv.fcgi?call=bv.View..ShowSection&rid=gnd](http://www.ncbi.nlm.nih.gov/books/bv.fcgi?call=bv.View..ShowSection&rid=gnd)

to determine which allelic variant is most closely linked (*segregating*) with the disease phenotype. Because the position of the linked marker is known, the area surrounding this locus is analyzed for the presence of genes. In turn, these genes are screened for mutations in individuals with the disease phenotype and compared with those of unaffected family members. Depending on the genomic region to be searched, investigators might have to identify and then sift through tens or hundreds of genes for mutations. This arduous, labor-intensive task commonly required tens to hundreds of personnel years to identify the correct gene. However, by having the complete genomic DNA sequence and list of genes for a region, investigators can make intelligent decisions about

which genes to analyze before conducting a single mutation screen. This candidate gene approach has significantly shortened the time (months) and person power (a few workers) needed to successfully isolate a disease-related gene.

Unlike for monogenic disorders, the identification of genes associated with complex traits, such as cancer, Alzheimer's disease, cardiovascular disease, and diabetes, is more difficult (Nabel, 2003; Nussbaum and Ellis, 2003; Wooster and Weber, 2003). In part, this difficulty is due to the limited contribution of many or at least several genes to a disease process as well as to the profound effects of environmental, behavioral, and epigenetic factors on disease prevalence. Moreover, the effects of variable penetrance

and expressivity of individual genes and the presence of heterogeneous disease phenotypes limit the use of simple pedigree analysis to analyze these disorders. Although any two individuals are 99.9% identical at the nucleotide level, the 0.1% difference translates to single-nucleotide polymorphisms (SNPs) occurring about once every thousand base-pairs. This inherent variability within the human genome provides an opportunity to combine SNP analysis with population studies to pinpoint *haplotypes* (clusters of SNPs that are inherited together on the same chromosomal segment and tend to be passed from generation to generation owing to their tight linkage) associated with disease phenotypes (Gibbs et al, 2003; Goldstein et al, 2003). By identifying common haplotypes associated with different individuals who have similar disease phenotypes (*linkage disequilibrium*), investigators can begin to identify regions of the genome (due to their common haplotypes) containing genes that contribute to the disease process or increase the risk of development of an abnormal phenotype.

### Newborn Screening

The expansion of newborn screening programs to detect amino acidemias, organic acidemias, and disorders of fatty acid oxidation has been facilitated by the use of tandem mass spectrometry (Wilcken et al, 2003). The use of mass spectrometry along with DNA sequence-based techniques to detect disease-related genes and their mutations, genotype-phenotype correlations are providing greater

insight into the molecular basis and developmental import of these genetic disorders. See Chapter 27 for a more detailed discussion of this topic.

### Molecular Cytogenetics

Classic karyotyping using Giemsa-banded chromosomes has been a diagnostic stalwart for aneuploidy syndromes (trisomies and monosomies) and for segmental chromosomal deletions and translocations for decades. The advent of fluorescence in situ hybridization (FISH) and spectral karyotyping (SKY) permits the diagnosis of many of these disorders more precisely and rapidly with the use of interphase nuclei or standard metaphase spreads (Tonnie, 2002). These techniques have also proved invaluable for pre-conception testing of polar bodies, chorionic villus cells, and amniocytes for trisomies 13, 18, and 21 and aneuploidies of the sex chromosomes (Lim et al, 2002). Also, FISH has been useful in identifying subsegmental deletions associated with, for example, the DiGeorge and Miller-Dieker syndromes and single-gene defects (Table 17-5). Subtelomeric fluorescent probes have been used in detecting submicroscopic deletions (<4 megabases [Mb]) in a subset of children with mental retardation (Clarkson et al, 2002). The availability of bacterial artificial chromosomes (BACs) and other types of clones spanning the entire human genome provide a complete array of probe material for identifying additional disorders associated with subtle chromosomal aberrations.

**TABLE 17-5**

#### Disorders Detected by Fluorescence In Situ Hybridization or Spectral Karyotyping

Disorder	Locus	Gene(s)
Wolf-Hirschhorn syndrome (4p- syndrome, del[4p] syndrome, monosomy 4p)	4p16.3	<i>WHCR</i>
Cri du chat syndrome (5p-syndrome)	5p15.2	
Sotos syndrome (cerebral gigantism)	5q35	<i>NSD1</i>
Williams syndrome	7q11.2	<i>WBSCR</i>
Prader-Willi syndrome	15q11.2-q13	<i>PWCR</i>
Angelman syndrome	15q11.2-q13	Ubiquitin-protein ligase E3A ( <i>UBE3A</i> )
Rubinstein-Taybi syndrome (broad thumbs-hallux syndrome)	16p13.3	CREB-binding protein ( <i>CREBBP</i> )
17-linked lissencephaly (17-linked subcortical band heterotopia, isolated 17-linked lissencephaly, Miller-Dieker syndrome)	17p13.3	Platelet-activating factor acetylhydrolase IB alpha subunit ( <i>PAFAH1B1</i> )
Hereditary neuropathy with liability to pressure palsies	17p11.2	Peripheral myelin protein 22 ( <i>PMP22</i> )
Smith-Magenis syndrome (del[17][p11.2])	17p11.2	Retinoid-acid induced protein 1 ( <i>RAI1</i> )
22q11.2 deletion syndrome (Cayler cardiofacial syndrome, conotruncal anomaly face syndrome, DiGeorge syndrome, Opitz G/BBB, Sedlackova syndrome, Shprintzen syndrome, velocardiofacial syndrome)	22q11.2	<i>DGCR</i>
Chromosome 22q13.3 deletion syndrome	22q13.3	Arylsulfatase A ( <i>ARSA</i> )
Ichthyosis, X-linked (steroid sulfatase deficiency)	Xp22.32	Steryl-sulfatase ( <i>STS</i> )
Kallmann syndrome, X-linked (hypogonadotropic hypogonadism/anosmia)	Xp22.3	Anosmin 1 ( <i>KALI</i> )
Aneuploidy for chromosomes 21, 18, 13, X, and Y	—	—
Subtelomeric regions	—	—

## Molecular Therapeutics

### Gene Replacement

The realization that genes are an underlying component of all human disease led to the anticipation that once the human genome was deciphered, clinicians would set about manipulating the genes for therapeutic purposes. For example, monogenic disorders (e.g., sickle cell disease, galactosemia, and cystic fibrosis) might be cured by providing endogenous cells with functional copies of wild-type genes, and tumor cells could be killed by giving them genes that make them more susceptible to inducible cell death signals. Although multiple gene therapy trials are under way and there have been some limited successes (as well as some well-publicized failures), this discipline is in its infancy (Balicki and Beutler, 2002).

The treatment of a monogenic disorder such as cystic fibrosis underscores the current difficulties in translating genomic science into effective gene therapy (West and Rodman, 2001). Cystic fibrosis is an autosomal recessive disorder associated with a variety of mutations involving the cystic fibrosis transmembrane conductance regulator (CFTR). The disease is characterized by multi-organ dysfunction due to decreased (or null) CFTR-mediated chloride channel activity. In the lung, a mutant CFTR is associated with thickened secretions, bacterial overgrowth, inflammation, and tissue destruction. Attempts to cure or ameliorate this disorder via gene replacement techniques illustrates many of the barriers that must be overcome before gene therapies become a mainstay of clinical practice. Initial studies using a recombinant adenoviral vector containing the CFTR cDNA showed a low transfection efficiency, transient expression, and a limited effect on overall chloride transport. Immune reactivity to the adenovirus precluded subsequent dosing using the same vector. Several trials using liposomes to deliver the CFTR cDNA to respiratory epithelium achieved greater transfection efficiency and higher levels of CFTR activity, but in general, the response waned over time.

The reasons for these suboptimal effects are multifactorial. Regardless of the mechanism of gene delivery *in vivo*, the transgene must traverse several physical barriers and access the correct cell types. The barriers include secretions, blood components, phagocytes, innate or acquired immune system molecules, extracellular matrix proteins such as sticky proteoglycans, proteases, and nucleases, and cell membranes (Balicki and Beutler, 2002). Upon entering the cell, the transgene must evade destruction in the endosomal compartment and gain access to the nucleus. In the nucleus, the transgene may remain episomal or may integrate into the host genome. If the host cell is capable of proliferating and the transgene remains episomal and does not replicate autonomously, it will eventually be lost with successive cell divisions. Integration of the transgene may lead to activation or disruption of other genes. These integration events could have profound effects, including transformation to a malignant state. For example, several children with the X-linked severe combined immunodeficiency type XI (SCID-XI) syndrome underwent immunologic correction, in which hematopoietic stem cells were transduced with a retrovirus containing  $\gamma_c$  chain cytokine receptor (Hacein-Bey-Abina et al, 2003). Subsequently, a

few patients demonstrated a leukemia-like disorder driven by activation of the *LMO2* oncogene. Integration of the retroviral vector near *LMO2* appeared to be the inciting event. Expression of the transgene in the nucleus is also subject to silencing mechanisms such as DNA methylation. Finally, if the transgene is transcribed, it is unlikely to contain the correct *cis*-acting elements to ensure that it will be properly regulated. Unregulated expression of certain proteins could lead to the accumulation of toxic aggregates or polymers that injure or kill cells.

The delivery mechanisms for gene replacement strategies include simple transformation using naked DNA, cationic complexes of DNA with lipids or peptides, and an array of viral vectors (Balicki and Beutler, 2002) (Table 17–6). Although each method has a unique set of advantages and disadvantages, none currently possesses all of the features that allow precise cellular targeting of the appropriate stem cell or long-lived cell population at high efficiency and with the capacity to sustain appropriate levels of expression (Thomas and Klibanov, 2003; Thomas et al, 2003). Viral vectors themselves, viral and transgene proteins, and transduced or transformed cells may also prove to be immunogenic and thereby limit the effectiveness of any protocol. Also, these immune responses can lead to untoward systemic reactions, as occurred in the fatal episode of shock and multi-organ dysfunction during an ornithine transcarbamylase (OTC) deficiency gene therapy trial using an adenovirus vector.

### Gene Repair

A major problem associated with gene replacement strategies is that the defective gene remains within the host genome and the inserted transgene is unlikely to contain enough surrounding control elements to ensure proper regulation. In some situations, the mutations of the endogenous alleles can lead to the production of a mutant gene product with dominant negative effects. In Marfan syndrome, an abnormal fibrillin-1 gene can yield an aberrant protein that interferes with normal microfibrillar assembly. Thus, gene replacement would be ineffective unless the mutant allele were silenced.

Targeted genetic repair offers an attractive alternative to simply infusing a cell with multiple copies of a wild-type allele. The advantages of gene repair strategies include elimination of the mutant gene product, use of the endogenous regulatory elements, and, owing to the site-specific nature of the repair process, minimization of random genome integration events (Sullenger, 2003). Gene repair strategies are also in their infancy but are currently focused on targeting either the pre-messenger RNA (Garcia-Blanco, 2003; Long et al, 2003; Sazani and Kole, 2003) or the gene itself (Gruenert et al, 2003; Kmiec, 2003; Seidman and Glazer, 2003). RNA repair strategies either pre-empt (*trans*-splicing ribozymes) or utilize the normal splicing process (*trans*-splicing or the use of antisense oligonucleotides to stimulate alternative splicing) (see Table 17–6). DNA repair strategies employ oligonucleotides or short DNA fragments to stimulate nucleotide excision or repair, homologous recombination, or gene conversion events (see Table 17–6).

TABLE 17-6

## Genetic Therapy of Mutant Gene Products or Alleles

Gene Therapy	Method	Mechanism	Advantages	Disadvantages
Gene replacements	Naked DNA	Direct transformation	No vectors needed	Small size Not all cells transformed Can elicit innate immunity
	Nonviral: Cationic liposomes (lipoplexes) Cationic polymers (polyplexes) Viral (capacity): Adenovirus (8-30 kb) Adeno-associated (AAV) (5 kb) Retrovirus (8 kb) Lentivirus (8 kb) Herpes simplex virus-1 (HSV-1) (40-150 kb)	Endosomal uptake  Infection or transduction	No vectors  Some target specificity (HSV for neurons, transductional targeting by modifying vector capsids or by pseudotyping) Some vectors do not need dividing cells to integrate (lentivirus), whereas others do (retrovirus)	Targeting difficult Transformation efficiency Complex stability  Some viruses induce potent immune response Gene silencing Possible integration of vector into genome, causing gene inactivation or activation (retroviruses and lentiviruses) Repeated dosing in most cases may be necessary but difficult if immune reaction (adenovirus)
RNA repair	<i>Trans</i> -splicing using ribosomes	Group I or II introns (ribozymes) used to introduce new exon	No change in transcriptional regulation of gene Control specificity	Route of delivery Must get to nucleus Need continuous source of construct
	<i>Trans</i> -splicing using spliceosome	Spliceosome-mediated RNA trans-splicing (SMaRT) used to introduce new exon	Control specificity	Route of delivery Must get to nucleus Need continuous source of construct
	Alternative splicing using oligonucleotides	Binding of oligonucleotide to splice sites suppresses splicing	Can control specificity	May get antisense (RNase H) effect and loss of message Route of delivery Must get to nucleus Need to provide continuous source of oligonucleotide
DNA repair	Triplex-forming oligonucleotides	Triplex formation can induce nucleotide excision repair mechanism and recombination and/or gene conversion	Can be used for site specific DNA mutagenesis/repair if triplex-forming oligonucleotide is bound to a short DNA segment, with the desired base change that is homologous to the target site Can be used systemically, but oligonucleotides cannot cross blood-brain barrier	Targets limited to polypurine/polypyrimidine tracts Limited access to nucleus Inhibited by nucleosomes Unique chemistries needed to synthesize oligonucleotides with good binding kinetics and stability
	Chimeric RNA-DNA oligonucleotides	Nucleotide exchange, mismatch repair	Specificity Changes in situ One-time fix	Delivery of oligonucleotides to cell Poor uptake Low frequency of correction
	Small single-stranded or double-stranded DNA fragments	Small fragment homologous replacement	Functions in vivo and in vitro Transcription of target gene not necessary	

The use of gene repair processes in vivo requires targeting the correct cells and is likely to suffer the same hurdles associated with the delivery of transgenes by viral and nonviral methods. One attractive use of gene repair, especially in the newborn period, involves ex vivo stem cell repair. In this scenario, a population of stem cells from an affected fetus or newborn is harvested from cord blood. The cells are cultured and transfected with a repair construct. Clones are analyzed molecularly for evidence of DNA repair and protein expression. The repaired clones are expanded and infused into the patient. Greater understanding of the identity, plasticity and function as well as the purification and culturing conditions for various stem cell and progenitor pools make this approach a realistic possibility within the next decade.

### RNA Interference

Most gene therapy strategies attempt to achieve a gain of gene function. However, under certain conditions, a loss of gene function (*gene silencing*) may be desirable. Gene silencing can occur at the transcriptional, post-transcriptional, or post-translational steps. Post-transcriptional strategies such as the use of antisense oligonucleotide technologies have been available for at least 25 years (Pirollo et al, 2003). However, their clinical use has been limited by delivery systems and their unpredictable mechanisms of action.

Another type of post-transcriptional gene silencing can occur when cells are exposed to double-stranded RNA (dsRNA) molecules (Paddison and Hannon, 2002). Although the mechanism has not been fully elucidated, dsRNA molecules are cleaved into shorter, 21- to 25-nucleotide fragments (small interfering RNAs [siRNAs]) by the RNase III endonuclease Dicer (Shi, 2003). In turn, these siRNAs (presumably the antisense strand) bind to their target RNAs and guide their destruction by an RNA-induced silencing complex (RISC). This process, termed *RNA interference* (RNAi), is conserved among all eukaryotes and appears to be a natural defense against viruses and their dsRNA genomes or replication intermediates. RNAi-like processes also play a regulatory role in development. Initially, RNAi was thought to be impaired in higher eukaryotes, because the presence of dsRNA molecules more than 30 nucleotides in length induce a potent interferon response. This latter activity can result in a complete termination of protein synthesis and eventual cell death. However, if dsRNAs or short RNA “hairpins” (<30 nucleotides in length) are introduced into mammalian cells, RNAi can function (Brummelkamp et al, 2002). Under as yet undefined conditions, a modified or attenuated interferon response can still occur in the presence of small dsRNAs, but this response does not appear to disrupt the RNAi pathway (Sledz et al, 2003). RNAi is exquisitely sequence specific, and single-nucleotide mismatches may disrupt the process.

The clinical applications of RNAi require the delivery into cells of small dsRNA sequences or of vectors (plasmids or viral) expressing a small hairpin RNA construct driven by an RNA polymerase III promoter. Although this technology suffers from the delivery system limitations associated with all gene therapy strategies, RNAi will eventually

be applied to the treatment of human disease. RNAi could be used to disrupt viral infection within the cell or to inactivate oncogenes within tumors. In the newborn period, RNAi might prove effective in quelling a vigorous immune response or repair processes associated with chronic lung disease or interfering with prostaglandin synthesis in a patent ductus arteriosus. Other applications are suppressing the production of misfolded (mutated) proteins, whose accumulation over time is toxic to cells (e.g., mutant  $\alpha_1$ -antitrypsin).

### DNA Vaccines

For many infectious agents, it has been difficult to develop vaccines using intact organisms or purified sub-cellular components. Also, many vaccination strategies preferentially stimulate humoral (antibody) responses and not cytolytic T (CD8<sup>+</sup>) cell responses (Srivastava and Liu, 2003). Cytolytic T cells are important effectors in limiting the propagation of obligate intracellular pathogens, such as viruses and certain parasites and bacteria. The skewing of this immune response is due, in part, to the mechanism of protein handling by antigen-presenting cells (APCs). Exogenous proteins taken up by APCs are processed through the endosomal compartment, where the digested peptides combine with class II major histocompatibility (MHC) molecules. Class II MHC molecules loaded with peptides are transported to the surface, where they are presented to CD4<sup>+</sup> helper T cells. In turn, these activated, helper T cells can stimulate B cells to differentiate into antibody-producing plasma cells. In contrast, foreign proteins that gain access to the cytoplasm of APCs (e.g., by a viral infection) can be degraded and shuttled into the endoplasmic reticulum–Golgi pathway, where they encounter class I MHC molecules. After peptide loading, these MHC molecules are transported to the surface, where they can stimulate a CD8<sup>+</sup> cytolytic T cell response.

Because it is possible to construct bacterial plasmids or viral vectors to express either foreign or endogenous proteins in human cells, transgenes can be used to direct the synthesis and disposition (cytosolic or secreted) of any potential antigen (Garmory et al, 2003). DNA vaccines have been used to protect mice, guinea pigs, ferrets, and non-human primates against viral infections (e.g., influenza, herpes simplex virus [HSV], human immunodeficiency virus [HIV], hepatitis B virus [HBV]) and parasitic infections. However, phase 1 clinical trials in humans using genes from influenza, HIV, HBV, and *Plasmodium falciparum* have failed to generate significant protection. Vector modifications and combinations with more conventional vaccines or adjuvants are being used to augment the response to DNA vaccines. The results are too preliminary to allow one to determine whether these modalities will lead to a more effective use of DNA vaccines in humans.

### Pharmacogenomics

The individual response to a drug is governed by a multitude of factors, including age, environment, body mass, gender, intercurrent illness, and the presence of other

medications (Johnson, 2003). Variations in absorption, volume of distribution, transporters, metabolism, and excretion (traditional pharmacokinetic variables) as well as the reactivity of intended and unintended targets also influence overall drug effect and toxicity (Weinshilboum, 2003). Genes associated with a number of these latter factors have already been determined (Table 17-7).

As the drug-associated effects of different genes and their variants are revealed, comprehensive genotyping or haplotyping at birth, possibly on a sequencing microchip, will provide physicians with a patient's comprehensive drug response profile. The goal is to use this profile to predict whether a particular patient is capable of responding to a drug to achieve a beneficial therapeutic index with minimal risks for toxicity and idiosyncratic reactions. Although current technology and knowledge of gene function preclude the ascertainment of individual drug response profiles at this time, genetic analysis already precedes treatment in some patients. For example, individuals with the Leiden variant (R506Q) of factor V are at increased risk for thrombotic events (Weinshilboum, 2003). This risk is even higher in women who are using birth control pills. Thus, prior knowledge of the presence of this variant in a woman would deter a physician from prescribing birth control pills for her. Mercaptopurine and azathioprine are purine antimetabolites used to treat acute lymphoblastic leukemia and autoimmune disorders. These drugs are metabolized by S-methylation via thiopurine S-methyltransferase (TPMT). Individuals with homozygous mutations of TMPT who are receiving standard doses of thiopurines are at risk for development of fatal bone-marrow suppression through the buildup of active 6-thioguanine nucleotides. Thus, in many candidates for thiopurine therapy, TMPT activity is commonly analyzed to determine whether the dosing regimen should be adjusted.

## Host-Pathogen Interactions

### Vaccine Development

Killed, live attenuated, and subunit conjugate vaccines have proved to be extremely effective in inducing protective immunity. In certain cases, however, traditional approaches fail to yield vaccines that are immunogenic or protective against different strains of the same species. One of the best examples is that of *Neisseria meningitidis* serotype B. The main capsular polysaccharide of this meningococcus is identical to a carbohydrate moiety (polysialic acid) in humans. Attempts to produce a vaccine against major surface proteins failed because of the antigenic variability between strains. To circumvent these problems, Pizza and colleagues (2000) used the genomic DNA sequence of *N. meningitidis* serotype B to search for genes encoding for novel surface-exposed or secreted proteins. Of 650 candidates, about half were amenable to expression and purification using standard *E. coli* expression systems. Thirty-five of these recombinant proteins, when injected into mice, yielded bactericidal antisera. Comparative genomic sequence analyses from 34 heterologous *N. meningitidis* serotype B clinical isolates showed that 5 of the protein antigens were highly conserved among these strains. These antigens are now being tested in phase 1 clinical trials.

### Microbial Genomics and Virulence Factors

To date, more than 140 bacterial (and  $\approx 1600$  viral) genomes have been sequenced. Many of these organisms are significant human pathogens, including *Chlamydia trachomatis* and *Chlamydia pneumoniae*, *E. coli*, *Haemophilus influenzae*, *Listeria monocytogenes*, *Pseudomonas aeruginosa*, *Staphylococcus aureus*, *Streptococcus agalactiae* (group B

**TABLE 17-7**

**Examples of Types of Variant Genes That Effect Drug Responses**

Phase I Drug-Metabolizing Enzymes	Phase II Drug-Metabolizing Enzymes	Drug Transporters	Drug Targets	Unintended Drug Targets
Cytochrome P-450 (CYP) enzymes	Thiopurine S-methyltransferase	ATP-binding cassette membrane transporters (e.g., <i>MDRI</i> )	$\beta_2$ -adrenergic receptors	Factor V Leiden
CYP3A5	N-Acetyltransferase 2		Angiotensin-converting enzyme (ACE)	Apolipoprotein E (ApoE)
CYP3A4	Uridine diphosphate-glucuronosyltransferase 1A1		Arachidonate-5-lipoxygenase	Ion channels
CYP2D6 CYP2C9			Dopamine receptors Serotonin transporters	Prothrombin Cholesterol ester transfer protein (CETP)
CYP2C19 Butyrylcholinesterase				

Modified from Evans WE, McLeod HL. Pharmacogenomics: Drug disposition, drug targets, and side effects. *N Engl J Med* 348:538-549, 2003; and Weinshilboum R. Inheritance and drug response. *N Engl J Med* 348:529-537, 2003.

streptococcus), *Streptococcus pneumoniae*, and *Streptococcus viridans* (see The Institute for Genomic Research Web site, the Internet address of which is listed in Table 17–8). These bacterial genomes range in size from 580 kilobases (kb) (*Mycoplasma genitalium*) to 6300 kb (*P. aeruginosa*), with an average gene density of 1 per kilobase. Unlike DNA in the human genome, of which only about 2% contains coding sequence, 90% of DNA in bacterial genomes contains coding sequence (Chan, 2003; Fraser et al, 2000).

One of the most astonishing features of bacterial genome analysis is the significant variability among organisms. Depending on the species, 7% to 30% of the identified genes are unique to that species. Moreover, the variability between members of the same species can be significant. For example, the genome of the *E. coli* K-12 strain is 4600 kb in size and encodes for about 4300 genes,

whereas the genome of the pathogenic *E. coli* O157:H7 strain is 5500 kb and encodes for about 5400 genes (Perna et al, 2001). Thus, the pathogenic strain contains about 1000 more genes, 25% of which are unique to that organism. On the basis of the percentage of similarity between the coding regions, these two *E. coli* strains appear to be more diverse evolutionarily than mice and humans.

Although some of this genomic diversity between strains may be due to local genomic duplications (e.g., O157:H7 strain) or deletions (e.g., K-12 strain), horizontal gene transfer appears to account for many of the differences between related bacterial genomes. *Horizontal gene transfer* is the acquisition of foreign DNA by various means such as simple transformation, phage infection, and conjugation (Chan, 2003). This type of genomic material frequently occurs in clusters or islands within the host genome and may encode for virulence factors (pathogenicity

TABLE 17–8

## Genomic and Genetic Web Resources

Site	Internet Address	Description
National Center for Biotechnology Information (NCBI)	<a href="http://www.ncbi.nlm.nih.gov/">www.ncbi.nlm.nih.gov/</a>	National resource for molecular biology information, biomedical information, public databases, and software tools for analyzing genome data
Ensembl	<a href="http://www.ensembl.org/">www.ensembl.org/</a>	Joint project between European Molecular Biology Laboratory-European Bioinformatics Institute (EMBL–EBI) and the Sanger Institute to develop a software system that produces and maintains automatic annotation on eukaryotic genomes
University of California, Santa Cruz (UCSC) Genome Bioinformatics Site	<a href="http://genome.cse.ucsc.edu/">genome.cse.ucsc.edu/</a>	Human genome browser gateway
Human genome resources	<a href="http://www.ncbi.nlm.nih.gov/genome/guide/human/">www.ncbi.nlm.nih.gov/genome/guide/human/</a>	NCBI site for human genomic data
Gene expression atlas	<a href="http://expression.gnf.org/">expression.gnf.org/</a>	Expression data for many genes
Online database of Mendelian Inheritance in Man (OMIM)	<a href="http://www.ncbi.nlm.nih.gov/omim/">www.ncbi.nlm.nih.gov/omim/</a>	Database describes correlations between genes and disease phenotypes
Human Gene Mutation Database (HGMD)	<a href="http://www.hgmd.org">www.hgmd.org</a>	Database of mutations associated with disease-related genes
The Institute for Genomic Research	<a href="http://www.tigr.org/">www.tigr.org/</a>	Keeps track of microbial genome sequences
GeneTests/GeneClinics	<a href="http://www.geneclinics.com/">www.geneclinics.com/</a>	Resource for finding laboratories that perform different types of genetic testing; locations of genetics clinics; and reviews on genetic diseases
The Transgenic/Targeted Mutation Database	<a href="http://tbase.jax.org/">tbase.jax.org/</a>	Database and lists of phenotypes for transgenic and knockout mice
Mouse Genome Database Project (MGD)	<a href="http://www.informatics.jax.org/">www.informatics.jax.org/</a>	Central repository for mouse genomic and genetic data
Mouse knockout and mutation database	<a href="http://research.bmn.com/mkmd">research.bmn.com/mkmd</a>	Biomednet's comprehensive database of phenotypic and genotypic information on mouse knockouts and classic mutations
The Journal of Gene Medicine Clinical Trial site	<a href="http://www.wiley.co.uk/genmed/clinical/">www.wiley.co.uk/genmed/clinical/</a>	Comprehensive source of information on gene therapy clinical trials
Silicon Genetics	<a href="http://www.silicongenetics.com/cgi/SiG.cgi/index.smf">www.silicongenetics.com/cgi/SiG.cgi/index.smf</a>	Source for software for analyzing, interpreting, and managing microarray data
Whitehead Institute for Genomic Research	<a href="http://www.broad.mit.edu/cancer/software/software.html">www.broad.mit.edu/cancer/software/software.html</a>	Source for microarray data analysis software

islands). Because these pathogenicity islands commonly distinguish virulent from nonvirulent strains, an understanding of their function will help identify potential therapeutic targets. The DNA sequence of these islands also may serve as unique diagnostic markers. For example, comparative genomic analyses of several pathogenic gram-negative organisms revealed the presence of a secretion system (type III) capable of using a syringe-like structure to inject bacterial toxins into eukaryotic cells (Blocker et al, 2003; Cornelis and Van Gijsegem, 2000). Because the activity of this secretion system can injure host cells, the development of drugs capable of interfering with bacterial secretory function should have clinical import. In the future, it should be possible to use genomic analysis to rapidly identify all types of bacteria as well as their virulence factors and their susceptibilities to antimicrobial agents.

Another important advantage of using genomic data is to obtain a comprehensive understanding of the interplay between pathogen and host (Rappuoli, 2000). Indeed, many host responses are far more damaging to the organism than the pathogen itself. Exposing mammalian cells in vitro to whole bacteria or bacterial products (cellular microbiology) and assaying their RNA profiles with microarrays (see later) enables one to discern how these organisms respond to each other at a molecular level. Extension of these studies to in vivo models of infection should make it possible to reconstruct the host response to a variety of infectious agents and determine how these responses can be modified to eliminate the infectious organism while minimizing collateral damage to the host and normal flora.

### DNA Microarray Analysis

Nearly 30 years ago, Southern (1975) published his seminal article describing the analysis of DNA by restriction endonuclease digestion, agarose gel electrophoresis, blotting to nitrocellulose, and hybridization with a radiolabeled probe (*Southern blot*). The simplicity and specificity of this technique are based on a fundamental aspect of nucleic acid chemistry: Complementary DNA strands anneal by Watson-Crick base-pairing.

Nucleic acid hybridization is also the basis for DNA microarray analysis. Instead of using nucleic acids to probe DNA blotted to nitrocellulose, microarrays contain thousands of nucleic acid probes attached to a solid support, such as a glass slide. The probes contain short oligonucleotides ( $\approx 25$  bp), long oligonucleotides (50 to 120 bp) or PCR products (typically, 100- to 3000-bp cDNA fragments) (Stears et al, 2003). Individual oligonucleotides are synthesized on the chip, whereas PCR products are spotted on the chip using photolithography or ink jet-like printing technology. Fluorescently or chemically modified targets can be derived from a complex mixture of RNA (e.g., labeled first-strand cDNAs or labeled cRNAs synthesized from linear amplification reactions) prepared from selected populations of cells or tissues (e.g., leukemia cells, bronchiolar lavage cells, peripheral blood leukocytes) or genomic DNA (e.g., PCR products of different alleles for sequencing or SNP analysis). Labeled targets are applied to the array under conditions that permit high-stringency hybridization.

Target-probe annealing is detected with the use of a scanning confocal laser device and captured digitally with a charge-coupled device. Transformed and normalized data are displayed with one of several computer algorithms. Computer programs are also used, for example, to show hierarchical clustering or to create self-organizing maps, which can illustrate the relationships among the expression patterns of thousands of genes (Leung and Cavalieri, 2003). Much of this software is freely available and can be utilized effectively by the uninitiated (see Table 17–8). The major advantages of microarray analysis are the requirement of small sample volumes and the detection and analysis of highly specific binding in a format that lends itself to automation and high throughput.

### Disease Phenotyping by Expression Profiling

DNA microarray analysis is a rapidly evolving technology that permits a semiquantitative assessment of the transcriptional activity of thousands of genes in parallel (Staudt, 2003). These types of analyses can be ascertained by comparing the hybridization patterns of RNA-derived targets from different tissues (or cells), from diseased or nondiseased tissue, from the same tissues over time, or from the same tissues before and after exposure to a drug or toxin. For example, a subset of very low-birth-weight infants with surfactant deficiency experience severe chronic lung disease, whereas other surfactant-deficient infants have a more benign neonatal course. What accounts for this difference? Can it be explained by genetic or environmental factors? One means to differentiate among these possible explanations is to assay the expression profiles of the two cohorts of patients over time. Cells in bronchiolar alveolar lavage fluid or tracheal aspirates might serve as sources of RNA. Identification of differentially expressed genes could provide critical insights into why these patient populations differ (e.g., an increase in levels of cytokines or inflammatory mediators in the patients who experience chronic lung disease might suggest that infection alters the course of postnatal lung development).

The development of microarrays using proteins, peptides, and other organic molecules (e.g., carbohydrates) as features or probes is improving steadily. These arrays should be useful in determining protein-protein interactions, the detection of ligand or toxins, the measurement of post-translational protein modifications, protein-based diagnostics, and transcriptional factor DNA–chromatin binding.

### Analyses of Constitutional and Somatically Acquired Human Diseases by Comparative Genomic Analysis

The complete genomic DNA sequences of humans and other organisms provide a more expeditious means of selecting tractable biologic platforms (model organisms) to help decipher the functions of human genes and biochemical pathways (see Table 17–3) (Hariharan and Haber, 2003). The study of human genes in simpler biologic systems during the pre-genomic era entailed the tedious process of screening multiple cDNA or genomic libraries from multiple species. Library screening could take several

months or years. If a clone was identified, the DNA sequence was obtained, and its homology confirmed. However, even if a similar gene was obtained, there was no guarantee that it was a true orthologue rather than a more distantly related family member.

With the advent of comparative genomic analysis, the amino acid or nucleotide sequence of a human gene is used to probe sequence databases with a simple search algorithm such as BLAST (basic local alignment search tool) (Altschul et al, 1990). With the touch of a keystroke, an entire list of closely related genes from different species can be displayed. The presence of other family members can be ascertained and, depending on the question being asked, a model system selected. Frequently, the cDNA and genomic clones can be obtained from ordered arrays of clones in public or private repositories. In turn, these reagents could be used to synthesize recombinant proteins or to prepare wild-type or mutant vectors capable of probing gene function in cells or intact organisms.

Approximately 20% of human disease-related genes show amino acid sequence similarity to those of the relatively simpler unicellular organism *S. cerevisiae*. Experimental genetics in yeast are very powerful because of their high degree of genomic annotation (i.e., the functions of many open reading frames have been identified), the ability to score phenotypes easily, the precision by which their genetic background can be modified by DNA transformation and high fidelity homologous recombination, the presence of haploid and diploid forms that facilitate the detection of lethal mutations, and the use of synthetic screens to detect the combined effects of multiple mutations. For example, *S. cerevisiae* has proved useful in defining the iron-binding function and mitochondrial localization of frataxin, the gene mutated in Friedreich ataxia (Walberg, 2000).

A search of the *C. elegans* genome for similarities to 100 human genes associated with inborn errors of metabolism as the query sequences revealed a worm orthologue for about 70% of the human genes (Culetto and Sattelle, 2000; Kuwabara and O'Neil, 2001; O'Kane, 2003). These findings suggest that many metabolic pathways are well conserved throughout evolution. Although the human pathways are likely to be more complex, the worm can be used to identify other proteins in the biochemical pathway, evaluate the effects of pathologic mutations on gene function, and test the effects of drugs in ameliorating the defect. Owing to the ease of creating transgenic worms (by micro-injection of naked DNA into the gonad), human diseases can be partially recapitulated in this simpler organism. For example, transgenic worms expressing human  $\beta$ -amyloid peptide or mutant huntingtin show peptide deposits or neuronal cell injury, respectively (Culetto and Sattelle, 2000). This model system will prove useful in identifying factors that contribute to deposit formation and cellular injury. Moreover, suppressor screens conducted on these animals may identify other genes that contribute to the disease phenotype. In worms, this screen is achieved by treating the mutant animals with a chemical mutagen and screening for progeny in which the mutant phenotype is suppressed.

Approximately 60% of human disease-associated genes have orthologues in *D. melanogaster* (Bernards and Hari-

haran, 2001). These genes are implicated in a multitude of disorders, including cancer, neurodegeneration, metabolic derangements, renal disease, and malformation syndromes. Conversely, genes isolated in *Drosophila* have provided insight into human gene function. For example, *sonic hedgehog* (*SHH*), which is critical for brain development and is associated with one form of holoprosencephaly in humans, was characterized initially in *Drosophila*. Transgenic approaches combined with enhancer-suppressor screens are also useful in delineating pathologic pathways in *Drosophila*. A model system for spinocerebellar ataxia type 1 (SCA1) was generated through expression of a wild-type and mutant form (containing a polyglutamine expansion) of ataxin-1 in flies (Fernandez-Funez et al, 2000). Genes capable of modifying the degenerative effect were identified, including ubiquitin conjugases, glutathione-S-transferases, and a nucleoporin. In turn, these genes may serve as therapeutic targets that can be tested subsequently in mouse models and eventually in humans. The ability to identify such a diverse array of modifier genes is simply not possible in human systems at this time, underscoring the utility of model organisms in gleaning important insights into human disease processes.

The use of mutagenesis screens in zebrafish is providing unparalleled insights into human developmental disorders and malformations. Although mutagenesis screens and natural mutations in mice yield similar types of disease phenotypes, the ease of cultivation, the ability to generate transgenic animals inexpensively, and the accessibility of developing embryos make zebrafish a preferred platform for the study of vertebrate morphogenesis (Dooley and Zon, 2000). With the use of positional cloning techniques, multiple genes associated with hematopoiesis have been cloned and characterized. Orthologues of some of these genes are associated with human diseases, such as sideroblastic anemia (D-aminolevulinatase synthase) and a type of porphyria (uroporphyrinogen decarboxylase). This work in zebrafish has provided valuable insights into the genesis of developmental defects of the heart (coarctation of the aorta, rhythm disturbances, cardiomyopathy), kidney (polycystic kidney disease), and brain (holoprosencephaly).

For the study of specific mammalian developmental disorders and diseases, the laboratory mouse continues to serve as an irreplaceable resource. More than 3000 genes have been characterized by targeted deletions (knockouts) or by natural mutations. Information on many of these strains can be obtained through the Internet (see Table 17–8). With the advent of chromosomal engineering techniques, the mouse can also be used to study contiguous gene deletion disorders, such as those associated with DiGeorge syndrome, or aneuploidies (complete or partial) such as trisomy 21 (Baldini, 2002).

### Molecular Imaging in Vivo

Intermolecular interactions and biochemical pathways associated with normal or pathologic processes can be assayed in vitro with the use of isotope- or fluorescent-labeled probes by direct (e.g., a ligand to a receptor) or indirect (e.g., an enzyme substrate or a marker of channel permeability) techniques. The concentration or spectral

emissions of the probes change upon association of the probes with targets in the pathway under investigation. These types of markers can also be detected in real time in vivo with positron emission tomography (PET), magnetic resonance imaging (MRI), and charge-coupled device (CCD) cameras to measure isotope-, radiowave- and light- (fluorescent or near-infrared) emitting probes, respectively (Herschman, 2003).

The opportunity to follow the fates of these probes over time allows for a longitudinal and in situ evaluation of multiple biologic processes, such as disease progression, growth and development of organs, response to drug therapy, activation of specific biochemical pathways under different experimental conditions, and the correct targeting and activity of gene therapy vectors. For example, a recombinant reporter construct containing a luciferase (reporter) gene flanked by caspase-cleavable silencing domains can be transfected into cells (Laxman et al, 2002). Upon activation of apoptosis, caspase-3 cleaves the silencer domains, allowing the recombinant enzyme to oxidize luciferin with the release of a photon. Bioluminescence imaging is used to detect the cells undergoing programmed cell death within these animals. The use of genomics and proteomics to identify and to expand upon biochemical pathways will aid in the identification of specific probes that could be used, for example, to help pinpoint the location and extent of gastrointestinal injury in the presence of a systemic inflammatory response associated with necrotizing enterocolitis.

### Resources

Nearly all of the species-specific genomic databases are freely available. Many of these repositories are accompanied by useful programs that permit a novice to explore the world of genomic biology. In addition, numerous Web sites offer a variety of software tools that facilitate the manipulation of nucleic acid and protein sequences as well as links to databases that help explore their clinical relevance. A selected set of sites is listed in Table 17-8.

### ETHICAL, LEGAL, AND SOCIAL IMPLICATIONS

Together with the research efforts focusing on the characterization of the human genome and its related technology development, the identification and analysis of the ethical, legal, and social implications of this field are integral and essential goals of the IHGP (Collins et al, 1998). Although the benefits of determining the human genome sequence and understanding the implications of genetic variation among individuals and groups are clear, several concerns have been raised (Table 17-9). They include the ethically sound (as well as scientifically sound) conduct of genetic research, the interpretation and use of genetic information, the integration of genetic information into clinical medicine, and the effect of this information in nonclinical and research settings.

These research issues will be of particular importance among communities of people who traditionally have not been the focus of genetic research. The exclusion of certain groups from research studies has contributed to well-

documented disparities in health and available diagnostic and treatment options. There is equal, if not greater, concern among those communities that have been adversely affected by genetic research in the past. The potential for stigmatization and discrimination in employment, health care, and insurance as well as more broadly in society is of great concern. These issues will be particularly important as data on the interactions among genotype, diseases, or traits, and traditional concepts of race, ethnicity, and culture emerge. The great strides that have been made to ensure that research is safe for human subjects will have to be matched by efforts to ensure that the research is also fair (Greely, 1998).

The concerns that genetic information might be used in ways that will harm people have been reflected in recent policy development, particularly as it relates to privacy and the fair use of genetic information in health insurance, employment, and medical research. The passage of the Health Insurance Portability and Accountability Act (HIPAA), in which Congress specifically banned certain uses of genetic information in determining insurance eligibility, is one example of this focus (Collins, 1999). The issues are complex, because the tools of genomic medicine may reveal information about health risks faced by family members as well as the patient. One could argue effectively that physicians should inform their patients about the risks faced by family members, but whether the physicians are permitted or obligated to contact the relatives themselves has been a topic of debate and litigation (Clayton, 2003).

Our approach to population screening is likely to undergo tremendous change. Currently, population screening involving genetics has greatly focused on the perinatal field, including the identification of babies with certain mendelian disorders before the appearance of symptoms (e.g., phenylketonuria), the testing of selected populations for carrier status (e.g., sickle cell trait), and the use of prenatal diagnosis to reduce the frequency of disease in subsequent generations (e.g., Tay-Sachs). In the future, genetic information will increasingly be used in screening pediatric and adult populations to determine individual susceptibility to common disorders, such as heart disease, diabetes, and cancer. The responses to these findings will be more complex and will require efforts in primary prevention (e.g., diet and exercise) or secondary prevention (early detection or pharmacologic intervention). The American Academy of Pediatrics (AAP) has recommended that persons younger than 18 years be tested only if (1) testing offers immediate medical benefits or (2) another family member benefits and there is no anticipated harm to the person being tested. The AAP further currently recommends against predictive testing for adult-onset disorders in persons younger than 18 years. Informed consent processes with specific information on the clinical validity and value of genetic testing will be developed, much like the specific language in drug labeling requirements, over the coming years. Legislation to prevent discrimination on the basis of genetic information and substantive regulatory and professional oversight of genetic testing will necessarily evolve (Khoury et al, 2003).

It has been stated that the study, scope, and funding of the ethical, legal, and social implications of the Human Genome Project have made it the world's largest bioethics

TABLE 17-9

## Societal Concerns Arising from the IGHP

Concerns	Considerations
Fairness in the use of genetic information by insurers, employers, courts, schools, adoption agencies, and the military, among others	Who should have access to personal genetic information, and how will it be used?
Privacy and confidentiality of genetic information	Who owns and controls genetic information?
Psychological effect and stigmatization due to an individual's genetic differences	How does personal genetic information affect an individual's self-perception and society's perceptions of the individual?
	How does genomic information affect members of minority communities?
Reproductive issues, including adequate informed consent for complex and potentially controversial procedures, use of genetic information in reproductive decision-making, and reproductive rights	Do health care personnel properly counsel parents about the risks and limitations of genetic technology?
	How reliable and useful is fetal genetic testing?
	What larger societal issues are raised by new reproductive technologies?
Clinical issues, including the education of doctors and other health service providers, patients, and the general public in the capabilities, scientific limitations, and social risks of genetic testing and the implementation of standards and quality-control measures in testing procedures	How will genetic tests be evaluated and regulated for accuracy, reliability, and utility?
	How do we prepare health care professionals for the new genetics?
	How do we prepare the public to make informed choices?
	How do we as a society balance current scientific limitations and social risks with long-term benefits?
Uncertainties associated with gene tests for susceptibilities and complex conditions linked to multiple genes and gene-environment interactions	Should testing be performed when no treatment is available?
	Should parents have the right to have their minor children tested for adult-onset diseases?
	Are genetic tests reliable and interpretable by the medical community?
Conceptual and philosophical implications regarding human responsibility, free will versus genetic determinism, and concepts of health and disease	Do people's genes make them behave in a particular way?
	Can people always control their behavior?
	What is considered acceptable diversity?
	Where is the line between medical treatment and enhancement?
Health and environmental issues concerning genetically modified foods and microbes	Are genetically modified foods and other products safe to humans and the environment?
	How will these technologies affect developing nations' dependence on the West?
Commercialization of products, including property rights (patents, copyrights, and trade secrets) and accessibility of data and materials	Who owns genes and other pieces of DNA?
	Will patenting DNA sequences limit their accessibility and their development into useful products?

program. This development is clearly fortunate, given the great complexities of these issues and the potential effects on individuals, families, communities, and society.

## Prenatal Genetic Diagnosis

Diana W. Bianchi

As a result of the ever-expanding number of prenatal diagnostic tests that are performed on pregnant women, clinicians know a lot about their patients long before they even touch them. This chapter discusses the common methods of prenatal genetic diagnosis, the information they convey, and the implications for the newborn.

### NONINVASIVE TECHNIQUES

#### Maternal Serum Screening

Maternal serum screening has been incorporated into routine obstetric care. It is used to identify a high-risk pregnancy in a low-risk population of pregnant women. Currently, maternal serum screening consists of measurement of alpha-fetoprotein (AFP), human chorionic gonadotropin (hCG), unconjugated estriol (uE<sub>3</sub>), and inhibin A, proteins that are made by the fetus or placenta. More than 20 years of clinical experience has accrued with the assay of AFP.

AFP is one of the major proteins in fetal serum. Its precise physiologic role is unknown. It can be detected as early as 4 weeks of gestation, when it is synthesized by the yolk sac (Bergstrand, 1986). Subsequently, it is produced in the fetal liver and peaks in the fetal serum between 10 and 13 weeks of gestation. AFP is then excreted into the fetal urine or leaks into the amniotic fluid through the skin before keratinization at 20 weeks of gestation. It is also present in cerebrospinal fluid. AFP in maternal serum is exclusively fetal in origin (Crandall, 1981). Maternal serum AFP peaks at 32 weeks of gestation owing to greater placental permeability for the protein (Ferguson-Smith, 1983). Most clinical assays of AFP are performed at 16 weeks of gestation. Accurate gestational dating as well as race, weight, and presence or absence of diabetes in the mother are critical to the interpretation of results.

In 1972, Brock and Sutcliffe observed that there were markedly increased levels of AFP in the amniotic fluid of fetuses with anencephaly and open neural tube defects. Subsequently, it was shown that elevated amniotic fluid AFP levels were associated with increased maternal serum AFP (Ferguson-Smith, 1983). The possibility of a screening test for open neural tube defects became apparent. In the initial collaborative efforts aimed at studying maternal serum AFP, results were expressed as multiples of the median (MoM) to allow comparisons between laboratories. It has become a convention to describe results greater than 2.5 MoM as abnormally high and less than 0.6 MoM as abnormally low. Both findings require further investigation.

If the AFP is elevated, the patient is offered an ultrasonographic examination to verify gestational age, determine fetal viability, and diagnose many of the structural abnormalities that can be associated with an elevated AFP. Although the AFP test was developed to screen for neural tube defects, abnormally high results are not specific for this condition (Table 18–1). If the ultrasonographic examination is unrevealing, the patient undergoes amniocentesis to assay the amniotic fluid for the presence of AFP and acetylcholinesterase, which are elevated in open spina bifida (Crandall et al, 1983). Even though an elevated AFP is compatible with a normal diagnosis, a study of 277 infants with elevations of maternal serum AFP and normal levels of amniotic fluid AFP revealed a higher incidence of intrauterine growth restriction and non-neural tube anomalies (Burton and Dillard, 1986).

Maternal serum AFP screening has also been used to detect chromosomally abnormal fetuses since the observation was made that a low AFP value was more likely in a fetus with trisomy 18 or 21 than in a normal fetus (Merkatz et al, 1984). Several prospective studies have demonstrated that, expressing risk for Down syndrome as a combined function of maternal age and AFP value and offering amniocentesis to all women with a risk of 1 in 270 or greater (the equivalent risk in a 35-year-old woman based on age alone) makes it possible to detect approximately one third of otherwise unexpected cases of Down syndrome in fetuses (Dimairo et al, 1987; Palomaki and Haddow, 1987). Low AFP values are probably caused by decreased hepatic production in the affected fetus. Although it would make sense to ascribe this phenomenon to the small size of the liver, one study found no association between fetal weight and low AFP values in chromosomally abnormal fetuses (Librach et al, 1988). The differential diagnosis of a decreased AFP level is shown in Table 18–2. Because a low AFP value detects only one third of fetuses with Down syndrome, a normal AFP value does not rule out trisomy 21.

Experience with using low maternal AFP levels as a screen for fetal chromosome abnormalities has led to the evaluation of many other proteins produced by both the fetus and placenta. Three of these, uE<sub>3</sub>, hCG, and inhibin A, have been incorporated into maternal serum screening panels (Wenstrom et al, 1999). Measurements of all four can be combined to improve the sensitivity and specificity of Down syndrome detection. AFP, uE<sub>3</sub>, and hCG are only weakly correlated with one another, and their values are all independent of maternal age (Norton, 1994). Elevations of hCG are the most specific markers for fetal trisomy 21 (Bogart et al, 1987; Rose and Mennuti, 1993), whereas estriol levels are approximately 25% less than normal. Pregnancies affected by fetal trisomy 18 also have reduced levels of uE<sub>3</sub> and hCG. Each measurement is compared with population-specific normal values (MoM), which are then converted to a likelihood ratio, which is expressed as a numeric risk for Down syndrome. Women whose serum screen results indicate a fetal Down syndrome risk of greater than 1 in 270 are offered amniocentesis. Approximately 5% of all serum screen values are calculated to be false-positive results in order to achieve a sensitivity of detection of at least 70% for cases of Down syndrome.

TABLE 18-1

**Differential Diagnosis of Abnormally High Maternal Serum Alpha-Fetoprotein Levels**

Incorrect gestational dating  
 Multiple pregnancies  
 Threatened pregnancy loss  
 Fetomaternal hemorrhage  
 Anencephaly  
 Open spina bifida  
 Anterior abdominal wall defects  
 Congenital nephrosis  
 Acardia  
 Lesions of the placenta and umbilical cord  
 Turner syndrome  
 Cystic hygroma  
 Renal agenesis  
 Polycystic kidney disease  
 Epidermolysis bullosa  
 Hereditary persistence (autosomal dominant trait)

TABLE 18-2

**Differential Diagnosis of Abnormally Low Maternal Serum Alpha-Fetoprotein Levels**

Incorrect gestational dating    Trisomy 18  
 Trisomy 21                            Intrauterine growth restriction

Future trends in maternal serum screening include measurements during the first trimester of pregnancy. Particularly promising are pregnancy-associated plasma protein A (PAPP-A) and the free  $\beta$  subunit of hCG ( $\beta$ -hCG) (Brambati et al, 1994), both of which are abnormal in cases of fetal trisomy 21. Initial studies indicate that sensitivity and specificity of fetal Down syndrome detection using PAPP-A and free  $\beta$ -hCG are the same in the first trimester as in second trimester (Haddow et al, 1998).

**Ultrasonographic Examination of the Fetus**

Recommendations regarding the routine use of ultrasound imaging for all pregnant women have been controversial in the United States (Bakketeig et al, 1984; Eik-Neis et al, 1984; Ewigman et al, 1993). Nevertheless, it remains the best noninvasive method for gestational dating, definition of fetal anatomy, serial measurements of fetal growth, and evaluation of dynamic parameters such as cardiac contractility, fetal urine production, and fetal movement. Additionally, it has been suggested that antenatal visualization of the fetus promotes maternal-infant bonding (Fletcher and Evans, 1983). Despite controversies, 40% of obstetric patients are estimated to undergo at least one ultrasonographic examination during pregnancy (Hill et al, 1983). The advent of antenatal ultrasonography has had a large impact on the types of patients who present to the neonatal intensive care unit.

**Structural Assessment**

Within the context of prenatal genetic diagnosis, ultrasonography may be used to detect congenital anomalies. In 2% to 3% of live births, a malformation is present (Nelson and Holmes, 1989). This risk is doubled in twins. Fetal structures that are normally filled with fluid are especially well visualized by ultrasonography. In approximately 10% of infants with anomalies, the central nervous system is involved (Hill et al, 1983). Ultrasonography is particularly useful in the diagnosis of anencephaly, microcephaly, encephalocele, and hydrocephalus. By 20 weeks of gestation, the fetal facial structures may be examined with this method for cyclopia, cleft lip, and micrognathia. Nuchal membrane thickening is suggestive of Down syndrome, familial pterygium coli, and other chromosome abnormalities (Benacerraf et al, 1987; Chervenak et al, 1983). Fetal cardiovascular structures may be reliably examined at 20 weeks of gestation. The presence or absence of four cardiac chambers, the dynamic relationships between the cardiac valves, and the locations of the vessels allow such diagnoses as hypoplastic left heart, double-outlet right ventricle, tricuspid atresia, tetralogy of Fallot, and Ebstein anomaly to be made. Pericardial effusion and arrhythmias may be similarly observed.

Gastrointestinal anomalies occur in approximately 0.6% of live births, and one third of them are associated with chromosome abnormalities (Barss et al, 1985). The decrease in fetal swallowing seen in some cases of bowel obstruction (from atresia, stenosis, annular pancreas, or diaphragmatic hernia) may lead to polyhydramnios that results in a uterine size greater than expected for gestational dates. Although gastroschisis and omphalocele are readily diagnosed on ultrasonography, they may be confused with each other, and their differing prognoses may cause considerable parental anxiety (Griffiths and Gough, 1985). Gastroschisis usually occurs as an isolated anomaly; infants generally do well after surgical repair. The kidneys are identifiable by 14 weeks of gestation, but the presence of perirenal fat and large adrenal glands may obscure the diagnosis of renal agenesis (Hill et al, 1983). Renal cysts, hydronephrosis, and obstructive uropathy are easily visualized. Oligohydramnios is indicative of poor renal function.

Multiple standard curves have been developed for fetal anthropometric measurements (Elejalde and Elejalde, 1986; Saul et al, 1988). These instruments are particularly helpful in the diagnosis of skeletal dysplasias and the evaluation of growth retardation. Fetal genitalia may be reliably determined by 24 weeks of gestation (Birnholz, 1983). Additionally, ultrasonographic examination is of benefit in the diagnosis and management of multiple pregnancies.

Although there have been no documented adverse outcomes related to ultrasound exposure during human pregnancy, the reported experimental biologic effects—altered immune response, cell death, change in cell membrane functions, formation of free radicals, and reduced cell reproductive potential—necessitate judicious use of this technology. Another concern is the appropriate pediatric follow-up for prenatally observed conditions with unclear clinical significance, such as minimal hydronephrosis and echogenic bowel.

The accuracy of ultrasonographic diagnosis has been addressed in several papers. In one study of 1737 referrals,

244 malformations were correctly diagnosed; six results were falsely called abnormal (0.3%), and 16 were incorrectly called normal (0.9%) (Campbell and Pearce, 1983). Of 596 women referred for ultrasonography, fetal anomalies were diagnosed in 81, with a falsely abnormal rate of 0.6% and a falsely normal rate of 0.5% (Sabbagha et al, 1985). The limitations of ultrasonography were delineated in a study correlating anatomic pathologic findings at autopsy with prenatal diagnosis (Rutledge et al, 1986). Fifty-two malformations in 45 fetuses were correctly diagnosed antenatally, but 90 additional malformations were missed.

The RADIUS (Routine Antenatal Diagnostic Imaging with Ultrasound) trial was a randomized study involving 15,151 pregnant women to determine whether the routine use of ultrasonographic screening decreased the occurrence of adverse perinatal outcomes (Ewigman et al, 1993). This study, which received considerable attention, did not show that ultrasonographic screening improved rates of preterm delivery or birth weight. Approximately 35% of the fetuses with anomalies were detected by antenatal ultrasonography in the screened population versus only 11% in the control group (Crane et al, 1994). Despite this difference, neither clinical management nor outcome of the pregnancy was significantly improved in the screened population.

Continuous ultrasonographic fetal imaging is important to improvement of the safety and efficacy of the more invasive diagnostic procedures, such as amniocentesis, chorionic villus sampling (CVS), and cordocentesis, which are discussed later.

### Nuchal Translucency Measurement or Absence of Nasal Bone

Ultrasonographic visualization and quantification of the fluid-filled space at the back of the fetal neck is known as the *nuchal translucency measurement*. This particular fluid-filled space is especially well seen in the first-trimester fetus (10 to 14 weeks of gestation) (Fig. 18–1). In normal fetuses, the maximal thickness of the subcutaneous translucency between the skin and soft tissue overlying the fetal spine increases as a function of crown-rump length. Normal standards have been established for each gestational week. An increased nuchal translucency (NT) thickness is associated with a higher risk of fetal trisomy 21 (Snijders et al, 1998), cardiac defects in chromosomally normal fetuses (Hyett et al, 1996), and other genetic syndromes and chromosome abnormalities. In a study of 96,127 pregnant women in the United Kingdom, Snijders and associates (1998) developed likelihood ratios for the extent of deviation of NT thickness from normal. Using a combination of maternal age and fetal NT thickness, these investigators detected 82.2% of the cases of trisomy 21 at a false-positive rate of 8.3%. Assessment of the risk of fetal chromosomal abnormalities in the first trimester allows pregnant women the option of earlier (invasive) diagnostic testing. The disadvantage of this approach is that earlier diagnosis of aneuploidy may preferentially identify fetuses already destined for miscarriage.

First-trimester ultrasonographic examination of the fetus, which is routinely performed in the United Kingdom

**FIGURE 18–1.** Sagittal ultrasonographic image of a first trimester fetus. The nuchal translucency measurement is the distance between the two crosses. A measurement larger than normal standards for gestational age indicates that the fetus is at high risk for Down syndrome, congenital heart disease, or both. (Image courtesy of Dr. Fergal Malone.)

and Europe, has identified other new markers for the noninvasive prenatal diagnosis of trisomy 21. In one study, absence of the nasal bone in the fetal facial profile was noted in 43 of 59 (73%) of fetuses with trisomy 21 and 3 of 603 (0.5%) of chromosomally normal fetuses (Cicero et al, 2001). Absence of the nasal bone is independent of NT thickness. Combination of the two ultrasonographic markers increases the sensitivity and specificity of detection of fetal Down syndrome.

### AMNIOCENTESIS

*Amniocentesis* refers to the removal of up to 20 mL of amniotic fluid from the pregnant uterus. Contained within this fluid are cellular components (desquamated fetal epithelial and bladder cells) that serve as sources of chromosomes, DNA, or enzymes. Most of the cellular elements are nonviable. Hence, amniocytes generally require tissue culture under specific conditions to provide enough material for diagnosis (Gosden, 1983). Herein lies one of the major disadvantages of the procedure, in that results are received late in the second trimester after fetal movement has been perceived by the pregnant woman. In contrast, the amniotic fluid itself may be assayed biochemically right after being removed for the presence of AFP, acetylcholinesterase, bilirubin, lecithin, sphingomyelin, or phosphatidylcholine.

The indications for genetic amniocentesis are (1) maternal age 35 years or older at the time of delivery, because there is an increased risk for fetal chromosome abnormalities, (2) a previous pregnancy that resulted in a fetus or an infant with chromosome abnormalities, (3) one parent with a balanced chromosome translocation, (4) an abnormal maternal serum screen value, (5) a family history of a child with a neural tube defect, (6) a family history of a metabolic disorder for which the enzyme defect is known, (7) maternal history of an X-linked disorder, and (8) a family history of a disorder for which DNA diagnosis is available.

Extensive clinical experience with amniocentesis has accrued since the results of the first large-scale randomized trials were published in the 1970s (Simpson et al, 1976; U.S. National Institutes of Health [NIH], 1976). Most institutions in the United States currently quote a 1% to 2% incidence of minor complications, such as amniotic fluid leakage, uterine cramping, and vaginal spotting after the procedure; the incidence of more serious complications, such as chorioamnionitis and miscarriage, is 0.25% to 0.5% (Chorionic villus sampling, 1995). There is a significant inverse relationship between the operator's experience with the procedure and the risk of miscarriage (Verjaal and Leschot, 1981).

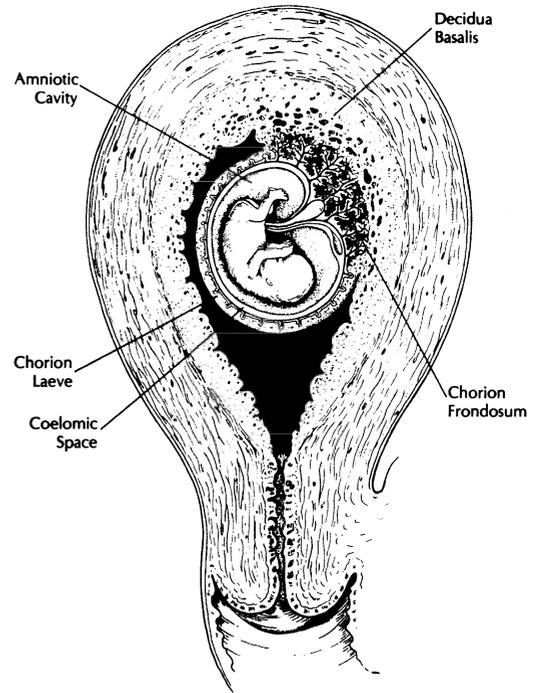

In a series of 3000 amniocenteses performed at a single institution over 8 years, the diagnostic accuracy rate exceeded 99%. Chromosome abnormalities were detected in 2.4% of 2404 women with advanced maternal age, in 1.2% of 240 women who had previously had an infant with trisomy 21, and in 9.1% of 55 women with other cytogenetic indications for the procedure (Golbus et al, 1979).

Because results of amniocentesis are received relatively late in the pregnancy, research efforts have focused on evaluation of the procedure if performed between 12 and 15 weeks of gestation. Unfortunately, the Canadian Early and Mid-Trimester Amniocentesis Trial (CEMAT) showed both a higher fetal loss rate and a 1.3% risk of fetal clubfoot when amniocentesis was performed between 11 and 13 weeks of gestation (Randomised trial, 1998). The rate of clubfoot in the early amniocentesis group was 10 times the risk in the general population. The cause of clubfoot is thought to be a disruption of normal foot development secondary to transient oligohydramnios (Farrell et al, 1999). For these reasons, early amniocentesis is not generally recommended.

### CHORIONIC VILLUS SAMPLING

Despite the wealth of experience with amniocentesis, its usefulness has been somewhat limited by the late timing of the procedure. Since the publication of the first English language report on sampling of the chorion (Kazy et al, 1982), medical and scientific interest in first-trimester prenatal diagnosis has been significant.

*Chorionic villus sampling* involves the aspiration of the chorion frondosum between 10 and 11 weeks of gestation (Fig. 18-2). The fact that the procedure is performed early is advantageous, because most women at this point do not have external manifestations of pregnancy and have not yet perceived fetal movement. The chorionic villi are composed of syncytiotrophoblast and mesenchymal core cells that are actively growing and dividing. In contrast to the dying epithelial cells shed into the amniotic fluid, chorionic villus cells do not require prolonged culture to provide enough mitoses for a cytogenetic diagnosis. Karyotype results are generally available within 1 week of the procedure. Initially, direct preparations derived from syncytiotrophoblast were used for analysis, but the number of apparently mosaic abnormal results proved unacceptable. Cultured preparations derived from the cell of the mesenchymal core are more closely related in embryonic origin to the actual fetus (Bianchi et al, 1993). It is currently recom-

**FIGURE 18-2.** A pregnant uterus containing a fetus at about 9 weeks of gestation. The chorion frondosum, if sampled for biopsy, can provide fetal cells for chromosome, enzyme, or DNA analysis. (From Jackson LG: *First trimester diagnosis of fetal genetic disorders. Hosp Pract [Off Ed]* 20:40 1985.)

mended that both direct and cultured preparations be used for cytogenetic analysis. *Mosaicism*, defined as the presence of two or more cell lines carrying different chromosomal constitutions, is a true biologic (not technical) problem in CVS. In several large studies, 0.8% to 1.7% of 1000 cases demonstrated a chromosome abnormality that was present in the villus but not in the fetus (Hogge et al, 1986; Ledbetter et al, 1992). This finding has led to the observation that postzygotic nondisjunction is more common than was previously suspected.

The indications for CVS are the same as those for amniocentesis, with two exceptions. First, neural tube defects cannot be diagnosed by this procedure, and AFP or other serum screening is not routinely offered at this early point in gestation. Second, evidence shows that the fetomaternal hemorrhage associated with placental biopsy results in elevated maternal serum AFP immediately after the procedure (Brambati et al, 1988).

CVS is performed transcervically or transabdominally. With the transcervical technique, the inherent risks of fetal and maternal infection appear to be greater because it is impossible to sterilize the cervix. Under ultrasonic guidance, a flexible catheter is passed through the endocervix and placed into the chorion frondosum. A small segment of placenta is then aspirated into sterile tissue culture medium, and the catheter is withdrawn (Jackson, 1985). In contrast, the transabdominal technique uses a needle to obtain villus material; sterilization of the skin surface is straightforward (Brambati et al, 1988). With either method, approximately 10 to 50 mg of tissue are obtained.

Subsequently, the villi are dissected from maternal decidua and processed for tissue culture or DNA extraction.

The safety and accuracy of these techniques have been extensively monitored. A randomized NIH clinical trial compared amniocentesis with CVS (Rhoads et al, 1989). The Centers for Disease Control and Prevention and the NIH held a consensus conference to summarize worldwide experience. After adjustment for confounding factors such as gestational age, the risk of miscarriage after CVS was found to be on the order of 0.5% to 1.0% (Chorionic villus sampling, 1995).

The advantages and disadvantages of CVS are summarized in Table 18–3. For patients at high risk for single-gene disorders amenable to DNA diagnosis (e.g., cystic fibrosis, sickle cell anemia, Duchenne muscular dystrophy), CVS is probably the preferred prenatal diagnostic method. On the other hand, for patients with relatively low risk (e.g., a 35-year-old woman being tested for chromosome abnormalities), an amniocentesis may be more appropriate. There have been a few reports of serious maternal sepsis and transient bacteremia in association with transcervical CVS (Barela et al, 1986; Blakemore et al, 1985; Silverman et al, 1994).

The 1% incidence of mosaicism in villus samples may necessitate a further invasive technique, such as amniocentesis or cordocentesis, to confirm or refute diagnoses. However, the detection of mosaicism in a CVS sample may identify a fetus at risk for uniparental disomy (UPD). *Uniparental disomy* refers to the inheritance of both copies of a chromosome pair from a single parent. This occurs when a trisomic fetus undergoes “rescue” and loses the extra copy of the chromosome. One third of the time, the fetus will be left with two chromosomes that originated in a single parent. UPD is an important mechanism in conditions such as Prader-Willi syndrome.

The biggest concern regarding CVS is the risk of limb deficiencies in infants whose mothers underwent the procedure. The risk of limb malformations was initially suggested by a number of studies describing an increased incidence of transverse limb anomalies and the hypoglossia-hypodactyly syndrome in infants whose mothers had undergone CVS (Burton et al, 1992; Firth et al, 1991, 1994; Hsieh et al, 1995). The overall rate of non-syndrome-related transverse

limb deficiency from 65 centers performing CVS is 7.4 per 10,000 procedures (Chorionic villus sampling, 1995). This number is reasonably similar to that in population-based registries that monitor infants with all limb deficiencies, which give a rate of 5 to 6 per 10,000 live births (Chorionic villus sampling, 1995). Of concern, however, are studies in which cases of limb malformation were classified to match the phenotype of CVS-exposed infants with limb deficiencies. In these studies, a background rate of 1.5 to 2.3 per 10,000 live births was found, suggesting that CVS does raise the risk for limb malformations (Chorionic villus sampling, 1995). Factors likely to influence the rate of limb malformations include gestational age (risk of limb deficiencies being greatest at or before 9 weeks of gestation and decreased at or after 10 weeks of gestation), type of catheter used, and operator experience. The overall risk of limb deficiency appears to be on the order of 1 per 3000 procedures (Chorionic villus sampling, 1995). Furthermore, a higher incidence of hemangioma has been suggested in infants born after CVS (Burton et al, 1995).

## CORDOCENTESIS

Percutaneous umbilical blood sampling (PUBS), or cordocentesis, was first described as a means of obtaining fetal immunoglobulin M (IgM) measurements in the prenatal diagnosis of congenital toxoplasmosis (Daffos et al, 1985). Under continuous ultrasonographic imaging, the insertion site of the umbilical cord into the placenta is identified. The umbilical vein is punctured with a 20-gauge needle, the sample is withdrawn, and the umbilical cord is observed for signs of hemorrhage. The technique has been used diagnostically in many clinical settings (Forestier et al, 1988) (Table 18–4). With regard to genetic diagnosis, the lymphocytes are a source of cells for a rapid karyotype. This is helpful in two situations: (1) when anomalies have been noted on ultrasonographic examination but it is too late in gestation to perform an amniocentesis (antenatal diagnosis of trisomy 13 or 18 influences delivery room management) and (2) for confirmation of a fetal karyotype when amniocentesis or CVS has shown mosaicism (Gosden et al, 1988).

## PREIMPLANTATION GENETIC DIAGNOSIS

The desire to avoid termination of pregnancy for fetuses affected with genetic disease has led to the development of techniques of preimplantation genetic diagnosis (PGD)

**TABLE 18–3**

### Advantages and Disadvantages of Chorionic Villus Sampling (CVS)

#### Advantages of CVS

Performed in first trimester; results available quickly  
Cells obtained are mitotically active  
Amount of tissue obtained is preferable for DNA analysis  
Placental mosaicism is detected

#### Disadvantages of CVS

Miscarriage rate slightly higher  
Increased fetomaternal hemorrhage after procedure  
Risk of serious maternal infection  
Risk of fetal limb and jaw malformations

**TABLE 18–4**

### Indications for Fetal Blood Sampling

Thrombocytopenia	Acid-base abnormalities
Rapid third-trimester diagnosis of chromosome abnormalities*	Metabolic disorders*
Immunodeficiency	Fetal blood type incompatibility*
Congenital infection	Hemoglobinopathy*

\*Diagnosis can also be made by a DNA-based test performed on any nucleated fetal material, such as amniocytes.

(Handyside et al, 1992). In a limited number of laboratories, it is possible to analyze the DNA or chromosomal constitution from the polar body of the oocyte, a blastomere, or a blastocyst. The underlying rationale is that if disease-causing genes are identified in the embryo, the embryo will not be transferred into the uterus for implantation. Various forms of assisted reproductive technology are needed for the performance of PGD. In a worldwide survey, only approximately 15% of couples with normal fertility who underwent PGD procedures have ended with a “take home” baby (Harper, 1996). Furthermore, misdiagnoses have been reported (Harper and Wells, 1999).

More than half of the PGD cycles carried out to date worldwide have been performed for age-related aneuploidy (Harper and Wells, 1999). Other indications for PGD are the couple in which one partner carries a balanced translocation and couples at risk for a single-gene disorder such as cystic fibrosis. PGD is technically challenging, in that analysis is carried out on DNA or chromosomes from the nucleus of only a single cell. It is likely that new developments in DNA analysis, such as comparative genomic hybridization and microarrays, will be applied to the preimplantation embryo to improve pregnancy success rate.

## THE FUTURE

### Fetal Cells in Maternal Blood

All nucleated fetal cells from the same individual contain identical genetic information. As a result, research efforts are currently focused on noninvasive methods of fetal genetic diagnosis. An attractive potential population are the rare fetal cells that cross the placenta and circulate within the mother. The fetal cell types currently being studied include the trophoblast (Johansen et al, 1995) and nucleated erythrocyte (Bianchi et al, 1990). Genetic diagnoses that have already been made successfully in fetal cells isolated from maternal blood include trisomies 18 and 21, triploidy, Klinefelter syndrome (47,XXY), exclusion of beta globin mutations, inheritance of HLA-DR and DQ alpha types, and Rhesus D genotype (Bianchi, 1995; Simpson and Elias, 1993). On the basis of these encouraging preliminary results, the National Institutes of Child Health and Human Development sponsored a multicenter clinical evaluation designed to evaluate cytogenetic accuracy of fetal cells in maternal blood in comparison with that of amniocentesis and CVS (de la Cruz et al, 1995). Results of this trial have shown a 78% detection rate for at least one aneuploid cell in maternal blood when the fetus has aneuploidy (Bianchi et al, 2002). The major limitation in the clinical use of this technique appears to be the very small number of fetal cells present in most maternal blood samples.

### Cell-Free Fetal DNA in Maternal Plasma and Serum

In 1997, Lo and associates first described the circulation of large amounts of cell-free fetal DNA in maternal plasma and serum samples. A multitude of potential clinical applications for the noninvasive diagnosis of the complications of pregnancy from this DNA has been reported

(Pertl and Bianchi, 2001). These applications have largely focused on the *quantitation* of male fetal DNA in maternal plasma or serum samples and its associated increase in conditions such as fetal trisomy 21, maternal hyperemesis gravidarum, preeclampsia, invasive placenta, and preterm labor. In addition, *qualitative* detection of uniquely fetal DNA sequences in maternal plasma or serum has facilitated the noninvasive prenatal diagnosis of Rhesus D genotype, myotonic dystrophy, and achondroplasia. It is likely that in the near future, noninvasive diagnosis of fetal Rhesus D genotype will be performed exclusively through the analysis of fetal DNA in maternal plasma or serum. The presence of amplified Rh D product in a sample from an Rh D-negative woman can come only from an Rh D-positive fetus.

## Evaluation of the Dysmorphic Infant

Sulagna C. Saitta and Elaine H. Zackai

Genetic disorders have a major impact on public health, as indicated by several large epidemiologic studies (Cassidy et al, 2000; Hall et al, 1978; Scriver et al, 1973; Table 19–1). The latest data indicate that genetic factors contribute to approximately two thirds of the conditions prompting admission to a children's hospital (Cassidy et al, 2000). Early identification of the genetic nature of a given condition may then help to appropriately focus resources for providing better care to these individuals. It is therefore critical to implement a systematic approach to evaluating a dysmorphic, or malformed, infant. This chapter outlines such a general approach.

The clinical geneticist incorporates the following five essential tools in the evaluation of a child suspected of having a primary genetic disorder:

1. History: prenatal, birth, and medical
2. A pedigree analysis or family history
3. A specialized clinical evaluation that includes a detailed dysmorphology examination
4. A comprehensive literature search
5. Focused special cytogenetic and molecular genetic laboratory analyses

### HISTORY

#### Prenatal History

A complete gestational history should be generated, including results of prenatal testing such as serum triple-screen test, ultrasonography, chorionic villus sampling (CVS), and amniocentesis (Table 19–2). The maternal age at conception should be documented, because the risk of chromosomal anomalies such as improper separation and nondisjunction rises with maternal age. It is important to identify prenatal exposures to infection and medications, maternal habits such as alcohol and drug use, maternal chronic illnesses, and pregnancy-related complications.

It is also important to identify exposure to environmental agents that might act as teratogens. *Teratogens* are environmental agents that may cause structural and functional diseases in an exposed fetus. Each teratogen may have a characteristic expression pattern, with a specific range of associated structural anomalies and dysmorphic features. Effects and the extent of effect depend on the time of exposure, duration, and dosage as well as interactions with maternal and genetic susceptibility factors. In general, more severe effects are typically correlated with exposure early

in the pregnancy and with more extensive (higher-dose) exposure. The list of well-documented human teratogens is short, and if history of an exposure is documented, an effort should be made to identify the developmental time and level of exposure. This information is critical, because the counseling and calculation of recurrence risk for a given malformation are vastly different if environmental exposures are involved.

#### Birth History

Another important component of the gestational history is obtaining information on fetal activity, size, and position. Often, the mother's subjective impressions can be further confirmed by examining obstetric records of the perinatal period. A history of hypotonia may be further supplemented by reports of poor fetal movements and breech presentation. Perinatal information including gestational age, fetal position at delivery, the length of labor and type of delivery, and any evidence of fetal distress, such as passage of meconium, are all relevant data (Table 19–3). Apgar scores, the need for resuscitation, birth parameters, any malformations noted at birth, and all abnormal test results should be noted.

#### Medical History

A full review of the medical issues of the child should include the baby's general health, results of tests, identification of any chronic medical issues, and need for hospitalization. Evaluation of growth, review of systems, developmental assessment, and notation of unusual behaviors can also provide important clues to a diagnosis.

### PEDIGREE ANALYSIS AND FAMILY HISTORY

A critical part of any genetic evaluation is to obtain the family history (Table 19–4). This is best accomplished by creating a three-generation *pedigree*, or schematic diagram depicting familial relationships using standard accepted symbols (Fig. 19–1). This formal record can also be used to summarize positive responses elicited during the interview. Special attention should be paid to ethnic origins of both sides of the family, consanguinity, and any first-degree relatives with similar malformations to those of the patient being evaluated, also known as the index case, *proband*, or *propositus*. An extended family history should be used to identify relatives with congenital anomalies, developmental abnormalities, or physical differences. Often photographs can provide clear objective evidence of a descriptive history.

Reproductive histories, especially of the parents, should be elicited. Specifically, questions should be asked about infertility, miscarriages, and stillbirths. The occurrence of more than two first-trimester miscarriages increases the probability of finding a balanced translocation in one parent (Campana et al, 1986; Castle and Bernstein, 1988). A *balanced translocation* is a rearrangement of genetic material such that two chromosomes have an equal exchange without loss or gain of material. There are

**TABLE 19-1**

<b>Genetic Disorders in Pediatric Hospital Admissions</b>			
Genetic disorders (%)	Montreal (1973)	Seattle (1978)	Cleveland (2000)
Chromosome/single gene	7.3	4.5	8.5
Polygenic	29	49	55
Nongenetic disorders (%)	64	47	35
Total number of admissions	12,801	4115	4200

Data from Scriver et al (1973), Hall et al (1978), and Cassidy et al (2000).

**TABLE 19-2**

Malformations noted	

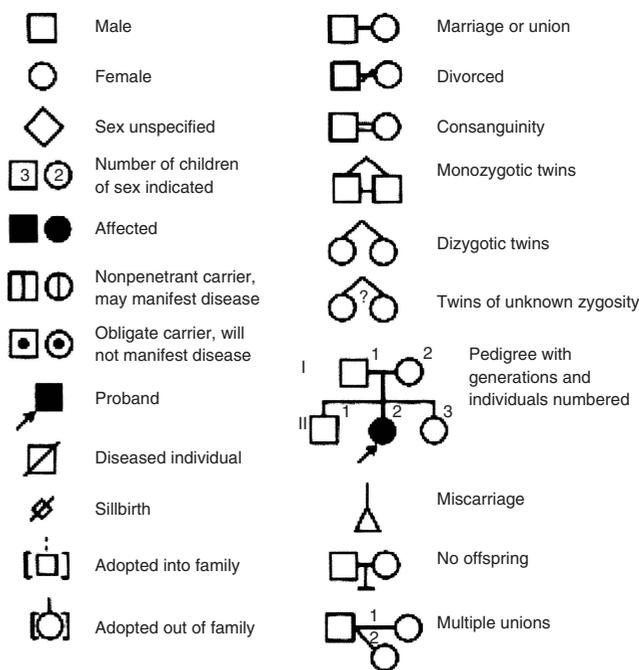

typically no associated clinical features with such a rearrangement. However, when chromosomes align to recombine for meiosis in the sperm or egg, this exchange produces a risk of unequal distribution and an unbalanced translocation in the resulting fetus. In this case, there would be aneuploidy for part of a chromosome. It has been estimated that 25% of stillbirths exhibit single or multiple malformations, and in at least half of these cases

**TABLE 19-4**

<b>Elements of Pedigree Analysis and Family History for the Dysmorphic Infant</b>
Identification of relatives with: Congenital anomalies (especially those similar to proband's) Mental retardation

Parental reproductive history: Pregnancy losses (gestational ages) Infertility
Medical histories of primary relatives
Ethnic origin(s)
Consanguinity

there is a genetic etiology for the malformations. Couples with two or more pregnancy losses should undergo routine chromosome analysis or karyotyping, and when possible, such analysis should be performed on the stillborn fetus or on products of conception.

Obtaining a formal family history is helpful in bringing out information that is often critical to making a diagnosis. Positive responses may help discern the mendelian pattern of inheritance of a given genetic disorder. For example, a disease affecting every generation, with both males and females involved, such as Marfan syndrome, would most likely be autosomal dominant. A pattern of X-linked recessive disease, such as hemophilia, would show affected males related through unaffected or minimally affected females; transmission in this pattern should not occur from father to son.

**FIGURE 19-1.** Symbols commonly used for pedigree notation. (From Nussbaum RL, McInnes RR, Willard HF [eds]; *Thompson and Thompson's Genetics in Medicine*, 6th ed. Philadelphia, WB Saunders, 2001.)

## PHYSICAL EXAMINATION FOR DYSMORPHOLOGY

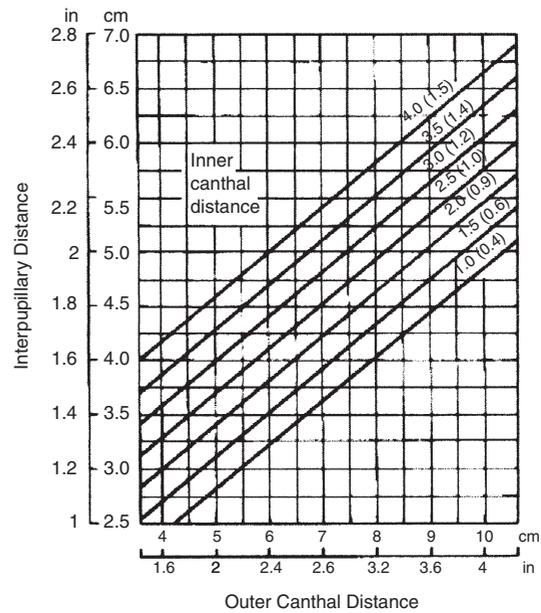

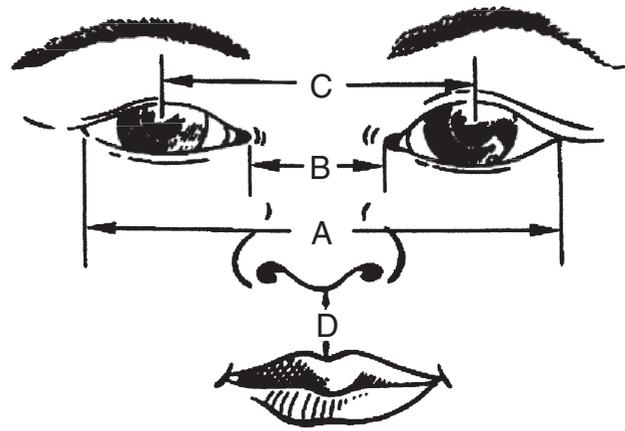

A congenital *malformation* can be described as a “morphologic defect of an organ, part of an organ, or larger region of the body resulting from an intrinsically abnormal developmental process” (Jones, 1997). *Dysmorphology* was introduced by Dr. David Smith in the 1960s to describe the study of human congenital malformations. This study of “abnormal form” emphasizes a focus on structural errors in development with an attempt to identify the underlying genetic etiology and pathogenesis of the disorder.

In a landmark study, Feingold and Bossert (1974) examined more than 2000 children to define normal values for a number of physical features. These standards were devised as screening tools to objectively identify children with differences possibly attributable to a genetic disorder. Important measurements that are further discussed here include head circumference, inner and outer canthal distances, interpupillary distances, ear length and ear placement, internipple distances, chest circumference, and hand and foot lengths. Other graphs and measurements using age-appropriate standards can be found in compendia such as the *Handbook of Normal Physical Measurements* (Hall et al, 1989).

The assessment should begin with newborn growth parameters that can reflect the degree of any prenatal insult. Measurements such as height, weight (usually reflecting nutrition), and head circumference should be plotted on newborn graphs. Gestational age-appropriate graphs should be used for premature infants. It is often helpful to express values that are outside the normal range as 50th percentile for a different gestational age. For example, a full-term baby with microcephaly may have a head circumference of less than the 5th percentile for 38 weeks. This can be expressed as a measurement at the 50th percentile for 33 weeks, which imparts the degree of microcephaly more clearly.

A complete physical examination should include assessment of patient anatomy for features varying from usual or normal standards. This assessment can often provide clues to embryologic mechanisms. The data obtained should then be interpreted with respect to normal standards using comprehensive standard tables that are available for these purposes. Special attention to familial variants should be given.

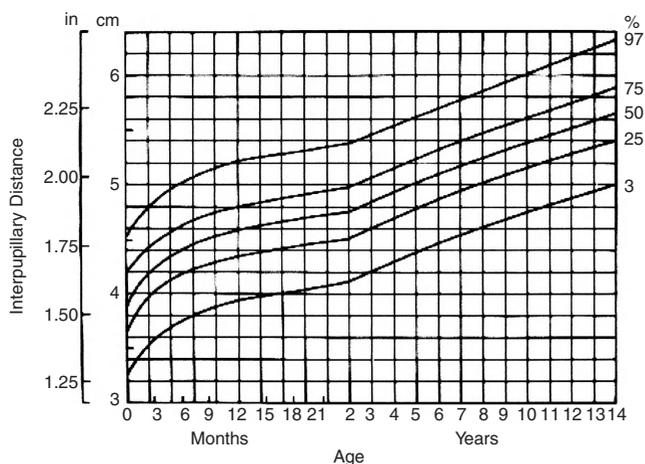

The shape and size of the *head* and fontanels should be noted as well as the cranial sutures, with assessment for evidence of craniosynostosis or an underlying brain malformation. Any scalp defects should also be noted. The shape of the forehead, appearance of eyebrows (noting synophrys, or “mono-brow”), and the texture and distribution of hair should be noted. The spacing of the *eyes*, or canthal measurements (Fig. 19-2), the interpupillary distances (Fig. 19-3; see also Fig. 19-2), palpebral fissure lengths (Fig. 19-4), presence or absence of colobomata and epicanthal folds, and noting whether the palpebral fissures are turned upward or downward are components of the dysmorphology examination. Examination of the *ears* should include a search for preauricular and postauricular pits, or ear tags, and assessment of the placement (Fig. 19-5), length (Fig. 19-6), and folding of the ear is important. Ear development occurs in a temporal frame similar to that of the kidneys, and often, external ear anomalies are associated

**FIGURE 19-2.** Top, Various eye measurements are depicted. A indicates the outer canthal distance, B the inner canthal distance, and C the interpupillary distance (IPD), which is difficult to measure directly. The IPD can be determined using the graph at the bottom or with the Pryor formula:  $IPD = (A - B) \times 2 + B$ . (From Feingold M, Bossert WH: *Normal values for selected physical parameters: An aid to syndrome delineation. Birth Defects* 10:1-16, 1974).

with renal anomalies. Evaluation of the *nose* should cover the shape of nasal tip, the alae nasi, presence of anteverted nares, the length of the columella, and patency of the choanae. The *mouth* and throat are examined for the presence of a cleft lip or palate; the shape of the palate and uvula are noted, and the presence of unusual features, such as tongue deformities, lip pits, frenula, and natal teeth, are recorded. A small retrognathic or receding chin, which can be a part of several syndromes or an isolated finding, should be noted. The neck is inspected for excess nuchal folds or skin and evidence of webbing. Any bony abnormalities in the neck should prompt an evaluation of the cervical vertebrae to confirm cervical and airway stability.

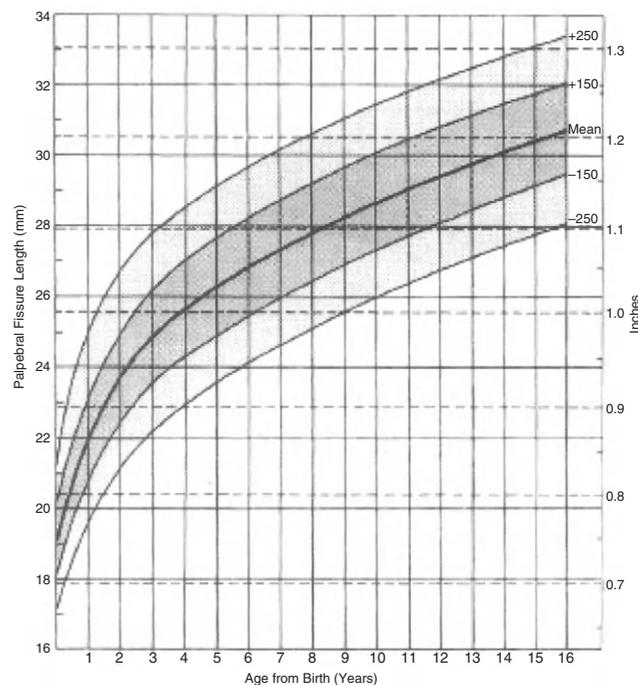

Evaluation of the *chest* and thorax involves lung auscultation and cardiac examination. Abnormal findings should

**FIGURE 19-3.** A nomogram for interpupillary distance (IPD) at different ages for both sexes (From Feingold M, Bossert WH: *Normal values for selected physical parameters: An aid to syndrome delineation. Birth Defects 10:1-16, 1974.*)

prompt consultation with a cardiologist and appropriate echocardiographic or invasive studies as needed. External measurements include determining the internipple distance and its ratio with respect to the chest circumference (Fig. 19-7). The *abdominal* examination is focused on determining whether organomegaly is present, a finding typically associated with an inborn error of metabolism. The umbilicus should also be examined, with any hernias as well as the number of vessels present in the newborn cord noted. A two-vessel cord, in which only a single artery is present, can be associated with renal anomalies. The *genitourinary* examination concentrates on determining whether anomalies such as hypospadias, chordee, cryptorchidism, microphallus, and ambiguous genitalia are present. These external anomalies may be associated with internal anomalies involving the upper urinary tract as well. The anus is examined for evidence of tags, its placement, and its patency.

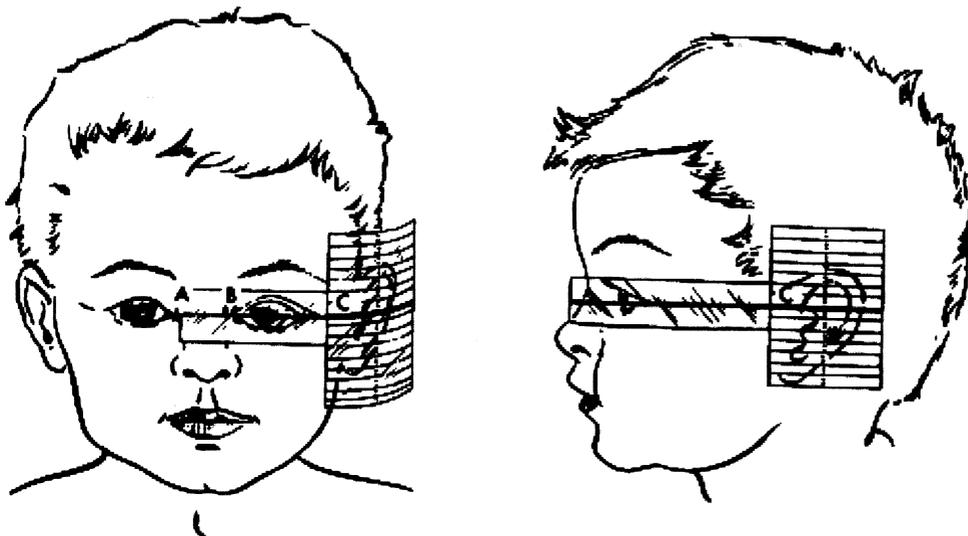

The *back* should be assessed especially for the shape of the *spine* and any associated defects, such as myelomeningo-

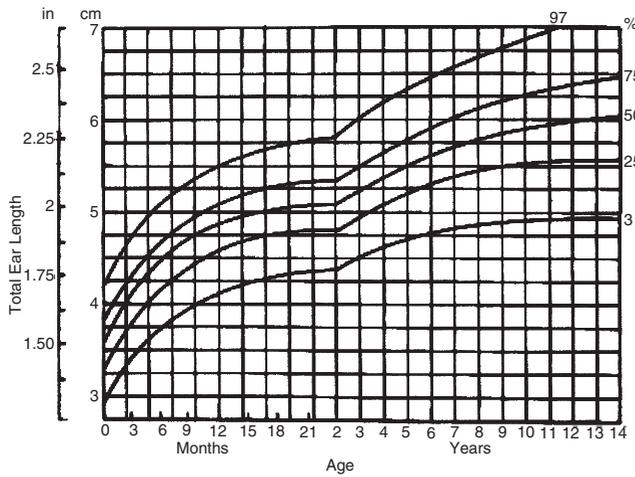

**FIGURE 19-4.** A graph of palpebral fissure length from birth to age 16 years for both sexes. (From Hall JG, Froster-Iskenius UG, Allanson JE: *Handbook of Normal Physical Measurements. Oxford, UK, Oxford University Press, 1989.*)

cele. These defects prompt further radiologic evaluation to assess for potential functional limitations. Additionally, a sacral dimple or hair tuft at the base of the spine should be noted because either could signify developmental abnormalities in the underlying neural tissue.

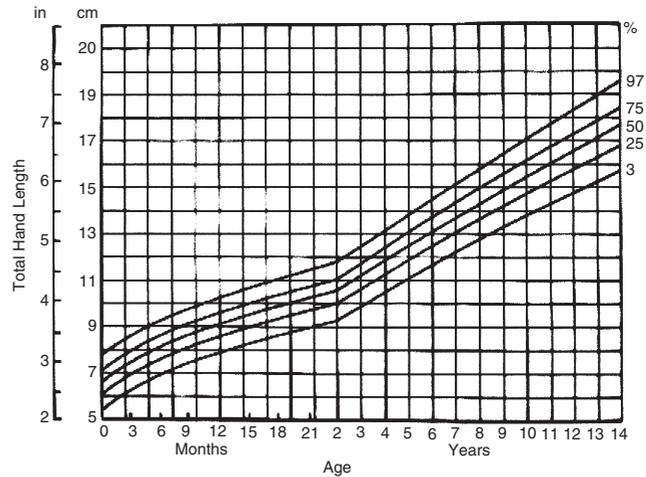

Minor anomalies are often manifested in the extremities. Gross differences in the hands and feet include polydactyly (more than five digits; whether the extra digits are located in a pre-axial or post-axial position should be noted, syndactyly (fusion of the digits), clinodactyly (incurving of the digits), and extremity length, which should be expressed as

**FIGURE 19-5.** Ear placement. Using the medial canthi (A and B) as landmarks, one draws a central horizontal line and extends it to a point (C) on the side of the face. Ears placed below this line are considered low set.

**FIGURE 19-6.** Graph showing various percentiles for ear length plotted against age. (From Feingold M, Bossert WH: *Normal values for selected physical parameters: An aid to syndrome delineation. Birth Defects 10:1-16, 1974.*)

a percentile measured on age-appropriate graphs (Figs. 19-8 and 19-9). Often these data can provide important clues to a unifying syndrome.

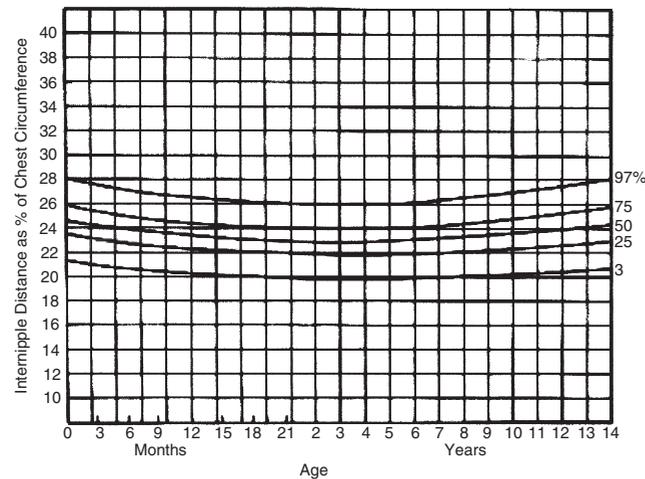

Dermal ridge patterns, or *dermatoglyphics*, are formed on the palms and soles early in embryonic life, and vary considerably among individuals. This variation can be inherited and can be influenced by disturbances to the development of the peripheral limb buds. Environmental exposures and chromosomal aberrations can greatly affect the formation of these structures and are reflected by the dermatoglyphic pattern of an individual. Each of the distal phalanges has one of three basic dermal ridge patterns: arches, whorls, or loops (Fig. 19-10). The predominance of a single pattern can be an associated feature of a genetic disorder; for example, the occurrence of arches on eight or

more digits is a very rare event but is frequently encountered in children with trisomy 18 (Table 19-5).

Deltas, or *triradii*, form at the convergence of three sets of ridges on the palm. This junction is where the hypothenar, thenar, and distal palmar patterns converge. There are typically no triradii in the hypothenar area of the palm, but when patterning is present or is large, a distal triradius arises, which is found in only 4% of normal white persons but in 85% of patients with trisomy 21 (Down syndrome). A single transverse (simian) crease is found in 4% of controls, but in more than half of patients with trisomy 21 (Fig. 19-11) and in even greater proportions in patients with other trisomies. The hallucal area of the foot, located at the base of the big toe, also has a dermal ridge pattern, usually a loop or whorl. A simple pattern or *open field* in this region is found in less than 1% of controls but in more than 50% of patients with Down syndrome (Fig. 19-12). This unusual dermal pattern is also associated with hypoplasia of the hallucal pad and a wide space between the great and second toes in these patients.

An examination of the *skin* is also important, to look for *phakomatoses* or skin manifestations that herald the presence of an underlying disorder. Examples are café-au-lait spots (associated with neurofibromatosis type I) and ash leaf spots (associated with tuberous sclerosis and detected with the use of a Wood's lamp). Hemangiomas, irregular pigmentation, and skin diseases are noteworthy.

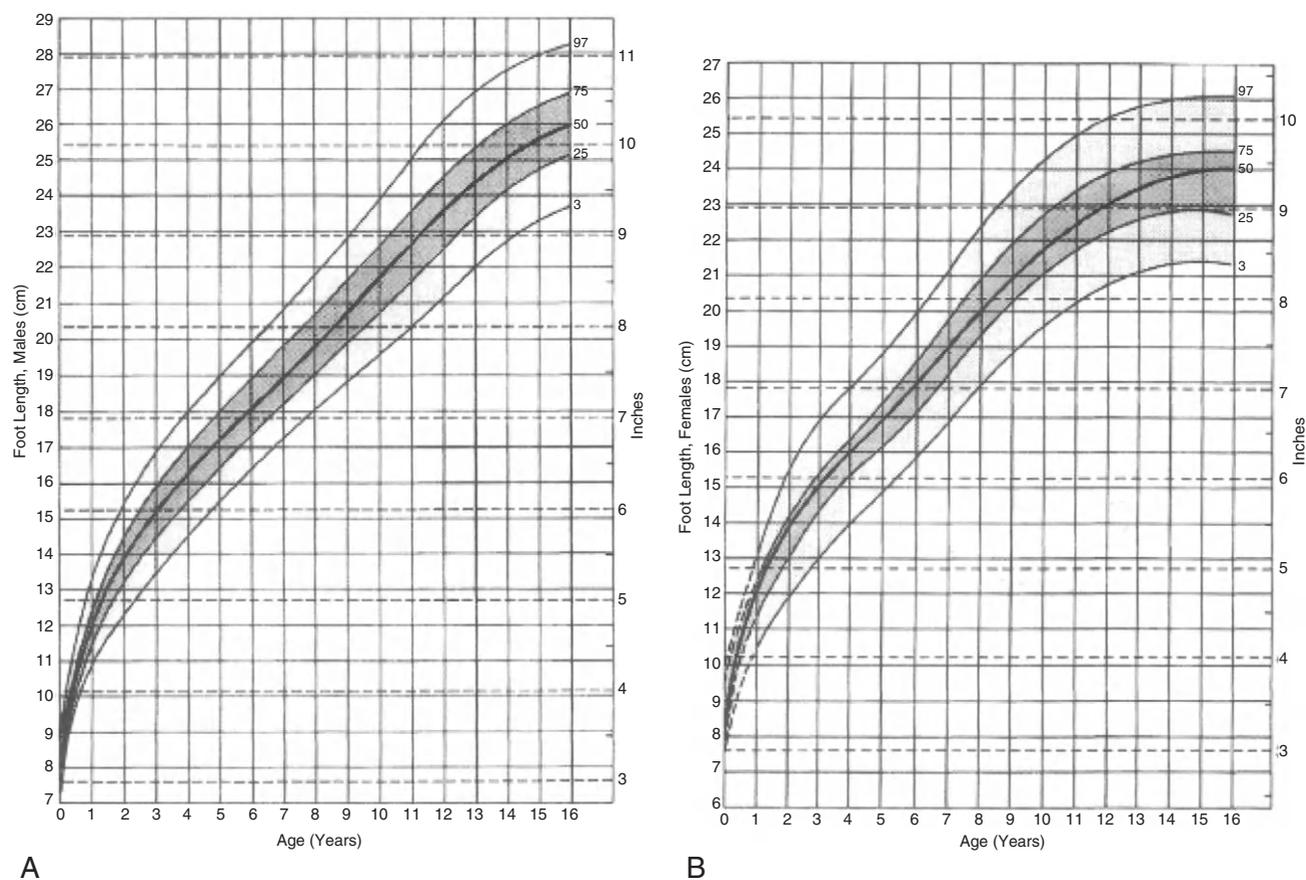

Finally, a careful neurologic examination with input from a specialist is often warranted in the child with multiple anomalies, because the neurologic status is often the most reliable prognostic indicator. Evaluation of tone, feeding, unusual movements, and the presence of seizure activity are critical pieces of diagnostic information.

**FIGURE 19-7.** The internipple distance as a percentage of the chest circumference plotted against age for both sexes. (From Feingold M, Bossert WH: *Normal values for selected physical parameters: An aid to syndrome delineation. Birth Defects 10:1-16, 1974.*)

### Adjunct Studies

An exhaustive physical examination often reveals differences that require further evaluation for diagnostic, prognostic, and treatment purposes (Table 19-6). Poor feeding

**FIGURE 19-9.** Total foot lengths plotted against age for boys (A) and girls (B). (From Hall JG, Froster-Iskenius UG, Allanson JE: *Handbook of Normal Physical Measurements*. Oxford, UK, Oxford University Press, 1989.)

or cyanosis may lead to detection of internal organ malformations on echocardiogram or abdominal ultrasonography. Differences in head shape suggest the need for skull films, three-dimensional computed tomography (CT), or magnetic resonance imaging (MRI) of the brain. A disproportion of the limbs prompts a skeletal survey and bone age measurement.

It is prudent, in children with anomalies involving multiple systems, to obtain the input of relevant specialists. This step is often essential to medical decision-making and the planning of interventions. Abnormal neurologic findings consultation from a trained specialist and interpretation of studies such as head ultrasonography, brain MRI, brainstem auditory evoked responses, and electroencephalogram (EEG) for seizure activity. Muscle dysfunction might result in the ordering of electromyography (EMG) or nerve conduction studies. Visual involvement requires a funduscopic examination by an experienced pediatric ophthalmologist, and sometimes, studies of visual evoked responses or electroretinograms are needed to predict visual prognosis. Often, there are well-characterized genetic disorders that have a specific pattern of abnormal findings on these highly specialized studies. Even when a unifying diagnosis is reached, there is often variation in the clinical phenotype, and determining the patient's prognosis on a system-by-system basis is typically the most appropriate and accurate way to proceed.

## LITERATURE REVIEW

The occurrence of malformations can fit into one of several categories (Table 19-7). The next step toward reaching a diagnosis is to analyze the data generated from the evaluation and attempt to categorize the findings. A *syndrome* is a "collection of anomalies involving more than one developmental region or organ system." The word itself means a "running together" or "pattern of multiple anomalies thought to be pathogenetically related." Thus, a given congenital anomaly may be an isolated defect in an otherwise normal person or part of a multiple malformation syndrome. Further, the primary malformation itself can determine additional defects through an interrelated cascade of physical and functional processes; if ensuing malformations are related to one primary defect, factor, or event, a pathogenetic *sequence* has occurred. A classic example is the Pierre-Robin sequence or constellation, consisting of a small recessed jaw, midline U-shaped cleft palate, and relatively large and protruding tongue. The primary anomaly is the small jaw, which does not allow adequate room for the tongue and displaces it superiorly. The displaced tongue prevents closure of the palatine shelves, causing the cleft palate. The recurrence risk with this isolated occurrence is negligible. However, one should also remember that such sequences can also be part of a larger constellation of findings that does fit into a

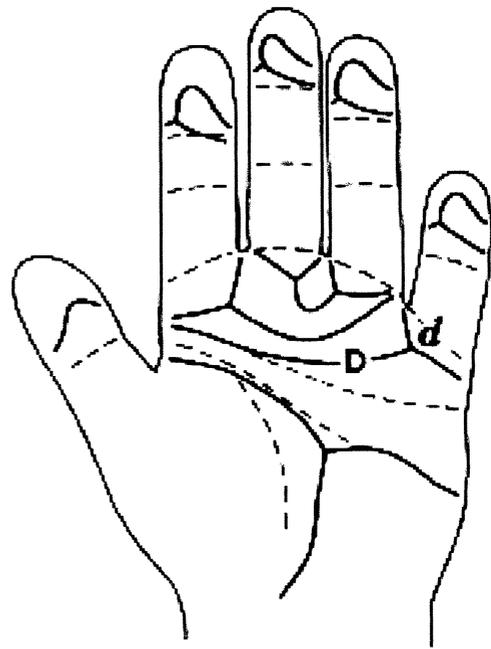

**FIGURE 19-10.** Basic fingerprint patterns (dermatoglyphics). (From Holt SB: *The Genetics of Dermal Ridges*. Springfield, IL, Charles C Thomas, 1968.)

syndrome, as Pierre-Robin sequence can when it is part of velocardiofacial syndrome (caused by a deletion of chromosome 22q11) or Stickler syndrome (associated with mutations in the type II collagen gene). The recurrence risk for an affected individual passing on these syndromes to their children is 50%.

**TABLE 19-5**

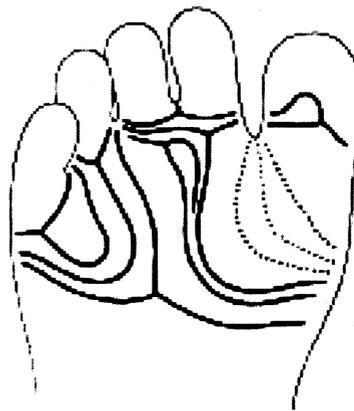

**Dermatoglyphic Patterns Associated with Specific Dysmorphic Disorders**

Dermatoglyphic Pattern	Associated Disorder(s)
Excess arches	Trisomy 13, trisomy 18, Kline felter syndrome (47,XXY) Deletion chr 5p (cri du chat), fetal phenytoin exposure
Excess ulnar loops	Trisomy 21
Excess whorls	Smith-Lemli-Opitz syndrome Turner syndrome (45,X0)

**FIGURE 19-11.** The patterns on the hand of a patient with trisomy 21 (Down syndrome) depicting the palmar crease (D). (From Holt SB: *The Genetics of Dermal Ridges*. Springfield, IL, Charles C Thomas, 1968.)

Additionally, a cluster of several malformations that are not developmentally related can occur in a nonrandom fashion called an *association* that may appear without characteristic dysmorphic features. The CHARGE association (coloboma, heart disease, atresia choanae, retarded growth and development, genital anomalies, and ear anomalies/deafness) is an example. It should be noted that not all features need to be present and that the extent of involvement of each system is widely variable. Another such statistically nonrandom association of defects consists of vertebral defects, imperforate anus, tracheoesophageal fistula, and radial or renal dysplasia (VATER). Cardiac defects can also be a feature of the VATER spectrum.

**FIGURE 19-12.** The distal sole of the foot of a patient with trisomy 21, depicting the characteristic “open field” pattern. (From Holt SB: *The Genetics of Dermal Ridges*. Springfield, IL, Charles C Thomas, 1968.)

Identification of organ systems involved	Prognosis
	Treatment and intervention

These associations often manifest as sporadic rather than familial occurrences. Because they are not clearly related by a common etiology or pathogenesis, they are not considered syndromes and do not technically constitute a diagnosis. Instead, they are a recognition of a statistically significant association of features. It is important to remember that many of these same anomalies can occur as features of chromosomal aneuploidy or other syndromes. Syndromic malformations tend to occur in more than one developmental field. A *field defect* or complex is a set of primary malformations in a developmental field that originates from a single or primary abnormality in embryonic development (see Table 19-7).

When generating a differential diagnosis of malformations that might occur together, the evaluator must also consider structures that may look “abnormally formed” but in fact are structures that underwent normal development and then received some insult that distorted their true form (Table 19-8). For example, a *deformation* describes the abnormal form, shape, or position of a part of the body that was caused by mechanical forces. Examples are clubfoot, a hip dislocation, and craniofacial asymmetry. They can result from intrinsic (embryonic) or extrinsic (intrauterine) mechanical forces that alter the shape or position of an organ or part that had already undergone *normal* differentiation. Deformations are estimated to occur in 2% of births, and such factors as fetal crowding from the presence of multiple fetuses and uterine malformations, as well as oligohydramnios and a face presentation during delivery can cause them.

TABLE 19-7

**Underlying Mechanisms of Malformation**

Syndrome	Pathogenetically related pattern of anomalies
Sequence	Pattern of anomalies derived from a presumed or known prior anomaly or mechanical disturbance
Association	Nonrandom occurrence of multiple anomalies
Field defect	Disturbance of a developmental field leading to a pattern of anomalies

TABLE 19-8

**Processes Leading to Altered Form or Structure**

Deformation	Abnormal form resulting from mechanical forces
Disruption	Morphologic defect caused by interference with a previously <i>normal</i> developmental process
Dysplasia	Altered morphology due to abnormal organization of cells into a given tissue

Along similar lines, a *disruption* describes a “morphologic defect of an organ, part of an organ, or larger region of the body resulting from the extrinsic breakdown of, or an interference with, an originally normal developmental process.” The classic example of a disruption is entanglement of the fetus in amniotic bands. Amniotic bands are ribbons of amnion that have ruptured in utero and cause disruptions of normal developmental processes in the fetus, either through physical blockage or interruption of the blood supply or by entangling and tearing of developing structures. This effect is most often seen with digits and limbs, and remnants of the bands, or constriction marks, can frequently be seen at birth. If the fetus should swallow a band, a cleft palate might result; the etiology is a very different etiology from that of cleft palate occurring as a primary malformation. Counseling of the parent would be very different in these two scenarios.

*Dysplasias* occur when there is “an abnormal organization of cells into tissue(s) and its morphologic results.” Dysplasia tends to be tissue specific rather than organ specific (e.g., skeletal dysplasia) and can be localized or generalized.

In summary, structural or morphologic changes identified at birth can occur during intrauterine development as a result of malformations, deformations, disruptions, or dysplasia. However, approximately 90% of deformations undergo spontaneous correction. Malformations and disruptions often require surgical intervention, when possible. Dysplasias are typically not correctable, and the affected individual experiences the clinical effects of the underlying cell or tissue abnormality for life (see Table 19-8). Examples of these entities are listed in Table 19-9.

After the history and physical evaluation are complete, a cross-reference of two or more anomalies is useful to generate a differential diagnosis. When the rest of the baby’s physical and history findings are added, the possibilities can often be narrowed down to a few entities that

TABLE 19-9

**Examples of Morphologic Differences**

Malformation	Cardiac septal defects, cleft lip
Deformation	Club foot
Disruption	Amniotic bands
Dysplasia	Localized: hemangioma
	Generalized (skeletal): achondroplasia

may be amenable to diagnostic testing. If multiple anomalies are present, it is usually best to start with the least common. As Aase (1992) has stated, “The best clues are the rarest. The physical features that will be the most helpful on differential diagnosis are those infrequently seen either in isolation or as part of syndromes. Quite often, these are not the most obvious anomalies or even the ones that have the greatest significance for the patient’s health.” Cross-referencing is usually best accomplished by using published compendia of malformation syndromes. These compendia have been supplemented by databases that are accessible on line (GeneTests, on line; OMIM, on line; PubMed, on line). The availability of such tools allows the cross-referenced features to be easily compared with those of other described syndromes that may include similar malformations. This systematic review produces a differential diagnosis for the constellation of features described and identifies references to pertinent literature.

Thus, the recognition of patterns of genetic entities involves the comparison of the proband with the examiner’s personal experience of known cases and a search of the literature. Multiple anomalies may be causally related, may occur together in a statistically associated basis, or may occur together merely by chance. Diagnosis of a genetic disorder relies heavily on the ability of the clinician to suspect, detect, and correctly interpret physical and developmental findings and to recognize specific patterns. Accurate diagnosis of a syndrome in a child is important to the identification of major complications and their treatment if possible. It is also crucial for long-term management of patients and for parental counseling about recurrence in future offspring.

### SPECIALIZED LABORATORY TESTS

In sorting through the array of possibilities listed, the geneticist utilizes one other important tool: the availability of highly specialized cytogenetic and molecular genetic testing, including:

- Karyotype
- Fluorescence in situ hybridization (FISH)
- Subtelomeric FISH
- Molecular analysis

The standard *karyotype*, or analysis of stretched and stained chromosome preparations usually taken from a peripheral blood sample, can often confirm a suspected diagnosis or explain a set of major malformations not classically encountered together. Further description of specific chromosomal abnormalities is addressed in Chapter 20; it is sufficient to note here that multiple malformation syndromes can result from large visible chromosome rearrangements that lead to deletion or addition of material (aneuploidy). These rearrangements can involve an entire arm of a chromosome or can be submicroscopic, requiring further special testing. Such small deletions can often be detected by *fluorescence in situ hybridization* (FISH) analysis, which is performed using a probe specific for the deleted region. FISH analysis utilizing probes from the tips of all chromosomes (*subtelomeric FISH*) has

uncovered previously undetectable rearrangements that could explain the patient’s clinical findings.

It has become the standard of care in several centers to offer such testing as an adjunct to karyotype analysis for newborns with multiple malformations that do not clearly fit into a recognizable syndrome. Additionally, as more information is becoming available about the role of mutations in specific individual genes, testing for these mutations is also becoming clinically available as an important confirmatory test. It can be useful to check with a geneticist or genetics counselor for the availability of gene mutation testing that may be performed on a research or diagnostic basis. GeneTests (on line) is one Web-based database of laboratories worldwide that provides such services. A more extensive discussion of single-gene disorders that can manifest in newborns is provided in Chapter 17.

### DIAGNOSIS

There are, however, cases in which, even after a detailed examination, exhaustive literature search, and genetic testing, no unifying diagnosis is evident. Aase (1992), a dysmorphologist, advises, “Don’t panic! The absence of a diagnosis may be distressing to the diagnostician and the family, but it is much less dangerous than the possibility of assigning the wrong diagnosis with the risk of erroneous genetic and prognostic counseling and possibly hazardous treatment.” Thus, in cases in which there is no clear diagnosis, prognosis and treatment should be determined according to the organ systems involved and the extent of their impairment. Additionally, when the infant has a severe untreatable impairment or the patient’s condition is critical, it may be prudent to offer and obtain consent for a full postmortem examination by an experienced pathologist. A blood or skin sample should also be taken for establishing a cell line or for extracting DNA for future testing. Information gained from such investigations may often become relevant for family members, including the parents, allowing one to provide accurate recurrence risk counseling and perhaps offer prenatal testing of a new pregnancy. Such information can often help provide closure for the family as well.

When should a genetics evaluation be considered? The following clinical situations prompt a further genetic evaluation and counseling by a specialist:

- Multiple anatomic anomalies
- History of maternal exposure to teratogens
- Familial disorders
- Increased carrier frequency or ethnic risk
- Multiple pregnancy losses

As described previously, if a birth defect is identified in the presenting patient or *proband*, especially if the defect is associated with other anatomic anomalies, short stature, or developmental delays, the features of a specific genetic syndrome may be present. A known history of maternal exposure to a potential teratogen would also be an indication for consultation. Conditions appearing to be familial, or a family history of hereditary disorders involving malformation of a major organ, or major physical differences such as

unusual body proportions, short stature, or irregular skin pigmentation, would warrant genetic investigation. Mental retardation, blindness, hearing loss, or neurologic deterioration in multiple family members suggests a genetic etiology. Likewise, a strong family history of cancer or a defined ethnic risk such as Ashkenazi Jewish heritage and its association with a higher carrier frequency for Tay-Sachs disease would be an indication for genetic evaluation. The occurrence of multiple pregnancy losses would also raise the suspicion of a genetically influenced cause and indicate the need for further investigation and counseling.

### CONCLUSION

Diseases with underlying genetic bases have significant effects on health care and its delivery. An appreciation of these entities, coupled with an organized, systematic evaluation, can help define the nature of a given disorder and aid in development of the optimal plan of treatment and care for the patient.

## Specific Chromosome Disorders in Newborns

Sulagna C. Saitta and Elaine H. Zackai

It has been estimated that 3% of newborns have a major structural anomaly that will affect their quality of life. Although most of these patients have a single malformation, 0.7% of infants have multiple major malformations. In an additional 2%, a major anomaly is discovered by age 5 years. Early identification of the genetic nature of a given condition can aid in treatment and help to identify resources for providing better health care to these individuals. Here we focus on genetic disorders and syndromes with underlying chromosomal abnormalities that typically manifest in the newborn period (see OMIM for a detailed online database).

### HUMAN KARYOTYPE

Chromosomes consist of tightly compacted DNA whose structure is maintained by association with histones and other proteins. When treated and stretched, chromosomes from dividing cells can be visualized under the light microscope as linear structures with two *arms* joined by a *centromere*. The short arm is designated *p* (*petit*) and the long arm is designated *q*. The ends of the *p* and *q* arms are known as *telomeres*. Human chromosomes were first visualized in 1956 (Lejeune and Turpin et al), and each pair shows a distinctive size, centromeric position, and staining or banding pattern after treatment with special dyes, allowing it to be identified and classified. Each chromosome is identified by a number, in general from largest to smallest, in standard international cytogenetic nomenclature. This presentation, or *karyotype* (Fig. 20–1), normally consists of 46 chromosomes, with 22 pairs of autosomes and one set of sex chromosomes—two X chromosomes for females (46,XX), and an X and Y for males (46,XY).

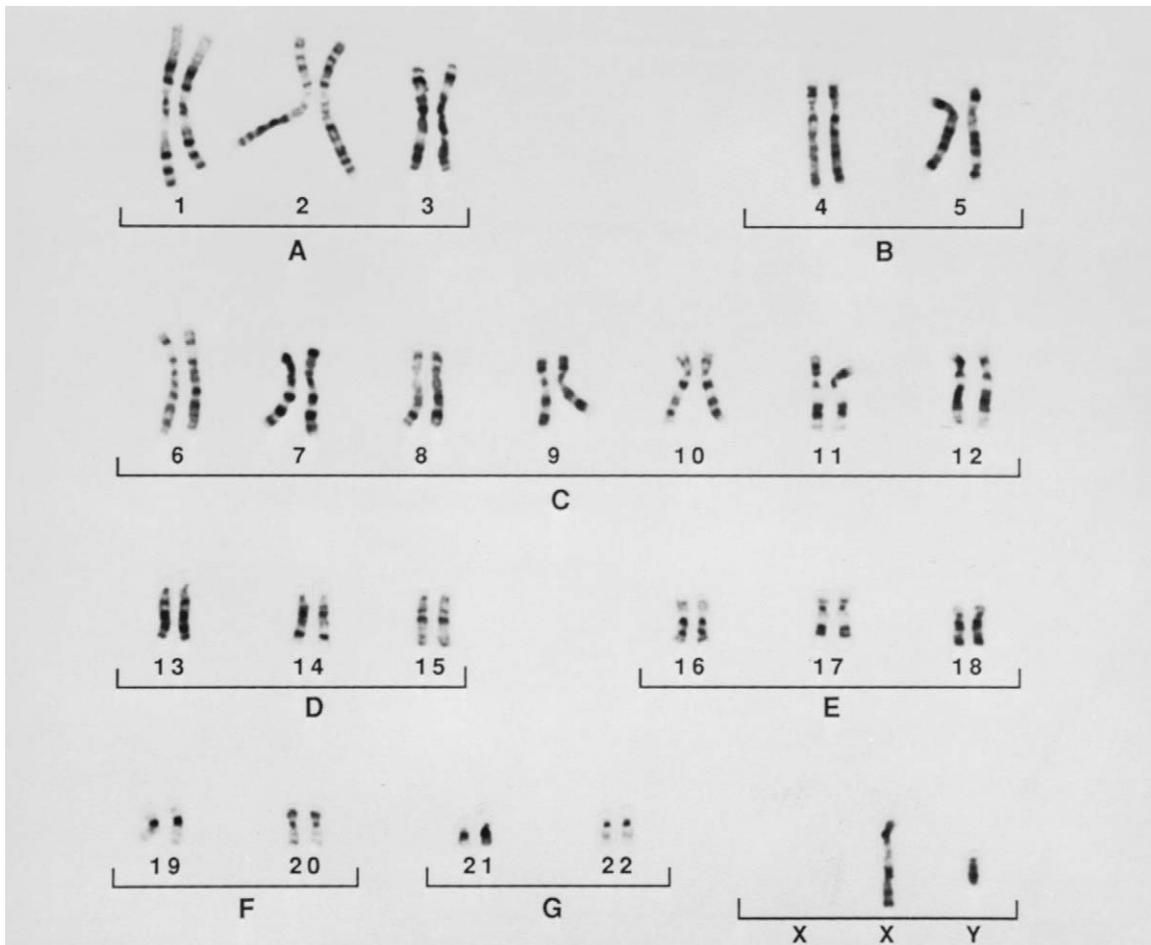

Karyotype analysis is performed in cells undergoing *mitosis*, or cell division, in which the chromosomes condense and can be stained and visualized. Thus, cells that can be stimulated to divide and grow in culture, such as peripheral blood lymphocytes, skin fibroblasts, and amniocytes, are typically used. Alternatively, cells normally undergoing rapid cell division, such as bone marrow and chorionic villus, can also be used successfully. Historically, several different staining methods have been described, however, G-banding (Giemsa staining) is the standard cytogenetic method used. This technique permits a resolution of at least 400 bands among all of the chromosomes and can be adapted to allow for high-resolution analysis of up to 800 bands to analyze subtle differences.

Gamete formation, either spermatogenesis or oogenesis, is accomplished by a process known as *meiosis*. In the first part of meiosis (*meiosis I*), homologous chromosomes line up as pairs and cross over, exchanging genetic material, also known as *recombination*. In the next stage, *meiosis II* or reduction division, the recombined pairs separate, and the typical *diploid* content (46 chromosomes) of the cell is reduced by half to a *haploid* complement of 23 chromosomes. The full diploid state of the cell will be restored at the time of fertilization.

An imbalance of genetic material, or *aneuploidy*, can occur from a net loss or gain of genetic material during sperm or egg formation or, less commonly, during the initial divisions of the embryo. This missing or extra genetic material can be small pieces or parts of chromosomes or an entire chromosome itself. The classic recognizable aneuploidy syndromes involve *trisomy* (three copies of a given chromosome) such as those of chromosomes 13, 18, 21, or *monosomy* (only a single copy) of a complete chromosome, such as X. Trisomies, especially, can occur from *non-disjunction*, a failure of normal chromosome separation. In such cases, a pair of homologues does not separate in meiosis; one daughter cell receives both homologues of that pair, and the other cell receives none. This can occur in either part of gamete division, meiosis I or meiosis II. Most human meiotic non-disjunctions occur in oocyte formation, specifically in maternal meiosis I. This is especially pronounced in trisomies of the acrocentric chromosomes (13, 14, 15, 21, and 22) and in XXX trisomy (MacDonald et al, 1994; Zaragoza et al, 1994). The occurrence of meiotic non-disjunction increases significantly with maternal age. Thus, prenatal karyotyping from amniocentesis or chorionic villus sampling (CVS) is offered to women ages 35 years and older (Hook and Cross, 1982).

Non-disjunction can also occur in mitosis, with uneven division of genetic material during early embryonic cell division. This can result in two cell lines, one *trisomic* lineage that is potentially viable and another *monosomic* line. If this event occurs after the first postzygotic division, cells with a normal chromosome complement may also exist with cells containing an aneuploid complement as a *mosaic* chromosome constitution.

Partial aneuploidies can occur through several mechanisms, such as rearrangements of material between nonhomologous chromosomes that can occur in the gametes of a balanced translocation carrier. The carrier parent who has no net loss or gain of genetic material is usually phenotypically normal; however the offspring are at increased risk for an unbalanced rearrangement and its phenotypic consequences. Attention has also been focused on deletion syndromes caused by the loss of genetic material from several chromosomes (e.g., 1p-, 4p-, 5p-), with a resulting, often recognizable phenotype. Other microdeletions have been associated with segmental duplications, or large blocks of DNA that contain chromosome-specific repetitive sequences. It is thought that the repeats can mediate misalignment between two homologues and have been shown to be present in regions of the genome prone to instability, such as the pericentromeric regions of

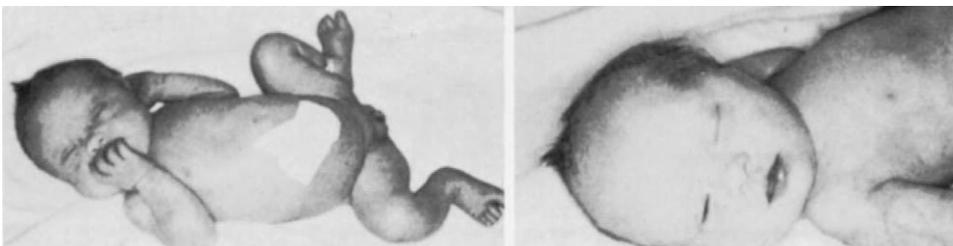

**FIGURE 20-1.** G-banded human male karyotype. The 46 chromosomes are arranged into 23 pairs, each with a specific banding pattern.

chromosomes 7q11, 15q11, 17q11, and 22q11, leading to the phenotypes seen in Williams-Beuren syndrome, Prader-Willi or Angelman syndrome, Charcot-Marie-Tooth disease or hereditary neuropathy with liability to pressure palsies (HNPP), and DiGeorge or velocardiofacial syndrome, respectively (Emanuel and Shaikh, 2001; Lupski, 2002). The advent and application of highly specific *fluorescent in situ hybridization* (FISH) probes to assess for these submicroscopic deletions as well as of chromosome-specific subtelomeric FISH (see later) has allowed the identification of smaller chromosomal rearrangements that were largely unrecognized only a decade ago.

## TRISOMIES

### Trisomy 21 (Down Syndrome)

In 1959, Lejeune and coworkers demonstrated that trisomy of human chromosome 21 caused the constellation of findings recognized as Down syndrome (Fig. 20-2). This was the first described chromosome disorder and is the most common viable autosomal trisomy, occurring in about 1 in 700 to 800 live births (Hook, 1992). The vast majority (>90%) occurs secondary to meiotic non-disjunction, and a pronounced maternal age effect is encountered. Approximately 3% to 5% of cases are due to a translocation, passed

**FIGURE 20-2.** Newborn with Down syndrome (trisomy 21) illustrating some of the characteristic facial features, including upslanting palpebral fissures and a flat facial profile.

from a balanced translocation-carrier parent, that becomes unbalanced and trisomic in the baby. Typically, the translocated chromosome 21 rearranges with another acrocentric chromosome (often chromosome 14), resulting in a robertsonian translocation. Mitotic non-disjunction, or mosaic Down syndrome, has been demonstrated in approximately 3% of cases as well, with variable features ranging from normal to a typical Down syndrome phenotype.

### Clinical Features

It is the more common occurrence of Down syndrome in the babies of older mothers that has led to the use of prenatal karyotyping for advanced maternal age (>35 years) at the time of conception, with samples typically obtained by amniocentesis after 15 weeks of gestation, or CVS at 10 to 12 weeks. Maternal serum analyte (triple- or quadruple-screen) testing is for prenatal screening purposes. Associated ultrasonographic findings for trisomy 21, including a cardiac defect, shortened long bones, nuchal translucency or thickening, echogenic small bowel, and duodenal atresia (double-bubble sign), may be seen in 50% to 60% of fetuses with trisomy 21. Most patients with Down syndrome, if not diagnosed prenatally, are usually recognized at birth because of the typical phenotypic features, which then prompt karyotype analysis.

The constellation of physical findings associated with trisomy 21 consists of brachycephaly, presence of a third fontanelle, upslanted palpebral fissures, epicanthal folds, Brushfield spots in the irises, flattened nasal root, small posteriorly rotated ears, prominent tongue, short neck with excess nuchal skin, single palmar creases, brachydactyly, fifth-finger clinodactyly, exaggerated gap between first and second toe, open field hallucal pattern, and hypotonia (see Fig. 20–2). Often the physical features conform to an easily distinguishable phenotype, but in some cases, prematurity or ethnic variations may make a clinical diagnosis difficult. In any case, an immediate karyotype is indicated to confirm the diagnosis and as preparation for counseling of the family.

Malformations involving many organ systems have been described in trisomy 21, and whether the diagnosis is known prenatally or determined in the newborn period, several clinical investigations are warranted when this diagnosis is suspected. The most common malformation is congenital heart disease (up to 60%; Epstein, 2001), which typically requires surgical intervention. Atrioventricular canal defects are often encountered (mean of 40%), although ventricular septal defects (VSDs), atrial septal defects (ASDs), tetralogy of Fallot, and patent ductus arteriosus (PDA) are all described in the disorder. Thus, an echocardiogram is indicated in all cases, and medical and surgical intervention of cardiac lesions is routine. Gastrointestinal malformations, especially duodenal atresia (2% to 5%), and Hirschsprung disease as well as less frequently encountered conditions, such as esophageal atresias, fistulas, and webs throughout the tract, have been described. It is critical to carefully monitor the baby's feeding and bowel function before considering discharge.

Although growth parameters can be in the range of 10% to 25% at birth, significantly decreased postnatal

growth velocity is encountered in these patients (Clementi et al, 1990). Separate growth curves have been devised for patients with trisomy 21 (Fernandes et al, 2001), because growth retardation involving height, weight, and head circumference has been well documented. An initial ophthalmologic evaluation is also indicated in the first few months of life and then annually, because strabismus, cataracts, myopia, and glaucoma have been shown to be more common in children with trisomy 21. Additionally, hearing loss of heterogenous origin is present in approximately half of patients, with middle ear disease contributing to this problem.

Spinal cord compression due to atlantoaxial subluxation and subsequent neurologic sequelae can be a complication of the disorder, and physicians should be vigilant in evaluating the cervical spine especially before administration of anesthesia as well as before an older child's participation in sports. The instability is thought to be due to ligamentous laxity in the region. Other associated disorders that merit screening are hypothyroidism, described in approximately 5% of patients with trisomy 21, often with the presence of thyroid autoantibodies. Additionally, bone marrow dyscrasias, such as neonatal thrombocytopenia, and transient self-resolving myeloproliferative disorders, such as leukemoid reaction, have been observed in the first year of life. An elevated rate of leukemia with a relative risk of 10 to 18 times normal up to age 16 years has been described. Acute nonlymphoblastic leukemia (ANLL) is seen at higher rates in congenital or newborn cases, but the distribution becomes similar to that of non-trisomy 21 patients after age 3 years. Survival of patients with Down syndrome is shorter after a diagnosis of acute lymphoblastic leukemia (ALL) than in diploid patients (Epstein, 2001).

Patients with trisomy 21 demonstrate a wide range of developmental abilities, with highly variable personalities and behavioral phenotypes as well (Pueschel et al, 1991). Central hypotonia with concomitant motor delay is most pronounced in the first 3 years of life, as are language delays. Thus, immediate and intensive early intervention and developmental therapy are critical for maximizing the developmental outcome. A wide IQ range has been described, with conflicting data on genetic and environmental modifiers of outcome (Epstein, 2001). Seizure disorders occur in 5% to 10% of patients, often manifesting in infancy.

The most common causes of death in patients with trisomy 21 are related to the congenital heart disease, to infection that is thought to be associated with defects in T-cell maturation and function, and to malignancy (Fong and Brodeur, 1987). Once medical and surgical interventions for correction of associated congenital malformations are complete and successful, the long-term survival rate is good. However, less than half of patients survive to 60 years, and less than 15% past 68 years. Neurodegenerative disease with features of Alzheimer disease is encountered in most patients with trisomy 21 who are older than 40 years, although frank dementia is not typical. Men with trisomy 21 are almost always infertile, while small numbers of affected women have reproduced (Epstein, 2001).

In counseling the family of a newborn diagnosed with trisomy 21 or Down syndrome, it is important to include

the organ systems affected in their baby and the severity of each malformation when defining a prognosis. Above all, the wide variability of the phenotype should be emphasized, with a care plan tailored to the needs of the individual patient.

### Genetic Counseling

If a complete (full chromosome) or mosaic trisomy 21 is found, parental karyotypes are generally not analyzed, because in virtually all cases, the karyotypes are normal. After having one child with trisomy 21, a mother's recurrence risk for another affected child is approximately 1% higher than her age-specific risk (Hook, 1992). This fact is especially significant in younger mothers, whose age-specific risks are low. If a *de novo* translocation resulting in trisomy 21 is found, the recurrence risk is less than 1%. If the mother is found to carry a constitutional balanced robertsonian translocation, the risk for another translocation Down syndrome fetus is about 15% at the gestational age when amniocentesis is offered, and 10% at birth. However, if the father is the translocation carrier, the recurrence risk is significantly smaller, approximately 1% to 2% (Epstein, 2001).

### Trisomy 18 (Edwards Syndrome)

Trisomy 18 is encountered in 1 in 6000 live births and is associated with a high rate of intrauterine demise. It is estimated that only 5% of conceptuses with trisomy 18 survive to birth and that 30% of fetuses diagnosed by second-trimester amniocentesis die before the end of the pregnancy (Hook, 1992). Findings on prenatal ultrasonography can raise suspicion for the disorder—growth retardation, oligohydramnios or polyhydramnios, heart defects, myelomeningocele, clenched fists, excess of arches on dermatoglyphic examination, and limb anomalies. Maternal serum analyte or triple screening can show low values for alpha-fetoprotein, estradiol, and total human chorionic gonadotropin, indicating subsequent karyotype analysis and fetal ultrasonographic monitoring.

### Clinical Features

Phenotypic features present at birth consist of intrauterine growth restriction (1500 to 2500 g at term), small narrow cranium with prominent occiput, open metopic suture, low-set posteriorly rotated ears, micrognathia with small mouth, clenched hands with overlapping digits, hypoplastic nails, and “rocker-bottom” feet or prominent heels with convex soles (Fig. 20–3). Additional malformations encountered in this syndrome are congenital heart disease (ASD, VSD, PDA, pulmonic stenosis, aortic coarctation), cleft palate, clubfoot deformity, renal malformations, brain anomalies, choanal atresia, eye malformations, vertebral anomalies, hypospadias, cryptorchidism, and limb defects, especially of the radial rays.

The prognosis in this disorder is extremely poor, with more than 90% of babies succumbing in the first 6 months of life and only 5% alive at 1 year. Death is due to

**FIGURE 20-3.** Newborn with trisomy 18, showing prominent occiput, characteristic facial appearance, and clenched hands.

central apnea, infection, and congestive heart failure. The newborn period is characterized by poor feeding and growth, typically requiring tube feedings. A few patients have been described who have survived into childhood and beyond. Universal poor growth and profound mental retardation with developmental progress not beyond that of a 6-month-old infant (Baty et al, 1994) have been documented. Malignant tumors such as hepatoblastoma, and Wilms tumor, have been described in some of the survivors. In the few patients in whom cardiac surgery was performed, outcome was not shown to be improved.

### Genetic Counseling

The typical estimate of a recurrence risk for trisomy 18 in a future pregnancy is a 1% risk over the maternal age-specific risk for *any* viable autosomal trisomy (Hook, 1992). Trisomy occurring from a structural rearrangement such as a translocation warrants parental karyotype analysis before the recurrence risk can be assessed.

### Trisomy 13 (Patau Syndrome)

It has been estimated that only about 2% to 3% of fetuses with trisomy 13 survive to birth, with a frequency of 1 in 12,500 to 21,000 live births (Hook, 1992). As with other trisomies, amniocentesis performed for advanced maternal age or indicated by fetal ultrasonographic findings may lead to a prenatal diagnosis of trisomy 13.

### Clinical Features

Trisomy 13-associated malformations include congenital heart disease, cleft palate, holoprosencephaly, renal anomalies, and postaxial polydactyly (Fig. 20–4). Additionally, microcephaly, eye anomalies, and scalp defects can suggest the diagnosis. Brain malformations such as

**FIGURE 20-4.** Stillborn with trisomy 13. The facial appearance is that of cebocephaly, which is associated with holoprosencephaly. There is an extra digit on the ulnar border of the right hand.

holoprosencephaly are found in more than half the patients, with concomitant seizure disorders. Microcephaly, split sutures, and open fontanelles are encountered. A scalp defect (cutis aplasia) that can sometimes be mistakenly attributed to a fetal scalp monitor is quite specific to the disorder, being found in 50% of cases. Eye malformations, including iris colobomas and hamartomatous cartilage “islands,” can be found on funduscopic examination.

Congenital heart disease is present in about 80% of patients, usually VSD, ASD, PDA, or dextrocardia. Limb anomalies, such as postaxial polydactyly, single palmar creases, and hyperconvex narrow fingernails, are also seen. The fingers can be flexed and overlapped, and can show camptodactyly as well. An increased frequency of nuclear projections in neutrophils, giving a “drumstick” appearance similar to that of Barr bodies, can also be found. This finding would be especially striking in males, in whom Barr bodies would not be expected.

As with trisomy 18, prognosis for the fetus with trisomy 13 is extremely poor, with 80% mortality in the neonatal period, and less than 5% of patients surviving to age 6 months. Mental retardation is profound, and many

patients are blind and deaf as well. Feeding difficulties are typical.

### Genetic Counseling

Recurrence risk data suggest that as with trisomy 18, the chance that a woman will have a child with any trisomy after a pregnancy affected by trisomy 13 is rare. The estimated risk is 1% higher than the maternal age-related risk for the recurrence of any viable autosomal trisomy in a subsequent pregnancy.

### Turner Syndrome (45,X0)

In early embryogenesis, two active X chromosomes are required for normal development. Turner syndrome, a phenotype associated with loss of all or part of one copy of the X chromosome in a female conceptus, occurs in approximately 1 in 2500 female newborns. The 45,XO karyotype or loss of one entire X chromosome accounts for roughly half the cases. A variety of X chromosome anomalies, including deletions, isochromosomes, and translocations, account for the remainder of the causes. It is important to note that only about 0.1% of fetuses with a 45,XO complement survive to term, the vast majority (>99%) being spontaneously aborted; this fact underscores the requirement for both X chromosomes during embryonic development. Further studies indicate that in approximately 80% of cases, it is the paternally derived X chromosome that is lost (Willard, 2001).

### Clinical Features

There is wide phenotypic variability in patients with Turner syndrome. Features present at birth include short stature, webbed neck, craniofacial differences (epicanthal folds and high arched palate), hearing loss, shield chest, renal anomalies, lymphedema of the hands and feet with nail hypoplasia, and congenital heart disease. Typical cardiac defects are bicuspid aortic valve, coarctation of the aorta, valvular aortic stenosis, and mitral valve prolapse.

Growth issues, especially short stature, are the predominant concern in childhood and adolescence; the mean adult height of patients with Turner syndrome is 135 to 150 cm without treatment. Growth hormone therapy, which is routinely offered starting around age 4 to 5 years, can lead to an average gain of 6 cm or more in final adult height (Willard, 2001). Primary ovarian failure due to gonadal dysplasia (streak gonads) can result in delay of secondary sexual characteristics and primary amenorrhea. Cyclic hormonal therapy is initiated at the age of puberty to aid the development of secondary sex characteristics and menses as well as to help bone mass. Infertility, related to gonadal dysplasia, is typical and has been successfully treated with assisted reproduction techniques and donor oocytes. It is important to evaluate for structural cardiovascular defects in the patient before pregnancy.

In terms of intellectual development, specific difficulties with spatial and perceptual thinking lead to a lower performance IQ; however, this syndrome is not characterized by mental retardation.

### Triploidy (69,XXX or 69,XXY)

As its name implies, *triploidy* is a karyotype containing three copies of each chromosome. Mechanisms that can lead to this state include fertilization of the egg by two different sperm, (dispermy) and complete failure of normal chromosome separation in maternal meiosis. The vast majority of triploid fetuses are spontaneously aborted, accounting for up to 15% of chromosomally abnormal pregnancy losses. Live births of affected fetuses are rare, and reports of survival beyond infancy are only anecdotal. Mosaicism with combinations of diploid and triploid cells (*mixoploid*) has also been documented. Malformations, including hydrocephalus, neural tube defects, ocular and auricular malformations, cardiac defects, and 3-4 syndactyly of the fingers, are associated findings. Additionally, the placenta is often abnormal, typically large and cystic.

### DELETION SYNDROMES

In addition to the aneuploid conditions described previously, monosomy or partial monosomy of a chromosome can lead to a recognizable pattern of malformation as well. Two classic syndromes are described that are associated with the deletion or loss of genetic material from the *p* arms of chromosomes 4 and 5. A newer constellation of findings consistent with loss of material from chromosome 1p has also been reported (Shaffer et al, 2001). All of these syndromes are associated with deletions that involve the loss of many genes located in a specific region.

### Cri du Chat Syndrome (5p-)

Partial monosomy of chromosome 5p is seen in approximately 1 in 50,000 live births and is associated with a multiple congenital anomaly syndrome named for the unusual cry of the affected babies, which sounds like a cat's. The constellation of features associated with this disorder includes low birth weight, microcephaly, round face, hypertelorism or telecanthus, down-slanting palpebral fissures, epicanthi, and broad nasal bridge. Hypotonia and cardiac defects are also seen, including ASD, VSD, and tetralogy of Fallot. Early issues include failure to thrive and pronounced developmental delay. The cat's cry usually resolves during infancy, and survival into adulthood is possible but often with severe mental retardation. Intensive therapy appears to provide some benefit, and more sensitive measures of cognition demonstrate clearly better language receptive skills than expressive language ability. Thus, children may understand more complex verbal language than their expressive skills might demonstrate (Cornish et al, 1999).

It is estimated that nearly 100 genes are lost when the putative critical region from 5p15.2 to p15.3 is deleted (Shaffer et al, 2001). Close to 90% of 5p deletions arise de novo in the affected child, incurring a minimal risk of recurrence (<1%). The remainder arise from malsegregation of a balanced translocation in a carrier parent, which would be associated with a 10% to 15% risk of recurrence of an unbalanced karyotype in a future liveborn. Parental karyotype analysis is indicated for proper recurrence risk counseling.

### Wolf-Hirschhorn Syndrome (4p-)

Distal deletions of the short arm of chromosome 4 are associated with a recognizable pattern of malformation. This syndrome is estimated to occur in 1 in 50,000 births and has features such as intrauterine growth restriction, microcephaly, midline structural defects such as cleft lip and cleft palate, cardiac septal defects, and hypospadias. The characteristic facial features are described as the "Greek helmet" facies, as evidenced by hypertelorism with epicanthi, a high forehead with a prominent glabella, and a beaked nose. Prominent, low-set ears are also seen. Hypotonia, failure to thrive, and developmental delay are the rule, with one third of infants dying in the first year of life. Many patients have lived well into childhood and even into adulthood, although profound growth and mental retardation, often accompanied by seizures, is typical.

Although most deletions are cytogenetically visible on karyotype analysis, small submicroscopic deletions have also been described. In cases in which the clinical features are suggestive but the karyotype is not revealing, further cytogenetic analysis using specific probes from the 4p region for FISH analysis is indicated. More than 80% of 4p deletions arise de novo in the patient, with minimal risk of recurrence. In the 10% to 15% of cases resulting from a translocation, obtaining parental karyotypes is clinically indicated for appropriate recurrence risk counseling.

### Chromosome 1p Deletion Syndrome (1p-)

Monosomy for the distal short arm of chromosome 1, or deletion of 1p36, has been associated with a constellation of clinical findings. A characteristic facies, consisting of frontal bossing, large anterior fontanelle, flattened mid-face with deep set eyes and developmental delay, has been described (Fig. 20-5). Orofacial clefting, hypotonia, seizures, deafness, and cardiomyopathy are also noted.

This deletion syndrome is estimated to occur in approximately 1 in 10,000 live births, a figure that is most probably an underestimate; the availability of a specific FISH test and greater recognition of the phenotype will likely lead to improved diagnosis of this condition. The vast majority of deletions arise de novo in the patient, with about 3% attributable to malsegregation of a balanced parental translocation. The size of the deletion varies, from submicroscopic (<5 Mb) to 32 cm. There appears to be a correlation between the size of the deletion and the severity of clinical features.

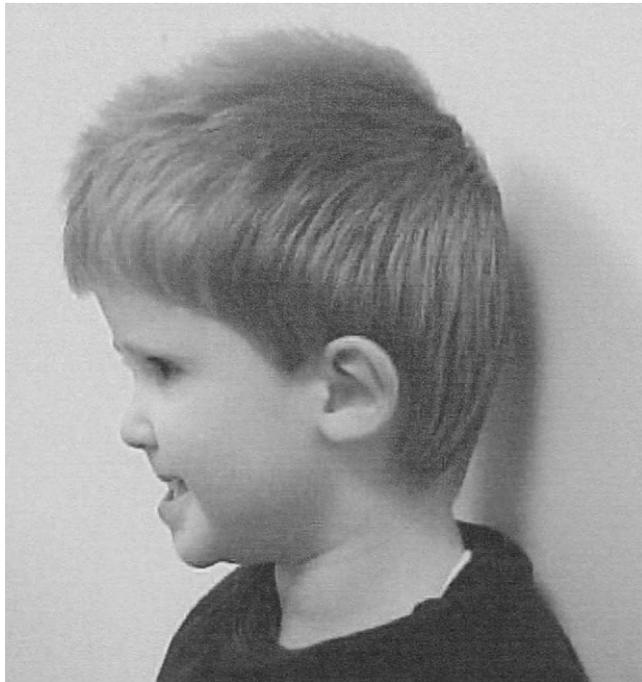

Diagnosis has been made with karyotype analysis, but 50% of patients do not have a cytogenetically visible deletion. FISH studies targeted to this region in cases with suggestive clinical features have uncovered most of the other cases. The use of subtelomeric FISH to screen for deletions in any chromosome, as an adjunct to routine karyotyping, has led to the diagnosis in a number of patients.

### Subtelomeric FISH

The subtelomeric regions of human chromosomes have been difficult to evaluate with standard cytogenetic means (karyotype), small rearrangements being undetectable at

A

B

**FIGURE 20-5.** Child with deletion of chromosome 1p.

the current threshold of resolution. The development of commercially available chromosome-specific probes for use in subtelomeric FISH has emerged as the newest breakthrough in the identification of many submicroscopic rearrangements in these genomic regions. Use of subtelomeric repeat sequences that are distinctive for each chromosome for FISH analysis allows one to scan an entire karyotype for small rearrangements that were previously undetectable by high-resolution banding. Subtelomeric FISH has rapidly become part of routine

genetic evaluations as an important adjunct to the standard or high-resolution karyotype for many situations.

Clinical indications for subtelomeric FISH include the evaluation of a newborn with multiple congenital anomalies that do not clearly fit into a recognizable pattern of malformation associated with a known chromosomal abnormality. As more subtelomeric rearrangements are characterized at the cytogenetic level, a greater recognition of their associated phenotypic features will emerge, ultimately leading to earlier diagnosis and better care for affected infants.

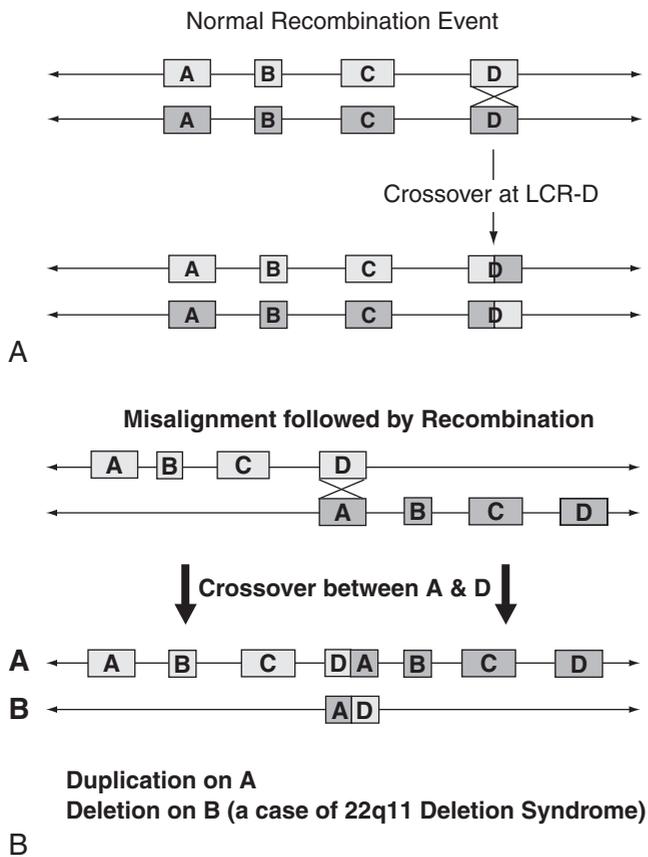

### SEGMENTAL DUPLICATIONS AND MICRODELETION SYNDROMES

A greater appreciation of the complexity of the human genome and an initial glimpse at its structure has now been afforded with the completion of the human genome sequence (see Chapter 17). This work has focused attention on regions of the genome that are prone to rearrangement. The presence of such “unstable” regions appears to play a significant role in the etiology of several genetic disorders (Emanuel and Shaikh, 2001). These disorders result from inappropriate dosage of crucial genes in a given genomic segment via either structural mechanisms (deletion or duplication) or functional mechanisms (imprinting, uniparental disomy). It has also been demonstrated that many of these regions of genomic instability have a common element: the presence of large, chromosome-specific low copy repeats that most likely mediate misalignment and unequal cross-over during recombination, leading to rearrangements such as a deletion and duplication (Fig. 20-6). Many of these large repeat structures are localized to a single chromosome or within a single chromosomal band. Examples of such “genomic” disorders are hemophilia A (inversion of Xq28), Charcot-Marie-Tooth disease (interstitial duplication on 17p12), the deletion of this same region of 17p12 leading to hereditary neuropathy with liability to pressure palsies (HNPP), and a small percentage of patients with neurofibromatosis type I (deletion involving 17q11.2).

In this section, we focus on several deletion syndromes that occur on chromosomes whose underlying genomic structure contains such segmental duplications: Williams-Beuren syndrome (involving chromosome 7q11.2), Prader-Willi syndrome or Angelman syndrome (involving an imprinted region of chromosome 15q11 through 15q13) and DiGeorge or velocardiofacial syndrome (DGS/VCFS), the most commonly occurring microdeletion syndrome in humans, involving chromosome 22q11.2.

#### Williams-Beuren Syndrome (7q11 Deletion)

The estimated incidence of Williams-Beuren syndrome is 1 in 20,000 to 50,000 live births. The phenotype has a variable spectrum but usually consists of distinctive facies, growth and developmental retardation, cardiovascular anomalies, and, occasionally, infantile hypercalcemia (see Fig. 24-8). Babies with Williams-Beuren syndrome usually show some degree of intrauterine growth restriction with mild microcephaly. Facial features are epicanthal folds

**FIGURE 20-6.** A, Alignment of low copy repeats (LCRs) before exchange. B, Misalignment of LCRs before exchange can result in rearrangement.

with periorbital fullness of subcutaneous tissues, flat mid-face, anteverted nostrils, long philtrum, thick lips, large open mouth, and stellate irises that may not be discernible at birth. Most infants have a cardiovascular abnormality; supravalvular aortic stenosis (SVAS) is the most commonly associated defect, seen in over 50% of cases. Pulmonary artery stenosis is also often encountered. It is interesting to note that isolated SVAS can also exist as a separate autosomal dominant trait and has been shown to occur from mutations of the elastin gene that is located within the region on 7q11 that is deleted in patients with Williams-Beuren syndrome. Patients with Williams-Beuren syndrome are typically missing one copy of the elastin gene as well (Shaffer et al, 2001).

Hypercalcemia, which is manifested in about 10% of patients with this disorder, is severe and persists through infancy. Umbilical and inguinal hernias are also associated features. Issues in infancy include feeding and growth problems, with pronounced irritability and “colicky” behavior. Hoarse voice, strabismus, hypertension, and joint mobility restrictions may develop later in childhood. In terms of development, the typical mild to moderate mental retardation can be masked by advanced language skills, although gross motor and visual-motor integration skills are especially affected. Attention deficit disorders are common, and a characteristic outgoing personality is often described in affected children.

Many of the classic features of Williams-Beuren syndrome are not clearly discernible in the newborn period, but the diagnosis should be suspected in any child with SVAS, hypercalcemia, and facial features consistent with the disorder. The diagnosis can be quickly confirmed by performing FISH using probes specific for the deleted region of chromosome 7q11. Because the condition is typically sporadic and most deletions arise de novo, the risk of recurrence in subsequent pregnancies is minimal. An affected adult, however, would pass on the condition in an autosomal dominant manner, with a 50% risk of the disorder in his or her child.

### The 22q11 Deletion Syndrome

A deletion of chromosome 22q11.2 has been identified in the majority of patients with the DiGeorge syndrome, VCFS, and conotruncal anomaly face syndrome (CAFS), leading to the realization that these clinical entities all reflect features of the same genomic disorder (McDonald-McGinn et al, 1997). The list of findings associated with the 22q11.2 deletion is extensive and varies from patient to patient. Estimates indicate that the 22q11 deletion occurs in approximately 1 in 3000 live births (Burn and Goodship, 1996). This disorder is the most common microdeletion syndrome occurring in humans and is a significant health concern in the general population.

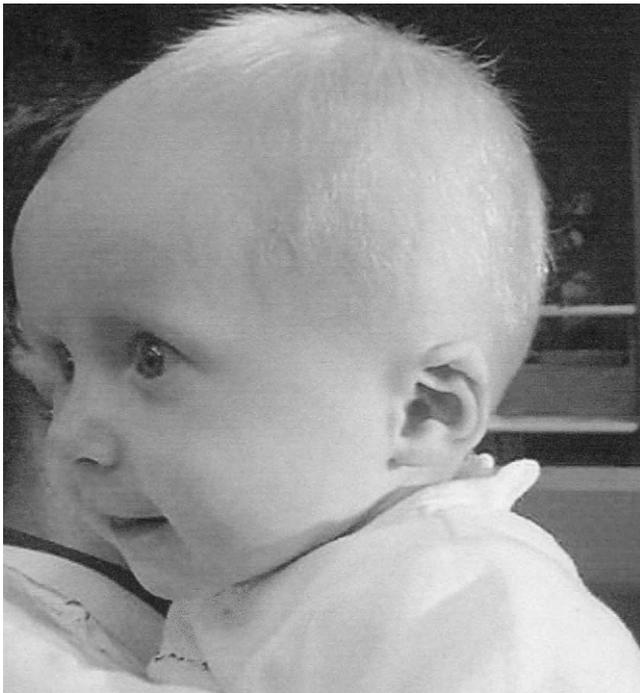

The phenotype is characterized by a conotruncal cardiac anomaly and, often, aplasia or hypoplasia of the thymus and parathyroid glands. The majority of patients diagnosed with a deletion can present as newborns or infants with significant cardiovascular malformations, including interrupted aortic arch (IAA) type B, truncus arteriosus (TA), or tetralogy of Fallot, along with functional T-cell abnormalities and hypocalcemia. In addition, facial dysmorphism (Fig. 20-7), including hooded eyelids, hypertelorism, overfolded ears, bulbous nasal tip, a small mouth, and micrognathia, may be present. Since the initial report by DiGeorge in 1965, the spectrum of associated clinical features has been expanded to include anomalies such as vascular rings, cleft palate, renal agenesis, neural tube defects, and hypospadias (McDonald-McGinn et al, 1997). Before advances in the medical and surgical management of children with complex congenital cardiac disease and immune deficiencies, this disorder was associated with significant morbidity and mortality.

Developmental delays or learning disabilities have been reported in 90% to 100% of patients with the 22q11.2 deletion, and a wide range of developmental and behavioral findings have been observed in young children (Emanuel and Shaikh, 2001). In the preschool years, children with a 22q11.2 deletion were most commonly found to be hypotonic and developmentally delayed with language and speech difficulties. Severe or profound retardation was not seen, and a few patients functioned within the average range.

The vast majority of patients (80% to 90%) has the same large deletion, approximately 3 million base pairs (3 Mb), that is detected by FISH (Fig. 20-8). The deletion remains unchanged when inherited from an affected parent. However, the phenotype can be widely variable, even

A

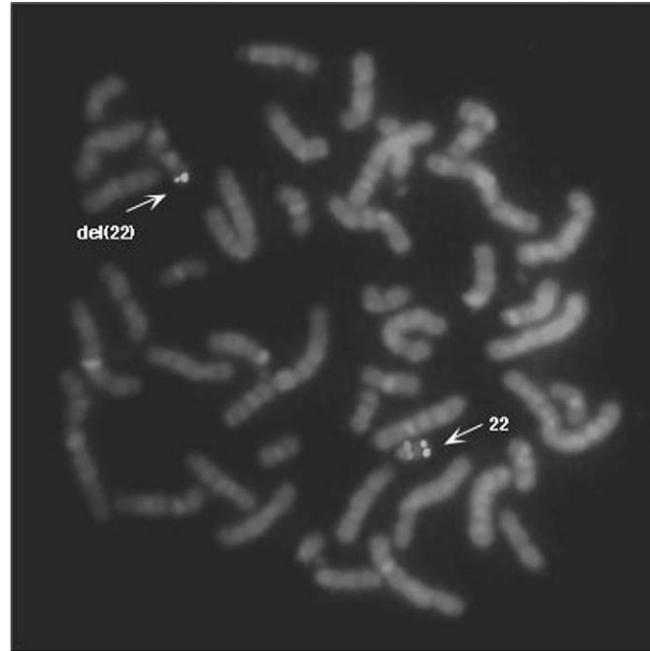

B

**FIGURE 20-7.** Facial differences associated with the 22q deletion.

within a family. Although smaller recurrent deletions that are half the size of the common deletion occur (1.5 Mb), a smaller size does not indicate milder symptoms, making genotype-phenotype correlations difficult. To date, no explanation for the great phenotypic variability has been forthcoming, and it is currently an area of active investigation (Emanuel and Shaikh, 2001).

Most 22q11 deletions occur as *de novo* lesions, less than 10% of them being inherited from an affected parent. The prevalence of these *de novo* 22q11.2 deletions indicates an extremely high mutation or rearrangement rate within this genomic region that is probably related to

**FIGURE 20-8.** (See also Color Plate 20-8.) FISH study of a 22q deletion. (Photograph courtesy of Dr. Beverly S. Emanuel.)

the presence of “recombination-permissive” duplicated DNA sequences or low copy chromosome 22-specific repeats in 22q11 (Emanuel and Shaikh, 2001).

### DISORDERS OF IMPRINTED CHROMOSOMES

A growing recognition of mechanisms regulating gene expression has emerged in the last decade. Two of the most exciting concepts with important clinical correlates are imprinting and uniparental disomy. *Genomic imprinting* implies that a whole region of a chromosome or a group of genes in a given region are subject to a difference in their expression that depends on whether they reside on the maternally inherited or paternally inherited chromosome. In these cases, a genetic disorder might manifest according to which parent the genomic region was inherited from. The genes in an imprinted region are not necessarily mutated, but they are marked such that the cell can distinguish between the maternal and paternal copies and coordinate expression on the basis of that distinction. At the molecular level, it appears that differences in the methylation of the DNA, and its replication and regulation at the transcriptional level, appear to be involved in this mechanism.

#### Prader-Willi Syndrome

It has been demonstrated that occasionally, instead of inheriting one copy of each chromosome from each parent, both copies of a given chromosome can come from the same parent. This phenomenon, known as *uniparental disomy* (UPD), is associated with advanced maternal age. It becomes a significant issue when the

involved chromosome is imprinted or has regions on it that are imprinted.

Prader-Willi syndrome (PWS) involves the loss of activity from the *paternally* derived proximal long arm of chromosome 15 (15q11). This loss can occur through deletion or disruption of this region or through maternal uniparental disomy such that no paternal chromosome 15 is present at all (Nicholls et al, 1989). Newborns have pronounced central hypotonia and weak cry. Hyporeflexia is often encountered as well. The poor tone manifests as sucking and swallowing difficulties that can lead to failure to thrive and the need for feeding tubes in infancy. Facial differences that have been described include bifrontal narrowing, “almond-shaped” eyes, and a small, downturned mouth. Genitalia are often hypoplastic, with cryptorchidism quite common in boys with the syndrome. The commonly reported small hands and feet are not usually demonstrated in the newborn. Strabismus and hypopigmentation relative to the family are also common.

A history of poor fetal activity during the pregnancy can often be elicited, especially if the mother has had prior pregnancies. Consistent with the hypotonia, breech presentation and perinatal insults are found more frequently than usual. The extreme hypotonia begins to improve in the first year of life, as does motor development, although developmental delay is the rule, especially for gross motor skills and speech. The feeding improves in the first few years of life and gives way to often uncontrollable hyperphagia and obesity. This issue and other behavioral problems, including severe temper tantrums, are encountered throughout life. The majority of patients manifests mild to moderate mental retardation. Early diagnosis and preemptive implementation of behavioral therapy are essential components of the optimal management of these issues.

Deletions of the region critical in Prader-Willi syndrome have been demonstrated in up to 70% of patients. The deletion can be detected by FISH analysis using a probe specific for this region of chromosome 15. A small number of patients has a disruption of this area as the result of a rearrangement such as a translocation. To date, no single gene in this region has been implicated as the cause, but expression of the genes in this region is under intense investigation. It has been noted, however, that patients who have Prader-Willi syndrome as a result of a deletion of the region are more likely to be hypopigmented. This feature has been attributed to deletion of a gene involved in pigmentation, the so-called P gene (Rinchik et al, 1993). Recurrence risks are negligible in cases in which de novo deletions are found, and sporadic occurrence is usually encountered.

Approximately 20% to 25% of patients with Prader-Willi syndrome show maternal UPD that can be detected by means of a molecular assay designed to assess specific methylation differences between maternal and paternal alleles. A maternal age effect has been demonstrated in UPD cases, and recurrence risks in families without deletions are estimated at 1 in 1000. Additionally, this region of the genome is subject to regulation by imprinting. Large chromosome-specific segmental duplications are found in 15q11 and have been implicated in mediating the recurrent deletion of this genomic region (Emanuel and Shaikh, 2001).

## Angelman Syndrome

Loss of genetic material from the 15q11 region from the *maternal* copy of chromosome 15 is associated with Angelman syndrome. Clinical features are not evident in the newborn period and infancy but include significant mental retardation, seizures, ataxic gait, tongue thrusting, inappropriate bursts of laughter, and facial differences including protruding jaw, wide mouth, thin upper lip, and widely spaced teeth. The mental retardation and hypopigmentation overlap with features of Prader-Willi syndrome, but Angelman syndrome is a distinct entity.

Seventy percent to 75% of patients have a deletion of 15q11 that is detectable by FISH analysis. A small percentage (3% to 5%) have evidence of *paternal* isodisomy (two paternal copies) of the entire chromosome 15, with no apparent maternal chromosome. Unlike in Prader-Willi syndrome, Angelman syndrome has been associated with mutations in a single gene, UBE3A, an enzyme involved in the ubiquitin pathway of protein degradation, detected in up to 10% of patients. Additionally, mutations of an imprinting center locus on chromosome 15 are thought to be associated with 1% to 2% of Angelman phenotypes (Shaffer et al, 2001). Thus, the vast majority of cases result from a sporadic event, and risk of recurrence can be best evaluated once the genetic mechanism has been determined for a given patient.

## Beckwith-Wiedemann Syndrome

Beckwith-Wiedemann syndrome affects about 1 in 14,000 newborns and manifests as an overgrowth syndrome in the neonatal period. The characteristic findings are macrosomia, abdominal wall defect, and macroglossia (Fig. 20–9). Affected babies are large for gestational age with proportionate length and weight. Infants of diabetic mothers also manifest with macrosomia, but are more likely to have a weight disproportionately greater than length. Advanced bone age is also noted in Beckwith-Wiedemann syndrome. Hemihypertrophy due to asymmetric growth is common, as is visceromegaly of various organs, including the spleen, kidneys, liver, pancreas, and adrenal glands.

Other characteristic features of the syndrome are macroglossia, linear creases of the earlobe with indentations on the posterior helix, and severe hypoglycemia. Although the hypoglycemia responds quickly to therapy, it can be present for several months; thus, recognition of the condition and immediate therapeutic intervention are critical in these cases. The hypoglycemia resolves spontaneously with age, and the physical diagnostic features also become less prominent with age, making the diagnosis more difficult to ascertain.

Equally important is the establishment of routine ultrasonographic surveillance at regular intervals, because children with Beckwith-Wiedemann syndrome are at increased risk of malignant tumors, especially Wilms tumor. The estimated risk is 5% for patients with hemihypertrophy. Many centers currently perform ultrasonography at 3-month intervals until the school-age years and at least annually through adolescence. Monitoring of serum alpha-fetoprotein levels at the same intervals

**FIGURE 20-9.** Macrosomic infant with macroglossia and lax abdominal musculature. These findings are typical of Beckwith-Wiedemann syndrome. (From Viljoen DL, Jaquire Z, Woods DL. Prenatal diagnosis in autosomal dominant Beckwith-Wiedemann syndrome. *Prenat Diagn* 11:167-175, 1991.)

has proved valuable, as several cases of hepatoblastoma have also been reported and detected with this adjunct study.

Although most cases of Beckwith-Wiedemann appear to arise de novo, up to 15% may be familial. In familial cases, autosomal dominant transmission but with variable phenotype seems to be the mode of inheritance. Additionally, this region of the genome (11p15) appears to be imprinted such that the maternal allele is not usually expressed. The insulin-like growth factor type 2 (IGF2) gene is located in this region and encodes an important factor involved in fetal growth. Mutations causing overexpression of the paternal allele or underexpression of the maternal allele can result in an imbalance of expression leading to the overgrowth and tumor formation encountered in these patients. Paternal UPD has proved to be a mechanism involved in up to 20% of sporadic cases of Beckwith-Wiedemann syndrome.

### CONCLUSION

We have summarized the rapidly expanding field of chromosomal or genomic disorders, concentrating on those that commonly manifest in the newborn. The widespread development and clinical implementation of molecular cytogenetic techniques such as FISH and subtelomeric FISH have allowed the identification of subtle rearrangements that were previously undetectable. These advances now enable the discernment of “new” syndromes in which the chromosomal anomaly may be defined before a characteristic phenotype is recognized. Additionally, a greater understanding of the role of segmental duplications and their effects on human genetic disorders as well as of the influence of mechanisms that regulate gene expression, such as imprinting, is emerging. The tremendous advances in genomics lead by the completion of the Human Genome Sequencing Project and the development of new molecular diagnostic tools present new challenges for clinicians to better diagnose, understand, and care for patients with genetic disorders and their families.

# CONGENITAL METABOLIC PROBLEMS

Editors: ROBERTA A. BALLARD and GERARD T. BERRY

## CHAPTER 21

### Introduction to the Metabolic and Biochemical Genetic Diseases

Gerard T. Berry

For the sake of simplicity, genetic diseases may be divided into the chromosome disorders, the contiguous gene deletion syndromes, nucleotide repeat disorders, imprinting/methylation silencing disorders, the single-gene defects, the polygenic disorder, and mitochondrial DNA diseases. Biochemical genetic disease is almost always the consequence of a single-gene defect, and most inborn errors of metabolism are inherited as autosomal recessive traits. However, not all biochemical genetic disorders are usually thought of as metabolic diseases. The clinician caring for sick newborns tends to consider metabolic diseases in terms of certain well-recognized clinical presentations—the catastrophically ill, comatose newborn infant; the baby with failure to thrive, recurrent feeding problems and emesis, hypotonia, or seizures; and the infant with physical stigmata such as hepatosplenomegaly, characteristic of the storage diseases. Acidosis, ketosis, hypoglycemia, or hyperammonemia frequently alerts the pediatrician or neonatologist to initiate evaluation for a metabolic disorder in the infant with life-threatening disease. In contrast, cystic fibrosis, a biochemical genetic disorder, has little in common with these kinds of inborn errors, except perhaps autosomal recessive transmission. The examples of the inborn errors described in Chapters 22 through 24 help clarify this clinical nosologic concept. A list of general references or reviews that emphasize the genetic metabolic diseases is provided at the end of this chapter.

The purpose of this section on Congenital Metabolic Problems is to review the biochemical genetic diseases and, specifically, the metabolic diseases that manifest in the extended newborn period, considering the appropriate laboratory testing for diagnosis and the therapeutic modalities for treatment of these disorders. With the exception of some rare contiguous gene deletion syndromes, the non-single-gene defects, such as the chromosome and polygenic genetic disorders, are not causes of

metabolic disease. Yet as discussed in the context of biochemical genetic diseases producing dysmorphism, the distinction between what constitutes classic clinical genetics and metabolic diseases is becoming blurred. Although a few metabolic disorders are inherited as X-linked traits, autosomal dominant inheritance is not considered common, particularly in the group of inborn errors that can be readily detected by measuring the levels of chemicals such as amino and organic acids in body fluids. The biochemical genetic defects due to expansion of trinucleotide repeats, such as the fragile X syndrome, and disorders due to mitochondrial DNA mutations rarely manifest during the newborn period. Defects in the imprinting of a single parental gene of maternal or paternal origin, such as in the Prader-Willi, Angelman, and Beckwith-Wiedemann syndromes, are covered in other chapters.

In general, metabolic diseases in the newborn are the consequence of the malfunctioning of both the maternally and paternally inherited alleles at one specific gene locus. Some biochemical genetic diseases transmitted in such an autosomal recessive manner are not covered here because of the unique involvement of one organ or physiologic system, which places that disease within a particular subspecialty. Examples are cystic fibrosis, disorders of hemostasis and coagulation, methemoglobinemias, and immunodeficiencies. Other metabolic disorders, such as familial hyperinsulinism, congenital adrenal hyperplasia, and Crigler-Najjar syndrome, are thoroughly discussed in other chapters.

Of the 10,000 genetic diseases or polymorphic traits that follow a mendelian inheritance pattern, more than 500 are considered biochemical genetic diseases and have been defined at the protein or gene level. As discussed earlier, not all manifest during the newborn period. Almost 50 inborn errors of amino acid, organic acid, or ammonia metabolism can be recognized in the first weeks or months of life (Table 21–1). The primary lactic acidoses are rare, as are the storage, peroxisomal, and connective tissue diseases, which individually number few. Aside from hyperinsulinism, galactosemia is the most common of the defects in carbohydrate metabolism. Because of the number and rarity of these metabolic diseases, a practical general approach to patients with a potential metabolic disease is essential. For the clinician, it is helpful to focus not on the individual diseases, except when characteristic syndromes are readily recognizable, but rather on the different general modes of presentation and the classes or types of inborn errors that fit a particular mode of presentation.

In general, the metabolic diseases affecting the newborn can be divided into those involving complex molecules, such as the storage diseases, and those concerning the intermediary metabolism of small molecules, such as glucose,

 Connective tissue diseases

pyruvate, lactate, amino acids, organic acids, ammonia, and mitochondrial respiration and oxidative phosphorylation. Overwhelming, acute, life-threatening illness is the outstanding feature of the group of metabolic diseases involving metabolism of small molecules. Acute encephalopathy may be due to the buildup of metabolic poisons such as ammonia and organic acids (Table 21-2), to hypoglycemia (Table 21-3), or to the failure to convert glucose to CO<sub>2</sub> and H<sub>2</sub>O associated with diminished mitochondrial adenosine triphosphate formation and lactate buildup (see Table 21-2).

 Hereditary fructose intolerance  
 Glycogen storage disease type I

As is well known to neonatologists and pediatricians, the newborn or young infant has a limited array of responses to acute, severe illness with encephalopathy. The signs are nonspecific and include poor feeding, spitting up, lethargy, skin color changes, hypothermia, and poor weight gain. In fact, few newborn infants in whom a metabolic disease is suspected should have escaped evaluation for sepsis. In many of these diseases, respiratory distress is also a presenting feature because of the presence of an acid-base disturbance. Metabolic acidosis and hyperammonemia both produce hyperventilation. During the progression of metabolic coma, cerebral edema or other complications such as intracranial hemorrhages may develop in the patient, making it more difficult to establish the diagnosis.

Because a specific metabolic disorder may be associated with different amounts of residual enzyme activity—as the exact gene mutations often vary from patient to patient—or because different rates of protein ingestion lead to a variable accumulation of amino or organic acids, there may be different modes of presentation even for the same metabolic disorder. Examples of the different modes of presentation are shown in Table 21-4. A characteristic odor may provide the clue to the presence of phenylketonuria (musty), maple syrup urine disease (maple syrup), isovaleric aciduria (sweaty socks), and glutaric aciduria type 2 (sweaty socks). Often the physical findings are not specifically helpful in metabolic diseases involving small molecules. Conversely, the diseases involving cellular processing of complex molecules such as the storage diseases are usually associated with characteristic or unique physical findings (Table 21-5).

Although there are exceptions to both of these rules, this approach represents an easy and diagnostically helpful way to think about these rare disorders of metabolism. The characteristic unique or physical findings that

Agenesis of corpus callosum	Pyruvate dehydrogenase complex deficiency Pyruvate carboxylase deficiency Mitochondrial respiratory/electron transport chain defects

content, glucose, ammonia, and amino acids are not particularly helpful in the evaluation of these infants with abnormalities in the metabolism of complex molecules whose evaluation must be dictated by the history and important findings on physical examination. The enigmatic picture of hydrops fetalis, although uncommon as a mode of presentation, is exclusively associated with the storage diseases. Neurologic signs including seizures may also be seen in the storage diseases. Congenital chloride malabsorption, glucose-galactose malabsorption, and acrodermatitis enteropathica may manifest as congenital or persistent diarrhea.

Severe liver disease with jaundice or elevated serum transaminase determinations is characteristic of a few metabolic diseases; they are listed in Table 21–8. Of these disorders, only  $\alpha_1$ -antitrypsin deficiency, the peroxisomal disorders such as Zellweger disease and neonatal adrenoleukodystrophy, and Niemann-Pick type C disease are secondary to impaired disposition of complex molecules. Mild or transient liver function test abnormalities may also be seen in the glycogen storage diseases, fructose-1,6-bisphosphatase deficiency, and hyperammonemic conditions, but bridging fibrosis is not usually detected. A renal tubulopathy may also be detected in galactosemia, hereditary fructose intolerance, tyrosinemia type 1, and the mitochondrial respiratory chain or electron transport chain deficiencies. Hyperchloremic metabolic acidosis, therefore, may be an important clue to their presence.

Significantly, it is now recognized that some patients with multiple malformations may have a metabolic disease. The best example is Smith-Lemli-Opitz syndrome. Congenital craniofacial dysmorphic features, microcephaly, limb malformations, and progressive liver disease are secondary to a deficiency of the enzyme 7-dehydrocholesterol reductase. Another example of an autosomal recessive disorder resulting in malformations is Zellweger disease. In the classic form, the cellular organelle, the peroxisome, is not formed, resulting in multiple enzyme deficiencies such as those involved in very-long-chain fatty acid oxidation and plasmalogen biosynthesis. As a consequence, the brain, cranium, face, long bones, and kidney fail to develop

normally. A list of the different metabolic diseases that can, but do not always, produce congenital dysmorphism or malformations is shown in Table 21–9. It is important, when confronted with an infant with these types of findings, that the physician not assume that a chromosome disorder is the cause or that congenital disease excludes a single-gene defect. In Chapter 18 the state of newborn screening, including metabolic diseases, is reviewed.

The next three chapters discuss various inborn errors of metabolism, including key clinical and laboratory findings, sophisticated biochemical and molecular diagnostic testing, therapy, and newborn screening. It is impractical to cover all known biochemical genetic diseases exhaustively and still provide useful and readily accessible information for the clinician. For this reason, the succeeding chapters focus on the major categories of disease as discussed earlier.

In Chapter 22, the metabolic defects involving small and simple molecules such as glucose, galactose, amino and organic acids, ammonia, and lactate are reviewed. These include the inborn errors that can produce acute, life-threatening disease with coma in the newborn infant. In Chapter 23, the storage diseases that manifest in the extended neonatal period are reviewed. This includes the disorders that involve handling of complex molecules. The lysosomal enzyme deficiencies are the most notable members of the group. They include the storage diseases that may manifest as nonimmune hydrops fetalis. Because physical examination is the key to the diagnosis of complex molecule diseases, the defects in peroxisomal metabolism such as Zellweger disease and Smith-Lemli-Opitz syndrome are also included in the chapter on storage diseases. In Chapter 24, the connective tissue diseases that involve metabolism of the complex molecules, collagen, fibrillin, and elastin and the osteochondrodystrophies that present in the newborn period are reviewed. Most metabolic diseases discussed in Chapters 22 through

**FIGURE 21-1.** Algorithm for the metabolic work-up of a comatose infant with hyperammonemia. **A,** The presence of a metabolic acidosis is a key factor in the identification of the underlying disorder. Most infants with urea cycle defects present with a primary respiratory alkalosis. Please note that some infants with defects in organic acid metabolism and usually fatty acid oxidation display no acidosis. **B,** Defects in organic and fatty acid can be detected by the analysis of acyl carnitines by tandem mass spectrometry (MS-MS), as well as by the use of gas chromatography–MS for analysis of organ acids in urine. ACT, acyl carnitine translocase deficiency; ASA, argininosuccinic acid; ASAL, argininosuccinic acid lyase deficiency; ASAS, argininosuccinic acid synthetase deficiency; CIT, citrulline; CPS, carbamyl phosphate synthetase deficiency; GAI, glutaric aciduria type 2; GLN, glutamine; HCS, holocarboxylase synthetase deficiency; IVA, isovaleric acidemia; LCHAD, 3-hydroxy long-chain acyl CoA dehydrogenase deficiency; MCAD, medium-chain acyl CoA dehydrogenase deficiency; MMA, methylmalonic acidemia; NAGS, *N*-acetyl glutamate synthetase deficiency; OTC, ornithine transcarbamylase deficiency; PA, propionic acidemia; SCAD, short-chain acyl CoA dehydrogenase deficiency; VLCAD, very-long-chain acyl CoA dehydrogenase deficiency.

24 are not detected in the newborn screening programs currently in place. Accordingly, another purpose of this section is to help the clinician develop a conceptual framework to fashion a useful and practical approach to diagnostic testing.

To illustrate the effective use of the metabolic laboratory, an algorithm for the work-up of a comatose infant with hyperammonemia described in the following case study is shown in Fig. 21-1.

### CASE STUDY 1

A full-term infant was breast-fed from birth. During the first 2 weeks of life, she failed to regain her birth weight and had decreased interest in feeding, with vomiting and progressive lethargy. By 3 weeks of age, the baby exhibited obtundation, tachypnea, hypothermia, hypotonia, and an ileus.

Laboratory studies performed on her admission to the neonatal intensive care unit (NICU) showed respiratory alkalosis, neutropenia, thrombocytopenia, and slight increase in urinary ketones. In addition, there were elevated plasma values for ammonium (900  $\mu\text{mol/L}$ ), glycine (1485  $\mu\text{mol/L}$ ) and lactate (3.0 mmol/L). Urine organic acid analysis by gas chromatography-mass spectrometry revealed the presence of 3-hydroxypropionate, methylcitrate, propionylglycine, and tiglylglycine, consistent with propionyl-coenzyme A carboxylase deficiency. Acyl carnitine analysis of a plasma sample by tandem mass spectrometry (MS-MS) showed elevated propionylcarnitine content.

Hemodialysis was utilized primarily for the management of hyperammonemia. Plasma ammonium levels were less than 100  $\mu\text{mol/L}$  after 24 hours of treatment. A modified parenteral nutritional therapy with insulin was employed. Intravenous L-carnitine and metronidazole were added on the second day of hospitalization. Finally, a low-protein diet was initiated, and after a period of convalescence in the NICU, the patient was discharged. At 4 years of age, the patient has hypotonia, developmental delay, and anorexia requiring gastrointestinal tube feeding.

This case shows how an infant with a life-threatening hyperammonemic syndrome due to a defect in organic acid metabolism may not have a severe metabolic acidosis. In this instance, newborn screening with plasma acyl carnitine analysis by MS-MS led to the diagnosis of propionic acidemia because of the diagnostic elevation in plasma propionylcarnitine.

## Inborn Errors of Carbohydrate, Ammonia, Amino Acid, and Organic Acid Metabolism

Gerard T. Berry

The inborn errors of carbohydrate, ammonia, amino acid, and organic acid metabolism have one factor in common: All may be associated with acute, life-threatening disease during the newborn period. The most notable exception in this broad group of small-molecule disorders is phenylketonuria (PKU). There are often few signs secondary to classic PKU in the first 6 months of life, underscoring the importance of newborn screening in establishing the diagnosis of this disease. As discussed in Chapter 21, a single biochemical genetic defect may be associated with more than one mode of presentation. This chapter presents the most common phenotype for each disorder. The disorders that constitute each group are listed in Tables 22–1 to 22–4. The interrelationships among the major metabolites, biochemical cycles, and organelle pathways in the most critical facets of intermediary metabolism are simplified and depicted in Fig. 22–1. The primary lactic acidosis and mitochondrial respiratory chain disorders, as well as the defects in fatty acid oxidation, are included in the section on inborn errors of organic acid metabolism.

### INBORN ERRORS OF CARBOHYDRATE METABOLISM

#### Hereditary Galactosemia

##### Galactose-1-Phosphate-Uridyltransferase (GALT) Deficiency

- Enzyme: homodimer
- Gene location: chromosome 9p13
- Frequency: 1 in 35,000 to 60,000

#### CASE STUDY 1

A gravida 3, para 2 mother delivered a 10 lb, 3 oz male infant. On discharge from the nursery, the mother continued breast-feeding. The baby was noted to be jaundiced, with a total serum bilirubin of 28 mg/dL on day 4. He was readmitted to the local hospital, intravenous fluids were administered, and phototherapy was instituted. A sepsis work-up was performed, and the infant was treated with ampicillin. A second serum total

bilirubin value was 24 mg/dL with a direct bilirubin value of 1 mg/dL, and 3+ reducing substances were detected in a urine specimen. Because galactosemia was suspected, the baby was switched to Nutramigen formula. The serum aspartate transaminase (AST) value was 232, and the  $\gamma$ -glutamyl-transferase (GGT) value was 132. On day 7, a trial of breast-feeding was resumed, and the urinary reducing substances value again became positive. On day 8, a bleeding diathesis was noted, and the prothrombin time (PT) and partial thromboplastin time (PTT) were longer than 30 and 150 minutes, respectively. Only a urine culture revealed the growth of *Escherichia coli*. The breast-feeding was again discontinued, and ProSobee formula was started. A Beutler fluorescent spot test performed on a filter paper specimen showed no fluorescence compatible with a diagnosis of hereditary galactosemia secondary to galactose-1-phosphate-uridylyltransferase (GALT) deficiency. The infant's jaundice and laboratory abnormalities disappeared with the soy-based, lactose-free formula regimen.

After discharge, another blood specimen was obtained for confirmation of the enzyme deficiency. However, instead of a quantitation of erythrocyte GALT activity, an erythrocyte galactokinase (GALK) analysis was performed by a commercial laboratory that, not unexpectedly, demonstrated normal activity. Although the parents were reassured by the testing result that the diagnosis of galactosemia was incorrect, they continued to administer the lactose-free formula. Over the next year of life, the infant demonstrated normal growth and development.

Subsequently, the mother became pregnant and delivered a female infant, who was started on breast-feeding because the parents believed that galactosemia had been dismissed in the older infant. The newborn female infant began to have jaundice with vomiting. Despite the use of broad-spectrum antibiotics, she died of *E. coli* sepsis on day 13. A Beutler fluorescent spot test revealed no GALT activity compatible with classic galactosemia. Quantitation of erythrocyte GALT activity in the male confirmed the severe reduction in enzyme activity, and a GALT molecular analysis on DNA extracted from blood showed that the two siblings were homoallelic for the most common GALT gene defect, the Q188R mutation.

The three enzymes of the galactose metabolic pathway that are responsible for the rapid hepatic conversion of galactose to glucose after ingestion of dietary lactose are GALK, GALT, and uridine diphosphate (UDP) galactose-4-epimerase (Fig. 22–2). All three enzymes have been associated with inborn errors of galactose metabolism (Segal and Berry, 1996). However, when one refers to the disease galactosemia or hereditary galactosemia in clinical medicine, the reference is usually to GALT deficiency. The most common of these disorders, GALT deficiency is probably the most common of the inborn errors of carbohydrate metabolism that come to clinical attention in the newborn period. The clinical syndrome of transferase-deficiency galactosemia has changed since the advent of newborn screening for galactosemia. In the past, a severe multiorgan toxicity syndrome was a much more common occurrence, associated with weeks of unlimited intake of lactose in the proprietary formula or breast milk. However, as Case Study 1 illustrates, the disease can be devastating even in the first 1 or 2 weeks of life because of *E. coli* sepsis.

The most common initial clinical sign of GALT deficiency is poor growth; vomiting and poor feeding also occur in most patients. Jaundice may be present in the

**TABLE 22-1****Inborn Errors of Carbohydrate Metabolism**

 Glycogen storage diseases  
 Hereditary fructose intolerance  
 Fructose-1,6-bisphosphatase deficiency

first few weeks of life and may persist. Initially the jaundice may be due to indirect hyperbilirubinemia, and only later associated with an elevation of direct bilirubin as well. While consuming lactose, many infants with galactosemia manifest in the first 2 to 3 weeks with only poor feeding and growth, jaundice, and mild irritability or lethargy. With continual ingestion, multiorgan toxicity syndrome ensues, associated with liver disease that may progress to cirrhosis with portal hypertension, splenomegaly, ascites, renal tubular dysfunction, sometimes the full-blown renal Fanconi syndrome, with anemia primarily due to decreased red blood cell (RBC) survival, lethargy, and brain edema associated with a bulging fontanelle. Two clinical phenomena deserve further mention, cataracts and *E. coli* sepsis. Cataracts may be evident in the first few weeks of life, but often, they are detected after 2 weeks of age. However, some infants are born with congenital cataracts that are associated with abnormalities of the embryonal lens; they are central in nature and require slit-lamp examination for documentation. *E. coli* sepsis is the most devastating complication in the newborn period, the mortality rate exceeding 50%. The reason that *E. coli* or gram-negative bacteria are uniquely present in newborns with GALT deficiency remains unknown.

After initiation of a lactose-free diet in the newborn period, the problems related to liver and kidney disease, anemia, and brain edema usually disappear, unless there has been severe organ damage such as hepatic cirrhosis. Most infants begin to grow and develop at a normal rate. However, we know now that even prospectively treated patients may manifest long-term complications related to speech defects, delays in language acquisition, learning problems in school, and hypergonadotropic hypogonadism in most of the females. The cause of these so-called dietary-independent complications is unknown. Patients with galactosemia must continue with a lactose-restricted diet for their entire lives. When an infant is initially diagnosed,

either through the newborn screening program or because of the recognition of clinical signs, blood galactose levels may be as high as 5 to 20 mM, and the RBC galactose-1-phosphate level is significantly elevated, as are urine galactitol levels. During this phase of severe hypergalactosemia, positive reducing substances are present in the urine.

One of the first abnormalities to be detected—albuminuria—reflects a poorly understood renal glomerular component. This develops within 24 to 48 hours of ingestion of lactose and disappears as quickly after elimination of lactose from the diet. In addition to hyperbilirubinemia, there may be mild to severe elevations of serum alanine transferase (ALT) and AST levels and various abnormalities related to renal tubular dysfunction, such as hyperchloremic metabolic acidosis, hypophosphatemia, glucosuria, and generalized aminoaciduria. Vitreous hemorrhages are newly recognized complications in the

**FIGURE 22-1.** Intermediary metabolism interactions among the glycolytic, citric acid, mitochondrial respiratory–electron transport chain (ETC), amino acid, organic acid, and urea cycle pathways. Defects in these primarily catabolic pathways are the chief source of inborn errors of metabolism that involve the small, simple—not the large—complex molecules. ATP, adenosine triphosphate. (Adapted from Cowett RM [ed]: *Principles of Perinatal-Neonatal Metabolism*, 2nd ed. New York, Springer-Verlag, 1998, p 800.)

newborn period. After the patient is started on a lactose-free diet, the RBC galactose-1-phosphate levels in patients with classic galactosemia fall, but they never return to the normal range, remaining mildly elevated for the lifetime of the patient. This is also true for the urinary metabolite galactitol and may be related to endogenous galactose production (Berry et al, 1995).

The deficiency of the enzyme GALT may be detected in RBCs in patients with most common forms of galactosemia. The newborn screening programs in various states use an enzymatic method, a metabolite method, or both. When metabolites are assayed, either galactose-1-phosphate or total galactose and galactose-1-phosphate in RBCs are usually measured. Most of the gene defects that

**FIGURE 22-2.** The important reactions in the galactose metabolic pathway are shown in relation to exogenous, via lactose primarily, and endogenous de novo synthesis of galactose. The reactions catalyzed by enzymes that have not been well delineated or are purported to exist are shown by *broken* or *dotted lines*. Carbon skeletons exit the galactose pool via galactokinase (GALK)-mediated conversion to galactose-1-phosphate (galactose-1-P), aldose reductase-mediated conversion to galactitol, and as galactonate. In patients with severe galactose-1-P-uridylyltransferase (GALT) deficiency, there is little or no conversion of galactose-1-P to uridine diphosphate galactose (UDPgalactose). The epimerization of UDPglucose to UDPgalactose by UDPgalactose-4-epimerase, the utilization of UDPgalactose in the synthesis of glycoconjugates such as glycoproteins, and their subsequent degradation may constitute the pathways of de novo synthesis of galactose. (Adapted from Berry GT, Nissim I, Gibson JB, et al: *Quantitative assessment of whole body galactose metabolism in galactosemic patients*. *Eur J Pediatr* 156:S44, 1997.)

produce galactosemia are now known; therefore, some patients or siblings may be screened for the disease or for being carriers via genotype analyses. Liver disease of any cause and congenital hepatic vascular shunts may lead to impaired galactose tolerance and a positive newborn screening test result for galactosemia (Gitzelmann et al, 1992; Matsumoto et al, 1993).

## Glycogen Storage Diseases

The glycogen storage diseases (GSDs) may be divided into those types that primarily affect the liver and those that affect striated muscle (Chen and Burchell, 1995; Cornblath and Schwartz, 1991; Fernandes, 1988; Hirschhorn, 1995). With some forms, such as GSD type 3, or debrancher deficiency, both striated muscle and the liver may be affected. According to European prevalence data, the overall frequency of GSD is 1 in 20,000 to 25,000 (Chen and Burchell, 1995). With the exception of GSD type 2, or Pompe disease (a lysosomal defect), most of the patients with glycogenosis do not come to clinical attention in the newborn period. As Case Study 2, of a child with GSD type 1a illustrates, however, there are exceptions. Patients with the three most common forms of GSD—types 1, 3, 6—have a phenotype that mimics a small-molecule disorder because glucose homeostasis is affected.

### Glucose-6-Phosphatase Deficiency

Glucose-6-Phosphate + H<sub>2</sub>O → Glucose + Phosphate

- Enzyme: heterodimer (catalytic and regulatory subunit)
- Catalytic subunit gene location: chromosome 17
- Frequency: 1 in 100,000

#### CASE STUDY 2

A 6 lb, 11 oz boy was born to consanguineous Lebanese parents. Despite hypoglycemia, for which he received intravenous glucose in the first 48 hours of life, the baby was discharged from the newborn nursery on day 2. He was fed Carnation Good Start formula. At 10 weeks of age, he demonstrated gastroenteritis and was treated with Pedialyte at home. He was subsequently admitted to a local hospital because of respiratory distress associated with fever and lethargy. Laboratory studies revealed a blood glucose value of 5 mg/dL, serum total CO<sub>2</sub> value of 5 mEq/L, an increased anion gap, and 3+ ketonuria. A chest radiograph was normal. The baby was intubated, started on ventilatory support, and given intravenous fluids with glucose, sodium bicarbonate, and antibiotics. He was subsequently transferred to the neonatal intensive care unit (NICU) at Children's Hospital of Philadelphia. Physical examination showed the patient to be lethargic with generalized hypotonia and enlarged liver. The liver edge was full, rounded, and palpated 7 cm below the right costal margin with a span of more than 10 cm. A liver ultrasonogram showed hepatomegaly with a coarsened echogenic texture. On the day of admission, a seizure was detected, in association with focal leg and jaw twitching and an increase in blood pressure. There was no recurrence of seizures after phenobarbital administration, which was later discontinued. Urine organic acid quantitation showed increased excretion of 3-hydroxybutyrate, acetoacetate, and lactate. A plasma amino acid quantitation showed alanine to be elevated, at 769 μM (normal is 88 to 440 μM).

After correction of the acid-base imbalance and hypoglycemia, the patient appeared to stabilize while receiving intravenous fluids with glucose. He was subsequently restarted on a proprietary formula, the Carnation Good Start formula. Results of a sepsis work-up were negative, and antibiotics were discontinued. Findings of a head magnetic resonance imaging (MRI) scan were normal. Subsequently, a blood glucose reagent strip test (Dextrosix) reading was 46 mg/dL 4 hours after a feeding. The blood lactate level was slightly increased at 2.2 mM (normal <2.0 mM). The liver remained enlarged, and a liver biopsy was performed. The histologic examination showed microsteatosis. The periodic acid–Schiff (PAS) stain response was positive but sensitive to diastase. Electron microscopy demonstrated increased glycogen. The glycogen content in the liver was high, at 6.8% (control, 2.3%). Glucose-6-phosphatase activity was measured in frozen liver homogenate and found to be markedly decreased (0.4 units; control value is 3.8 units), a finding compatible with glucose-6-phosphatase deficiency, specifically glycogen storage disease type 1a. A fasting study showed that the infant had a blood glucose level in the range of 40 mg/dL or lower 4 hours after a bottle feeding. This finding was associated with an increase in blood lactate levels. The serum uric acid and triglyceride levels were also elevated.

The baby was stabilized on ProSobee formula, given every 2 hours during the day, and a continuous glucose infusion administered at night via nasogastric tube. The baby was discharged with this regimen. The parents were instructed on home glucose monitoring. At discharge, the liver remained palpable to the level of the umbilicus, but the spleen was not enlarged. There were no further episodes of symptomatic hypoglycemia. By 4 months of age, the boy's weight was at the 95th percentile, and his length at the 90th percentile.

GSD type 1 is due to a decreased activity of glucose-6-phosphatase, the enzyme that is perched at the terminus of both glycogenolysis and gluconeogenesis. Several different biochemical abnormalities can result in this phenotype, now classified as GSD types 1a, 1b, and 1c. The enzyme that resides on the anticytoplasmic side of internal membrane spaces of the hepatocyte catalyzes the hydrolysis of glucose-6-phosphate to glucose and phosphate. Impairments in the transport of either glucose-6-phosphate or phosphate may result in decreased function of this enzyme. The major clinical findings are poor growth and enlarged abdominal girth, hepatomegaly, and any of the signs that may be related to hypoglycemia. The major laboratory findings are fasting hypoglycemia, ketosis, lactic acidosis, hyperlipidemia (specifically, hypertriglyceridemia), and hyperuricemia. In patients with type 1b disease due to a defect in the microsomal transporter of glucose-6-phosphate, there may be a history of recurrent infections due to neutropenia and defective neutrophil function. Diagnosis is based on hepatic enzyme analyses or, in some instances, molecular diagnostic testing (Burchell and Waddell, 1993; Chen and Burchell, 1995). The most important aspect of therapy is to prevent brain damage from hypoglycemia and growth failure. The mainstay of therapy is frequent feedings and restriction of lactose and sucrose (Chen and Burchell, 1995; Fernandes, 1988). The use of continuous nasogastric feedings or uncooked cornstarch, particularly during the night, has significantly improved the care of affected children, and although it does not correct all the

biochemical perturbations, it does improve growth and can prevent hypoglycemic spells.

### Lysosomal $\alpha$ -Glucosidase Deficiency

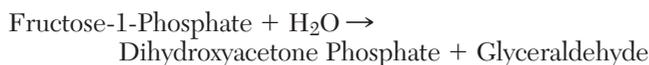

- Enzyme:  $\alpha$ -1,4-glucosidase monomer
- Gene location: chromosome 17q23
- Frequency: 1 in 100,000

GSD type 2, or Pompe disease, is a deficiency of the lysosomal enzyme  $\alpha$ -glucosidase. In the newborn period, the main clinical finding relates to heart disease. There is usually marked cardiomegaly and a typical abnormal electrocardiogram, with biventricular hypertrophy and a short PR interval. Decreased cardiac output may lead to heart failure and passive congestion. Infants may also have generalized hypotonia, not just because of heart failure but also because of skeletal myopathy. There is increased deposition of glycogen within striated muscle. Except in the instance of passive congestion, the liver is not usually enlarged. Diagnosis is based on muscle enzyme analysis (Hirschhorn, 1995). Cardiac transplantation has been performed to prevent death in infancy.

### Hereditary Fructose Intolerance

#### Fructose-1,6-Bisphosphate Aldolase B Deficiency

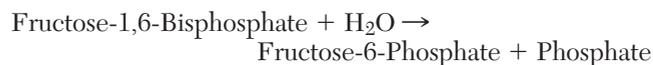

- Enzyme: homotetramer
- Gene location: chromosome 9q13-q32
- Frequency: very rare, except approximately 1 in 20,000 in Swiss persons

Hereditary fructose intolerance is secondary to a deficiency of the enzyme fructose-1,6-bisphosphate aldolase (Cornblath and Schwartz, 1991; Gitzelmann et al, 1995). There are different isoforms of aldolases in human tissues. The enzyme deficiency in this disease results in an impairment in the conversion of fructose-1-phosphate to glyceraldehyde and dihydroxyacetone phosphate and, to a much lesser degree, in the conversion of fructose-1,6-bisphosphate to glyceraldehyde-3-phosphate and dihydroxyacetone phosphate. The disorder is inherited as an autosomal recessive trait. Manifestations of clinical disease depend on sucrose or fructose ingestion. Thus, it usually does not come to clinical attention in the newborn period unless fruits are started early in the diet or the patients are started on a formula that contains sucrose or fructose.

The major clinical findings are poor feeding, vomiting, loose stools, poor growth, hepatomegaly, and any sign that could be related to hypoglycemia. Classically, the infants become ill soon after ingesting fructose. The acute signs may include pallor and lethargy, an altered state of central nervous system (CNS) function due to hypoglycemia. The major laboratory findings consist of hypoglycemia; hypophosphatemia; elevations of serum

ALT and AST, including any of the findings that may be associated with hepatocellular disease per se; and the presence of reducing substances in the urine. The liver disease may be severe. Patients may be jaundiced with hyperbilirubinemia. There may be a bleeding diathesis. In addition to liver disease, renal tubular dysfunction may lead to full-blown renal Fanconi syndrome. Thus, one may detect metabolic acidosis due to a renal tubular acidosis, hypophosphatemia, impaired urate handling, spillage of glucose as well as fructose into the urine, and generalized amino aciduria. It is believed that the severity of the clinical findings is related to the amount of fructose ingested. Infants, however, probably because of decreased intake, may manifest only the signs of poor growth and may have few findings related to liver disease, except perhaps intermittent hypertransaminasemia. The suspicion of the physician is crucial in establishing the diagnosis. An intravenous fructose test may be performed under controlled circumstances, such as in the NICU or clinical research center, to determine whether, after 15 to 30 minutes of fructose administration, serum phosphate and glucose levels decrease and serum AST and ALT values rise. In the past, diagnosis depended on enzyme analysis, but molecular diagnostic testing is more available now. The treatment consists of elimination of dietary fructose and sucrose.

#### Fructose-1,6-Bisphosphatase Deficiency

- Enzyme: homotetramer
- Gene location: unknown
- Frequency: very rare

The deficiency of the enzyme fructose-1,6-bisphosphatase results in an inability to hydrolyze fructose-1,6-bisphosphate to fructose-6-phosphate (Baker and Winegrad, 1970; Gitzelmann et al, 1995). This enzyme is key in gluconeogenesis. The main clinical features of the disease are hypoglycemia and the signs related to glucose deprivation in the CNS. The disease is primarily brought on by fasting, not by fructose ingestion, although fructose may exacerbate the abnormalities induced by fasting adaptation. Enlargement of the liver due to diffuse steatosis may be present only during periods of fasting and enhanced gluconeogenesis. The laboratory findings consist of hypoglycemia, ketosis, and lactic acidosis. The acidosis due to accumulation of lactic, 3-hydroxybutyric, and acetoacetic acids may be severe in this disease. Diagnosis depends on enzymatic analysis. The therapy consists primarily of avoidance of fasting.

### INBORN ERRORS OF AMMONIA METABOLISM

#### Ornithine Transcarbamylase (OTC) Deficiency

- Enzyme: homotrimer
- Gene location: chromosome X p21.1
- Frequency: 1 in 70,000 to 100,000

### Argininosuccinate Lyase (ASAL) Deficiency

- Enzyme: homotetramer
- Gene location: chromosome 7 cen-p21
- Frequency: 1 in 70,000 to 100,000

### Argininosuccinate Synthetase (ASAS) Deficiency

- Enzyme: homotetramer
- Gene location: chromosome 9q34
- Frequency: 1 in 70,000 to 100,000

### Carbamylphosphate Synthetase I (CPSI) Deficiency

- Enzyme: homodimer
- Gene location: chromosome 2p
- Frequency: 1 in 70,000 to 100,000

#### CASE STUDY 3

A male infant born at term after an uncomplicated pregnancy, labor, and delivery was noted to be lethargic with poor feeding at 2 days of age. Laboratory studies showed his plasma ammonium level to be more than 1500  $\mu\text{M}$ . A plasma amino acid quantitation revealed massive elevations of glutamine (2640  $\mu\text{M}$ ; normal is 422 to 849  $\mu\text{M}$ ) and alanine (2540  $\mu\text{M}$ ; normal is 120 to 449  $\mu\text{M}$ ) and an undetectable level of citrulline. The most likely diagnosis was the X-linked disease ornithine transcarbamylase (OTC) deficiency in a male infant. Because of hyperammonemic coma, arrangements were immediately made for hemodialysis. Before catheter placements, the infant was given an intravenous bolus of sodium benzoate and sodium phenylacetate, both at 250 mg/kg per 24 hours. Intravenous arginine hydrochloride at 400 mg/kg per 24 hours was administered as a continuous infusion. In addition, the infant was given 10% glucose intravenously to suppress catabolism. The medications were continued during hemodialysis. After several hours of hemodialysis, the plasma ammonium level had fallen to the 200- $\mu\text{M}$  range, and peritoneal dialysis was instituted. Normalization of the plasma alanine and glutamine levels occurred more gradually. After 3 days of peritoneal dialysis therapy, the plasma ammonium levels were within the normal range, and the severe encephalopathy resolved.

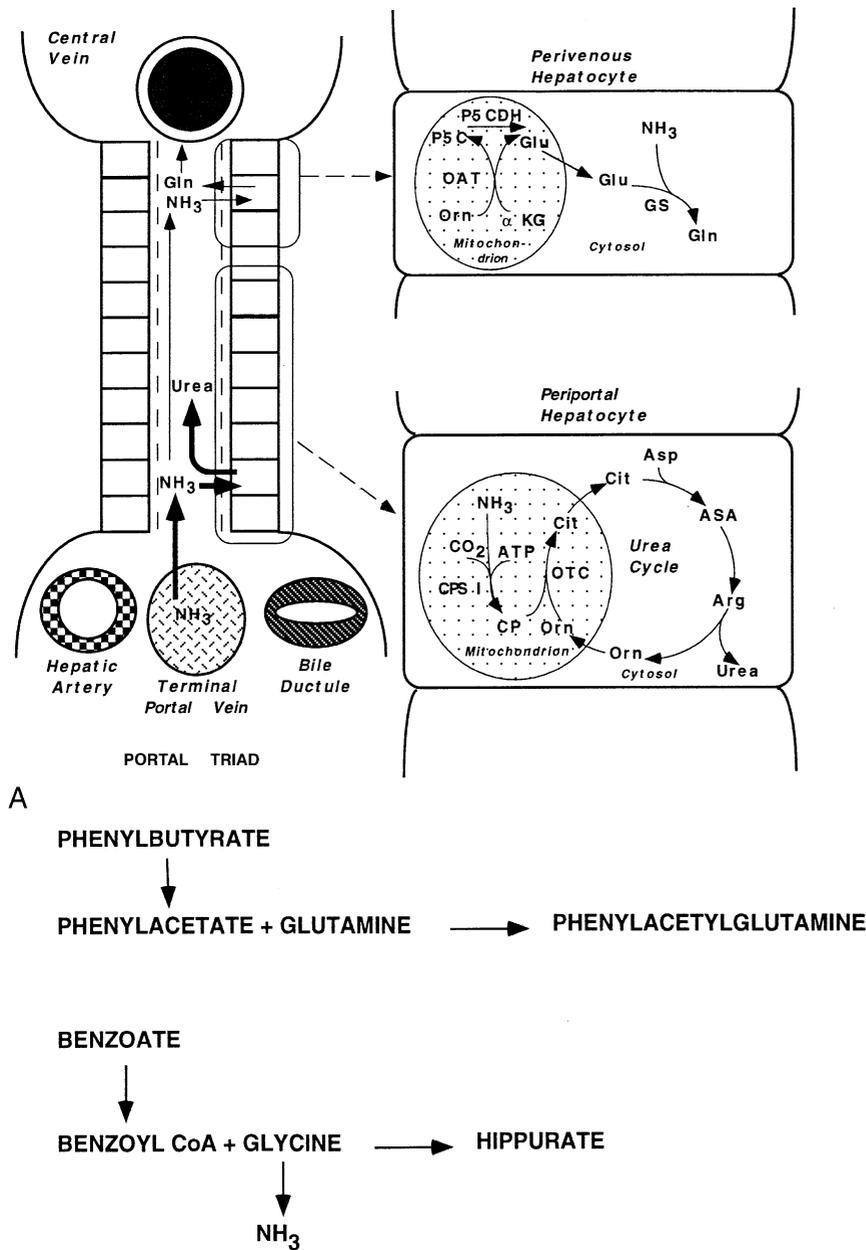

The patient was discharged at 2½ weeks of age on a very-low-protein diet (0.7 g/kg per day) with supplementation of essential amino acids (0.7 g/kg per day), oral sodium benzoate (250 mg/kg per day), sodium phenylacetate (250 mg/kg per day) and arginine (174 mg/kg per day). He suffered no further episodes of hyperammonemia during the first year of life, and at 15 months of age, he underwent a liver transplantation. The OTC activity in the liver that was removed was undetectable. An analysis of genomic DNA revealed a CGA to CAA mutation in codon 141 of exon 5 of the OTC gene, thus producing an arginine to glutamine substitution (R141Q), which is a severe mutation involving the active site of the OTC enzyme. After transplantation, the therapy was discontinued, and although the patient has been on a regular-protein diet, plasma ammonium levels have completely normalized. Plasma citrulline levels remained undetectable.

Genetic diseases involving each of the five enzymes of the hepatic mitochondrial urea cycle have been described (Brusilow and Horwich, 1995). In the urea cycle, carbamylphosphate, which carries the nitrogen atom from ammonia, condenses with ornithine to form citrulline in a reaction catalyzed by the enzyme OTC. The most common defect among the inborn errors of the urea cycle is OTC deficiency. Citrulline subsequently interacts with aspartate to form argininosuccinate (ASA), and in the process, another waste nitrogen atom is shuttled into the urea cycle substrate. Arginine is formed from ASA, and the terminal enzyme in this cycle, arginase, converts arginine to urea for urinary excretion while regenerating ornithine to complete the cycle (Fig. 22–3). The first step in this cycle involves the synthesis of carbamylphosphate, and this reaction, catalyzed by carbamylphosphate synthetase type I (CPS-I), requires an activator, *N*-acetylglutamate, which is synthesized from acetyl coenzyme A (CoA) and glutamate via the enzyme *N*-acetylglutamate synthetase (NAGS). Rare patients may have reduced activity of NAGS.

With the exception of arginase deficiency, each of these enzyme deficiencies has been associated with disease in the newborn period. Clinical presentation in the newborn period is similar for all these defects (Batshaw, 1984). Almost all the infants are well in the first 12 to 24 hours of life when they begin to manifest poor feeding, vomiting, hyperventilation, lethargy, and coma, usually with seizures. When these diseases are untreated, they are almost always fatal. The treatment requires specific therapy to lower the waste nitrogen burden, including the toxic substance ammonia. An additional clinical finding is increased intracranial pressure. As with maple syrup urine disease (MSUD), the severe encephalopathic and life-threatening features may be related to brain edema. Chronic hepatomegaly has been reported in patients with argininosuccinic aciduria, whereas in the other urea cycle disorders, hepatomegaly is evident only during hyperammonemic episodes. Histologic examination of the liver shows modest fatty infiltration and fibrosis. Children with argininosuccinic aciduria may also manifest a specific abnormality of the hair, *trichorrhexis nodosa*.

The main laboratory finding in the urea cycle enzyme defects (UCEDs) is a plasma ammonium elevation. Plasma ammonium values may vary in different laboratories. In general, however, with automated chemistry testing for ammonia, the normal plasma values in older infants, children, and adults range between 10 and 35  $\mu\text{mol/L}$ . However, in the Clinical Chemistry Laboratory at the Children's Hospital of Philadelphia, the normal plasma ammonium value in newborns may be as high as 110  $\mu\text{mol/L}$ . In patients with newborn-onset UCEDs who are acutely ill, the plasma ammonium levels are often higher than 1000 or 2000  $\mu\text{mol/L}$ . Patients with UCEDs usually do not have metabolic acidosis unless they are in a terminal state with vascular collapse or respiratory failure. Instead, the characteristic acid-base abnormality associated with hyperammonemia is respiratory alkalosis due to the effect of ammonia on the respiratory control centers in the brainstem.

The various UCEDs can usually be distinguished on the basis of the pattern and levels of plasma amino acids. Because citrulline is the product of the CPS-I and OTC reactions and the substrate for argininosuccinate synthetase

**FIGURE 22-3. A**, Depicted is the nonhomogeneous distribution of enzymes involved in ammonia metabolism in the hepatocytes of an acinar sinusoid as they are linearly distributed from the portal triad to the region of the central vein or terminal hepatic venule. The specific enzymatic reactions are shown for an individual periportal and perivenous hepatocyte. The glutamine synthetase (GS) and ornithine aminotransferase (OAT) enzyme activities are expressed exclusively in the one to three cell layers surrounding the central vein, that is, the region of zone 3 of the liver lobule, whereas the urea cycle enzymes are concentrated within the periportal hepatocytes. However, the urea cycle enzyme activities are higher in zone 1 immediately surrounding the portal triad than in the middle zone 2. The hepatocytes are shown as *squares*, the hepatic mitochondria as *shaded circles*, and the lining of the space of Disse as the *interrupted lines* on either side of the linear array of hepatocytes. Arg, arginine; ASA, argininosuccinate; Asp, aspartate; ATP, adenosine triphosphate; Cit, citrulline; CP, carbamylphosphate; CPS-I, carbamylphosphate synthetase type 1; Gln, glutamine; Glu, glutamate;  $\alpha$ -KG,  $\alpha$ -ketoglutarate; NH<sub>3</sub>, ammonia; CO<sub>2</sub>, CO<sub>2</sub> or bicarbonate; Orn, ornithine; P5C, pyrroline 5-carboxylate; P5CDH, pyrroline-5-carboxylate dehydrogenase. **B**, The medications sodium phenylacetate and phenylbutyrate and sodium benzoate promote alternative waste nitrogen disposal by participating in these two mitochondrial reactions. (Adapted from Tuchman M, Lichenstein GR, Rajagopal BS, et al: Hepatic glutamine synthetase deficiency in fatal hyperammonemia after lung transplantation. *Ann Intern Med* 127:447, 1997.)

(ASAS), its value is critical. In newborn-onset CPS-I and OTC deficiencies, plasma citrulline concentrations are zero to trace. With *OTC deficiency*, there is increased urinary orotate excretion secondary to carbamylphosphate accumulation and pyrimidine synthesis. With *CPS-I deficiency*, carbamylphosphate production is decreased or absent, and orotate excretion is decreased. Theoretically, a defect in the production of the activator of CPS-I, namely NAG, resembles a partial CPS-I deficiency. In citrullinemia, the plasma citrulline concentrations are markedly elevated. With argininosuccinic aciduria, plasma citrulline concentration is moderately elevated, in the range of 100 to 300  $\mu\text{mol/L}$ , and can be readily detected during an analysis of plasma by amino acid column chromatography.

Because the ability of infants with these disorders to excrete waste nitrogen as urea is impaired, therapy initially

centered around on the reduction of nitrogen intake by decreasing dietary protein and providing essential amino acids or the ketoacid analogues. This approach theoretically permits adequate growth without an excess nitrogen load. Excessive protein leads to hyperammonemia. However, too great a restriction of protein during long-term therapy leads to poor growth. Actually, this approach fails when the patient is in negative nitrogen balance, as occurs in the catastrophically ill infant presenting in the first week of life with massive hyperammonemia. For such an infant with hyperammonemia and coma, the mainstay of therapy is dialysis treatment. Hemodialysis is the most effective way of reducing plasma ammonium levels because it affords the greatest clearance of ammonia (Rutledge et al, 1990). Next in efficacy is continuous arteriovenous hemofiltration (CAVH) (Thompson et al, 1991). Although

the clearance rate is not as great as with hemodialysis, the method has the added benefit of not being administered intermittently; with steady administration, there is less likelihood of major swings in intravascular volume that may exacerbate an already catabolic state. Ammonia clearance with peritoneal dialysis is only approximately one tenth that of CAVH and is not recommended for specific UCED therapy in the newborn period.

While the intensive care personnel are waiting for dialysis therapy to be instituted, alternative waste nitrogen therapy using intravenous sodium benzoate, sodium phenylacetate, and, for patients with ASAS and ASAL deficiencies, arginine hydrochloride should be initiated (Brusilow, 1991; Brusilow and Batshaw, 1979; Brusilow et al, 1979). (The medications as well as the proper dose for a bolus and 24-hour sustaining infusion are available from Ucylyd Pharma, Inc., Scottsdale, AZ.) Patients with OTC and CPS-I deficiencies should also receive intravenous arginine hydrochloride, because body arginine pools can begin to deplete as arginine becomes an essential amino acid with a complete block in cycle function (Brusilow, 1984). The plasma arginine levels are usually low in all sick newborns with UCED. Unless corrected, arginine deficiency accentuates the hyperammonemia by promoting negative nitrogen balance and, theoretically, by failing to provide its usual stimulation of NAGS. A second role of arginine is to stimulate alternative pathways of waste nitrogen excretion. It does so by promoting synthesis and excretion of citrulline and ASA in citrullinemia and argininosuccinic aciduria, respectively. Argininosuccinate contains both waste nitrogen atoms destined for excretion as urea. It has a renal clearance rate equal to the glomerular filtration rate, provided that it is continuously synthesized and excreted. Accordingly, ASA should serve as an effective substitute for urea as a waste nitrogen product.

Like ASA, citrulline can be a means to excrete waste nitrogen, but it contains only the one nitrogen atom derived from ammonium, lacking the second nitrogen derived from aspartate. Citrulline also has a more limited urinary excretory capacity than ASA. Thus, therapy with arginine is less effective for citrullinemia. With citrullinemia and the other urea cycle disorders, arginine therapy is combined with sodium benzoate and sodium phenylacetate, both of which promote excretion of waste nitrogen. Sodium benzoate is conjugated with glycine to form hippurate, which is cleared by the kidney at five times the glomerular filtration rate (see Fig. 22-3). Theoretically, 1 mole of waste nitrogen is synthesized and excreted as hippurate for each mole of benzoate ingested. The hippurate synthetic mechanism resides primarily in the hepatic mitochondria and depends on an intact mitochondrial energy system for adenosine triphosphate (ATP) synthesis. The glycine consumed in this reaction can be replaced by either serine or the glycine cleavage pathway. Sodium phenylacetate, as well as sodium phenylbutyrate, which is used for long-term therapy in the absence of sodium benzoate, conjugates with glutamine to form phenylacetylglutamine, which is excreted by the kidney (see Fig. 22-3). Sodium phenylbutyrate is converted to phenylacetate in the liver. Glutamine contains two nitrogen atoms, whereas glycine contains one. Two moles of waste nitrogen are removed for each

mole of phenylacetate administered. This acetylation reaction occurs in the kidney and the liver.

The outcome for patients with severe newborn-onset CPS-I and OTC deficiencies is poor. Sometimes, even dialysis therapy cannot rescue severely affected boys with X-linked OTC deficiency in the first few days of life. Prospectively administered alternative pathway therapy in conjunction with administration of high-calorie fluids usually prevents death and severe hyperammonemia in these patients. Even after institution of successful therapy, the morbidity and mortality rates are high in such patients. At present, liver transplantation is recommended for patients with CPS and OTC deficiencies who present in the newborn period and have almost no residual enzyme activity. Alternative pathway therapy has led to a 92% 1-year survival rate in newborns who recover from hyperammonemic coma, but most of the survivors are mentally retarded (Msall et al, 1984). There is a significant correlation between the duration of newborn hyperammonemic coma and the developmental quotient (DQ) score at 12 months of age (Msall et al, 1984). Four of five reported children in whom duration of coma was 2 days or less had normal IQ scores, whereas all seven children in whom coma lasted 5 days or longer were severely mentally retarded. This fact points to the devastating effects of prolonged newborn hyperammonemic coma and the importance of early diagnosis and treatment. Mutational analysis of DNA is available for most of these disorders (Brusilow and Horwich, 1995). If the lesion in a particular family is known, prenatal diagnosis by means of direct DNA analysis is also feasible. With the exception of OTC deficiency, all the UCEDs are inherited as autosomal recessive traits.

### Transient Hyperammonemia of the Newborn

Transient hyperammonemia of the newborn (THAN) is a distinct clinical syndrome that was first identified by Ballard and colleagues in 1978. The disease usually develops in premature infants during the course of treatment for respiratory distress syndrome. The plasma ammonium level may be enormously elevated, as high as that found in any of the patients with the most severe type of UCED. Its onset is usually in the first 24 hours after birth, when the infant is undergoing mechanical ventilatory support. Affected babies can manifest all the signs associated with hyperammonemic coma. The diagnosis may be difficult to determine, however, because many of these same infants are receiving sedatives and muscle relaxants to optimize therapy of their life-threatening pulmonary disease. Important clues are the absence of deep tendon reflexes, the absence of the normal newborn reflexes, and decrease or absence of response to painful stimuli. As with hyperammonemic coma in the UCED, this medical emergency requires dialysis therapy.

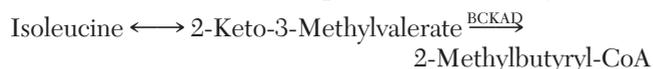

The cause of this disease is unknown. The plasma amino acid levels are similar to those found in CPS-I or OTC deficiency. Investigators have hypothesized that the disorder may be caused by impairment of hepatic mitochondrial energy production or shunting of portal blood away from the liver, such as in patent ductus venosus. However, patients with congenital portal shunting defects have been

described with disturbances in liver function such as impaired galactose metabolism, but they are not premature and do not have life-threatening hyperammonemia (Gitzelmann et al, 1992; Matsumoto et al, 1993). The mortality rate in THAN is high. A patient who can be treated early and aggressively may survive the episode. There is no evidence that any of the survivors has suffered any further episodes of hyperammonemia, nor has there been any further evidence of impaired ammonia metabolism.

## INBORN ERRORS OF AMINO ACID METABOLISM

### Maple Syrup Urine Disease

#### Branched-Chain 2-Keto Dehydrogenase (BCKAD) Complex Deficiency

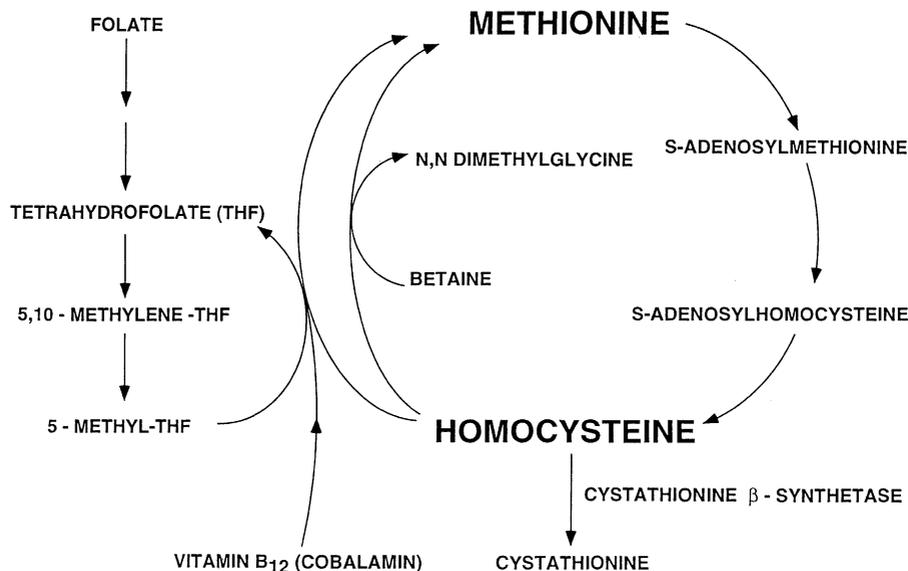

- Enzyme: 6 subunits:  
BCKA decarboxylase subunits ( $E_1$ ),  $2\alpha$  and  $2\beta$   
1 dihydrolipoyl transacylase ( $E_2$ ) subunit

1 dihydrolipoyl dehydrogenase ( $E_3$ ) subunit  
1 BCKAD kinase subunit  
1 BCKAD phosphatase subunit

- Gene locations:  
 $E_1\alpha$  on chromosome 1q13.1-q13.2  
 $E_1\beta$  on chromosome 6p21-p22  
 $E_2$  on chromosome 2p31  
 $E_3$  on chromosome 7q31-q32
- Frequency: for MSUD, 1 in 200,000; except for Pennsylvania Mennonites, in whom frequency is 1 in 358.

MSUD is a rare inborn error of amino acid metabolism (Chuang and Shih, 1995; Menkes et al, 1954). It is inherited as an autosomal recessive trait and is secondary to a deficiency of the enzyme branched-chain 2-keto dehydrogenase (BCKAD) complex. This enzyme catalyzes the conversion of each of the 3-ketoacid derivatives of the branched-chain amino acids (BCAAs) into their decarboxylated coenzyme metabolites within the mitochondria (Fig. 22-4). The disease occurs in 1 in 200,000 newborn infants around the world, but in the Mennonite communities of the United States, the frequency is 1 in 358 because of a founder effect for a point mutation in the  $E_1\alpha$  gene. In most of the patients around the world, as well as in the Mennonite community, the classic form of the disease occurs. It is associated with severe and catastrophic illness in the newborn period and usually results

**FIGURE 22-4.** The pathways, metabolites, and vitamin cofactors important in the interconversion of methionine and homocysteine are shown in this abbreviated scheme of the trans-sulfuration pathway. In a methyl-transfer reaction, homocysteine is converted to methionine; the reaction is catalyzed by a cobalamin-containing enzyme, 5-methyl-tetrahydrofolate-homocysteine methyltransferase or methionine synthase. An alternate reaction involves betaine-homocysteine methyltransferase. Thus, vitamin B<sub>12</sub> and folate are important vitamins in homocysteine and methionine metabolism. The 5,10-methylene tetrahydrofolate (THF) derived from dietary folate is converted to 5-methyl THF by the enzyme 5,10-methylene THF reductase. In classic homocystinuria, the deficient enzyme is the cystathionine  $\beta$ -synthetase, which catalyzes the conversion of homocysteine to cystathionine, a precursor of cysteine. This pathway is readily operative in the adult so that cysteine is a nonessential amino acid. In newborn infants, however, synthesis of cysteine does not occur at the same rate as in adults. Adenosylmethionine-dependent methyl transfer may be extremely important in the central nervous system. Most of the patients who come to clinical attention in the newborn period have defects in the remethylation of homocysteine to methionine, and thus, these patients may have a severe deficiency of adenosylmethionine in the brain and spinal cord.

in death without specific medical intervention. Typically, the infants are well at birth; only after 2 or 3 days of ingestion of breast milk or formula do they begin to manifest poor feeding and spitting up. Lethargy becomes evident; the cry may be shrill and high pitched. There may be hypotonia alternating with hypertonia and opisthotonic posturing. The odor of maple syrup may be detected in the saliva, on the breath, in the urine and feces, and in cerumen obtained from the ear. The babies become more and more obtunded and eventually lapse into a deep coma. The anterior fontanelle may be bulging. Seizures may develop. The life-threatening encephalopathic features may simply be related to brain edema (Lungarotti et al, 1982; Riviello et al, 1991).

Laboratory findings consist of metabolic acidosis. The anion gap may be raised but not necessarily so. There is almost always ketonuria. The plasma ammonium values are not usually elevated. The complete blood count (CBC) is not usually abnormal. The levels of the plasma BCAAs leucine, isoleucine, and valine are elevated, with striking elevation in leucine. The normal ranges for plasma leucine, isoleucine, and valine in the newborn period are 29 to 152  $\mu\text{mol/L}$  (or 0.4 to 2.0 mg/dL), 11 to 87  $\mu\text{mol/L}$  (0.1 to 1.1 mg/dL), and 71 to 236  $\mu\text{mol/L}$  (0.8 to 2.8 mg/dL), respectively. In these patients who are critically ill, the leucine levels may range between 1.9 and 6.9 mM (or 25 and 90 mg/dL). In the past, almost every newborn infant who was recognized to have MSUD and was in a severely decompensated state received peritoneal dialysis in a tertiary care center. The treatment was successful in most instances, but it did not allow for as rapid a rate of reduction in plasma BCAA levels as did hemodialysis or CAVH (Rutledge et al, 1990; Thompson et al, 1991).

It is now clear that a nutritional approach works just as well as peritoneal dialysis in newborns with MSUD (Berry et al, 1991; Parini et al, 1993; Shih et al, 1975; Townsend and Kerr, 1982). The approach consists of the use of a BCAA-free modified parenteral nutrition therapy for infants as well as older children with acute metabolic decompensation (Berry et al, 1991). Usually, insulin therapy is also necessary to curtail the effects of catabolic stress (Berry et al, 1991; Wendel et al, 1982). On the basis of the rate of plasma leucine decline, my colleagues and I have found that this nutritional therapy is comparable to peritoneal dialysis when the plasma leucine levels are as high as 25 to 40 mg/dL. It is unclear, however, whether CAVH or hemodialysis is more beneficial in achieving a greater rate of reduction of the plasma BCAAs and their corresponding branched-chain ketoacids (BCKAs) when the levels of leucine are in the range of 60 to 90 mg/dL. Most patients who are successfully treated by 7 days of age do not have mental retardation. Patients whose diagnosis and therapy are delayed, however, and perhaps even in those whose disorder is diagnosed in the first week of life but who have suffered such severe damage because of increased intracranial pressure often have substantial decreases in DQ or IQ, as well as signs compatible with spastic diplegia or quadriplegia.

The mainstay of long-term therapy for patients with MSUD who survive the newborn period is a special formula devoid of the BCAAs. The amount of BCAAs necessary to sustain growth but maintain the plasma,

leucine, isoleucine, and valine levels in the normal range is supplied with a regular proprietary formula in limited amounts. In the first week of life, this is about 100 mg of leucine per kilogram of body weight daily and 50 mg/kg daily of both isoleucine and valine. The BCAA requirements and thus the rates of utilization of the BCAAs for protein accretion drop rapidly in the first year of life in conjunction with the decline in growth velocity in young infants. As with PKU, it is imperative that the administration of the special amino acid formula be carefully monitored by means of frequent plasma amino acid quantities. One of the most common errors made in the treatment of MSUD is the failure to administer adequate amounts of supplemental isoleucine and valine solutions to maintain the normal plasma levels, because proprietary formulas alone do not always meet the needs of each growing baby (i.e., adequate amounts of each BCAA are not supplied by a formula alone). Deficiency of BCAAs may result in a severe exfoliative rash and anemia. The rash may mimic that of severe acrodermatitis enteropathica (Diliberti et al, 1973; Giacoia and Berry, 1993).

As with many of the inborn errors of amino acid, organic acid, and ammonia metabolism, protein administration in the infant whose disease is under previous good control and in metabolic balance with diet therapy must be discontinued during periods of intercurrent infections because catabolism, possibly driven by counter-regulatory hormones or cytokines, triggers metabolic decompensation through release of BCKA from skeletal muscle. Metabolic decompensation is further exacerbated by poor nutritional intake. It is imperative that during these times, adequate calories and fluids be given to prevent the crisis from escalating into a medical emergency.

In selected instances, a molecular diagnosis of MSUD may be undertaken; such a diagnosis is especially useful in targeted populations such as the Mennonites. Rarely, patients may have a defect in the E<sub>2</sub> component (Danner et al, 1985) or, as discussed in the Primary Lactic Acidosis section, in the E<sub>3</sub> component.

## Hereditary Tyrosinemia Type 1

### Fumarylacetoacetate Hydrolase (FAH) Deficiency

- Enzyme: homodimer
- Gene location: chromosome 15q23-q25
- Frequency: very rare, except in French-Canadians in Quebec

Tyrosinemia type 1 is due to a deficiency of the enzyme fumarylacetoacetate hydrolase (FAH) (Lindblad et al, 1977; Mitchell et al, 1995). This enzymatic reaction is distal in the phenylalanine and tyrosine pathway, and the disorder is actually an inborn error of organic acid metabolism, with hypertyrosinemia being a secondary and variable biochemical effect. Tyrosinemia type 1 is a rare disease inherited in an autosomal recessive manner. The highest incidence is found in those of French-Canadian ancestry as a result of a founder effect (De Bracketeer and Laroche, 1990).

Two clinical phenotypes may be detected. The first occurs in early infancy and is a severe, usually fatal disease in which liver disease dominates the clinical picture. The second is a more chronic phenotype, and patients present with hypophosphatemic rickets related to renal Fanconi syndrome. These patients usually also have evidence of liver disease, albeit milder. Most of the patients with the severe liver disease phenotype do not come to clinical attention in the newborn period. Careful search, however, may reveal the laboratory findings compatible with this disease even in newborn infants (Hostetter et al, 1983). When the disease does manifest in the newborn period, the abnormalities are related to liver disease. Like hereditary fructose intolerance and hereditary galactosemia, tyrosinemia type 1 is one of the inborn errors of metabolism in which hepatocellular disease is also associated with renal Fanconi syndrome. In the phenotype seen in early infancy, the clinical findings are hepatomegaly, bleeding from coagulation defects, and jaundice. Ascites is not uncommon. The laboratory findings consist of abnormal liver function tests with increases in serum AST, ALT, and direct and indirect bilirubin; prolongations of PT and PTT; and the findings related to renal Fanconi syndrome, such as glycosuria, hypophosphatemia, hypouricemia, proteinuria due to  $\beta_2$ -microglobulin hyperexcretion, and generalized amino aciduria and organic aciduria.

More specific laboratory abnormalities consist of an increase in serum alpha-fetoprotein levels. In fact, levels of this protein may be elevated even in cord blood (Hostetter et al, 1983). There may be an elevation of plasma tyrosine. However, the hypertyrosinemia is due to a secondary impairment in the function of the liver enzyme, *p*-hydroxyphenylpyruvic acid oxidase, and is not seen in all patients at all times. This statement also is true for the hypermethioninemia. Some patients may have only hypertyrosinemia or only hypermethioninemia. The most important metabolites are those related to the substrate, fumarylacetylacetic acid, the handling of which is defective. Increased levels of the diagnostic metabolite succinylacetone can be detected on urine organic acid quantitation by gas chromatography–mass spectrometry (GC-MS) and in RBCs by the  $\delta$ -aminolevulinic acid dehydratase inhibition assay. One must be careful about the interpretation of these test results. We have encountered patients who, because of the severity of their illness and poor dietary intake or because they were receiving intravenous fluids, had elevations of neither methionine nor tyrosine in plasma and only minute amounts of succinylacetone detectable in urine or RBCs. In any infant with severe liver disease and renal Fanconi syndrome that is not obviously due to other causes, I suggest that succinylacetone, FAH activity, or both be measured in RBCs, even if the urinary succinylacetone metabolites cannot be detected by GS-MS.

In the past, most of the infants with the hepatic form of tyrosinemia type 1 died in early to late infancy. It is now recommended that patients with this disease receive a liver transplantation. However, a medical therapy has been developed that uses the agent 2-(2-nitro-4-trifluoromethylbenzoyl)-1,3-cyclohexanedione (NTBC), which inhibits *p*-hydroxyphenylpyruvate dioxygenase (Lindstedt et al, 1992), thus blocking the conversion of

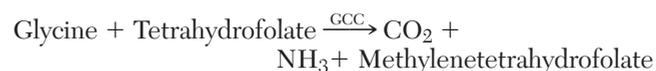

*p*-hydroxyphenylpyruvate, the transamination product of tyrosine, to fumarylacetoacetate and thereby retarding the synthesis and accumulation of succinylacetate and succinylacetone. This therapy has been used successfully to improve liver and renal function as well as to normalize or improve the various laboratory abnormalities. It is unclear, however, whether NTBC therapy will eliminate the need for liver transplantation.

One of the most devastating complications for older infants with tyrosinemia type 1 who have become stabilized is the development of hepatocellular carcinoma. This complication is quite prevalent in tyrosinemia, and most patients who survive infancy or who have a chronic phenotype succumb to the liver disease. Unfortunately, several older infants who underwent successful liver transplantation had pulmonary metastases from liver cancer at the time of the transplant and did not survive. It is recommended that NTBC therapy be started in infants who are acutely ill while they are waiting for a liver transplantation. Tyrosinemia type 1 has no effect on the CNS in this disease other than as a secondary complication of the severe liver disease. So far, most of the liver transplantations have been successful, and the patients have done well on immunosuppressive therapy with only minimal persistent evidence of renal tubular dysfunction while eating a normal diet.

This entity is not to be confused with *transient tyrosinemia of the newborn*, which is prevalent in premature infants and is probably the most common disturbance of amino acid metabolism in humans, secondary to a delayed maturation of *p*-hydroxyphenylpyruvate dioxygenase activity (Levine et al, 1939; Mitchell et al, 1995) or with the *hypertyrosinemia* secondary to liver disease, per se (David et al, 1970).

## Nonketotic Hyperglycinemia

### Glycine Cleavage Complex (GCC) Deficiency

- Enzyme complex: 4 subunits:
  - 1 pyridoxal-phosphate–dependent glycine decarboxylase P protein
  - 1 lipoate-containing hydrogen carrier H protein
  - 1 tetrahydrofolate-dependent T protein
  - 1 lipoamide dehydrogenase L protein
- P protein gene location: chromosome 9p13
- Frequency: 1 in 250,000; except 1 in 12,000 for P protein gene mutation in Finns

Nonketotic hyperglycinemia (NKH) is a rare defect of glycine metabolism (Gerritsen et al, 1965; Hamosh et al, 1995; Tada and Hayasaka, 1987). Inherited as an autosomal recessive trait, the disorder is due to deficient activity of the glycine cleavage enzyme complex (GCC). Its frequency is fewer than 1 in 200,000 newborn infants. Although several variant forms exist, most infants who come to clinical attention in the newborn period—presumably most patients with this disease—have a severe, catastrophic type of disease that mimics the most acute forms of ammonia, amino acids, or organic acid metabolism. The infants are usually well at birth but begin to

manifest hypotonia and seizures after 12 to 36 hours. They quickly become comatose, and there is a loss of all the newborn reflexes as well as the deep tendon reflexes.

The clinical findings relate predominantly to those associated with CNS intoxication. The electroencephalogram (EEG) usually shows a characteristic pattern of spike and slow waves. The babies may manifest hiccups due to diaphragmatic spasms. The main laboratory finding is a massive elevation of plasma glycine. The urine glycine is usually also elevated. The cerebrospinal fluid (CSF) glycine value is elevated and out of proportion to the elevation in blood. A fraction of patients with an atypical biochemical form of NKH have elevated levels of glycine only in CSF. The amino acid serine, which is also a product of the defective enzyme reaction, is depressed in plasma, and there is a corresponding increase in the glycine-to-serine ratio in body fluids. Prenatal CNS lesions have been reported (Dobyns, 1989).

The pathophysiology of this brain disease is not well understood; it is believed that glycine may interfere with the activity of specific chloride channels, thus perturbing the membrane potential and depolarization of neurons. There also appears to be an impairment in alpha-motor neuron outflow tract activity, producing a clinical state that mimics Werdnig-Hoffmann disease. Uncommonly, the plasma ammonium value may be elevated. However, no acidosis or ketosis is seen in this disease—thus the name, *nonketotic hyperglycinemia*. Many of the disorders of organic acid metabolism, such as methylmalonic acidemia and propionic acidemia, are also associated with elevations of plasma glycine, presumably due to a secondary impairment in the GCC, and have been referred to in the past as the *ketotic hyperglycinemia syndromes*.

Although many therapies have been tried in this disease, such as protein restriction, benzoate to trap glycine as the byproduct hippurate, strychnine to affect the lower motor neuron function, and dextromethorphan to block N-methyl-D-aspartate (NMDA) receptors, there is no effective therapy. Most affected babies die in the newborn period despite medical support with assisted ventilation. A transient form of NKH has also been reported in newborns (Luder et al, 1989; Schiffman et al, 1989). Valproate may result in hyperglycinemia due to secondary inhibition of the GCC, as is postulated to explain secondary hyperglycinemia in the disorders of organic acid metabolism, such as propionic acidemia.

### Methionine Synthetase Deficiency

In humans, the essential amino acid methionine is converted to homocysteine, and in the process, a methyl group is transferred to an acceptor molecule from S-adenosylmethionine that serves as a donor for methyl groups in many different reactions (see Fig. 22-4) (Mudd et al, 1995). Subsequently, the homocysteine may either be completely metabolized through the cysteine pathway to sulfate or it may be remethylated back to methionine. Defective methionine remethylation or a deficiency in methionine synthetase leads to an uncommon remethylation form of homocystinuria. Patients with classic homocystinuria, due to a deficiency of the cystathionine beta-synthase enzyme, rarely manifest signs in early infancy (Mudd et al, 1995). In

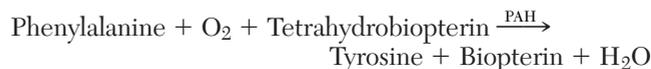

contrast, patients with methionine synthetase deficiency or methionine remethylation defect may come to clinical attention in the newborn period (Fenton and Rosenberg, 1995b). The patients may have either an abnormality in vitamin B<sub>12</sub> metabolism, which may also produce methylmalonic acidemia as well as homocystinuria, or an isolated defect in folate metabolism or the methionine synthetase enzyme (Rosenblatt, 1995). In this reaction, the methyl group from 5-methyltetrahydrofolate, which is derived from 5,10-methylene tetrahydrofolate, is transferred to methylcobalamin and subsequently to homocysteine.

The clinical findings associated with methionine synthetase deficiency are poor growth and development. There may be severe cortical atrophy and possible brain lesions due to thromboses of the arteries or veins, as in classic homocystinuria. The laboratory findings consist of an elevation in plasma homocysteine values and a normal or decreased methionine value. Often the homocysteine values are not as elevated as in classic cystathionine β-synthetase deficiency. If there is a defect in folate or vitamin B<sub>12</sub> metabolism that produces secondary impairment in methionine and synthetase activity, there may also be megaloblastic anemia.

Some patients with a defect in cobalamin metabolism may show response to megadose therapy with hydroxycobalamin. The treatment of the methionine synthetase deficiency is methionine supplementation to restore methionine levels in plasma to normal and to restore CNS pools of methionine, which may be critical in one carbon transfer reaction within the CNS. One can also retard homocysteine accumulation as well as restore methionine levels by administering betaine, which can enhance remethylation of homocysteine to methionine through the alternate betaine methyltransferase pathway. Some investigators have also used pharmacologic doses of cobalamin, folate, and pyridoxine to stimulate flux either through the methionine synthetase or the classic homocysteine pathway. Unfortunately, if infants with this type of disorder are not treated early, there is usually a permanent and devastating effect on cognitive and motor function.

## Phenylketonuria

### Phenylalanine Hydroxylase (PAH) Deficiency

- Enzyme: multimer; identical subunits
- Gene location: chromosome 12q22-q24.1
- Frequency: 1 in 10,000

### CASE STUDY 4

The patient was an 8 lb, 1 oz boy born after a full-term, uncomplicated gestation. Apgar scores were 8 at both 1 minute and 5 minutes. The newborn period passed without difficulty. He demonstrated bronchiolitis at 5 months of age. During the hospitalization for this event, no neurologic abnormalities were detected on physical examination. His parents reported that he walked at 1½ years of age.

At 4 years of age, the patient was referred for neurologic evaluation because of lack of speech development. A behavioral problem was evident: He was noted to be hyperactive. In

addition, he was not toilet trained, was unable to feed or undress himself, related poorly to other people, and occasionally engaged in rocking and head banging. Physical examination found a plantar extension response in the right toe. An EEG showed discharges consistent with seizure activity, and he was started on phenytoin.

At 6 years of age, because this blonde, blue-eyed boy with eczema of the palms had a chronic, nonprogressive encephalopathy manifested as severe mental retardation and idiopathic seizure disorder, a plasma sample was submitted for amino acid column chromatography analysis. The plasma phenylalanine level was 23 mg/dL (normal is 0.4 to 1.6 mg/mL). Result of a urinary ferric chloride test was positive for phenylketonuric derivatives despite the absence of a musty or mousy odor. Further research into the neonatal history showed that the original newborn filter-paper screen for PKU had been omitted.

PKU is the most common inborn error of amino acid metabolism that can result in mental retardation (Scriver et al, 1995). It is due to a defect in the activity of the enzyme phenylalanine hydroxylase (PAH), which converts phenylalanine to tyrosine, a reaction that resides primarily in the liver. Thus, in PKU, it is the deficiency of this liver enzyme that results in brain disease. Because of the paucity of findings in the newborn period or even early infancy, PKU usually went undiagnosed before newborn screening was instituted. As discussed in Chapter 27, newborn screening has enabled us to routinely prevent mental retardation from PKU. It is important for physicians caring for newborns to be aware of the pitfalls of screening that are summarized in Chapter 27. This disease, inherited as an autosomal recessive trait, has an overall frequency of about 1 in 12,000 newborns. It exemplifies the interaction of a gene and the manipulatable environment (i.e., diet) in the expression of a disease (Scriver and Clow, 1980a, 1980b).

The preceding case study illustrates that patients may easily escape detection even during childhood. After birth, the baby with PKU who is ingesting adequate amounts of breast milk or a proprietary formula will experience a gradual and persistent increase in plasma phenylalanine levels. The cutoff value for newborn screening results in most states is 4 mg/dL, with the upper range of normal being approximately 2 mg/dL. In the first 24 hours after birth, the plasma phenylalanine value in most infants with PKU readily exceeds the 4 mg/dL cutoff, but by the end of the first week of life, it is usually between 20 and 40 mg/dL. At that time, the derivatives of phenylalanine, the so-called phenylketonuric compounds, are excreted in urine in excess, and the greater excretion of phenylpyruvic acid gives rise to the positive ferric chloride test result, in which the urine turns green. The odor in PKU is due to increased production of the derivative phenylacetic acid, which has a musty or mousy odor. This odor may be detected when the levels of phenylalanine exceed 10 to 15 mg/dL, but it is not detected in every patient.

In the first 6 months of life, the affected babies may have difficulties with feeding and vomiting. In some instances, the persistent vomiting has been associated with the diagnosis of pyloric stenosis, for which corrective surgery has been performed, perhaps inappropriately. Developmental delay is usually evident in the second 6 months of life. Patients may have seizures, sometimes infantile spasms in early infancy associated with a hypsarrhythmic EEG pattern. Persistent

elevation of plasma phenylalanine levels above 10 mg/dL is sufficient to result in mental retardation.

The mechanism of brain disease in PKU is still unknown. It may be related to the effect of high phenylalanine levels on transport of amino acids across the blood-brain barrier and then into brain neurons or glial elements. The plasma levels of tyrosine may be decreased, especially in those patients not receiving tyrosine supplementation in the special amino acid powder used as a daily nutrient. For many years investigators have speculated that hypotyrosinemia may also play a role in the CNS deficits because tyrosine (only a liver enzyme) cannot be synthesized within the CNS by PAH. Older infants often exhibit long tract findings, such as spastic quadriparesis and spastic quadriplegia. The untreated infant demonstrates postnatally acquired microcephaly and may also have severe behavioral problems. Average findings consist of elevated serum plasma phenylalanine levels, normal or subnormal plasma tyrosine levels, and increased urinary excretion of phenylpyruvic acid, phenyllactic acid, and phenylacetic acid.

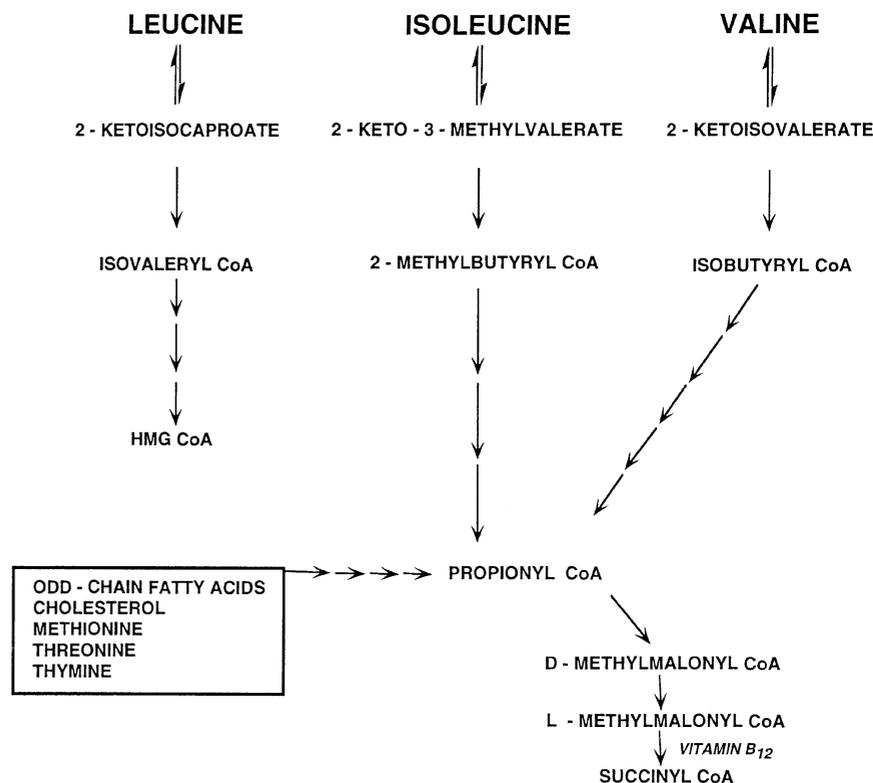

The mainstay of therapy is a low-protein diet and the use of a special amino acid-containing formula that does not include phenylalanine. The patients must receive an adequate amount of phenylalanine from the protein in proprietary formulas and later from table foods, which is tracked by means of a phenylalanine exchange system, to allow for the normal daily utilization of phenylalanine for protein synthesis while maintaining plasma phenylalanine levels in a range as close as possible to normal. Deviations from normal plasma levels are believed to be associated with chronic, perhaps even acute, effects on CNS function and testing performance. Thus, the diet should be one for life. The phenylalanine hydroxylase gene has been cloned and sequenced, and the mutations that are responsible for most abnormalities in humans are known. DNA sequencing and mutational analysis may be used to identify carriers in families and to provide a scientific rationale during family counseling.

Some rare patients with hyperphenylalaninemia have a most severe disease not because of the deficiency of the phenylalanine hydroxylase apoenzyme but rather because of deficiency of the active cofactor of this enzyme, tetrahydrobiopterin. Several defects in the metabolism of biopterin can produce this type of hyperphenylalaninemia. Patients with these uncommon types of PKU usually come to attention in the newborn period because of severe seizure activity. Patients with the biopterin deficiency can have evidence of severe brain damage despite treatment with a low-phenylalanine diet. This may be related to deficiencies of other neurotransmitters whose synthesis also depends on adequate levels of tetrahydrobiopterin. These various other defects, such as the dihydropteridine reductase, 6-pyruvoyl tetrahydropterin synthetase, and the guanosine triphosphate cyclohydrolase deficiencies, can be ascertained by urinary measurements of neopterin and biopterin in urine.

## INBORN ERRORS OF ORGANIC ACID METABOLISM

Defects in the catabolism of the BCAAs are responsible for most of the disorders of organic acid metabolism (Fig. 22-5). Typical examples are methylmalonic, propionic,

**FIGURE 22-5.** The branched-chain amino acids leucine, isoleucine, and valine are reversibly transaminated to their corresponding 2-keto analogues, which are the substrates for the single decarboxylase (branched-chain 2-keto dehydrogenase) ([BCKAD]) enzyme deficient in maple syrup urine disease. Reduced activity of isovaleryl coenzyme A (CoA) dehydrogenase, the next enzyme in the leucine degradative pathway, is the cause of isovaleric acidemia. The immediate precursor of ketones, 3-hydroxy-3-methylglutaryl CoA (HMG-CoA), is the final product of the leucine catabolic pathway. However, its production more strongly depends on oxidation of fatty acids as in ketogenesis and in cholesterol biosynthesis. Propionyl CoA, which accumulates in both propionic and methylmalonic acidemia, may be synthesized from isoleucine, valine, odd-chain fatty acids, cholesterol, methionine, threonine, and thymine. The adenosyl form of vitamin B<sub>12</sub> is the important cofactor in the L-methylmalonyl CoA mutase-catalyzed conversion of L-methylmalonyl CoA to the citric acid cycle intermediate, succinyl CoA.

and isovaleric acidemias. An organic acid is any organic compound that contains a carboxy functional group but no  $\alpha$ -amino group as in an amino acid. In this section, we consider the disorders of fatty acid oxidation, ketone body metabolism, and lactic acid metabolism as well as the more classic inherited defects in organic acid metabolism. What is true for all these disorders is that the ability to establish a diagnosis depends primarily on the suspicion of the clinician caring for the sick infant. Most of the disorders also require sophisticated testing such as GC-MS to identify the specific organic compound responsible for the toxic syndrome. As discussed earlier, acidosis and encephalopathy are usually the hallmarks of these syndromes when they manifest in the newborn period.

## Methylmalonic Acidemia

### L-Methylmalonyl-CoA Mutase (MCM) Deficiency

- Enzyme: homodimer
- Gene location: chromosome 6p12-p21.2
- Frequency: 1 in 20,000

#### CASE STUDY 5

A 2954-g boy was the product of an uncomplicated pregnancy and delivery. He was breast-feeding at discharge, but on day 4 he began to feed less and sleep more. On day 5, the parents noted him to be unarousable at times and to be breathing fast. He was brought to the local hospital, where he was found to be obtunded and severely tachypneic. A sepsis work-up was performed, and antibiotics were administered. A serum total

CO<sub>2</sub> value was 6 mEq/L. The urine ketone test result was strongly positive. The arterial blood pH was 7.15, the PCO<sub>2</sub> 40 mm Hg, and the PO<sub>2</sub> 62 mm Hg. Because of impending respiratory failure, the patient was intubated and started on mechanical ventilation.

Despite the use of intravenous fluids with glucose and sodium bicarbonate, he remained comatose. By day 8, his pupils were not reactive to light and he was unresponsive to painful stimuli. A plasma NH<sub>4</sub><sup>+</sup> level was 2059  $\mu$ M. By this time, the results of the newborn screen performed on day 2 using the technology of tandem mass spectrometry on filter paper cards revealed elevated levels of propionylcarnitine in blood. Subsequently, GC-MS analysis of urine revealed a massive increase in methylmalonic acid along with the other metabolites such as 3-hydroxypropionate, propionylglycine, and methylcitrate, confirming the diagnosis of methylmalonic acidemia. Because of the terminal neurologic condition, dialysis therapy was not instituted and life support was withdrawn; the baby died on day 9.

Methylmalonic acidemia, along with propionic acidemia, is the most common of the disorders of organic acid metabolism (Fenton and Rosenberg, 1995a, 1995b). Although more than one enzyme defect may result in methylmalonic acidemia, all are inherited as autosomal recessive traits. The enzyme that is most often deficient is L-methylmalonyl-CoA mutase (see Fig. 22-5). This enzyme is present in mitochondria, and it depends on adenosyl-cobalamin for activity. Impaired function may result from either a mutation of the L-methylmalonyl-CoA mutase apoenzyme or deficient availability of the adenosyl form of vitamin B<sub>12</sub>. The latter may result from impaired cellular metabolism of vitamin B<sub>12</sub>, including defective activity of the enzyme adenosylcobalamin synthetase.

Some patients, but not usually newborn infants with methylmalonic acidemia, are responsive to pharmacologic therapy with vitamin B<sub>12</sub>. Methylmalonic acidemia, therefore, is one of the important disorders that can be considered a vitamin-responsive inborn error of metabolism. Because of the deficient activity of L-methylmalonyl-CoA mutase, the substrate L-methylmalonyl CoA accumulates in mitochondria and is subsequently hydrolyzed to methylmalonic acid. Methylmalonic acid is capable of diffusing out of cells in which it is being produced, so it may be detected in excess in the blood, CSF, and urine of patients with these various forms of the disease. The precursors of L-methylmalonyl CoA are the BCAAs isoleucine and valine, as well as methionine, threonine, thymine, and odd-chain fatty acids (see Fig. 22–5).

There are many different phenotypes of methylmalonic acidemia. They range from severe, catastrophic newborn-onset disease in the first week of life to an almost benign form that has been detected in adults with partial L-methylmalonyl-CoA mutase deficiency. The phenotypes are the newborn-onset type, the intermediate variety with onset in early and late infancy, the intermittent form with onset usually in late infancy and childhood, and an adult or benign phenotype.

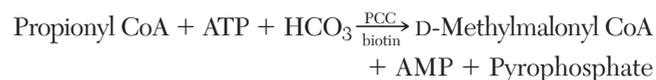

Most patients who present in the newborn period have a severe phenotype. In some of the patients who present in the first week of life with catastrophic illness, even dialysis therapy is not effective, possibly because of a delay in diagnosis and treatment. The most striking presentation is in the second or third day of life. The baby is usually well at birth, as in the UCEDs, but then gradually begins to manifest problems with feeding, vomiting, lethargy, and perhaps seizures. There may be respiratory distress as a manifestation of metabolic acidosis. The liver may be enlarged as a consequence of diffuse steatosis. The important laboratory findings include a metabolic acidosis usually associated with an increased anion gap, ketosis, and hyperammonemia. The elevation of plasma ammonium may be as high as in the severe newborn-onset hyperammonemic syndromes. Because ketonuria is relatively uncommon in newborn infants, even in stressed infants with hypoglycemia due to poor feeding, and because diabetes mellitus is so uncommon in the newborn period, the physician caring for newborn infants must always consider an inborn error of organic acid metabolism when confronted with an acutely ill baby with ketosis. Other laboratory findings are thrombocytopenia, leukopenia, and anemia due to effects of the metabolite on the hematopoietic elements in bone marrow. Older patients with methylmalonic acidemia during crisis have suffered acute pancreatitis as well as devastating lesions to the basal ganglia. Plasma amino acid analysis may reveal elevations of several amino acids such as glycine and alanine. Secondary carnitine deficiency with elevations of carnitine esters is expected (Chalmers et al, 1984). Methylmalonic acid may be detected in urine with GC-MS.

The diagnosis can be confirmed with an assay of the activity of L-methylmalonyl-CoA mutase enzyme in cultured skin fibroblasts. In addition, the various other disturbances in vitamin B<sub>12</sub> metabolism can also be studied by analyzing skin fibroblasts in culture. The treatment of acute disease consists of protein restriction, empirical therapy

with vitamin B<sub>12</sub> (1 mg IM per day), intravenous fluids with 10% glucose and sodium bicarbonate to correct dehydration, electrolyte imbalance and acidosis, high-calorie feeds via a nasogastric tube, and, often, dialysis. The use of carnitine, 25 to 200 mg/kg/day intravenously or orally, is controversial. The treatment of the chronic state centers on the judicious use of a low-protein diet and administration of alkali to eliminate any acid-base imbalance.

## Propionic Acidemia

### Propionyl CoA Carboxylase (PCC) Deficiency

- Enzyme: 6  $\alpha$  subunits and 6  $\beta$  subunits
- Gene locations:  $\alpha$  subunits, chromosome 13q32;  $\beta$  subunits, chromosome 3q13.3-q22
- Frequency: rare

Propionic acidemia was the first classic defect in organic acid metabolism to be described in humans (Fenton and Rosenberg, 1995a). The first patient, described by Childs and colleagues in 1961, was sick on the first day of life with severe metabolic acidosis and ketosis. He responded to massive alkali therapy and survived the newborn period. He subsequently suffered multiple episodes of recurrent attacks of metabolic decompensation with ketoacidosis usually precipitated by infections or protein ingestion; he also had developmental delay, a seizure disorder, and episodic neutropenia and thrombocytopenia. He died at age 7. His sister also demonstrated ketosis and metabolic acidosis in the first week of life, but because of better control of her disease, there were few severe episodes of decompensation in the first and second decades of life.

Propionic acidemia, due to a selective deficiency of propionyl-CoA carboxylase, is inherited as an autosomal recessive trait. This disorder was originally called *ketotic hyperglycinemia* because of the elevations of plasma glycine in conjunction with ketosis. The precursors of propionyl CoA include the amino acids isoleucine, and valine plus methionine, threonine, the pyrimidine compound, thymine, and odd-chain fatty acids (see Fig. 22–5). Of the several hundred patients described with this disease, most present in the newborn period with poor feeding, vomiting, lethargy, and hypotonia. Not uncommonly, the patients manifest seizures and hepatomegaly due to steatosis. The metabolic acidosis may be severe with or without an increase in the anion gap. Ketosis is usually but not always present. Please refer to the case report in Chapter 21. Patients who survive may often manifest choreoathetosis because of persistent damage to the basal ganglia. Usually, episodes of metabolic decompensation characterized by acidosis and ketosis can be precipitated by excessive protein intake or infection. Such episodes may result in permanent neurologic damage. Subsequent findings therefore include developmental delay, seizures, cerebral atrophy, and EEG abnormalities. During the acute attacks, leukopenia, thrombocytopenia, and, less rarely, anemia, probably due to suppression of maturation of bone marrow hematopoietic precursors, may occur.

The diagnosis may be confirmed by GC-MS analysis of urine in an organic acid quantitation. The urine has excess concentrations of various propionate metabolites, such as methylcitrate, propionylglycine, 2-methyl-3-hydroxybutyrate, 2-methylacetoacetate, as well as several other, rarer compounds. The plasma glycine value may be elevated, and during acute attacks, the plasma ammonium value is frequently increased. The enzyme activity of propionyl-CoA carboxylase may be assayed in white blood cells (WBCs) or extracts of cultured skin fibroblasts for definitive diagnosis. Several mutations have been identified in the genes that encode the two nonidentical subunits ( $\alpha$  and  $\beta$ ) of the propionyl-CoA carboxylase enzyme.

Therapy consists of a low-protein diet and adequate calories. As in L-methylmalonyl, there is secondary carnitine deficiency with elevations of propionylcarnitine. The use of L-carnitine to relieve a deficiency of free carnitine and promote greater urinary excretion of propionylcarnitine to lower mitochondrial propionyl CoA levels is controversial. This therapy has never been shown to result unequivocally in an improvement in the clinical state. Because gut bacteria can also contribute to propionate production, antimicrobial therapy with metronidazole has been used during an acute attack. In the acutely ill newborn, the immediate treatment consists of elimination of protein administration or total parenteral nutrition; administration of an adequate amount of calories (10% glucose intravenously and/or administration of a nonprotein formula, such as Mead-Johnson 80056 or Ross Prophree products, via nasogastric tube infusion); administration of alkali to eliminate metabolic acidosis; and platelet transfusion if warranted by thrombocytopenia. Often, because of the severe acidosis and coma, patients may need dialysis therapy. It is unclear whether administration of sodium benzoate and sodium phenylacetate, as in the treatment of hyperammonemia associated with UCEDs, is of benefit to the patient with secondary hyperammonemia. Several patients with propionic acidemia have undergone liver transplantation, with mixed success. Most of the patients with severe newborn-onset disease do not survive the first decade of life.

## Isovaleric Acidemia

### Isovaleryl-CoA Dehydrogenase (IVCD) Deficiency

- Enzyme: homotetramer
- Gene location: chromosome 15q14-q15
- Frequency: very rare

Isovaleric acidemia is caused by a selective deficiency of the enzyme isovaleryl-CoA dehydrogenase (Budd et al, 1967; Sweetman and Williams, 1995; Tanaka et al, 1966). It is inherited as an autosomal recessive trait. There are two major phenotypes; an acute form manifests as catastrophic disease in the newborn period, and the late-onset type is characterized by chronic, intermittent episodes of metabolic decompensation. In the acute form, the infants become extremely sick in the first week of life. There is usually a history of poor feeding, vomiting, lethargy, and,

often, seizures. The characteristic sweaty feet or rancid cheese odor due to isovaleric acid (IVA) is noted. Metabolic acidosis, usually with an elevated anion gap and ketosis, is present. There may be secondary hyperammonemia, thrombocytopenia, neutropenia, and sometimes anemia, resulting in pancytopenia. The babies usually lapse into a coma. Dialysis therapy may be necessary. As with other organic acid disorders for which an amino acid determines organic acid production (see Fig. 22-5), treatment also consists of protein or total parenteral nutrition restriction, intravenous fluids with glucose and perhaps sodium bicarbonate, protein-free formula with calories via nasogastric tube, and glycine, 250 mg/kg/day (Cohn et al, 1978). Intravenous L-carnitine may be beneficial.

In the chronic, intermittent form of isovaleric acidemia, the patients have repeated episodes of metabolic decompensation precipitated by infections or protein intake. Some of these episodes may mimic Reye syndrome. The same principles are applied to therapy for acute metabolic decompensation beyond the newborn period; they are no protein content, sufficient calories, and administration of alkali to correct acidosis, glycine (Krieger and Tanaka, 1976; Naglak et al, 1988; Velazquez and Prieto, 1980), and L-carnitine (De Sousa et al, 1986; Roe et al, 1984). The mainstay of long-term therapy is a low-protein diet. Patients may benefit from the long-term administration of glycine (Berry et al, 1988), which enhances the production of the nontoxic compound isovalerylglycine and serves to reduce the free levels of IVA in body fluids (Krieger and Tanaka, 1976; Yudkoff et al, 1978). In addition, carnitine administration may augment the excretion of isovalerylcarnitine (Berry et al, 1988; Mayatepek et al, 1991); the benefit of carnitine treatment in the chronic state, however, remains unknown.

Most patients with the late-onset type of isovaleric acidemia are mentally retarded. In contrast, most of the patients with the acute phenotype are not severely retarded, but most have not survived the newborn period, attesting to the severely toxic nature of this organic acid disorder in the newborn period. The diagnosis may be made from measurement of marked elevations of isovalerylglycine in urine. There is usually also increased excretion of 3-hydroxyisovaleric acid. The enzyme isovaleryl-CoA dehydrogenase can be assayed in extracts of cultured skin fibroblasts. The gene has been identified and assigned to human chromosome 15. Various mutations have been described.

## Multiple Carboxylase Deficiency

There are two specific forms of multiple carboxylase deficiency, holocarboxylase synthetase deficiency and biotinidase deficiency (Wolf, 1995). All the carboxylase enzymes, such as propionyl-CoA carboxylase, pyruvate carboxylase, 3-methylcrotonyl-CoA carboxylase, and acetyl-CoA carboxylase, require covalent linkage with biotin for normal activity. In form, holocarboxylase synthetase deficiency, the enzyme that accomplishes the addition of biotin to these various carboxylases is deficient. In the second form of the disorder, the absence of the enzyme biotinidase does not allow for biotin recycling after a

carboxylase enzyme is degraded and hydrolyzed. The biotinidase deficiency does not usually manifest in the newborn period.

Patients with the holocarboxylase synthetase deficiency, however, have a severe disease and characteristically are catastrophically ill in the newborn period. Few cases have been reported (Michalski et al, 1989). Patients have severe metabolic acidosis with lactic acidosis and are in coma. As with the biotinidase deficiency, administration of biotin is life-saving. Holocarboxylase synthetase deficiency is one of the few disorders of organic acid metabolism for which the administration of a vitamin in megadoses produces a dramatic turnabout in the clinical and laboratory findings. Diagnosis depends on GC-MS analysis of urine and the demonstration of markedly increased levels of lactate, 3-methylcrotonylglycine, and propionate metabolites. In most patients the affinity of the holocarboxylase synthetase enzyme for biotin is diminished, and for the biochemical disturbances to normalize or improve, patients need between 10 and 60 mg of biotin daily. The enzyme deficiency may be confirmed in cultured skin fibroblasts. The disorder is inherited as an autosomal recessive trait. There are also rare cases of isolated 3-methylcrotonyl-CoA carboxylase deficiency; these patients usually do not come to clinical attention until after early infancy. Of great interest, however, is our new understanding that previously asymptomatic women have demonstrated “acute fatty liver of pregnancy” syndrome. Recurrent episodes of this potentially lethal syndrome have now also been reported in heterozygous mothers who were carrying infants with fatty acid oxidation defects (Schoeman et al, 1991).

### Glutaric Acidemia Type 1

#### Glutaryl-CoA Dehydrogenase (GCDH) Deficiency

- Enzyme: homotetramer
- Gene location: chromosome 19p13.2
- Frequency: very rare, except in Saulteaux-Ojibway Canadian Indians and Pennsylvania Old-Order Amish

An isolated deficiency of glutaryl-CoA dehydrogenase (GCDH) causes glutaric acidemia type 1 (GA-1) (Goodman and Frerman, 1995; Goodman et al, 1975). Multiple phenotypes are known. In the most dramatic presentation, which accounts for less than half of the known patients with GA-1, the illness develops acutely in the first year of life, usually after an infection. Acute encephalopathy is followed by the development of what appears to be a severe form of extrapyramidal cerebral palsy (Hoffmann et al, 1991). In essence, the affected infants have incurred bilateral damage to the caudate and putamen in the basal ganglia, resulting in an incapacitating dystonic syndrome. Some patients have a slowly progressive course with developmental delay, hypotonia, dystonia, and dyskinesia in the first couple years of life. Other patients are relatively asymptomatic.

In general, GA-1 is not a disorder that is associated with acute disease in the newborn period. However, macrocephaly at birth is common (Iafolla and Kahler, 1989). The etiology of any of the CNS lesions is unknown. Magnetic resonance imaging (MRI) of the head typically shows bilateral widening of the sylvian fissures associated with hypo-opercularization, resulting in the “bat-wing” appearance. Sometimes the fluid accumulation mimics subdural hygromas, and a few patients have actually been noted to have subdural hematomas. The congenital nature of these findings suggests that GA-1 has its onset in utero and affects CNS development. Usually infants do not demonstrate bilateral damage to the basal ganglia in the newborn period. Diagnosis depends on the demonstration of glutaric acid and 3-hydroxyglutaric acid in urine and is confirmed by the demonstration of deficiency of GCDH activity or protein levels on Western analysis in cultured fibroblasts.

A rare disorder, GA-1 is especially common in the Saulteaux-Ojibway Indians in Canada (Greenberg et al, 1993) and in the Old-Order Amish of Lancaster County, Pennsylvania (Morton et al, 1991). A low-protein diet may help in the treatment of these patients; acute illnesses, usually viral in nature, should be treated vigorously with fluids containing glucose and adequate amounts of calories to prevent catabolism. Bicarbonate may be necessary to correct acid-base imbalance. Carnitine has also been used to reduce mitochondrial glutaryl-CoA levels.

### Fatty Acid Oxidation Disorders

#### Glutaric Acidemia Type 2

Glutaric acidemia type 2 (GA-2) is due to multiple acyl-CoA dehydrogenase deficiency (Frerman and Goodman, 1995; Przyrembel et al, 1976). The mitochondrial acyl-CoA dehydrogenases are the very-long-chain acyl-CoA dehydrogenase, the medium-chain acyl-CoA dehydrogenase, the short-chain acyl-CoA dehydrogenase (all of which are involved in fatty acid oxidation), isovaleryl-CoA dehydrogenase and 2-methylbutaryl-CoA dehydrogenase (important in BCAA catabolism), glutaryl-CoA dehydrogenase (important in lysine, hydroxylysine, and tryptophan metabolism), and the dimethylglycine and sarcosine dehydrogenases (important in choline degradation). All of these dehydrogenase proteins have in common the binding of a protein called *electron transfer flavoprotein* (ETF). This protein is responsible for accepting the electrons in any of these oxidative dehydrogenation reactions; a deficiency of either ETF or the ETF dehydrogenase enzyme, which is responsible for further transferring the electrons from ETF to coenzyme Q<sub>10</sub> within the mitochondria, causes GA-2. The three phenotypes of GA-2 are (1) a newborn-onset type with congenital anomalies, (2) a newborn-onset type without anomalies, and (3) a milder or later-onset type, sometimes called *mild acyl-CoA dehydrogenase deficiency* or *ethylmalonic adipic aciduria*.

Patients with GA-2 who have multiple malformations are often premature; severe disease is usually evident in the first week of life (Lehnert et al, 1982). The patients demonstrate hypotonia, encephalopathy, hepatomegaly, hypoglycemia, and metabolic acidosis; often the odor of IVA is

present, because these patients also have a defect in metabolism of isovaleryl CoA as in isolated IVA. There may be facial dysmorphism consisting of a high forehead, low-set ears, hypertelorism, and a hypoplastic mid-face. The kidneys may be palpably enlarged associated with large renal cysts (Böhm et al, 1982), rocker-bottom feet, muscular defects of the inferior abdominal wall, and anomalies of the external genitalia, including hypospadias and chordee. Most of the patients with GA-2 and multiple malformations do not survive the first weeks of life. In some, the malformations are not so noticeable, and only renal cysts are identified at autopsy. Infants without the congenital abnormalities usually present in the first 24 to 48 hours of life with hypotonia, tachypnea due to a metabolic acidosis, liver enlargement, hypoglycemia, and the sweaty feet odor. Some of these patients have cardiomyopathy. In contrast, some of these infants can survive the newborn period.

The phenotype in the third form of GA-2 is quite variable. Some patients are relatively disease free and have intermittent episodes of vomiting, dehydration, hypoglycemia, and acidosis during childhood or adult life. In some, there may be hepatomegaly and muscle disease.

Laboratory studies in patients with the newborn-onset type usually show severe metabolic acidosis with lactic acidosis and increased anion gap, mild to moderate hyperammonemia, and hypoglycemia without a moderate or large ketonuria. The liver function values may be abnormal, with increases in the serum transaminases and prolongations of PT and PTT. A chest radiograph may show heart enlargement due to hypertrophic cardiomyopathy. Abdominal ultrasonography or computed tomography (CT) may reveal the renal cysts. The diagnosis is made from the characteristic pattern of organic acid metabolites on urine GC-MS analysis. It consists of glutarate, ethylmalonate, 3-hydroxyisovalerate, 2-hydroxyglutarate, 5-hydroxyhexanoate, adipic, subaric, sebacic, and dodecanedioic acids, isovaleryl-glycine, isobutyrylglycine, and 2-methylbutyrylglycine. The ketones, acetoacetic acid, and 3-hydroxybutyric acid are usually not present or are only minimally elevated if present, being inappropriate for the degree of fatty acid metabolites that indicate free fatty acid mobilization and the potential for enhanced ketogenesis. The renal cystic disease may also be associated with evidence of impaired renal tubular function. Generalized aminoaciduria may be present. The amino-containing compound sarcosine may be elevated in serum as well as in urine. There may be secondary carnitine deficiency, and abnormal carnitine esters such as isovalerylcarnitine and butyrylcarnitine can be detected in blood. The ETF and ETF dehydrogenase deficiency may be detected through the use of specific antibodies on Western analysis of cultured skin fibroblasts or of functional assays in skin cells.

Prenatal diagnosis can be achieved by demonstration of glutarate in amniotic fluid or from results of dehydrogenase assays in cultured amniocytes. The ETF and the  $\alpha$  and  $\beta$  subunits of the ETF dehydrogenase genes have been cloned and sequenced. Several mutations of the  $\alpha$  subunit of the ETF dehydrogenase have been described. In the future, in certain families, mutational analysis of DNA from the probands, as well as other family members, may be performed to establish the diagnosis or to perform prenatal testing using chorionic villus samples or

cultured amniotic cells. A complete deficiency of the ETF dehydrogenase is often associated with the newborn type of GA-2 with congenital anomalies.

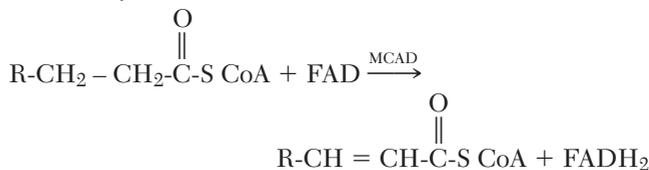

Although treatment with intravenous glucose, riboflavin, carnitine, and diets low in protein and fat generally have not been successful for catastrophically ill newborns, there has been some success in patients with milder or later-onset disease. Riboflavin is suggested to be administered to the newborn with severe disease, but riboflavin at a dosage of 100 to 300 mg/day has been effective in only a few older patients (Gregersen et al, 1982; Harpey et al, 1983). The rationale behind this therapy is that riboflavin, being a precursor of flavin adenine dinucleotide (FAD), may increase the concentrations of FAD and allow for better interaction with mutated and defective ETF or ETF dehydrogenase proteins. Finally, some artificial electron acceptors such as methylene blue have been used in the newborn period without success.

### **Very-Long-Chain Acyl-CoA Dehydrogenase, Medium-Chain Acyl-CoA Dehydrogenase, and Short-Chain Acyl-CoA Dehydrogenase Deficiencies**

In general, the defects in fatty acid oxidation have been associated with coma, hypoglycemia, liver disease, cardiomyopathy, and skeletal myopathy (Roe and Coates, 1995; Saudubray et al, 1997; Stanley, 1987). All of these defects involve abnormalities in the enzymes that participate in or facilitate the mitochondrial beta oxidation of fatty acids. In general, the pathophysiology associated with these disorders has the potential to put the patient in a life-threatening condition in which there is a state of catabolism and enhanced liberation of free fatty acids by adipose stores.

#### **Medium-Chain Acyl-CoA Dehydrogenase Deficiency**

Medium-Chain Acyl-CoA Dehydrogenase (MCAD) Deficiency

- Enzyme: homotetramer
- Gene location: chromosome 1p31
- Frequency: approximately 1 in 20,000

The most common of these disorders is the medium-chain acyl-CoA dehydrogenase (MCAD) deficiency (Roe and Coates, 1995). More than 200 patients with this disorder have been described. Most patients do not present until late infancy. The typical patient is an older infant who, after an infection, experiences anorexia, vomiting, dehydration, lethargy, and hypoglycemia that may be associated with seizures. Similarly, older patients have features that mimic those of Reye syndrome and can die because of brain edema. Onset of symptoms in the newborn period is rare. However, some patients in the extended newborn period or

in the first 6 months of life were originally believed to have sudden infant death syndrome (Ding et al, 1991; Mowat et al, 1984) but in retrospect turned out to have nonketotic hypoglycemia with coma after the development of fasting associated with an infection.

In MCAD deficiency, the initial episode is associated with a high mortality rate. The laboratory studies usually show hypoglycemia and an absence of moderate to large ketones in urine that would be expected to accompany hypoglycemia. The plasma ammonium values may be mildly elevated, the liver may be enlarged, and the serum ALT and AST levels may be slightly increased. During an acute episode, urine GC-MS analysis of organic acids characteristically shows increased levels of adipic, subaric, and sebacic acids as well as the unsaturated analogues of these medium-chain dicarboxylic acids. Greater urinary excretion of dicarboxylic acids is common in many of the defects of carnitine or fatty acid metabolism. However, this is not pathognomonic of a disorder of fat metabolism, because infants fed medium-chain triglyceride-enriched formulas also manifest dicarboxylic aciduria (Whyte et al, 1986). Fatty acid analysis of plasma from patients with MCAD deficiency demonstrates increased levels of octanoic and 4-decenedioic acids. Urine also contains glycine conjugates such as suberylglycine and hexanoylglycine. A secondary carnitine deficiency can be present, and the acylcarnitines analyzed by tandem MS have higher concentrations of 4-, 5-, 6-, 8-, and 10-carbon monounsaturated acylcarnitine species. The MCAD enzyme may be assayed in cultured skin fibroblasts.

The MCAD gene has been cloned and sequenced, and several mutations have been identified. The most conspicuous one is the *R329E*, a highly prevalent mutation in people of Northern European ancestry. The major treatment is the avoidance of fasting; if an episode occurs with hypoglycemia or encephalopathy, intravenous administration of glucose and calorie support should be instituted quickly. Because of the possibility of the development of brain edema, patients may have to be aggressively treated if obtunded to relieve increased intracranial pressure. Avoidance of free fatty acid mobilization during relative insulin deficiency and catabolic stress and prevention of hypoglycemia are the cornerstones of therapy.

### **Very-Long-Chain Acyl-CoA Dehydrogenase Deficiency**

Most of the patients who were previously diagnosed as having long-chain acyl-CoA dehydrogenase (LCAD) deficiency (Hale et al, 1985; Roe and Coates, 1995) actually had very-long-chain acyl-CoA dehydrogenase (VLCAD) deficiency (Yamaguchi et al, 1993). Patients with this disease may be ill in the newborn period because of liver disease with hypoglycemia, cardiomyopathy, and skeletal myopathy (Treem et al, 1991). The membrane-bound VLCAD, as opposed to the soluble LCAD, whose specific metabolic role is unknown, is the main enzyme for initiating the oxidation of free fatty acids that are derived from adipose stores, such as palmitic, stearic, and oleic acids. The fasting state may include coma. Even in its absence, however, the patients may exhibit hypotonia, hepato-

megaly, and cardiomegaly. With an acute metabolic decompensation, urine organic acid analysis may demonstrate dicarboxylic aciduria. However, acylglycine excretion is not usually present. There may be a secondary carnitine deficiency with increased concentrations of the long-chain fatty acids (LCFAs) bound to carnitine.

VLCAD deficiency may be fatal; sudden death in early infancy has been reported. Therapy is directed toward replenishment of glucose, calorie administration, and treatment of any potential brain edema. The myopathy and cardiomyopathy, however, may proceed even in the absence of fasting. Most investigators suggest a reduction in dietary fat intake or supplementation in medium-chain triglyceride. However, it is important not to provoke an essential fatty acid deficiency by too severe dietary fat restriction. Diagnosis can be made through enzyme assay in cultured skin fibroblasts.

### **Short-Chain Acyl-CoA Dehydrogenase Deficiency**

The short-chain acyl-CoA dehydrogenase (SCAD) deficiency is a rare disorder (Amendt et al, 1987; Roe and Coates, 1995). Only a few patients have been reported. One patient manifested severe newborn-onset disease with feeding problems and vomiting, lethargy, and hypotonia in the first week of life. Laboratory findings indicated metabolic acidosis, hypoglycemia, and moderate hyperammonemia. The organic acid analysis of urine showed increased levels of lactate, ketone bodies, butyrate, ethylmalonate, and adipic acid. The patient died at 6 days of age. Postmortem examination showed brain edema, hepatosplenomegaly with steatosis, cholestasis, and focal hepatocellular necrosis. Other cases, however, suggest a disease associated with neurologic abnormalities with later onset as well as neuromuscular disease in adults. Diagnosis can be made by assaying the SCAD enzyme in cultured skin fibroblasts. The human gene has been cloned and sequenced, and mutations have been described; this development should enable a more rapid genetic diagnosis as well as make prenatal diagnosis feasible.

### **Long-Chain 3-Hydroxy Acyl-CoA Dehydrogenase Deficiency**

The long-chain 3-hydroxy acyl-CoA dehydrogenase (LCHAD) deficiency is associated with acute illness, fasting-induced hypoketosis, hypoglycemia, cardiomegaly, and muscle weakness (Bertini et al, 1992; Duran et al, 1991; Roe and Coates, 1995). As with LCFA oxidative abnormalities, some older patients may have episodes of illness associated with elevated serum creatine phosphokinase levels and myoglobinuria. A few patients have had sensory motor neuropathy and pigmentary retinopathy (Bertini et al, 1992). Half of the patients have not survived. Some patients may have severe liver disease with fibrosis in addition to necrosis and steatosis. Women who are carriers for this disease may also have acute fatty liver of pregnancy syndrome.

The diagnosis may be suggested by the demonstration of 3-hydroxydicarboxylic acids on urine organic acid analysis. However, some patients with liver disease per se may

also manifest 3-hydroxydicarboxylic aciduria. The demonstration of an enzyme deficiency in fibroblasts may be difficult in some patients. The specific LCHAD defect was demonstrated in cultured skin fibroblasts through the use of an antibody directed against its analogous activity associated with the short-chain 3-hydroxy acyl-CoA dehydrogenase. Treatment of this disorder has involved frequent high-carbohydrate feedings, dietary fat restriction, and supplementation with uncooked cornstarch. Administration of medium-chain triglycerides may be helpful. Carnitine and riboflavin have also been tried without benefit. As in the other defects of fatty acid oxidation, the treatment of the acute episode is associated with hypoglycemia and potential brain swelling. Liver and neurologic disease may progress despite any intervention.

### **Carnitine Transporter Defect and Deficiencies of Carnitine Palmitoyltransferase I and II and Acylcarnitine Translocase**

Carnitine is essential for fatty acid oxidation because transport of LCFAs into mitochondria depends on an adequate amount of carnitine and the presence of two enzymes that covalently link carnitine to the fatty acid or remove the linkage and one transporter that carries it across the inner mitochondrial membrane (Roe and Coates, 1995; Stanley, 1987). These enzymes are carnitine palmitoyltransferase I and II and a carnitine translocase. Cellular levels of carnitine in turn depend on a sodium-dependent carnitine transporter.

Primary carnitine deficiency appears to be primarily associated with the carnitine transporter defect (Treem et al, 1988). Since the first report of the carnitine transporter defect in 1988, more than 25 cases have been reported. However, many other patients previously reported as having cardiomyopathy or Reye syndrome may have had the transporter defect (Waber et al, 1982). Patients with the transporter defect may present in infancy or in childhood. Earliest reports concern the extended newborn period or early infancy. The disease is characterized by hypoketotic hypoglycemia, hyperammonemia, elevations of transaminases, cardiomyopathy, and skeletal muscle weakness. In some of the older patients, cardiomyopathy may be the presenting sign. The characteristic laboratory finding in this disease is extremely low plasma carnitine levels. The total carnitine levels are usually less than 10  $\mu\text{M}$  in plasma. A dicarboxylic aciduria is not usually evident on urine organic acid analysis. This is probably the only disorder in which pharmacologic administration of carnitine has dramatic effects on the clinical and laboratory abnormalities. The treatment is 100 to 400 mg of L-carnitine/kg/day. (Please note that investigators have used doses as high as 400 mg/kg/day, but because of limited GI absorption the clinical benefit of the higher doses remains unclear).

#### **Carnitine Palmitoyltransferase Type I Deficiency**

Carnitine palmitoyltransferase I (CPT-I) is responsible for covalently linking LCFAs such as palmitate to carnitine. Although one patient with deficiency of CPT-I presented

in the newborn period, most come to attention in early to late infancy (Roe and Coates, 1995). The clinical findings are hypoketotic hypoglycemia, encephalopathy, and hepatomegaly; there is usually no evidence of cardiomyopathy or skeletal myopathy in CPT-I deficiency. Renal tubular acidosis, which is due to impaired distal hydrogen ion secretion, has been reported in two patients. Characteristic laboratory findings are the absence of dicarboxylic aciduria and high plasma levels of total carnitine and free carnitine; however, the plasma acylcarnitine profile is not abnormal. The definitive diagnosis rests on measuring CPT-I enzyme activity in cultured skin fibroblasts. Frequent feeding, reduction of dietary fat, supplementation with medium-chain triglyceride oils, and avoidance of fasting all have been beneficial in the long-term management of patients with CPT-I deficiency.

#### **Acylcarnitine Translocase Deficiency**

Acylcarnitine translocase deficiency is an exceedingly rare defect. It was initially reported in a male infant who suffered a cardiac arrest at 36 hours of age in association with fasting stress and ventricular dysrhythmias (Stanley et al, 1992). Because of the failure to transport long-chain acylcarnitines across the intermitochondrial membrane after the synthesis by CPT-I, the patient had very low total plasma levels of carnitine, most of which was long-chain esterified carnitine; he also had recurrent episodes of hypoglycemia, vomiting, gastroesophageal reflux, and mild chronic hyperammonemia as well as severe skeletal myopathy and mild hypertrophic cardiomyopathy. The continuous nasogastric feeding of a low-fat, high-carbohydrate formula failed to normalize the clinical abnormalities, and the patient died at 3 years of age. At that time, liver failure had also developed. Pathophysiology in this patient suggests that accumulation of long-chain acylcarnitine species may be toxic for several organs, including the heart, liver, and skeletal muscle. In addition, the acute development of ventricular dysrhythmias may be related to the accumulation of such species in cardiac tissue.

#### **Carnitine Palmitoyltransferase Type II Deficiency**

There are two phenotypes of carnitine palmitoyltransferase type II (CPT-II) deficiency (Roe and Coates, 1995). The enzyme is responsible for the hydrolysis of the LCFA bound to carnitine after transport across the intermitochondrial membrane. Most of the patients reported with CPT-II deficiency have a mild deficiency of the enzyme and present in adulthood with episodes of muscle weakness and myoglobinuria brought on by prolonged exercise. The other phenotype is caused by a more serious enzyme defect and manifests in early infancy. The first detailed report was of a 3-month-old boy with hypoketotic hypoglycemia, coma, seizures, hepatomegaly, cardiomegaly, cardiac arrhythmias associated with an increase in long-chain acylcarnitine levels in tissues, and the absence of urinary dicarboxylic aciduria (Demaugre et al, 1991). The enzyme is also expressed in renal tissue as well as in skeletal muscle. Renal dysgenesis has been noted in three patients

(Zinn et al, 1991). Reports of onset in the newborn period (Hug et al, 1991) and in later infancy have been recorded. The gene for the human CPT-II is on chromosome 1. Several mutations have been described. Decreased activity of the CPT-II enzyme may be demonstrated in cultured skin fibroblasts.

### Defects in Ketone Metabolism

After LCFAs are broken down to medium-chain fatty acids and finally to short-chain fatty acids such as acetoacetyl CoA, they must be converted in the liver to 3-hydroxy-3-methylglutaryl CoA (HMG-CoA) before hydrolysis to acetoacetate. Depending on the mitochondrial redox potential—that is, the ratio of the reduced form of nicotinamide adenine dinucleotide (NAD) to its oxidized form (NADH/NAD<sup>+</sup>)—some of the acetoacetate is converted to 3-hydroxybutyrate, and both ketone bodies are transported out of liver mitochondria and hepatocytes into blood, where they may be used by other tissues, especially brain. Acetoacetyl CoA derived from the last turn of the beta oxidation spiral together with acetyl CoA forms HMG-CoA in a reaction catalyzed by HMG-CoA synthetase. Normally, acetoacetyl CoA can also be hydrolyzed to acetyl CoA by the mitochondrial acetoacetyl-CoA thiolase. Patients with a deficiency of this thiolase have not a defect in ketone body synthesis but, rather, metabolic acidosis associated with excess ketosis (Cornblath et al, 1971; Daum et al, 1971; Sweetman and Williams, 1995).

The clinical features of the thiolase deficiency are variable. Severe acute metabolic decompensation has been reported in infants, but there are also asymptomatic adults with the disorder. The episodes are heralded by fasting or increased protein intake, because isoleucine is a precursor of 2-methylacetoacetyl CoA, which is also a substrate for the mitochondrial acetoacetyl-CoA thiolase enzyme. Thus, this block leads to a defect in the distal catabolism of isoleucine and in the processing of the precursor of ketone body formation, namely, acetoacetyl CoA. Cardiomyopathy has been identified in rare patients. The characteristic urinary metabolite pattern detected on urine organic acid quantitation centers on the presence of the isoleucine metabolites, such as 2-methylacetoacetate, 2-methyl-3-hydroxybutyrate, and tiglylglycine. During acute decompensation, lactate as well as the traditional ketone bodies are detected in excess amounts in the urine. Some older children have been mistakenly identified as having ketotic hypoglycemia. The amino acid glycine may be elevated in plasma. Deficiency in the mitochondrial acetoacetyl-CoA thiolase can be demonstrated in cultured skin fibroblasts. The gene has been cloned and sequenced. Several mutations have been identified. Treatment of the acute episodes consists of intravenous glucose and administration of alkali to correct metabolic acidosis, which may be severe. Long-term therapy involves protein restriction and avoidance of fasting.

The synthesis of acetoacetate from HMG-CoA depends on the HMG-CoA lyase enzyme. A deficiency of this enzyme represents the most profound defect in ketone body synthesis (Gibson et al, 1988; Sweetman and

Williams, 1995). About one third of the patients with this disease present in the first week of life. The onset is dramatic and the disease is catastrophic, being characterized by vomiting, lethargy, coma, seizures, hepatomegaly, hypoglycemia, little or no ketones in the urine, and hyperammonemia. Most of the complications are related to the severe effects of hypoglycemia on the CNS in addition to the acidemia, which may be profound. The characteristic urine metabolites detected by GC-MS analysis are 3-hydroxy-3-methylglutaric acid, 3-methylglutaconic acid, and 3-hydroxyisovaleric acid. Only small, inappropriate amounts of acetoacetic acid and 3-hydroxybutyric acid may be detected. Lactate values may be elevated during the acute metabolic decompensation. Inherited as an autosomal recessive trait, the HMG-CoA lyase deficiency can be demonstrated in cultured skin fibroblasts. Treatment of the acute episode consists of administration of intravenous glucose and alkali to correct the metabolic acidosis. Most long-term therapy consists of a high-carbohydrate diet. Some patients are put on protein-restricted diets, but the most important element in long-term care is the avoidance of fasting.

The last defect to be discussed in the area of disturbances in ketone body metabolism is the succinyl-CoA:3-ketoacid-CoA transferase deficiency (Cornblath et al, 1971; Middleton et al, 1987; Sweetman and Williams, 1995). In this disease, the ketone bodies, acetoacetic acid, and 3-hydroxybutyric acid are synthesized adequately in the liver, but they cannot be metabolized in the extrahepatic tissues because of the failure of activation of acetoacetate to acetoacetyl CoA by the transferase enzyme. Conversion to a CoA derivative is required for hydrolysis to acetyl CoA for final metabolism in the Krebs citric acid cycle. This is a rare disorder, and most of the affected patients who have presented in the newborn period have not survived. Such patients usually exhibit severe ketolactic acidosis. The hallmark of the disease is that ketosis never disappears, even after correction of the overt metabolic acidosis and the institution of frequent feedings with the avoidance of fasting. Plasma values of acetoacetate and 3-hydroxybutyrate are always mild to moderately elevated, resulting in intermittent ketonuria. The most important aspect of therapy is the avoidance of fasting, during which time acidosis and ketosis can be overwhelming. The gene that encodes this enzyme has been cloned, and several mutations have been detected.

### Primary Lactic Acidosis

The term *primary lactic acidosis* (PLA) refers to a group of diseases in which impaired lactate metabolism is due to a defect in the mitochondrial respiratory or electron transport chain (ETC), the tricarboxylic acid (TCA) (Krebs) cycle, or the accessory components that support mitochondrial function and shuttling of reducing equivalents, or in which there is a primary defect in pyruvate metabolism that secondarily leads to impaired lactate handling (see Fig. 22–1) (Robinson, 1995; Shoffner and Wallace, 1995). However, there are a limited number of reports on inborn errors of the TCA cycle (Blass et al, 1972). Most of the information on PLA focuses on

mitochondrial ETC, pyruvate dehydrogenase (PDH) complex, and pyruvate carboxylase (PC) defects, all of which have been masterfully reviewed by Shoffner and Wallace (1995) and Robinson (1995). The approach taken in this section has been influenced by their reviews, as well as by the pioneering work of DeVivo and colleagues (1977, 1979), DiMauro and associates (1973, 1980, 1983, 1987), Blass and coworkers (1972), and Brown and colleagues (1987, 1988), to which the reader is directed for details beyond the scope of this chapter.

Some patients present with overwhelming lactic acidosis (Robinson, 1989). In others, lactate may be elevated only in CSF, a “cerebral” lactic acidosis syndrome (Brown et al, 1988). Depending on the nature of the enzyme deficiency, lactate and pyruvate as well as alanine can be elevated in blood. The ratio of blood lactate to pyruvate (L/P ratio) can be helpful in distinguishing the different types of inborn errors. For example, the L/P ratio is often normal (10 to 20) in the PDH and PC deficiencies but elevated in an ETC defect.

### Pyruvate Dehydrogenase Deficiency

#### *Pyruvate Dehydrogenase (PDH) Complex Deficiency*

- Enzyme: 12 subunits per functional component
  - 4 pyruvate decarboxylase (E<sub>1</sub>) subunits, 2 E<sub>1</sub>α and 2 E<sub>1</sub>β
  - 1 dihydrolipoyl transacylase (E<sub>2</sub>) subunit
  - 1 X-lipoate component
  - 2 dihydrolipoyl dehydrogenase (E<sub>3</sub>) subunits
  - 2 PDH kinase subunits
  - 2 PDH phosphatase subunits
- Gene locations:
  - E<sub>1</sub>α on Chromosome X p22.1-22.2
  - E<sub>1</sub>β on Chromosome 3 p13-q23
  - E<sub>3</sub> on Chromosome 7 q31-32
- Frequency: <1 in 250,000

#### CASE STUDY 6

A boy, the product of a 36-week gestation, was delivered by cesarean section because of breech presentation. He required assistance with ventilation at birth. The Apgar scores were 5 at 1 minute and 9 at 5 minutes. At 1 hour of life, the infant had generalized seizures. An arterial blood pH was 7.38, and the PCO<sub>2</sub> was 13 mm HG. Serum total CO<sub>2</sub> was 5 mmol/L, and glucose was 76 mg/dL. Blood lactate and pyruvate values were 9.93 mmol/L (normal ≤2.0 mmol/L) and 0.53 mmol/L (normal ≤0.20 mmol/L), respectively; the L/P ratio was 18.8 (normal ≤20).

Physical examination showed the infant to be lethargic and hypotonic. His weight (1770 g) and length (42 cm) were below the third percentile, and his head circumference (31 cm) was below the 10th percentile. Several minor craniofacial abnormalities, including hypertelorism, micrognathia, and low-set, posteriorly rotated ears, were detected. He also had a pectus excavatum, first-degree hypospadias, and rocker-bottom feet. There were few spontaneous movements, but he showed withdrawal in response to tactile stimulation. Neurologic findings included bilateral ptosis, bifacial palsy, and weak bulbar function.

The metabolic acidosis persisted, necessitating large amounts of intravenous sodium bicarbonate, and on day 2, the infant needed mechanical ventilation. By the third day of life, the baby

was completely unresponsive. An EEG showed a burst suppression pattern, and a head CT demonstrated bilateral grade II intraventricular hemorrhages, a subarachnoid hemorrhage, and agenesis of the corpus callosum. Phenobarbital was started. The infant had received only intravenous glucose since his initial resuscitation. Before initiation of total parenteral nutrition with triglycerides at 1 week of age, the neonatal reflexes, doll's eye, and pupillary light reflexes were absent.

Over the next few days, the infant's level of consciousness improved, he was weaned off the ventilator, and the metabolic acidosis resolved. The phenobarbital was eventually discontinued. Analysis of organic acids in urine by gas chromatography showed increased lactate excretion. Before discharge at 1 month of age with a proprietary formula, he had had several episodes of bradycardia and was still hypotonic.

Over the next several months, the patient failed to grow despite adequate caloric intake. The metabolic acidosis had returned and was associated with elevated blood lactate levels. He required more than 4 mEq of sodium bicarbonate per kilogram per day for partial correction. He was given a high-fat diet and megadoses of thiamine hydrochloride. Despite normalization of blood lactate levels, there was no clinical improvement. At age 7 months, his length, weight, and head circumference were less than the fifth percentile.

The patient remained extremely hypotonic, did not appear to have vision, and had normal reflexes in the upper limbs but none in the lower extremities. He was resuscitated from a respiratory arrest at 7 months, but at 8 months, he died of a nocturnal primary respiratory arrest.

In cultured skin fibroblasts, there was 20% residual activity of the PDH complex. Western blot analysis revealed trace amounts of both E<sub>1</sub>α and E<sub>1</sub>β subunits, but only the E<sub>1</sub>α peptide had abnormal electrophoretic mobility.

The most common cause of a primary defect in pyruvate metabolism is PDH complex deficiency (Robinson, 1995). This complex, located in the mitochondria, has several components, the E<sub>1</sub>α and E<sub>1</sub>β subunits, the E<sub>2</sub> subunit, the E<sub>3</sub> subunit, the X-lipoate subunit, and the PDH phosphatase and kinase subunits. Most mutations have been reported in the E<sub>1</sub> subunit (Robinson et al, 1987). Unlike the other components, the E<sub>1</sub>α subunit is encoded on the X chromosome. Because of the key importance of the PDH complex in energy metabolism, even partial defects of the complex may be associated with severe CNS disease. In addition, even though the E<sub>1</sub>α subunit defect is an X-linked disease, many females are also affected, so it can be considered a dominant mutation. All the other defects are inherited as autosomal recessive disorders.

There are several different phenotypes of PDH complex deficiency based on the severity of the enzyme deficiency. Most of the patients with less than 20% residual enzyme activity in cultured skin fibroblasts present in the newborn period with overwhelming lactic acidosis (Farrel et al, 1975; Federico et al, 1990; Robinson et al, 1987; Stromme et al, 1976). Some patients, but perhaps those without life-threatening acidosis, even have congenital lesions associated with cystic lesions in the cerebral hemisphere; cerebral atrophy; cystic lesions in the basal ganglia; and facial dysmorphism, including features that resemble those of fetal alcohol syndrome, such as a narrowed head, frontal bossing, wide nasal bridge with upturned nose, a long poorly developed philtrum, and flared nostrils. In addition, there may be partial or

complete agenesis of the corpus callosum and impaired migration of neurons within the cerebral hemispheres, identified as heterotopic dysplasia on neuropathologic examination of brain tissue. Patients with less severe defects manifest progressive psychomotor retardation (Miyabayashi et al, 1985), including the entity termed *Leigh disease*, or *subacute necrotizing encephalomyelopathy* (SNE) (DeVivo et al, 1979), as discussed later, and older male patients with variant lesions may manifest only intermittent ataxia during childhood (Blass et al, 1970) with a mild or intermittent lactic acidosis. Secondary hyperammonemia has been detected (Brown et al, 1987).

The E<sub>1</sub>α subunit gene on the X chromosome has been cloned and sequenced, and multiple mutations have been identified. The E<sub>2</sub> and protein X-lipoate defects are rare and usually result in chronic psychomotor retardation syndrome in late infancy and childhood (Robinson et al, 1990). The E<sub>3</sub> subunit defect is a unique syndrome (Taylor et al, 1978), because the subunit is important not only in the PDH complex but also in the BCKAD complex and the α-ketoglutarate dehydrogenase (KGDH) complex. Thus, these patients have multiple deficiencies involving the BCAA as in MSUD, as well as Krebs cycle metabolites indicative of a block in the TCA cycle (Munnich et al, 1982). Most of the patients present later than the newborn period and have severe progressive neurodegenerative disease. The key laboratory findings are elevations of lactic acid in blood, BCAAs in plasma, and detection of α-ketoglutarate in urine by urine organic acid analysis. PDH phosphatase deficiency is a rare cause of congenital lactic acidosis (Robinson and Sherwood, 1975).

There is no effective treatment for any of the defects in PDH complex metabolism that manifest in the newborn period. A response to thiamine megatherapy has been reported in a few patients. Metabolic imbalance in the patient with PDH deficiency, as well as in other PLA defects, may be further compromised by high- or selective-carbohydrate feedings. There has been some success in reducing lactate accumulation with the use of a ketogenic diet. Dichloroacetate, an inhibitor of the PDH kinase, is being studied as a treatment for several PLAs (Kuroda et al, 1986; McCormick et al, 1985; Stacpoole et al, 1983).

## Pyruvate Carboxylase Deficiency

### Pyruvate Carboxylase (PC) Deficiency

- Enzyme: homotetramer
- Gene location: chromosome 11q13
- Frequency: 1 in 250,000

There are three types of PC deficiency (Robinson, 1995; Robinson et al, 1984). Type A is characterized by lactic acidosis in the newborn period and delayed development (DeVivo et al, 1977). However, the disease is of a chronic nature. In type B, the catastrophic form of the disorder, the infant is acutely ill, usually in the first week of life, with encephalopathy, severe metabolic acidosis with lactic acidosis, and hyperammonemia (Saudubray et al, 1976). The mortality rate in this form is high. In one case, referred to as type C, the patient presented with mild

episodic metabolic acidosis and lactic acidosis, but with no evidence of CNS dysfunction (Van Coster et al, 1991).

As discussed earlier, PC is a biotin-containing enzyme. Most of the patients presenting with a type B form of PC deficiency have been of French or English origin. Unlike patients with a type A defect, in whom the blood L/P ratio is normal because both lactate and pyruvate are comparably elevated, patients with the type B defect often have an elevated L/P ratio. Because of the importance of the PC product oxaloacetate in providing adequate cellular levels of aspartate, citrulline metabolism in the urea cycle is defective, leading to elevations of plasma citrulline as well as plasma ammonium concentrations. Although PC is also an important enzyme in gluconeogenesis, hypoglycemia has not been commonly reported. The liver may be enlarged. There is no effective treatment for PC deficiency when it is associated with progressive neurodegeneration. The gene that encodes the PC subunits, of which four combine to make an active enzyme, has been cloned and sequenced. Several mutations have been identified. PC deficiency may be detected in cultured skin fibroblasts or in liver biopsy samples.

## Phosphoenolpyruvate Carboxykinase Deficiency

Phosphoenolpyruvate carboxykinase (PEPCK) enzyme also functions in gluconeogenesis, and there are two forms in liver, one in the cytosol, and the other in the mitochondrial compartment. Only three cases of PEPCK deficiency have been documented (Fiser et al, 1974; Robinson, 1995). In each, the activity of PEPCK was found to be deficient in liver tissue. Patients do not usually come to attention until childhood with hypotonia, failure to thrive, hepatomegaly, lactic acidosis, and hypoglycemia. One patient had a more severe phenotype associated with severe liver disease and died at 6 months of age (Clayton et al, 1986). The accuracy of the diagnosis of PEPCK in some other patients is in question. Although there is no adequate experience to draw from in identifying the optimal therapy for these patients, it is reasonable to assume that frequent feedings and avoiding of fasting are important in avoiding severe metabolic imbalance.

## Mitochondrial Respiratory Chain or Electron Transport Chain Defects

Oxidative phosphorylation is the key process performed by the mitochondria of cells. Any inborn error of metabolism that involves the tightly coupled and regulated process of mitochondrial energy metabolism may have profound effects on health and disease, because oxidative phosphorylation is the process by which we convert food into energy. The various derivatives of foodstuffs such as pyruvate and fatty acids are converted to CO<sub>2</sub> in mitochondria. The energy derived from such controlled chemical combustion is harnessed by allowing the reducing equivalences (in the form of NADH or the reduced form of flavin adenine dinucleotide [FADH<sub>2</sub>], which are derived from such metabolism) to combine with oxygen to form H<sub>2</sub>O, and in the process, the synthesis of ATP is coupled to the orderly flow of electrons down the respiratory chain components.

The important components in the mitochondrial respiratory chain are complex 1 (NADH dehydrogenase), complex 2 (ETF dehydrogenase); complex 3 (cytochromes *b*, *c*<sub>1</sub>) and the terminal complex in this chain; and complex 4, which is cytochrome *c* oxidase (COX) (Shoffner and Wallace, 1995). In addition, there is a complex 5, or ATP synthetase, and an adenine nucleotide translocase, which permits transport of adenosine diphosphate (ADP) into and ATP out of the mitochondria. Complex 2 is involved primarily in fatty acid oxidation and oxidation of succinate derived from the Krebs cycle, because the reducing equivalents extracted from fatty acids, glutaric acid, and succinate flow from ETF into complex 2. The polypeptides that compose these various complexes are derived from both the nuclear genes and the genes on mitochondrial DNA (mtDNA). Except for complex 2, mtDNA is important in production of the subunits of all the respiratory chain complexes. PLA involving the ETC components has been associated with both nuclear and mtDNA mutations.

On the basis of molecular diagnostic testing, the oxidative phosphorylation diseases can be divided into the following four genetic groups (Shoffner and Wallace, 1995):

- Group 1: nuclear DNA mutations
- Group 2: mtDNA point mutations
- Group 3: mtDNA deletions and duplications
- Group 4: unidentified genetic defects

The relationship between phenotype and mtDNA mutations is not straightforward, probably because of the phenomenon of heteroplasmy. Mitochondria with their unique mtDNA are inherited solely from the mother (Hutchinson et al, 1974). Random segregation of mitochondria having mtDNA mutations leads to heteroplasmy and, ultimately, a variable concentration of defective mitochondria within cells and among tissues (Shoffner and Wallace, 1995). Most of our understanding of the detailed molecular mechanisms that contribute to or produce the ETC gene disturbances concern the mtDNA mutations. However, with the exception of the neurogenic muscle weakness, ataxia, retinitis pigmentosa (NARP) mutation, few of the primary mtDNA defects actually manifest in the newborn period. Examples are the MELAS (mitochondrial encephalopathy, lactic acidosis, and stroke-like episodes) (Ciafaloni et al, 1992; Goto et al, 1990), MERRF (myoclonic epilepsy with ragged-red fiber) (Noer et al, 1991), Leber hereditary optic neuropathy (Wallace et al, 1988), and sporadic deletion syndromes (Holt et al, 1988). The diseases that affect young infants are benign infantile mitochondrial myopathy, cardiomyopathy, or both; lethal infantile mitochondrial disease; lethal infantile cardiomyopathy; SNE or Leigh disease; Pearson syndrome; Alpers disease; lethal infantile cardiomyopathy; and the most dramatic form, with presentation often in the first few days of life, during which an acid-base disturbance dominates the clinical picture.

### **Benign Infantile Mitochondrial Myopathy, Cardiomyopathy, or Both**

Benign infantile mitochondrial myopathy is associated with congenital hypotonia and weakness at birth, feeding difficulties, respiratory difficulties, and lactic acidosis.

In this poorly understood, developmental-like disorder, only skeletal muscle appears to be affected, and histochemical analyses show a COX deficiency that returns to normal levels after 1 to 3 years of age (DiMauro et al, 1983; Jerusalem et al, 1973; Roodhooft et al, 1986; Tritschler et al, 1991; Zeviani et al, 1987). A nuclear DNA mutation in a gene important in a fetal isoform of an ETC polypeptide specific for muscle oxidative phosphorylation is believed to be the cause of this problem, and a developmental switch from the defective fetal gene to the adult form may be responsible for the gradual improvement. This disorder may be inherited in an autosomal recessive or autosomal dominant fashion. It is the only example of a developmental defect in oxidative phosphorylation that is probably nuclear encoded and in which the treatment is only support during the early newborn period to prevent death from respiratory disease.

The form also associated with cardiomyopathy may just be a variant of the benign isolated myopathy and involves striated muscle in both skeletal and cardiac muscle. It manifests in the newborn period with lactic acidosis and a cardiomyopathy that improves during the first year of life. The exact gene defect is unknown. More attention must be paid to these two disease entities, because with early optimal medical care, affected infants may have excellent prognoses.

### **Lethal Infantile Mitochondrial Disease**

Infants with lethal infantile mitochondrial disease are severely ill in the first few weeks of life or in the extended newborn period (DiMauro et al, 1980; Zeviani et al, 1986). They present with hypotonia, muscle weakness, failure to thrive, and severe lactic acidosis. Death occurs by 6 months of age and almost always is associated with overwhelming lactic acidosis. Skeletal muscle shows lipid and glycogen accumulation and abnormally shaped mitochondria on electron microscopic examination. Hepatic dysfunction may be a prominent finding in these patients. Generalized proximal renal tubular dysfunction may occur, leading to full-blown renal Fanconi syndrome (DiMauro et al, 1980; Heiman et al, 1982; Zeviani et al, 1986). The ETC defects reported in these patients include defects in complexes 1, 3, and 4, (Birch-Machin et al, 1989; Moreadith et al, 1984; Robinson et al, 1985; Sengers et al, 1984; Shoffner and Wallace, 1995; Zheng et al, 1989). Original reports concerned infants with a phenotype resembling severe Wernig-Hoffman disease with COX deficiency and renal Fanconi syndrome (DiMauro et al, 1980; Heiman et al, 1982).

This entity is probably more than one disease. Some studies have suggested that the cause is tissue-specific depletions of mtDNA (Boustany et al, 1983). The cause of the depletion is believed to be a nuclear-encoded gene, perhaps inherited as an autosomal recessive trait. There are molecular precedents for this mechanism, in that mutations in the genes thymidine kinase and deoxyguanosine kinase have been shown to cause “myopathic” and “hepatocerebral” forms of mitochondrial DNA depletion syndromes (Mandel et al, 2001; Saada et al, 2001). In addition, some patients may have selective COX deficiency due to a defective nuclear-encoded complex 4 gene.

### **Lethal Infantile Cardiomyopathy**

Defects of the mitochondrial respiratory chain have varied neonatal presentations and are commonly due to isolated COX deficiency (DeVivo et al, 2002). Clinical features of COX deficiency reflect involvement of one or more tissues and include encephalopathy, myopathy, cardiopathy, liver disease, and nephropathy (Munnich et al, 2001). The heterogeneous clinical features are due, in part, to the dual genetic control of COX: the three catalytic subunits—COX I, COX II, COX III—are encoded by mtDNA, whereas the remaining subunits (COX IV to COX VIII) are encoded by nuclear DNA (nDNA). In addition, proper assembly of COX requires several nDNA-encoded proteins. The various syndromes due to COX deficiency are only partially understood at the genetic level. Most infants with isolated complex IV deficiency are likely to have nDNA gene defects in COX assembly genes, including *SURF1* (Zhu et al, 1998), *SCO2* (Papadopoulou et al, 1999), *SCO1* (Valnat et al, 2000a), *COX10* (Valnat et al, 2000b), and *COX15* (Antonicka et al, 2003).

#### **CASE STUDY 7**

A boy was born to non-consanguineous, healthy parents after a full-term gestation. Biventricular hypertrophy with a predominant right-sided component had been observed on a fetal ultrasonography at 24 weeks of gestation. He was delivered by cesarean section due to variable decelerations, and he emerged without meconium staining or passage. Respiratory distress developed shortly after birth. An echocardiogram showed concentric right ventricular hypertrophy with elevated right ventricular pressure (70 mm Hg). Initial laboratory studies showed acute metabolic acidosis (blood lactate >18 mmol/L, arterial pH 6.91).

His weight was 2.36 kg (10th percentile), his length 46 cm (5th percentile), and his head circumference 31 cm (5th percentile). He had a right ventricular heave and an intermittent fourth heart sound. There was no liver enlargement. Muscle bulk was normal, and deep tendon reflexes were intact. Metabolic investigations showed persistent arterial lactic acidemia (range 3 to 11 mM) with increased pyruvate (range 0.02 to 0.44 mM). The L/P ratio ranged from 25 to 290. The activities of the respiratory chain complexes II, III, and IV were normal in cultured skin fibroblasts. A left quadriceps muscle biopsy was used for histochemical analysis and to prepare a 10% extract for respiratory chain studies. Histochemistry showed no ragged-red fibers with the modified Gomori trichrome stain but a diffusely weak response to staining for cytochrome *c* oxidase (COX, ETC complex 4); biochemistry showed markedly reduced COX activity, contrasting with normal activities of other complexes. Direct sequencing of the three COXs and all 22 transfer RNA genes of mtDNA, all the COX-assembly nuclear genes known to harbor pathogenic mutations (*SURF1*, *SCO1*, *SCO2*, *COX10*, and *COX15*), and the two other nuclear ancillary genes (*COX11* and *COX17*) showed no mutations. Southern blot analysis showed no deletions but results were inconclusive regarding mtDNA depletion. However, sequencing of the two genes known to be associated with the “myopathic” (Saada et al, 2001) and the “hepatocerebral” (Mandel et al, 2001) mtDNA depletion syndromes (*TK2* and *dGK*) did not show any mutations.

A series of echocardiograms documented biventricular, hypertrophic, nonobstructive cardiomyopathy. The patient expired on the seventh hospital day after a sudden episode of hemoglobin desaturation. An autopsy was performed 4 hours after death. The right ventricle was found to be thickened and

enlarged, with relative sparing of the left side. The pulmonary vasculature of the lungs showed hypertrophy that extended to the most distal vessels. Routine microscopic findings in skeletal muscle were normal, and the CNS was without microscopic or macroscopic abnormalities.

This baby had a fatal syndrome defined clinically by prenatal cardiomyopathy and severe pulmonary hypertension in the newborn period. The syndrome was due to isolated ETC complex 4 deficiency. The pathophysiology centered on the heart and lungs. How much disease was due to the involvement of other organs remains unclear. As discussed later, this is an example of a mitochondrial metabolic disorder but without a specific molecular genetic cause.

### **Barth Syndrome**

Barth syndrome is an X-linked disorder associated with cardiomyopathy, skeletal muscle disease, and neutropenia (Barth et al, 1983; Neustein et al, 1979). Skeletal muscle shows abnormal mitochondrial morphology. Important laboratory findings include decreased plasma free carnitine, increased urinary excretion of 3-methylglutaconate on GC-MS analysis of urine organic acids, and decreased levels of serum cholesterol in early infancy (Kelley et al, 1991). Positional cloning identified a gene for this disorder on Xq28 that encodes for a phospholipid remodeling enzyme, cardiolipin acyl transferase. Several mutations have been identified. It was hypothesized that the organic acid, 3-methylglutaconate, accumulates because of defective mitochondrial transport. Patients must be supported from birth to early infancy. Investigators speculate that if severe cholesterol deficiency can be avoided, affected infants may survive and may be relatively free of cardiomyopathy during childhood. Of diagnostic importance, not all patients with 3-methylglutaconic aciduria have Barth syndrome. A few have isolated leucine-dependent 3-methylglutaconyl-CoA hydratase deficiency or Costeff syndrome, but most suffer from ill-defined mitochondrialopathies (Gibson et al, 1993).

### **Subacute Necrotizing Encephalomyelopathy or Leigh Disease**

Probably because of a failure to recognize the clinical signs, infants with SNE or Leigh disease usually come to clinical attention after the newborn period. This disease is best characterized as a progressive neurodegenerative disorder with severe hypotonia, seizures, extrapyramidal movement disorders, optic atrophy, and defects in automatic ventilation or respiratory control (Pincus, 1972). It is clear that there are many causes of SNE. As discussed earlier, PDH complex deficiency may lead to Leigh disease. Patients with defects in the ETC have also been reported to have findings compatible with SNE. Many neuropathologists believe that the diagnosis of SNE depends on an analysis of CNS tissue at autopsy. However, MRI characteristically shows bilateral symmetrical lesions of the basal ganglia.

There is no effective treatment for this disease. It is possible that most of the patients with Leigh disease have disturbances in nuclear-encoded genes. Although, as discussed later, the NARP lesion due to a group 2 mtDNA mutation is one important cause in early infancy. Clearly, this is not one disease entity, because the specific neuropathologic findings for SNE have also been reported in a patient with Menke disease, in which there exists a secondary ETC complex 4 deficiency because copper is an important metal cofactor of cytochrome *c* oxidase.

The following clinical findings have been noted in infants with SNE: optic atrophy, ophthalmoplegia, nystagmus, respiratory abnormalities, ataxia, hypotonia, spasticity, seizures, developmental delay, psychomotor retardation, myopathy, and renal tubular dysfunction. Some patients may manifest hypertrophic cardiomyopathy, liver dysfunction, and microcephaly. The neuropathologic lesions include demyelination, gliosis, necrosis, relative neuronal sparing, and capillary proliferation in specific brain lesions. There are lesions of the basal ganglia, which are bilaterally symmetrical, as well as of the brainstem, cerebellum, and, to a much lesser degree, the cerebral cortex. Commonly, the elevation in blood lactate is only slight to moderate, as well as intermittent, in this diverse group of patients. In some instances, lactate values may be elevated only in the CSF. The most commonly reported biochemical abnormalities are deficiencies in COX or complex 4 (DiMauro et al, 1987; Hoganson et al, 1984; Miranda et al, 1989; Willems et al, 1977), NADH dehydrogenase or complex 1 (Hoppel et al, 1987), and PDH. In a few rare patients, the abnormality in oxidative phosphorylation has been reported to be secondary to the NARP mutation. This involves a T→C transition at base pair 8993 of the adenosine triphosphatase (ATPase) 6 gene, changing a leucine to a proline at position 156 in the ATPase 6 polypeptide. Investigators have speculated that defects such as those in COX and the NADH dehydrogenase, when associated with the neuropathology of Leigh disease, are due to nuclear gene mutations (Miranda et al, 1989) and not to mtDNA gene defects such as the NARP point mutation in the ATPase 6 gene (Santorelli et al, 1993; Shoffner et al, 1992; Tatuch et al, 1992).

The diseases in group 3 (see earlier), exemplified by the Kearns-Sayre and chronic progressive external ophthalmoplegia syndromes (Shoffner and Wallace, 1995), are not familial and are due to mtDNA deletions (Morales et al, 1989) or duplications (Poulton et al, 1989) that are spontaneous mutations. These disorders do not usually come to clinical attention in infancy. The only example of such a mutation manifesting in early infancy is the Pearson syndrome (Cormier et al, 1991; Rotig et al, 1989). This is a systemic disorder that primarily affects the hematopoietic system and pancreas function. The characteristics are severe macrocytic anemia with varying degrees of neutropenia and thrombocytopenia. Bone marrow examination shows normal cellularity but extensive vacuolization of erythroid and myeloid precursors, hemosiderosis, and ringed sideroblasts. This disease of the bone marrow may lead to death in infancy. However, patients who are able to recover or who benefit from aggressive therapy may demonstrate other signs of this systemic disorder in late infancy or childhood, such as poor growth,

pancreas dysfunction, mitochondrial myopathy, lactic acidosis, and progressive neurologic damage (Majander et al, 1991; Nelson et al, 1992).

### **Unidentified Genetic Defects**

A number of diseases are believed to be caused by mitochondrial respiratory chain problems, but the specific mutations remain unknown. These constitute the group 4 mutations, or the disorders of unknown inheritance (Shoffner and Wallace, 1995). Alpers disease is one such example. It has also been called *progressive infantile poliodystrophy*. Infants and children with this progressive disease experience progressive cerebral cortical damage, sometimes also involving the cerebellum, basal ganglia, and brainstem; in some, liver disease may progress to cirrhosis. The neuropathologic lesions consist of spongiform or microcystic cerebral degeneration, gliosis, necrosis, and capillary proliferation (Sandbank and Lerman, 1972). Seizures are prominent, including myoclonus. Laboratory abnormalities include abnormal NADH oxidation or complex 1 defects, impaired pyruvate handling, and PDH complex deficiency, TCA cycle malfunction, and decreased mitochondrial cytochrome *a + a<sub>3</sub>* content (Prick et al, 1983). The diversity of these findings suggests that this may be more than one disease. Finally, some patients in this “wastebasket” category have manifested lethal infantile cardiomyopathy, as described in Case Study 7, in association with cardiac failure and cardiac dysrhythmias, including Wolff-Parkinson-White syndrome. The pathologic abnormalities have included a reduced number of myofibrils, cardiac fibers with high lipid and glycogen content, and abnormal number of mitochondria. Both cytochrome *b* and cytochrome *c + c<sub>1</sub>* deficiencies have been reported. The exact gene defects remain unknown.

### **Early Lethal Lactic Acidosis**

In an unknown fraction of patients with primary disturbances in mitochondrial oxidative phosphorylation or ETC defects, massive lactic acidosis develops within 24 to 72 hours after birth. Not uncommonly, the condition is untreatable, because it is relentless and unresponsive to alkali therapy. Dialysis is a remedy but not a cure. Often, affected infants have no obvious organ damage early in the course or evidence of malformations. This statement is also true for infants with the PDH complex deficiency, which is probably a more common cause of overwhelming acidosis in the first week of life. In addition, acidemia per se can easily explain the coma or impaired cardiac contractility that may be encountered. Some infants have survived with aggressive therapy. Anecdotal reports also suggest the existence of a transient disease process.

The care of babies with these different forms of severe lactic acidosis almost always brings an ethical and moral dilemma to the forefront for the physicians and nurses of the NICU as well as for the babies' families. To further complicate the issues, enzymatic and molecular analyses usually are not immediately available. The disease in most patients probably remains idiopathic, and no DNA

mutation, nuclear or mitochondrial, can be identified. A rigid approach to care is impractical and unwise. Decisions regarding management must be individualized because the mitochondrial dysfunction and resultant pathophysiology may vary among infants.

## Lysosomal Storage, Peroxisomal, and Glycosylation Disorders and Smith-Lemli-Opitz Syndrome Presenting in the Neonate

Janet A. Thomas, Carol L. Greene, and Robert M. Cohn

Lysosomal storage diseases, peroxisomal disorders, congenital disorders of glycosylation (CDGs), and Smith-Lemli-Opitz syndrome (SLO syndrome) are single-gene disorders, most of which demonstrate autosomal recessive inheritance. The incidence of peroxisomal disorders is estimated to be approximately 1 in 25,000 to 50,000. No collective estimate of frequency for the many disorders of lysosomal dysfunction exists, but most individual diseases affect less than 1 in 100,000 births in the general population. The most current estimate for SLO syndrome is 1 in 20,000. A similar frequency of 1 in 20,000 is estimated for congenital disorders of glycosylation.

These four categories of metabolic diseases involve molecules important in cell membranes and share overlapping clinical presentations. Clinical presentations are heterogeneous, with a broad range of age of presentation and severity of symptoms. All are chronic and progressive. Age of onset varies from prenatal to adulthood, and severity may range from severe disability and early death to nearly normal lifestyle and life span. For each condition, interfamilial variability is greater than intrafamilial variability. The genetic and clinical characteristics of conditions in these categories that may manifest in the neonatal period (except Pompe disease, which is addressed in Chapter 22) are also summarized in the tables.

Important presentations that should lead the neonatologist to consider these disorders in the differential diagnosis are as follows:

1. "In utero infection:" hepatosplenomegaly and hepatopathy, possibly with extramedullary hematopoiesis.
2. Nonimmune hydrops fetalis and/or ichthyotic or colloidion skin.
3. Neurologic only: early and often difficult to control seizures, hypertonia or hypotonia, with or without altered head size, and with or without eye findings.
4. Coarse features with bone changes, dysostosis multiplex, or osteoporosis.

5. Dysmorphic facial features with or without major malformations.
6. Rarely, known family history or positive prenatal diagnosis.

Only for the last three presentations are these conditions likely to be considered early in the differential diagnosis. Most babies with these conditions are born to healthy, nonconsanguineous couples with normal family histories, and these disorders are usually considered late, if at all, as in Case Study 1.

### CASE STUDY 1

CJ was a 2200-g girl, born to a 24-year-old mother (third pregnancy, second viable child) after a 32-week gestation, by cesarean section performed for fetal distress. Pregnancy was complicated by the finding on ultrasonography of fetal hydrops and ascites and possible hepatosplenomegaly at 24 weeks of gestation. Fetal blood sampling showed a hematocrit of 31% and elevations of  $\gamma$ -glutamyl-transferase (GGT) and aspartate transaminase (AST) values. Results of viral studies were negative, and chromosomes were normal. At delivery, the infant was limp and blue with a heart rate of 60 beats/min. Physical examination and chest radiograph showed marked abdominal distention, hepatosplenomegaly, multiple petechiae and bruises, a bell-shaped thorax, generalized hypotonia, talipes equinovarus, contractures at the knees, a large heart, and hazy lung fields with low volumes. Disseminated intravascular coagulopathy and evidence of liver disease, with elevated AST, GGT, and increasing hyperbilirubinemia, rapidly developed. The patient was maintained on a ventilator and treated with antibiotics for suspected sepsis.

Results of evaluations for bacterial and viral agents were negative. Metabolic studies, including ammonia, lactate, very-long-chain fatty acids (VLCFAs), and urine amino and organic acids, yielded unremarkable measurements. The white blood cells were noted to have marked toxic granularity consistent with overwhelming bacterial sepsis or metabolic storage disease.

The patient experienced continued cardiorespiratory deterioration, had bilateral pneumothoraces and pneumopericardium, and died on the third day of life. Consent for autopsy was obtained from the family. A standard autopsy was performed and showed the presence of large, membrane-bound vacuoles within hepatocytes, endothelial cells, pericytes, and bone marrow stromal cells, typical of a metabolic storage disorder. Similar cells were also found within the placenta. There was no evidence of an infectious cause. Unfortunately, because a lysosomal storage disorder was not considered as a possible etiology at the time of death, no frozen tissue or cultured fibroblasts were available to pursue the diagnosis. As a result of efforts by a research laboratory and the recurrence of disease in the couple's subsequent pregnancy, a diagnosis of  $\beta$ -glucuronidase deficiency, or mucopolysaccharidosis type VII, was confirmed.

### CASE STUDY 2

ME was born by normal spontaneous vaginal delivery, at full term according to dates based on early ultrasonography, with weight 2.2 kg, length 45 cm, and head circumference 31.5 cm. On the basis of physical examination, gestational age was assessed as 36 weeks. A heart murmur was noted, and investigation showed presence of a small ventricular septal defect with no hemodynamic significance. Submucous cleft

palate was noted. Examination for dysmorphic features showed simple, posteriorly rotated ears, mild epicanthic folds, micrognathia, and unilateral simian crease. Tone was moderately decreased. Irritability and severe feeding problems were noted, and gavage feeding was required; growth was poor despite adequate calories. Karyotype was normal, and results of studies for velocardiofacial syndrome were negative. Vomiting developed, and further evaluation showed no acidosis, hypoglycemia, or hyperammonemia; liver-associated values and cholesterol level were normal, as were results of studies of amino acids, organic acids, and acylcarnitine profile. Vomiting became more severe and did not respond to elemental formula, and pyloric stenosis was detected. Feeding problems persisted after successful surgical correction. Delivery of more than 140 kcal/kg by gavage was poorly tolerated but did result in weight gain; however, length and head growth remained very poor.

Smith-Lemli-Opitz syndrome was suspected despite the normal cholesterol value obtained on analysis in the hospital laboratory. Studies performed in a specialized laboratory showed the 7- and 8-dehydrocholesterol values to be elevated and the cholesterol value decreased. Cholesterol supplementation led to some improvement in behavior and feeding. Decrease to 110 kcal/kg/day was tolerated without worsening of growth, and weight for height gradually returned to normal. Review of records confirmed that the pregnancy had been accurately dated by ultrasonography at 10 weeks of gestation, confirming that ME was small for gestational age and microcephalic at birth with subsequent growth typical for SLO syndrome. The incorrect assessment of gestational age as 36 weeks on examination was found to result from failure to appreciate the effect of hypotonia on the findings for gestational age. The family was counseled about autosomal recessive inheritance, including the availability of prenatal diagnosis.

### CASE STUDY 3

HK was born at term to healthy parents by cesarean section performed for breech presentation after an otherwise uncomplicated pregnancy. Hypotonia and dysmorphic features were noted in the delivery room, including inner epicanthic folds, flat occiput, large fontanelles, shallow orbital ridges and low nasal bridge, micrognathia and redundant skin folds at the neck, and unilateral simian crease. Brushfield spots were present. Investigation of a heart murmur revealed patent ductus arteriosus and a small atrial septal defect. There was mild hepatomegaly but normal liver function, no acidosis, and no hypoglycemia. Suck was poor, and gavage feeding was required.

Karyotype was normal and there was no evidence of trisomy 21 in blood in 50 interphase cells examined; the option of skin biopsy to search further for evidence of mosaicism for trisomy 21 was considered. Thyroid function values were normal. Urine amino and organic acid values were normal, as was the acylcarnitine profile. Plasma VLFCA analysis showed elevation consistent with a diagnosis of Zellweger syndrome, along with a typical increase in pipercolic acid value and impaired capacity for fibroblast synthesis of plasmalogens. The baby died at 3 months, and autopsy showed polymicrogyria and small hepatic and renal cysts. The family was counseled about autosomal recessive inheritance, including availability of the prenatal diagnosis.

### CASE STUDY 4

MJ presented with hypotonia at birth after an uncomplicated pregnancy. Minor dysmorphic features were noted, including high nasal bridge, large ears, and inverted nipples. Feeding

difficulties were significant, and growth was poor. Findings of head ultrasonography were unremarkable, as were those of head magnetic resonance imaging, although the radiologist questioned whether the cerebellum might be slightly small. Karyotype was normal. Hypothyroidism, discovered on newborn screening, was promptly treated and closely monitored. There was no acidosis or hypoglycemia, and liver enzyme values were normal; results of amino and organic acid analyses and acylcarnitine profile were all normal.

The baby was discharged on 130 kcal/kg/day. On follow-up, growth remained poor, and development was severely delayed. At age 6 months, she was admitted to the hospital for an episode of acutely altered mental status and low blood pressure. Mild acidosis, borderline elevations of lactate and ammonia, and significant elevation of liver enzymes all resolved over the course of the hospital stay. Cardiac ultrasonography showed mild ventricular dysfunction, which also resolved. Amino and organic acid values were normal, as was the acylcarnitine profile. Urine oligosaccharide levels showed an unusual pattern, and urine mucopolysaccharide values were normal.

At 2 years of age, developmental delay remained marked, and hypotonia persisted with reflexes now absent. The creatinine phosphokinase level was normal, but liver function values were again abnormal. Because mitochondrial disease was suspected, the patient was scheduled for liver biopsy, but clotting values were abnormal. A congenital disorder of glycosylation was suspected, and a transferrin assay confirmed the diagnosis. Review of neonatal records revealed a comment from a neurology consultant about the unusual distribution of fat on the buttocks and thighs of MJ as a neonate. The family was counseled about autosomal recessive inheritance, including availability of prenatal diagnosis.

## LYSOSOMAL STORAGE DISORDERS

In this section, we first consider lysosomes in general, then the neonatal clinical presentation of individual diseases. We finish with a discussion of diagnosis and treatment.

*Lysosomes* are single-membrane-bound intracellular organelles that contain enzymes called *hydrolases*. These lysosomal enzymes are responsible for splitting large molecules into simple, low-molecular-weight compounds, which can be recycled. The material digested by lysosomes is either exogenous material taken up by endocytosis or endogenous material separated from other intracellular materials by autophagy. The common element of all compounds digested by lysosomal enzymes is that they contain a carbohydrate portion attached to a protein or lipid. These glycoconjugates include glycoproteins, glycosaminoglycans, and glycolipids.

*Glycolipids* are large molecules with carbohydrates attached to a lipid moiety. Sphingolipids, globosides, gangliosides, cerebroside, and lipid sulfates all are glycolipids. The different classes of glycolipids are distinguished from one another primarily by different polar groups at C1. *Sphingolipids* are complex membrane lipids composed of one molecule each of the amino alcohol sphingosine, a long-chain fatty acid, and various polar head groups attached by a  $\beta$ -glycosidic linkage. Sphingolipids occur in the blood and nearly all tissues of the body, the highest concentration being found in the white matter of the CNS (CNS).

Additionally, various sphingolipids are components of the plasma membrane of practically all cells. The core structure of the natural sphingolipids is ceramide, a long-chain fatty acid amide derivative of sphingosine. Free ceramide, an intermediate in the biosynthesis and catabolism of glycosphingolipids and sphingomyelin, makes up 16% to 20% of the normal lipid content of the stratum corneum of the skin. Sphingomyelin, a ceramide phosphocholine, is one of the principal structural lipids of the membranes of nervous tissue.

*Cerebrosides* are a group of ceramide monohexosides with a single sugar, either glucose or galactose, and an additional sulfate group on galactose. The two most common cerebrosides are galactocerebroside and glucocerebroside. The largest concentration of galactocerebroside is found in the brain. Glucocerebroside is an intermediate in the synthesis and degradation of more complex glycosphingolipids.

*Gangliosides*, the most complex class of glycolipids, contain several sugar units and one or more sialic acid residues. Gangliosides are normal components of cell membranes and are found in high concentrations in the ganglion cells of the CNS, particularly in the nerve endings and dendrites. GM<sub>1</sub> is the major ganglioside in the brain of vertebrates. Gangliosides function as receptors for toxic agents, hormones, and certain viruses, are involved in cell differentiation, and may also play a role in cell-cell interaction by providing specific recognition determinants on the surface of the cells.

Ceramide oligosaccharides, *globosides*, are a family of cerebrosides that contain two or more sugar residues, usually galactose, glucose, or *N*-acetylgalactosamine. Glycosaminoglycans and oligosaccharides are essential constituents of connective tissue, parenchymal organs, cartilage, and the nervous system.

*Glycosaminoglycans*, also called *mucopolysaccharides*, are complex heterosaccharides consisting of long sugar chains rich in sulfate groups. The polymeric chains are bound to specific proteins (core proteins). *Glycoproteins* contain oligosaccharide chains (long sugar molecules) attached covalently to a peptide core. Glycosylation occurs in the endoplasmic reticulum and the Golgi apparatus. Most glycoproteins are secreted from cells and include transport proteins, glycoprotein hormones, complement factors, enzymes, and enzyme inhibitors. There is extensive diversity in the composition and structure of the oligosaccharides.

The degradation of glycolipids, glycosaminoglycans, and glycoproteins takes place especially within the lysosomes of phagocytic cells, related to histiocytes and macrophages, in any tissue or organ. A series of hydrolytic enzymes cleaves specific bonds, resulting in the sequential, stepwise removal of constituents such as sugars and sulfate, degrading the complex glycoconjugates to the level of their basic building blocks. Lysosomal storage diseases most commonly result when an inherited defect causes significantly decreased activity in one of these hydrolases. Other causes are failure of transport of an enzyme, substrate, or product. Whatever the specific etiology, incompletely metabolized molecules accumulate, especially within the tissue responsible for the catabolism of the glycoconjugate. Additional excess storage material may be excreted in the urine.

Lysosomal storage diseases are classified according to the stored compound. Clinical phenotype depends partially on the type and amount of storage substance. The disorders selected for discussion in this chapter all have known presentation in the neonatal period.

## Clinical Presentations

Table 23–1 summarizes the clinical characteristics of the neonatal presentations of the lysosomal storage disorders.

### Niemann-Pick A Disease (Acute, Sphingomyelinase Deficient)

#### Etiology

Niemann-Pick A disease is caused by a deficiency of sphingomyelinase. Sphingomyelinase catalyzes the breakdown of sphingomyelin to ceramide and phosphocholine, and its deficiency results in sphingomyelin storage within lysosomes. Cholesterol is also stored, suggesting that its metabolism is tied to that of sphingomyelin. Sphingomyelin normally makes up 5% to 20% of phospholipid in the liver, spleen, and brain. In these disorders, it may make up to 70% of the phospholipids. Patients with Niemann-Pick A disease usually have less than 5% of normal enzyme activity.

#### Clinical Features

Clinical features of this disorder may appear in utero or up to 1 year of age. Affected infants usually present with massive hepatosplenomegaly (hepatomegaly greater than splenomegaly), constipation, feeding difficulties, and vomiting with consequent failure to thrive. Patients eventually appear strikingly emaciated with a protuberant abdomen and thin extremities. Neurologic disease is evident by 6 months of age, with hypotonia, decrease or absence of deep tendon reflexes, and weakness. Later, loss of motor skills, spasticity and rigidity, and loss of vision and hearing occur. Seizures are rare. A retinal cherry-red spot is present in about half of cases, and the electroretinographic findings are abnormal. Respiratory infections are common. The skin may have an ochre or brownish yellow color, and xanthomas have been observed. Radiographic findings consist of widening of the medullary cavities, cortical thinning of the long bones, and osteoporosis. In the brain and spinal cord, neuronal storage is widespread, leading to cytoplasmic swelling together with atrophy of the cerebellum. Bone marrow and tissue biopsies may show foam cells or sea-blue histiocytes, which represent lipid-laden cells of the monocyte-macrophage system. Similarly, vacuolated lymphocytes or monocytes may be present in the peripheral blood. Tissue cholesterol levels may be three to ten times normal, and patients may have a microcytic anemia and thrombocytopenia. Death occurs by 2 to 3 years of age.

### Niemann-Pick C Disease

#### Etiology

Niemann-Pick C disease is due to an error in the intracellular transport of exogenous low-density lipoprotein (LDL)-derived cholesterol, which leads to impaired esterification

TABLE 23-1

Lysosomal Storage Disorders Presenting in the Newborn Period: Genetic and Clinical Characteristics of Neonatal Presentation

Disorder	Onset	Facies	Neurologic Findings	Distinctive Features	Eye Findings	Cardiovascular Findings	Dysostosis Multiplex	Hepatomegaly/Splenomegaly	Defect	Gene Location and Molecular Findings	Ethnic Predilection
Niemann-Pick disease Type A	Early infancy	Frontal bossing	Difficulty feeding, apathy, deafness, blindness, hypotonia	Brownish-yellow skin, xanthomas	Cherry-red spot (50%)	—	—	+++	Sphingomyelinase deficiency	ASM gene at 11p15.1-p15.4 3 of 18 mutations account for ≈92% of mutant alleles in the Ashkenazi population	1/40,000 in Ashkenazi Jews with carrier frequency of 1/60
Type C	Birth–3 mo	Normal	Developmental delay, vertical gaze paralysis, hypotonia, later spasticity	—	—	—	—	+++	Abnormal cholesterol esterification	<i>NPCI</i> gene at 18q11 accounts for >95% of cases; <i>HE1</i> gene mutations may account for remaining cases	Increased in French Canadians of Nova Scotia and Spanish Americans in the southwest United States

TABLE 23-1

## Lysosomal Storage Disorders Presenting in the Newborn Period: Genetic and Clinical Characteristics of Neonatal Presentation—Cont'd

Disorder	Onset	Facies	Neurologic Findings	Distinctive Features	Eye Findings	Cardiovascular Findings	Dysostosis Multiplex	Hepatomegaly/Splenomegaly	Defect	Gene Location and Molecular Findings	Ethnic Predilection
Gaucher disease type 2	In utero–6 mo	Normal	Poor suck and swallow; weak cry; squint, trismus, strabismus, opsoclonus, hypertonic, later flaccidity	Congenital ichthyosis, collodion skin	–	–	–	+ / + + +	Glucocerebrosidase deficiency	1q21; large number of mutations known; 5 mutations account for ≈97% of mutant alleles in the Ashkenazi population, but only ≈75% in the non-Jewish population	Panethnic
Krabbe disease	3–6 mo	Normal	Irritability, tonic spasms with light or noise stimulation, seizures, hypertonía, later flaccidity	Increased CSF protein	Optic atrophy	–	–	– / –	Galactocerebrosidase deficiency	14q 24.3-q32.1; >60 mutations with some common mutations in specific populations	Increased in Scandinavian countries and in a large Druze kindred in Israel
G <sub>M1</sub> gangliosidosis	Birth	Coarse	Poor suck, weak cry, lethargy, exaggerated startle, blindness, hypotonia, later spasticity	Gingival hypertrophy, edema, rashes	Cherry-red spot (50%)	–	+	+ / +	β-galactosidase deficiency	3 pter-3p21; heterogeneous mutations; common mutations in specific populations	Panethnic

Farber disease Type I	2 wk- 4 mo	Normal	Progressive psychomotor impairment, seizures, decreased reflexes, hypotonia	Joint swelling with nodules, hoarseness, lung disease, contractures, fever, granulomas, dysphagia, vomiting, increased CSF protein	Grayish opacification sur- rounding retina in some patients, subtle cherry-red spot	Occasional	–	Hepato- megaly in 50%, spleno- megaly less common	Lysosomal acid ceramidase	8p21.3- 22: 9 disease- causing mutations identified	Panethnic
Types II and III	Birth- 9 mo ( $\leq 20$ mo)	Normal		Joint swelling with nodules, hoarseness	Normal macula, $\pm$ corneal opacities	–	HSM less com- mon than in type I			8p21.3- p22	Panethnic
Type IV (neonatal)	Birth	Normal	Nodules not consistent findings	Corneal opacities (1/3)	–	–	+++			Unknown	Panethnic
Congenital sialidosis	In utero- birth	Coarse, edema	Mental retardation, hypotonia	Neonatal ascites, inguinal hernias, renal disease	Corneal clouding	–	+/+		Neur- amini- dase deficiency	NEU1 gene (sialidase) at 6p21	Panethnic
Galacto- sialidosis	In utero- birth	Coarse	Mental retardation, occasional deafness, hypotonia	Ascites, edema, inguinal hernias, renal disease, telangiectasias	Cherry- red spot, corneal clouding	Cardio- megaly progressing to failure	+/+		Absence of a protective protein that safeguards neuramini- dase and beta- galactosidase from pre- mature degradation	20q13.1	Panethnic
Wolman disease	First weeks of life	Normal	Mental deterioration	Vomiting, diarrhea, steatorrhea, abdominal distention, failure to thrive, anemia, adrenal calcifications	–	–	+/+		Lysosomal acid lipase deficiency	10q23.2- q23.3; variety of mutations identified	Increased in Iranian Jews and in non- Jewish and Arab populations of Galilee

## Lysosomal Storage Disorders Presenting in the Newborn Period: Genetic and Clinical Characteristics of Neonatal Presentation—Cont'd

Disorder	Onset	Facies	Neurologic Findings	Distinctive Features	Eye Findings	Cardiovascular Findings	Dysostosis Multiplex	Hepatomegaly/Splenomegaly	Defect	Gene Location and Molecular Findings	Ethnic Predilection
Infantile sialic acid storage disease	In utero—birth	Coarse, dysmorphic	Mental retardation, hypotonia	Ascites, anemia, diarrhea, failure to thrive	—	Congestive heart failure	+	+/+	Defective transport of sialic acid out of the lysosome	SLC17A5 gene at 6q	Panethnic
I-cell disease	In utero—birth	Coarse	Mental retardation, ± deafness	Gingival hyperplasia, restricted joint mobility, hernias	Corneal clouding	Valvular disease, congestive heart failure, cor pulmonale	++	++ +/ ++	Lysosomal enzymes lack mannose-6-PO <sub>4</sub> recognition marker and fail to enter the lysosome (phosphotransferase deficiency, 3-subunit complex [ $\alpha_2\beta_2\gamma_2$ ])	Enzyme encoded by 2 genes; $\alpha$ and $\beta$ subunits encoded by gene at 12p; $\gamma$ subunit encoded by gene at 16p	Panethnic

Mucopolipidosis type IV	Birth— 3 mo	Normal	Mental retardation, hypotonia	—	Severe corneal clouding, retinal degeneration, blindness	—	—/—	Unknown; some patients with partial deficiency of gangli- oside sialidase	<i>MCOLN1</i> gene at 19p13.2-13.3 encoding mucopolipin; 2 founder mutations accounting for 95% of mutant alleles in Ashkenazi population	Increased in Ashke- nazi Jews
Mucopolysaccharidosis type VII	In utero— child- hood	Variable coarse- ness	Mild— severe mental retardation	Hernias	Variable corneal clouding	Variable	++	Variable	<i>GUSB</i> gene at 7q21.2- q22; hetero- geneous mutations	Panethnic

CSF, cerebrospinal fluid; HSM, hepatosplenomegaly; —, not seen; +, typically present, usually not severe; ++, usually present, and moderately severe; +++, always present, usually severe.

of cholesterol and trapping of unesterified cholesterol in lysosomes. Cell lines from patients can be divided into two complementation groups, NPC1 and NPC2, corresponding to different genes (Millat et al, 2001). In each group, the primary defect is abnormal cholesterol esterification, but the enzyme responsible for cholesterol esterification, acyl-coenzyme A (CoA):cholesterol acyltransferase (ACAT), is not deficient. The storage of sphingomyelin is secondary. It has been suggested that the defect is in the transport of cholesterol out of the lysosome, making cholesterol unavailable to ACAT (Natowicz et al, 1995). Sphingomyelinase activity appears normal or elevated in most tissues but partially deficient (60% to 70%) in fibroblasts from most patients with this disorder. Storage of sphingomyelin in tissues is much less than in Niemann-Pick A or B disease and is accompanied by additional storage of unesterified cholesterol, phospholipids, and glycolipids in the liver and spleen. Only glycolipids are increased in the brain.

### Clinical Features

The age of onset, clinical features, and natural history of Niemann-Pick C disease are highly variable. Onset may occur from birth to 18 years of age. Fifty percent of children with onset in the neonatal period have conjugated hyperbilirubinemia, which usually resolves spontaneously but is followed by neurologic symptoms later in childhood. In the severe infantile form, hepatosplenomegaly is common, accompanied by hypotonia and delayed motor development. Further mental regression is usually evident by the age of 1 to 1.5 years, in association with behavior problems, vertical supranuclear ophthalmoplegia, progressive ataxia, dystonia, spasticity, dementia, drooling, dysphagia, and dysarthria. Seizures are rare. Foam cells and sea-blue histiocytes may be found in many tissues. Neuronal storage with cytoplasmic ballooning, inclusions, meganeurites, and axonal spheroids are also seen. Death may occur in infancy or as late as the third decade. Niemann-Pick C disease may also manifest as fatal neonatal liver disease, often misdiagnosed as fetal hepatitis. Patients with mutations in the *NPC2* gene (*HE1*) may have remarkable features consisting of pronounced pulmonary involvement leading to early death due to respiratory failure (Millat et al, 2001).

### Gaucher Disease Type 2 (Acute Neuropathic)

#### Etiology

Three types of Gaucher disease have been defined. Type 1, the nonneuropathic form, is the most common type and is distinguished from types 2 and 3 by the lack of CNS involvement. Type 1 disease most commonly manifests in early childhood but may do so in adulthood. Type 2 disease, the acute neuropathic form, is characterized by infantile onset of severe CNS involvement. Type 3 disease, the subacute neuropathic form, is also late in onset with slow neurologic progression. Almost all types of Gaucher disease are caused by a deficiency of lysosomal glucocerebrosidase and result in the storage of glucocerebroside in visceral organs; the brain is affected in types 2 and 3. Although there is significant variability in clinical presentation among individuals with the same mutations, there is

a clear correlation between certain mutations and clinical symptoms involving the CNS (Beutler and Grabowski, 2001). The enzyme splits glucose from cerebroside, yielding ceramide and glucose. A few patients with Gaucher disease type 2 have a deficiency of saposin C, a cohydrolyase required by glucocerebrosidase.

### Clinical Features

Typically, the age of onset of Gaucher disease type 2 is approximately 3 months, consisting of hepatosplenomegaly (splenomegaly predominates) with subsequent neurologic deterioration. Hydrops fetalis, congenital ichthyosis, and collodion skin, however, are well-described presentations (Fujimoto et al, 1995; Ince et al, 1995; Lipson et al, 1991; Liu et al, 1988; Sherer et al, 1993; Sidransky et al, 1992). In a review of 18 cases of Gaucher disease manifesting in the newborn period, Sidransky and associates (1992) found 8 of the patients to have associated dermatologic findings and 6 patients to have presented with hydrops. The etiology of the association of such findings and Gaucher disease is unclear, although the enzyme deficiency appears to be directly responsible (Sidransky et al, 1992). Ceramides have been shown to be major components of the intracellular bilayers in epidermal stratum corneum and play an important role in skin homeostasis (Fujimoto et al, 1995). Thus, Gaucher disease should be considered in the differential diagnosis for infants presenting with hydrops fetalis and congenital ichthyosis. For the subset of patients presenting prenatally or at birth, death frequently occurs within hours to days, or at least within 2 to 3 months.

### Krabbe Disease (Globoid Cell Leukodystrophy)

#### Etiology

The non-eponymic synonym for Krabbe disease, globoid cell leukodystrophy, is derived from the finding of large numbers of multinuclear macrophages in the cerebral white matter that contain undigested galactocerebroside. Disease is caused by a deficiency of lysosomal galactocerebroside  $\beta$ -galactosidase, which normally degrades galactocerebroside to ceramide and galactose. Deficiency of the enzyme results in storage of galactocerebroside. Galactocerebroside is present almost exclusively in myelin sheaths. Accumulation of a toxic metabolite, psychosine, also a substrate for the enzyme, has been postulated to lead to early destruction of the oligodendroglia. Impaired catabolism of galactosylceramide is also important in the pathogenesis of the disease.

### Clinical Features

Age of onset ranges from the first weeks of life to adulthood. The typical age of onset of infantile Krabbe disease is between 3 and 6 months, but there are cases of very early onset in which neurologic symptoms are evident within weeks after birth. Symptoms and signs are confined to the nervous system; no visceral involvement is present. The clinical course has been divided into three stages. In stage I, patients who appeared relatively normal after birth present with hyperirritability, vomiting, episodic fevers, hyperesthesia, tonic spasms with light or noise stimulation, stiffness, and seizures. Peripheral neuropathy

is present, but reflexes are increased. Stage II is marked by CNS deterioration and hypertonia that progresses to hypotonia and flaccidity. Deep tendon reflexes are eventually lost. Patients with stage III disease are decerebrate, deaf, and blind with hyperpyrexia, hypersalivation, and frequent seizures. Routine laboratory findings are unremarkable with the exception of an elevation of cerebrospinal fluid protein. Cerebral atrophy and demyelination become evident in the CNS, and segmental demyelination, axonal degeneration, fibrosis, and macrophage infiltration are common in the peripheral nervous system. The segmental demyelination of peripheral nerves is demonstrated by the finding of decreased motor nerve conduction. The white matter is severely depleted of all lipids, especially glycolipids, and nerve and brain biopsies show globoid cells. Death from hyperpyrexia, respiratory complications, or aspiration occurs at a median age of 13 months.

### **G<sub>M1</sub> Gangliosidosis**

#### **Etiology**

Infantile G<sub>M1</sub> gangliosidosis is caused by deficiency of lysosomal  $\beta$ -galactosidase. The enzyme cleaves the terminal galactose in a  $\beta$  linkage from oligosaccharides, keratan sulfate, and G<sub>M1</sub> ganglioside. Deficiency of the enzyme results in storage of G<sub>M1</sub> ganglioside and oligosaccharides. Clinical severity correlates with the extent of substrate storage and residual enzyme activity. The same enzyme is deficient in Morquio disease type B.

#### **Clinical Features**

Age of onset ranges from prenatal to adult life. Infantile or type 1 G<sub>M1</sub> gangliosidosis may be evident at birth as coarse and thick skin, hirsutism on the forehead and neck, and coarse facial features consisting of a puffy face, frontal bossing, depressed nasal bridge, maxillary hyperplasia, large and low-set ears, wide upper lip, moderate macroglossia, and gingival hypertrophy. These dysmorphic features, however, are not always obvious in the neonate. A retinal cherry-red spot is seen in 50% of patients, and corneal clouding is often observed. Shortly after birth, or by 3 to 6 months of age, failure to thrive and hepatosplenomegaly become evident, as does neurologic involvement with poor development, hyperreflexia, hypotonia, and seizures. Cranial imaging shows diffuse atrophy of the brain, enlargement of the ventricular system, and evidence of myelin loss in the white matter.

The neurologic deterioration is progressive, resulting in generalized rigidity and spasticity and sensorimotor and psychointellectual dysfunction. By 6 months of age, skeletal features are present, including kyphoscoliosis and stiff joints with generalized contractures, and striking bone changes are seen—vertebral beaking in the thoracolumbar region, broadening of the shafts of the long bones with distal and proximal tapering, and widening of the metacarpal shafts with proximal pinching of the four lateral metacarpals. Tissue biopsies demonstrate neurons filled with membranous cytoplasmic bodies and various types of inclusions as well as foam cells in the bone marrow. Death generally occurs before 2 years of age. A severe neonatal-onset type of G<sub>M1</sub> gangliosidosis with cardiomyopathy has also been described (Kohlschütter et al, 1982).

### **Farber Lipogranulomatosis**

#### **Etiology**

Farber lipogranulomatosis results from a deficiency of lysosomal acid ceramidase. Ceramidase catalyzes the degradation of ceramide to its long-chain base, sphingosine, and a fatty acid. Clinical disease is a consequence of storage of ceramide in various organs and body fluids.

#### **Clinical Features**

Four types of Farber lipogranulomatosis may manifest in the neonatal period. Type I, classic disease, is a unique disorder with onset from approximately 2 weeks to 4 months of age. Patients present with hoarseness progressing to aphonia, feeding and respiratory difficulties, poor weight gain, and intermittent fever due to granuloma formation and swelling of the epiglottis and larynx. Palpable nodules appear over joints and pressure points, and joints become painful and swollen. Later, joint contractures and pulmonary disease appear. Liver and cardiac involvement may occur, and patients may have a subtle retinal cherry-red spot. Severe and progressive psychomotor impairment may occur, as may seizures, decreased deep tendon reflexes, hypotonia, and muscle atrophy. Affected patients die in early infancy, usually from pulmonary disease.

Type 2, or intermediate, Farber lipogranulomatosis manifests from birth to 9 months of age as joint and laryngeal involvement and nodules. Death occurs in early childhood. Type 3, or mild, disease, manifests slightly later, from approximately 2 months to 20 months of age, with survival into the third decade. Clinically, types 2 and 3 are both dominated by subcutaneous nodules, joint deformity, and laryngeal involvement. Liver and pulmonary involvement may be absent. Two thirds of patients have a normal intelligence quotient. Type 4, or neonatal visceral, Farber lipogranulomatosis manifests at birth as hepatosplenomegaly due to massive histiocyte infiltration of the liver and spleen, with infiltration also in the lungs, thymus, and lymphocytes. Subcutaneous nodules and laryngeal involvement may be subtle. Death occurs by 6 months of age.

In all types of Farber lipogranulomatosis, tissue biopsies show granulomatous infiltration, foam cells, and lysosomes with comma-shaped, curvilinear tubular structures called *Farber bodies*. Cerebrospinal fluid protein may be elevated in patients with type I disease.

### **Sialidosis**

#### **Etiology**

Sialidosis is caused by a deficiency of neuraminidase, which is responsible for the cleavage of terminal sialyl linkages of several oligosaccharides and glycopeptides. The defect results in the multisystem lysosomal accumulation of sugars rich in sialic acid.

#### **Clinical Features**

Type I sialidosis is characterized by retinal cherry-red spots and generalized myoclonus with onset generally in the second decade of life. Type II is distinguished from type I by the early onset of a progressive, severe phenotype with somatic features. Type II is often subdivided

into juvenile, infantile, and congenital forms. Congenital sialidosis begins in utero and manifests at birth as coarse features, facial edema, hepatosplenomegaly, ascites, hernias, and hypotonia, and, occasionally, frank hydrops fetalis. Radiographs demonstrate dysostosis multiplex and epiphyseal stippling. Delayed mental development is quickly apparent. The patient may have recurrent infections. Severely dilated coronary arteries, excessive retinal vascular tortuosity, and an erythematous macular rash may also be features of this disease (Buchholz et al, 2001). Most patients are stillborn or die before 1 year of age. Age of onset for the infantile form of sialidosis ranges from birth to 12 months. Clinical features are coarse features, organomegaly, dysostosis multiplex, retinal cherry-red spot, and mental retardation. Death occurs by the second or third decade. In both types of sialidosis, vacuolated cells can be seen in almost all tissues, and bone marrow foam cells are present.

### Galactosialidosis

#### Etiology

Galactosialidosis results from a deficiency of two lysosomal enzymes, neuraminidase and  $\beta$ -galactosidase. The primary defect in galactosialidosis has been found to be a defect in protective protein-cathepsin A (PPCA), an intralysosomal protein that protects the two enzymes from premature proteolytic processing. The protective protein has catalytic as well as protective functions, and the two functions appear to be distinct. Deficiency of the enzymes results in the accumulation of sialyloligosaccharides in tissue lysosomes and in excreted body fluids.

#### Clinical Features

Galactosialidosis has been divided into three phenotypic subtypes on the basis of age of onset and severity of clinical manifestations. Most patients present in adolescence and adulthood, but early infantile and late infantile presentations occur. Patients with early infantile galactosialidosis present between birth and 3 months of age with ascites, edema, coarse facial features, inguinal hernias, proteinuria, hypotonia, and telangiectasias, and, occasionally, frank hydrops fetalis. Patients subsequently demonstrate organomegaly, including cardiomegaly progressing to cardiac failure, psychomotor delay, and skeletal changes, particularly in the spine. Ocular abnormalities, including corneal clouding and retinal cherry-red spots, may occur. Death occurs at an average age of 8 months, usually from cardiac and renal failure. Galactosialidosis may be a cause of recurrent fetal loss or recurrent hydrops fetalis.

Late infantile galactosialidosis manifests in the first months of life as coarse facial features, hepatosplenomegaly, and skeletal changes consistent with dysostosis multiplex. Cherry-red spots and corneal clouding may also be present. Neurologic involvement may be absent or mild. Valvular heart disease is a common feature, as is growth retardation, partially because of spinal involvement and often in association with muscular atrophy. Early death is not a feature of the late infantile form. In all forms of galactosialidosis, vacuolated cells in blood smears and foam cells in bone marrow are present.

### Wolman Disease

#### Etiology

Wolman disease is caused by deficiency of lysosomal acid lipase, an enzyme involved in cellular cholesterol homeostasis and responsible for the hydrolysis of cholesterol esters and triglycerides. The result of the enzyme deficiency is the defective release of free cholesterol from lysosomes, which leads to up-regulation of the LDL receptors and 3-hydroxy-3-methylglutaryl-CoA reductase activity. De novo synthesis of cholesterol and activation of receptor-mediated endocytosis of LDL then occur, leading to further deposition of lipid in the lysosomes. The result is the accumulation of cholesterol esters and triglycerides in most tissues of the body, including the liver, spleen, lymph nodes, heart, blood vessels, and brain. An extreme level of lipid storage occurs in the cells of the small intestine, particularly in the mucosa. Additionally, the neurons of the myenteric plexus demonstrate a high level of storage, with evidence of neuronal cell death, which may account for the prominence of gastrointestinal symptoms (Wolman, 1995).

#### Clinical Features

Patients with Wolman disease present within weeks of birth with evidence of malnutrition and malabsorption, including symptoms of vomiting, diarrhea, steatorrhea, failure to thrive, abdominal distention, and hepatosplenomegaly. Adrenal calcifications may be seen on radiographs, and adrenal insufficiency appears. The presence of adrenal calcifications in association with hepatosplenomegaly and gastrointestinal symptoms is strongly suggestive of Wolman disease. Later, mental deterioration becomes apparent. Laboratory findings include anemia secondary to foam cell infiltration of the bone marrow and evidence of adrenal insufficiency. The serum cholesterol level is normal. Death usually occurs before 1 year of age.

### Infantile Sialic Acid Storage Disease

#### Etiology

A defective lysosomal sialic acid transporter that is responsible for the efflux of sialic acid and other acidic monosaccharides from the lysosomal compartment is the cause of infantile sialic acid storage disease. The defective transporter results in greater storage of free sialic acid and glucuronic acid within the lysosomes and increased sialic acid excretion.

#### Clinical Features

Infantile sialic acid storage disease often manifests at birth as mildly coarse features, hepatosplenomegaly, ascites, hypopigmentation, and generalized hypotonia. Mild dysostosis multiplex may be seen on radiographs. Failure to thrive and severe mental and motor retardation soon appear. Cardiomegaly may be present. Corneas are clear, but albinoid fundi have been reported (Lemyre et al, 1999). Vacuolated cells are seen on tissue biopsy, and electron microscopy demonstrates swollen lysosomes filled with finely granular material. CNS changes include myelin loss, axonal spheroids, gliosis, and neuronal storage. Death occurs

in early childhood. Infantile sialic acid storage disease may also manifest as fetal ascites, nonimmune fetal hydrops, or infantile nephrotic syndrome (Lemyre et al, 1999).

### I-Cell Disease (Mucopolipidosis Type II)

#### Etiology

In normal cells, targeting of the enzymes to the lysosomes is mediated by receptors that bind a mannose-6-phosphate recognition marker on the enzyme. The recognition marker is synthesized in a two-step reaction in the Golgi complex, and it is the enzyme that catalyzes the first step of this process, uridine diphosphate-*N*-acetylglucosamine: lysosomal enzyme *N*-acetylglucosaminyl-1-phosphotransferase, that is defective in I-cell disease. As a result, the enzymes lack the mannose-6-phosphate recognition signal, and the newly synthesized lysosomal enzymes are secreted into the extracellular matrix instead of being targeted to the lysosome. Consequently, multiple lysosomal enzymes are found in the plasma in 10 to 20 times their normal concentrations. Affected cells, especially fibroblasts, show dense inclusions of storage material that probably consists of oligosaccharides, glycosaminoglycans, and lipids. These are the “inclusion bodies” from which the disease name is derived.

#### Clinical Features

I-cell disease may manifest at birth as coarse features, corneal clouding, organomegaly, hypotonia, and gingival hyperplasia. Birth weight and length are often below normal. Kyphoscoliosis, lumbar gibbus, and restricted joint movement are often present, and there may be hip dislocation, fractures, hernias, or bilateral talipes equinovarus. Dysostosis multiplex may be seen on radiographs. Severe psychomotor retardation, evident by 6 months of age, and progressive failure to thrive occur. The facial features become progressively more coarse with a high forehead, puffy eyelids, epicanthal folds, flat nasal bridge, anteverted nares, and macroglossia. Linear growth slows during the first year of life and halts completely thereafter. The skeletal involvement is also progressive, with the development of increasing joint immobility and claw-hand deformities. Respiratory infections, otitis media, and cardiac involvement are common complications. Death usually occurs in the first decade of life due to cardiorespiratory complications.

### Mucopolipidosis Type IV

#### Etiology

Although mucopolipidosis type IV is associated with a partial deficiency of the lysosomal enzyme, ganglioside sialidase, it is not certain that the deficiency is the root cause of the disorder. Nevertheless, deficiency of this enzyme causes lysosomal storage of gangliosides and glycosaminoglycans. Mutations in a novel transient receptor potential cation channel gene have been found in patients with mucopolipidosis type IV (Sun et al, 2000). The gene, *MCOLN1*, encodes a protein, mucolipin 1, which is a member of a new protein family of unknown function (Bach, 2001).

#### Clinical Features

The age of onset for mucopolipidosis type IV ranges from infancy to 5 years. Presenting features are corneal clouding, retinal degeneration, blindness, hypotonia, and mental retardation. Survival of affected patients into the fourth decade has been reported (Chitayat et al, 1991). Cytoplasmic inclusions are noted in the conjunctiva, fibroblasts, liver, and spleen.

### Mucopolysaccharidosis Type VII (Sly Disease)

#### Etiology

Sly disease is a member of a group of lysosomal storage disorders that are caused by a deficiency of enzymes catalyzing the stepwise degradation of glycosaminoglycans. Skeletal and neurologic involvement is variable. There is a wide spectrum of clinical severity among the mucopolysaccharidoses and even within a single enzyme deficiency. Most of these disorders manifest in childhood, but type VII is included in this chapter because of its well-recognized neonatal and infantile presentations. Sly disease is caused by  $\beta$ -glucuronidase deficiency and results in lysosomal accumulation of glycosaminoglycans, including dermatan sulfate, heparan sulfate, and chondroitin sulfate, causing cell, tissue, and organ dysfunction.

#### Clinical Features

Sly disease may manifest as a wide spectrum of severity. Patients with the early-onset or neonatal form may present with coarse features, hepatosplenomegaly, moderate dysostosis multiplex, hernias, and nonprogressive mental retardation. Corneal clouding is variably present. Frequent episodes of pneumonia during the first year of life are common. Short stature becomes evident. Granulocytes have coarse metachromic granules. A severe neonatal form associated with hydrops fetalis, and, frequently, early death has been recognized. Milder forms of the disease with later onset are also known.

### Diagnosis, Management, and Prognosis

Growing recognition of lysosomal storage disorders in the neonate has led to expansion of the spectrum of possible clinical presentation in the newborn period. Diagnostic tools and options for treatment also continue to advance, and any textbook is likely to be out of date, especially with respect to therapeutic options, immediately upon publication. For example, efforts are currently under way to develop newborn screening for mucopolysaccharidoses (Whitley et al, 2002), with the goal to offer treatment with enzyme infusion or bone marrow transplantation (BMT) to affected babies (Vogler et al, 1999). The neonatologist is urged to work closely with appropriate experts to explore diagnostic and treatment protocols on an individual basis.

Recognition of lysosomal storage disorders in the newborn period can be difficult because they often mimic more common causes of illness in newborns, such as respiratory distress, nonimmune hydrops fetalis, liver disease, and sepsis. The initial step in the diagnosis of these disorders is, therefore, to consider them in the differential diagnosis

for a sick or unusual-appearing newborn. At times, the phenotype may suggest a specific diagnosis, such as respiratory distress and painful, swollen joints in Farber lipogranulomatosis or gastrointestinal symptoms, hepatosplenomegaly, and adrenal calcifications in Wolman disease. Subtle dysmorphic features, coarsening of features, and radiographic evidence of dysostosis multiplex are also strong indications that lysosomal storage disorders should be considered. Routine laboratory findings are often normal or nonspecific. Affected infants do not have episodes of acute metabolic decompensation. Anemia and thrombocytopenia may be seen due to bone marrow involvement. Vacuolated cells may be found in peripheral blood, but absence of this finding does not rule out lysosomal storage disease. Elevated cerebrospinal fluid protein is seen in Krabbe disease and Farber lipogranulomatosis type I.

Directed analysis of urine is helpful for those conditions in which characteristic metabolites are excreted in urine. One- or two-dimensional electrophoresis or thin-layer chromatography can detect excess excretion of urine glycosaminoglycans, oligosaccharides, or free sialic acid, but all urinary tests for the diagnosis of lysosomal storage disorders can have false-negative results. Examination of the bone marrow or other tissues may demonstrate storage macrophages in Gaucher disease and in Niemann-Pick A and C diseases. Small skin or conjunctival biopsy specimens may demonstrate storage within lysosomes in most of these disorders.

Definitive diagnosis for all lysosomal storage disorders, with the exception of Niemann-Pick C disease, is confirmed by enzymatic assays in serum, leukocytes, fibroblasts, or a combination of these. The diagnosis of Niemann-Pick C disease requires measurement of cellular cholesterol esterification and documentation of a characteristic pattern of filipin-cholesterol staining in cultured fibroblasts during LDL uptake. Analysis of DNA mutations may be helpful for the diagnosis of Gaucher disease and some other conditions. Additionally, prenatal diagnosis is available for most lysosomal storage disorders through the use of enzyme assays performed on amniocytes or chorionic villus cells or measurements of levels of stored substrate in cultured cells or amniotic fluid.

These conditions must also be considered in the dying infant, and the neonatologist must be prepared to request the appropriate samples for diagnosis at the time of death. In the surviving patients, treatment and management must be considered. All of the lysosomal storage disorders are chronic and progressive conditions for which there is no curative treatment. Gene transfer therapy holds promise but is not currently available for lysosomal storage disorders. With few exceptions, current standard medical management is supportive and palliative. Patients must be continually reassessed for evidence of disease progression and associated complications. These complications, which may include hydrocephalus, valvular heart disease, joint limitation, and obstructive airway disease, manifest at variable ages.

For several disorders, particularly neonatal Gaucher disease and Niemann-Pick C disease, splenectomy may be indicated to improve severe anemia and thrombocytopenia. This procedure enhances the risk of serious infections, however, and may accelerate the progression of the disease at other sites. Patients with Krabbe disease may suffer from

significant pain from radiculopathy and spasms, and alleviation of that pain is important for the comfort of the patient. The administration of the glutamic acid transaminase inhibitor vigabatrin has been used in a small number of patients with Krabbe disease, because part of the pathology may involve a secondary deficiency of  $\gamma$ -aminobutyric acid (Barth, 1995). Low-dose morphine has also been reported to improve the irritability associated with this disorder (Stewart et al, 2001).

Enzyme replacement therapy is available for Gaucher disease. Alglucerase (Ceredase), replacement enzyme purified from placentas, and imiglucerase (Cerezyme), recombinant enzyme, are available for use in affected patients. Although enzyme replacement therapy has successfully reversed many of the systemic manifestations of the disease, it has been suggested that enzyme replacement therapy should not be given to patients with Gaucher disease type 2 who already have severe neurologic signs, because no substantial improvement has been demonstrated to occur in the neurologic symptoms of patients treated (Erikson et al, 1993; Gaucher disease, 1996).

Bone marrow transplantation has been tried for a variety of lysosomal storage disorders. The rationale for the procedure is that circulating blood cells derived from the transplanted marrow become a source of the missing enzyme. Results of bone marrow transplantation in disorders of glycosaminoglycans show that after successful engraftment, leukocyte and liver tissue enzyme activity normalizes, organomegaly decreases, and joint mobility increases. Skeletal abnormalities stabilize but do not improve. Whether brain function can be improved in patients with CNS disease remains questionable. Some patients maintained their learning capability or intelligence quotient, but others continued to deteriorate. Clinical experience and studies in animal models indicate that BMT before the onset of neurologic symptoms can prevent or delay the occurrence of symptoms, whereas there is no clear benefit if transplantation is performed when symptoms are already present (Hoogerbrugge et al, 1995). BMT in patients with nonneuropathic Gaucher disease may result in complete disappearance of all symptoms. The procedure is associated with significant risks, however (Hoogerbrugge et al, 1995), which must be balanced against lifelong enzyme replacement therapy. Currently, it is unclear to what extent patients with the neuropathic types of Gaucher disease (types 2 and 3) would benefit from transplantation.

BMT has also been attempted in a small number of patients with infantile Krabbe disease, Farber lipogranulomatosis, and Niemann-Pick A disease. The outcome after transplantation for these few patients has been poor, with continued disease progression and death. Krivit and associates (2000) reported successful long-term bone marrow engraftment in a patient with Wolman disease that resulted in normalization of peripheral leukocyte lysosomal acid lipase enzyme activity; the patient's diarrhea resolved, cholesterol, triglyceride and liver function values normalized, and the patient was gaining developmental milestones. Lysosomal storage diseases are not all equally amenable to BMT, and the use of BMT as a treatment modality for most lysosomal storage disorders remains uncertain. In a small number of cases, BMT has been performed in utero

after prenatal diagnosis showing an affected infant, and experimental protocols are available for families who wish to pursue this option.

The goal of therapy for a dietary protocol proposed for the treatment of Wolman disease is lessened accumulation of storage material in the intestine and phagocytes. The diet, which should be started as soon as the diagnosis of Wolman disease is suspected, consists of (1) discontinuing breast-feeding or feeding with a formula containing triglycerides and cholesterol esters and (2) keeping the infant on a fatty ester-free diet (Wolman, 1995). The diet should include all the necessary vitamins, including the fat-soluble vitamins. In addition, daily smearing of the skin of a different extremity with a small amount (10 to 50  $\mu$ L) of sunflower or safflower oil or preferably soy, canola, flax, cod liver, or algal oil is required for the prevention of essential fatty acid deficiency, which complicates the restricted diet (Wolman, 1995). The absorption of fatty acids through the skin spares the gastrointestinal tract from accumulation and is associated with the formation of phospholipids and triglycerides (Wolman, 1995). Preliminary results of this approach suggest that treatment appears to halt disease progression.

## CONGENITAL DISORDERS OF GLYCOSYLATION

### Etiology

Congenital disorders of glycosylation, previously called “carbohydrate deficient glycoprotein syndromes,” are a group of disorders similar to the lysosomal storage diseases. In these conditions, there may be liver disease characterized by fibrosis, and electron microscopy shows myelin-like and granular lysosomal inclusions as well as abnormalities of the endoplasmic reticulum in hepatocytes. These disorders are due to the partial deficiency of carbohydrates on many glycoproteins with evidence of a defect in the addition of *N*-linked carbohydrates. Abnormalities of all classes of glycoproteins have been identified in CDG. These disorders are due to defective post-translational *N*-glycosylation of numerous proteins. Glycosylation occurs frequently and serves a number of functions, such as aiding in correct folding of the nascent protein, participating in cell adhesion phenomena, protecting against premature proteolytic destruction, and modifying biologic function. Given the ubiquitous occurrence of glycoproteins, it is not surprising that CDGs display diverse clinical manifestations. The description and classification of this group of disorders continue to expand (Jaeken et al, 2001).

Two main classes of congenital disorders of glycosylation are distinguished, and eleven subcategories of CDG type I (CDG-I) have been identified (types Ia through Ik), with Ia remaining the “classic” as well as the most common presentation. The basic defect in CDG-Ia has been shown to be a deficiency of the enzyme, phosphomannomutase, an enzyme required for the early steps of protein glycosylation (Jaeken et al, 2001; van Schaftingen and Jaeken, 1995). Type I CDG appear to be caused by defects in the biosynthesis of the dolichol-linked precursor oligosaccharides and their transfer to proteins (Westphal et al, 2000). This results in an insufficient amount of pre-

cursor oligosaccharide for glycosylation or an oligosaccharide that is poorly transferred to the protein. Type II disorders, of which four forms have been described (IIa through IIe), appear to result from defects in oligosaccharide processing, the addition of other kinds of sugar chains to the proteins, or both (Westphal et al, 2000).

A number of patients with features of CDG defy disease classification, as no specific biochemical defect has been identified. The number of patients described with CGS-II and unclassified CDG-x remains small. Because there are more than 40 enzyme and transport steps in the *N*-glycosylation pathway, one can anticipate that additional defects will be identified. Table 23-2 summarizes the current clinical and biochemical information on CDG. Autosomal recessive inheritance is most likely for all forms of CDG.

### Clinical Features

The clinical spectrum of CDG continues to expand as greater understanding of its biochemistry permits recognition of additional conditions and clinical variability (Grunewald and Matthijs, 2000). Patients with CDG-Ia present at birth with dysmorphic features, consisting of high nasal bridge, prominent jaw, large ears, and inverted nipples, feeding difficulties and subsequent growth failure, hypotonia, lipocutaneous abnormalities (including prominent fat pads on the buttocks), and mild to moderate hepatomegaly. The clinical progression of this disorder is divided into four stages. In stage I, the infantile, multisystem stage, patients show evidence of multisystem involvement, including variable stroke-like episodes, thrombotic disease, liver dysfunction, pericardial effusions and cardiomyopathy, proteinuria, and retinal degeneration. The coagulopathy likely stems from the number of clotting and anti-clotting proteins that are *N*-linked glycoproteins. Mental retardation, peripheral neuropathy, and decreased nerve conduction velocities are observed. Strabismus and alternating esotropia are present in nearly all patients, and retinitis pigmentosa and abnormalities of the electroretinogram in most. Cranial imaging shows varying degrees of cerebral, cerebellar, and brainstem hypoplasia. Electroencephalogram results are usually normal. Liver biopsies typically show steatosis and fibrosis, and multicystic changes in the kidneys have been noted.

Stage II, the childhood stage, is characterized by ataxia and mental retardation. Skeletal abnormalities may become more prominent, consisting of contractures, kyphoscoliosis, pectus carinatum, and short stature. Stage III, generally occurring in the teenage years, is characterized primarily by lower extremity atrophy. Adulthood, or stage IV, is characterized by hypogonadism. In general, patients have an extroverted disposition and happy appearance. About 20% of patients die during the first year of life due to severe infection, liver failure, or cardiac insufficiency.

Patients with CDG-Ib are unique among patients with these disorders. They may present with vomiting and diarrhea as well as hypoglycemia and liver disease (coagulopathy, hepatomegaly, hepatic fibrosis). In addition, they often have a protein-losing enteropathy. Development is normal. The remaining forms of CDG are similar in presentation

TABLE 23-2

## Common Congenital Disorders of Glycoprotein (CDGs)

Finding(s)	Types of CDG								x
	Ia	Ib	Ic	Id	Ie	Ila	Ilib	I	
Enzyme defect	Phosphoman- nosyl transferase	Phosphoman- nose isomerase	$\alpha$ 1,3-Glucosyl- transferase	$\alpha$ 1,3-Mannosyl transferase	Dol-P-Man synthase	GlcNAc transferase 2	Glucosidase I	Unknown	
Dysmorphic features	+	+/-	+/-	+/-	+	+	+	+	
Psychomotor retardation	+	-	+	+	+	+	+	+	
Hypotonia	+	+/-	+	+	+	+	+	+	
Cerebellar hypoplasia	+	-	+/-	-	+/-	-	-	-	
Seizures	+/-	+/-	+/-	+	+	+	+	-	
Eye findings	Strabismus, esotropia	-	Strabismus	Optic atrophy	Cortical blindness	-	-	-	
Liver disease	+	+	-	-	+	+	+	-	
Coagulopathy	+	+	+	-	+	+	+	-	
Other	Multifocal involvement, peripheral neuropathy, subcutaneous fat distribution, inverted nipples, stroke-like epi- sodes, cardiomyo- pathy, ataxia, microcephaly, hypothyroidism	Protein-losing enteropathy, cyclic vomiting, diarrhea, hypoglycemia	Microcephaly, feeding difficulties, ataxia	Microcephaly, reduced responsiveness, adducted thumbs	Microcephaly, delayed myelination	Stereotype behavior; frequent infections, ventricular septal defect, widely spaced nipples, delayed myelination	Early death, generalized edema, hypo- ventilation, apnea, demye- linating poly- neuropathy	Leukocyte adhesion deficiency syndrome type II (gua- nosine diphos- phate-fucose transporter); phenotype: elevated peripheral leukocytes, absence of CD 15, Bombay blood group phenotype, failure to thrive, recur- rent infec- tions, short arms and legs, simian crease	

Adapted from Westphal V, Srikrishna G, Freeze H: Congenital disorders of glycosylation: Have you encountered them? *Genet Med* 2:329-337, 2000.  
+, present; -, absent; +/-, occasionally present.

to type Ia. Additional features include seizures, normal cerebellar development, delayed myelination, optic atrophy, blindness, frequent infections, hypoventilation and apnea, and further dysmorphic features, such as adducted thumbs, high-arched palate, coarse facies, widely spaced nipples, and low-set ears.

The presence of carbohydrate-deficient transferrin in serum and cerebrospinal fluid is a distinctive biochemical feature of CDG. Normal serum transferrin is composed mainly of tetrasialotransferrin. When a protein is underglycosylated, it bears fewer negatively charged sialic acid residues, altering its migration on isoelectric focusing. Patients have prominent increases in asialotransferrin and disialotransferrin, and a pronounced decrease of tetrasialotransferrins, pentasialotransferrins, and hexasialotransferrins. Additionally, low serum levels of thyroxine-binding globulin, haptoglobin, transcortin, apolipoprotein B, cholesterol, coagulation factors, and various peptide and glycopeptide hormones are common.

### Diagnosis

CDG should be considered in newborns presenting with several of the following features:

- Neurologic signs, including hypotonia, hyporeflexia, or seizures
- Ophthalmic signs, including esotropia
- Abnormal eye movements or retinitis pigmentosa
- Hepatic and gastrointestinal signs, such as ascites or hydrops, hepatomegaly, diarrhea, and protein-losing enteropathy
- Endocrinologic signs, including hyperinsulinemic hypoglycemia and hypothyroidism
- Signs of renal or cardiac disease

Diagnosis of a CDG requires isoelectric focusing to analyze transferrin and quantitation of carbohydrate-deficient transferrin. Similar transferrin changes are also found in people with chronic alcoholism and galactosemia. Confirmatory testing via enzyme assay is now available for many forms of CDG. Patients with CDG can often be identified through neonatal screening for congenital hypo-thyroidism, because of an associated thyroid-binding globulin deficiency and an increased thyroid-stimulating hormone level. Prenatal diagnosis may be available with chorionic villus sampling (CVS) or cultured amniocytes. Prenatal diagnosis by transferrin isoelectric focusing is not reliable.

### Treatment and Management

The treatment and management for most types of CDG are primarily supportive and palliative. There is no curative or corrective treatment. In infancy, evidence of multisystem involvement and the resulting complications must be treated promptly. The exception is the treatment of CDG-Ib with oral mannose therapy. In this disorder, oral mannose effectively bypasses the impaired pathway and allows glycosylation to continue (Freeze, 1998). Therapy improves the protein-losing enteropathy and liver disease.

## PEROXISOMAL DISORDERS

In this section we first consider peroxisomes in general, then the clinical presentation of individual disorders of peroxisome biogenesis and disorders of peroxisomal  $\beta$ -oxidation. Diagnosis and treatment are discussed at the end of the section.

### Disorders of Peroxisome Biogenesis

Peroxisomes are single-membrane-bound cellular organelles that contain no internal structure or DNA and are characterized by an electron-dense core and a homogeneous matrix. Peroxisomes are found in all cells and tissues except mature erythrocytes and are in highest concentration in the liver and kidneys. They are formed by growth and division of preexisting peroxisomes and are randomly destroyed by autophagy. Their half-life is 1.5 to 2 days. Peroxisomal proteins are encoded by nuclear genes, synthesized in the cytosol, and imported post-translationally into the peroxisome. The import of the proteins into the peroxisome is mediated by receptors and requires adenosine triphosphate hydrolysis.

Peroxisomes contain enzymes that use oxygen to oxidize a variety of substrates, thereby forming peroxide. The peroxide is decomposed within the organelle by the enzyme catalase to water and oxygen. This process protects the cell against peroxide damage through compartmentalization of peroxide metabolism within the organelle. Peroxisomes may also function to dispose of excess reducing equivalents and may contribute to thermogenesis, producing heat from cellular respiration (Gould et al, 2001).

More than 50 enzymes have been found within peroxisomes (Gould et al, 2001). The proteins have multiple functions, both synthetic and degradative (Wanders et al, 2001). The primary synthetic functions are plasmalogen synthesis and bile acid formation. Plasmalogens constitute 5% to 20% of the phospholipids in cell membranes and 80% to 90% of the phospholipids in myelin. They are involved in platelet activation and may also protect cells against oxidative stress. Degradative functions include (1)  $\beta$ -oxidation of VLCFA ( $\geq$ C23), fatty acids (down to C8 to C6), long-chain dicarboxylic acids, prostaglandins, and polyunsaturated fatty acids; oxidation of bile acid intermediates, pipercolic acid and glutaric acid (intermediates in lysine catabolism), and phytanic acid, (2) deamination of D- and L-amino acids, (3) metabolism of glycolate to glyoxylate, (4) polyamine degradation (spermine and spermidine), and (5) ethanol clearance. At least 16 conditions due to single peroxisomal enzyme deficiencies have been confirmed so far (Wanders et al, 2001).

Peroxisomal disorders constitute a clinically and biochemically heterogeneous group of inherited diseases that result from the absence or dysfunction of one or more peroxisomal enzymes. Conditions in which multiple peroxisomal enzymes are affected may result from disturbance of biogenesis or the organelle. Pathophysiology apparently involves either deficiency of necessary products of peroxisomal metabolism or excess of unmetabolized substrates. Disorders with similar biochemical defects may have markedly different clinical features, and disorders with

similar clinical features may be associated with different biochemical findings. General features of peroxisomal disorders, each of which may manifest or may be evident in the newborn period, are as follows:

- Dysmorphic craniofacial features
- Neurologic dysfunction, primarily consisting of severe hypotonia, possibly associated with hypertonia of the extremities and seizures
- Hepatodigestive dysfunction, including hepatomegaly, cholestasis, and prolonged hyperbilirubinemia

Rhizomelic shortening of the limbs, stippled calcifications of epiphyses, renal cysts, and abnormalities in neuronal migration may also be seen.

Peroxisomal biogenesis disorders are composed of at least 12 complementation groups. All involve defects in the import of proteins into the organelle. Peroxins, which are encoded by PEX genes, are proteins necessary for the importation of targeted proteins into the peroxisome. The PEX genes responsible for 11 of the 12 complementation groups are known. Approximately 65% of patients with peroxisomal biogenesis disorders have mutations in *PEX1*.

We discuss here the peroxisomal disorders that may manifest in the newborn period. Zellweger syndrome is the prototype of neonatal peroxisomal disease. It is a disorder of peroxisome biogenesis due to failure to import newly synthesized peroxisomal proteins into the peroxisome. The proteins remain in the cytosol, where they are rapidly degraded. In this condition, peroxisomes are absent from liver hepatocytes or exist as “ghosts.” Neonatal adrenoleukodystrophy and infantile Refsum disease are also disorders of peroxisome biogenesis in which, as in Zellweger syndrome, disruption of function of more than one peroxisomal enzyme is demonstrable. A few residual peroxisomes, however, may be seen in the liver. These disorders represent a continuum of clinical severity. Rhizomelic chondrodysplasia punctata is caused by a defect in a subset of peroxisomal enzymes; in this disorder, liver peroxisomes are demonstrable and normal in number, but their distribution and structure are abnormal.

There is circumstantial evidence that in utero elevations of VLCFAs may be key to the congenital CNS abnormalities. Powers and Moser (1998) proposed that the VLCFAs and phytanic acid that accumulate in these peroxisomal disorders are incorporated into myelin and cell membranes and that alteration of the normal constituents of the membrane adversely affects membrane function. Specifically, these investigators suggest that the abnormal constituents accelerate cell death and impede neuronal migration, accounting for the conspicuous CNS abnormalities in disorders of peroxisomal biogenesis.

To date, four disorders of peroxisomal fatty acid  $\beta$ -oxidation have been defined: acyl-CoA oxidase deficiency, D-bifunctional protein deficiency, peroxisomal thiolase deficiency, and 2-methylacyl-CoA racemase deficiency (Wanders et al, 2001). The clinical presentation of the first three disorders resembles that of the biogenesis disorders. Individuals with the fourth disorder, 2-methylacyl-CoA racemase deficiency, do not present early in life but, rather, have a late-onset neuropathy.

## Clinical Presentations

Table 23–3 summarizes the clinical features of the congenital disorders of peroxisome biogenesis.

### Zellweger Syndrome

Zellweger syndrome is most often evident at birth, affected babies having dysmorphic facial features, including large fontanels, high forehead, flat occiput, epicanthus, hypertelorism, up-slanting palpebral fissures, hypoplastic supraorbital ridges, abnormal ears, severe weakness and hypotonia, hepatomegaly, multicystic kidneys, and congenital heart disease. Seizures, feeding difficulties, and postnatal growth failure soon manifest. Ophthalmologic examination may detect cataracts, corneal clouding, glaucoma, optic atrophy, retinitis pigmentosa, and Brushfield spots. Somatic sensory evoked responses and electroretinograms are abnormal. Hearing assessment often shows an abnormal brainstem auditory evoked response consistent with sensorineural hearing loss. Skeletal radiographs demonstrate epiphyseal stippling, and cranial imaging shows leukodystrophy and neuronal migration abnormalities. Later, hepatic cirrhosis and severe psychomotor retardation occur. Laboratory analysis may demonstrate abnormal liver function values, hyperbilirubinemia, or hypoprothrombinemia. Death usually occurs within the first year of life, the average life span being 12.5 weeks.

### Neonatal Adrenoleukodystrophy

Clinically, neonatal adrenoleukodystrophy is similar to, but less severe than, Zellweger syndrome. Differences include less dysmorphology, absence of chondrodysplasia punctata and renal cysts, and fewer neuronal and gray matter changes. Patients with neonatal adrenoleukodystrophy may have striking white matter disease, however, and often show degenerative changes in the adrenal glands. They also have slow psychomotor development followed by neurodegeneration that usually begins before the end of the first year of life. Disease progression is slower than that observed in Zellweger syndrome, and longer survival is usual, to an average of approximately 15 months of age.

### Infantile Refsum Disease

Patients with infantile Refsum disease also present at birth with relatively mild dysmorphic features, such as epicanthic folds, midface hypoplasia with low-set ears, and mild hypotonia. Early neurodevelopment is normal, possibly up to 6 months of age, but then slow deterioration begins. Later, sensorineural hearing loss (100%), anosmia, retinitis pigmentosa, hepatomegaly with impaired function, and severe mental retardation are evident. Patients learn to walk, although their gait may be ataxic and broad-based. Diarrhea and failure to thrive may also be seen. Chondrodysplasia punctata and renal cysts are absent. Neuronal migration defects are minor, and adrenal hypoplasia occurs. The life span of patients with infantile Refsum disease ranges from 3 to 11 years.

TABLE 23-3

## Disorders of Peroxisomal Biogenesis Presenting in the Newborn Period

Feature	Zellweger Syndrome	Neonatal Adrenoleukodystrophy	Infantile Refsum Disease	Rhizomelic Chondrodysplasia Punctata
Onset	Birth	Birth–3 mo	Birth–6 mo	Birth
Facies	High forehead, large fontanelles, upslanting palpebral fissures, hypoplastic supraorbital ridges, epicanthic folds, micrognathia, abnormal ears	Milder features of Zellweger syndrome	Epicanthic folds, midface hypoplasia, low-set ears	Depressed nasal bridge, hypertelorism, microcephaly
Neurologic findings	Weakness, hypotonia, seizures, psychomotor retardation, sensorineural hearing loss	Hypotonia, seizures, slow psychomotor development and neurodegeneration	Mild hypotonia, normal early development followed by degeneration, ataxia, sensorineural hearing loss	Severe psychomotor retardation
Ophthalmologic findings	Cataracts, glaucoma, corneal clouding, retinitis pigmentosa, optic nerve dysplasia, Brushfield spots	Retinopathy	Retinitis pigmentosa	Cataracts
Other findings	Hepatomegaly, multicystic kidneys, congenital heart disease, growth failure, chondrodysplasia punctata	Impaired adrenal function	Hepatomegaly, anosmia, diarrhea	Severe shortening of proximal limbs, joint contractures, ichthyosis
Diagnosis	↑ plasma VLCFA, phytanic acid, pipecolic acid, and bile acid intermediates, ↓ plasmalogens	Same as for Zellweger syndrome	Same as for Zellweger syndrome	↑ phytanic and pipecolic acids, ↓ plasmalogens, normal VLCFA and bile acid intermediates

VLCFA, very-long-chain fatty acid.

### Rhizomelic Chondrodysplasia Punctata

Patients with rhizomelic chondrodysplasia punctata present at birth with facial dysmorphism, microcephaly, cataracts, rhizomelic shortening of the extremities with prominent stippling, and coronal clefting of vertebral bodies. The chondrodysplasia punctata is more widespread than in Zellweger syndrome and may involve extraskelatal tissues. Infants with this disorder have severe psychomotor retardation from birth onward and severe failure to thrive. Additionally, patients may have joint contractures, and 25% experience ichthyosis. Neuronal migration is normal. Life span is usually less than 1 year.

### Disorders of Peroxisomal $\beta$ -Oxidation

More than 40 patients have now been described with D-bifunctional protein deficiency. In general, children present with severe CNS involvement, consisting of profound hypotonia, uncontrolled seizures, and failure to acquire any significant developmental milestones. Children are usually born full term without evidence of intrauterine growth restriction. Dysmorphic features, similar to those seen in Zellweger syndrome, are notable in most children. Also, in most cases, neuronal migration is disturbed with areas of polymicrogyria and heterotopic neurons in the cerebrum and cerebellum. Death generally occurs before 1 year of age, but survival to at least 3 years of age is possible.

Eight patients from six families have been described with acyl-CoA oxidase deficiency. Patients present with global hypotonia, deafness, and delayed milestones with or without facial dysmorphic features. Patients may demonstrate early developmental gains, but then show regression of skills. Retinopathy with extinguished electroretinograms, failure to thrive, hepatomegaly, areflexia, and seizures have also been reported.

One patient with peroxisomal thiolase deficiency has been described (Goldfischer et al, 1986). The child presented with marked facial dysmorphism, muscle weakness, and hypotonia. She demonstrated no psychomotor development during her 11 months of life. Autopsy showed renal cysts, atrophic adrenal glands, minimal liver fibrosis, hypomyelination in the cerebral white matter, foci of neuronal heterotopia, and a sudanophilic leukodystrophy (Goldfischer et al, 1986).

### Diagnosis, Management, and Prognosis of Peroxisomal Disorders

The key to the diagnosis of peroxisomal disease is a high index of suspicion. Peroxisomal disorders should be considered in newborns with dysmorphic facial features, skeletal abnormalities, shortened proximal limbs, neurologic abnormalities (including hypotonia or hypertonia), ocular abnormalities, and hepatic abnormalities. Babies with

abnormal visual, hearing, or somatosensory evoked potentials should also be considered for these diagnoses.

Peroxisomal disorders are not associated with acute metabolic derangements or abnormal routine laboratory tests. Measurements of VLCFAs, phytanic acid, pipecolic acid, bile acid intermediates, and plasmalogens are required for diagnosis. Zellweger syndrome is associated with elevations of VLCFAs, phytanic acid, pipecolic acid, and bile acid intermediates, and a decrease in plasmalogen synthesis. Neonatal adrenoleukodystrophy and infantile Refsum disease have similar biochemical findings; however, the defect in plasmalogen synthesis and the degree of VLCFA accumulation are less severe. Laboratory findings in rhizomelic chondrodysplasia punctata are elevations of phytanic and pipecolic acids, a decrease in plasmalogen, and normal levels of VLCFAs and bile acid intermediates. Thus, screening that uses only levels of VLCFA fails to detect rhizomelic chondrodysplasia punctata. D-bifunctional protein deficiency is associated with deficient oxidation of C23:0 and pristanic acid, leading to elevations of pristanic acid and, to a lesser extent, phytanic acid. This results in an elevated pristanic acid-to-phytanic acid ratio (this ratio is generally not elevated in peroxisomal biogenesis disorders). Abnormal VLCFA and elevation of varanic acid (an intermediate metabolite in  $\beta$ -oxidation) are also seen. Accumulation of bile acid intermediates is a variable finding. Abnormalities in phytanic acid and plasmalogens are age dependent. The elevation of phytanic acid may not be demonstrable in young infants, and the reduction in red blood cell plasmalogen levels may not be evident in children older than 20 weeks (Lazarow and Moser, 1995). A liver biopsy, to assess for the presence or absence and structure of peroxisomes, may be a useful adjunct diagnostic tool. Definitive diagnoses for all types of peroxisomal disease require cultured skin fibroblasts for measurement of VLCFA levels and their  $\beta$ -oxidation, and, as needed, assay of the peroxisomal steps of plasmalogen synthesis, phytanic acid oxidation, the subcellular localization of catalase, enzyme assays, and immunocytochemistry studies. Prenatal diagnosis with a variety of methods is available.

Treatment for all peroxisomal disorders presenting in the newborn period remains supportive. These disorders are chronic, progressive diseases with no currently available curative therapy. Setchell and associates (1992) described the effects of the administration of primary bile acids on the liver function in a 6-month-old infant with Zellweger syndrome. The effects included normalization of serum bilirubin and liver enzyme levels and a decrease in hepatic inflammation, bile duct proliferation, and canalicular plugs; the patient also showed an improvement in growth and neurologic function (Setchell et al, 1992).

Martinez (1992) reported the use of docosahexaenoic acid ethyl ester (DHA-EE) in two patients with neonatal adrenoleukodystrophy. Both patients had an increase in erythrocyte omega fatty acid levels and plasmalogens accompanied by significant improvement in clinical parameters, including alertness, motor performance, vocabulary, and visual evoked responses. Martinez and colleagues (2000) also reported on the effects of DHA supplementation in 13 patients with generalized peroxisomal disorders; the effects were normalization of blood DHA levels, increased plas-

malogen concentrations, decreased plasma VLCFA, and improvement to near normal of liver enzymes. Although the patients with the severe neonatal Zellweger syndrome presentation did not benefit, patients with milder peroxisomal biogenesis disorders—in which clinical course is more variable—did experience improvement in vision, liver function, muscle tone, and social contact. Three patients showed normalization of brain myelin, and in three others, myelination improved (Martinez et al, 2000).

Further studies are underway to explore the question of the relationship between the DHA supplementation and clinical course. In addition, a “triple” dietary approach has been proposed that consists of the oral administration of ether lipids, decreased phytanic acid intake, and the oral administration of glyceryl trioleate and glyceryl trierucate (Lorenzo’s oil) (Lazarow and Moser, 1995). This approach is now being tested in patients with mild forms of disordered peroxisomal biogenesis. Hence, future treatment protocols may be available for infants affected with peroxisomal disease, but long-term outcome remains unknown.

## SMITH-LEMLI-OPITZ SYNDROME

### Etiology

SLO syndrome is a well-recognized autosomal recessive malformation syndrome, with an estimated incidence ranging from 1 in 10,000 to 100,000 in various populations (Kelley and Hennekam, 2000). Because of the identification of an underlying biochemical defect, SLO syndrome has now been “reclassified” as an inborn error of metabolism. In 1993, it was discovered that SLO syndrome is caused by a defect in cholesterol biosynthesis that results in low levels of cholesterol and elevated levels of 7-dehydrocholesterol (7DHC) and its isomer, 8-dehydrocholesterol (8DHC). Patients have markedly reduced activity of the enzyme 7DHC reductase, the enzyme responsible for the conversion of 7DHC to cholesterol (Salen et al, 1995), which is located on chromosome 11 (Kelley and Hennekam, 2000). Patients are also noted to be deficient in bile acids, a problem that can interfere with absorption of dietary lipids (Natowicz and Evans, 1994).

The pivotal connection between cholesterol and SLO syndrome involves development and differentiation of the vertebrate body plan, although additional metabolic effects have not been ruled out. Among those proteins exerting decisive influence on patterning during embryogenesis are the Hedgehog proteins. One variant, Sonic hedgehog (Shh), becomes covalently linked to cholesterol at the protein’s amino-terminal signaling domain. This linkage is needed to restrict the locus of action of the Shh to the region of the plasma membrane. Although it was originally suggested that failure to so modify Shh could account for the multiplicity of structural abnormalities in patients with SLO syndrome (Farese and Herz, 1998), the process is now thought to be more complex and to involve other signaling proteins (Farese and Herz, 1998; Kelley and Hennekam, 2000).

### Clinical Features

Recognition of the biochemical defect in SLO syndrome provided the diagnostic test required to recognize the

most mild and most severe cases, substantially expanding the clinical spectrum of the condition. Classic SLO syndrome is often evident at birth; affected patients have microcephaly and facial dysmorphism, including bitemporal narrowing, ptosis, epicanthic folds, anteverted nares, broad nasal tip, prominent lateral palatine ridges, micrognathia, and low-set ears. Other features are 2- to 3-syndactyly of the toes, small proximally placed thumbs, and occasionally postaxial polydactyly and cataracts. Males usually have hypospadias, cryptorchidism, and a hypoplastic scrotum. Pyloric stenosis, cleft palate, pancreatic anomalies, and lung segmentation defects have also been reported (Baraitser and Winter, 1996). Hypotonia progressing to hypertonia and moderate to severe mental deficiencies are also present. Feeding difficulties and vomiting are common problems in infancy. Irritable behavior and shrill screaming may also pose problems during infancy. Cranial imaging studies show (and autopsy confirms) defects in brain morphogenesis, including hypoplasia of the frontal lobes, cerebellum, and brainstem, dilated ventricles, irregular gyral patterns, and irregular neuronal organization.

Historically, approximately 20% of patients die within the first year of life, although others may survive for more than 30 years. Life expectancy appears to correlate inversely with the number and severity of organ defects and with the kinds and numbers of limb, facial, and genital abnormalities (Kelley and Hennekam, 2000; Tint et al, 1995). Developmental outcomes are also highly variable, ranging from severe mental retardation to normal intelligence. Development of treatment protocols for SLO syndrome may contribute to improvements in prognosis, but improved recognition of more mildly affected patients may explain the increasing reports of SLO syndrome in patients with mild mental retardation or normal intelligence.

Some patients have a severe lethal form of SLO, type II. In this form, the external genitalia of male infants may be ambiguous or female. Postaxial polydactyly of the hands, valgus deformities of the feet with syndactyly of several toes, cleft palate, and hypoplasia of the anterior portion of the tongue are common. Other findings are unilobar lungs, hypoplastic kidneys, agenesis of the gallbladder, cerebellar hypoplasia, cardiac defects, and enlarged pancreatic islets with giant cells.

### Diagnosis

The diagnosis of SLO syndrome types I and II is based on the findings of elevated levels of 7DHC and 8DHC. Plasma cholesterol levels are usually but not always low; as many of 10% of patients at all ages have normal cholesterol levels (Kelley and Hennekam, 2000). In addition, the standard method for analysis of cholesterol in most hospital laboratories identifies 7DHC and 8DHC as cholesterol. Therefore, most laboratories report normal cholesterol levels in patients who have low cholesterol but elevations of 7DHC and 8DHC sufficient to bring the total level into the “normal” range (Kelley and Hennekam, 2000). The biochemical defect and findings are the same for both types. The difference between type I and type II appears to be one of degree: the enzyme defect is more severe and the block is more complete in patients with type II disease (Kelley and Hennekam, 2000; Tint et al,

1995). Prenatal diagnosis is possible. A mother carrying an affected fetus may have an abnormally low unconjugated estriol value. Ultrasonography detects many but not all affected fetuses, and biochemical analysis of amniotic fluid and of chorionic villus samples is accurate and unambiguous in most cases (Kelley and Hennekam). When molecular mutations are known, analysis may be useful.

### Treatment

The goal of therapy for SLO syndrome is twofold, (1) to increase the level of cholesterol in plasma and other body fluids and (2) to lower the level of 7DHC. Treatment consists of providing exogenous cholesterol, in the form of either dietary cholesterol or cholesterol suspension, to replenish body stores of cholesterol and to down-regulate the patient's endogenous cholesterol synthesis, thus decreasing the amount of 7DHC produced. A goal of cholesterol supplementation of 20 to 60 mg/kg per day was initially advocated, but doses higher than 300 mg/kg per day have been used without adverse outcome (Irons et al, 1995; Kelley and Hennekam, 2000). Provision of bile acids to facilitate adequate absorption of the dietary cholesterol is controversial, especially because fat malabsorption is unusual and certain bile acids may decrease tissue uptake of cholesterol (Kelley and Hennekam, 2000). Use of 3-hydroxy-3-methyl-CoA (HMG-CoA) lyase inhibitors such as lovastatin has also been suggested as a mechanism to decrease levels of 7DHC. However, because animal studies suggest that down-regulation of cholesterol synthesis may not decrease 7DHC, and because of concern about decrease in synthesis of other essential isoprenoid compounds, HMG-CoA reductase inhibitors are not routinely used in therapy (Kelley and Hennekam, 2000). In infants with SLO syndrome, the use of breast milk should be encouraged, because it supplies approximately 133 mg/L of cholesterol (Irons et al, 1995).

Although many questions remain about optimal therapy and outcomes, therapeutic interventions do appear to increase plasma cholesterol levels, decrease 7DHC levels, and improve irritability, behavior, and growth (Elias et al, 1997; Irons et al, 1995; Kelley and Hennekam, 2000). Parents report children to be more alert, active, and happier during therapy. Gain in developmental skills may be noted, and improvement in hypotonia may occur. Therapy appears to be well tolerated.

For maximal benefit, it has been suggested that treatment should begin prenatally, because SLO syndrome has many features consistent with in utero involvement of the disease process. Antenatal supplementation by fetal intravenous and intraperitoneal transfusions of fresh frozen plasma were shown in one patient to increase fetal cholesterol (Irons et al, 1999). Treatment should otherwise begin as soon as possible after birth or as soon as the diagnosis is confirmed. Patients with severe SLO syndrome may need gavage or gastrostomy feeding for management of reflux and gastrointestinal dysmotility, and many have protein allergies and require elemental formulas. Growth is often a problem, but the temptation to overfeed must be avoided because overfeeding would contribute to feeding problems and could not rescue the intrauterine growth restriction in severe SLO syndrome (Kelley and Hennekam, 2000).

# Skeletal Dysplasias and Connective Tissue Disorders

Paige Kaplan

The *skeletal dysplasias*, or osteochondrodysplasias, are disorders of the development and growth of cartilage and bone. The *connective tissues* disorders involve abnormalities of the cell's supporting and connecting structures in the matrix. With the growing use and accuracy of ultrasonography for prenatal care, a greater number of osteochondrodysplasias and connective tissue disorders are diagnosed in the second trimester (Gordienko et al, 1996; Rasmussen et al, 1996). In one series of 126,316 deliveries monitored over 15 years, the incidence of skeletal dysplasias was 2.14 in 10,000 (Rasmussen et al, 1996).

This chapter focuses on several of the more common dysplasias and connective tissue disorders that manifest prenatally or perinatally (Gordienko et al, 1996; Rasmussen et al, 1996), but the discussion is not exhaustive (Table 24–1). The osteochondrodysplasias are reviewed extensively by Cohen (2002), Rimoin and Lachman (1997), Spranger and Maroteaux (1990), and Superti-Furga and associates (2001).

There are a large number of different *connective tissue* molecules, including collagen (at least 16 types), elastin, fibrillin (2 types), and microfibril-associated glycoproteins. These are components of tissues such as bone, cartilage, vascular media, tendon, skin, basement membranes in the renal glomeruli and other organs, and the suspensory ligament of the lens. The heritable disorders of connective tissue are varied, may be very dissimilar clinically, and may manifest in utero or at any age postnatally. Most are rare, but some of the more common conditions that manifest at birth are discussed here.

## CLASSIFICATION

The *skeletal dysplasias* have been classified into 24 groups on the basis of radiologic criteria (Beighton et al, 1992). Other classifications vary according to etiologic, clinical, pathologic, and radiologic criteria and may be confusing; for example, osteogenesis imperfecta (OI) can be classified as either a skeletal dysplasia or a connective tissue disorder.

*Connective tissue disorders* that may manifest at birth include Marfan syndrome, congenital contractural arachnodactyly (Beals syndrome), cutis laxa, and Ehlers-Danlos and Williams syndromes.

## Molecular Basis

With advances in molecular knowledge, several different dysplasias have been recognized to have mutations in the same genes. In some of these disorders, clinical similarities had been noted previously. An example is achondroplasia, hypochondroplasia, severe achondroplasia with developmental delay and acanthosis nigricans (SADDAN), and thanatophoric dysplasia, all of which are due to mutations in the fibroblast growth factor receptor 3 (*FGFR3*) gene (Francomano et al, 1994; Le Merrer et al, 1994; Rousseau et al, 1995; Tavormina et al, 1995). Another group of disorders with mutations in the same gene comprises, from mildest to most severe, Kniest dysplasia, spondyloepiphyseal dysplasias, spondyloepimetaphyseal dysplasia, Stickler syndrome, hypochondrogenesis, and achondrogenesis type II. They are caused by mutations in the gene for collagen type II, *COL2A1* (Rousseau et al, 1995; Spranger et al, 1994; Wilkin et al, 1994; Winterpacht et al, 1993), encoded on chromosome 12q13.11 to q13.2. In other groups of disorders, the common cause is not as obvious clinically: Diastrophic dysplasia (the mildest), atelosteogenesis type II, and achondrogenesis type 1B (the most severe) are caused by mutations in the diastrophic dysplasia sulfate transporter (*DTDST*) gene, on chromosome 5q31 to q34 (Hastbacka et al, 1994, 1996; Kaitila et al, 1989; Rousseau et al, 1995; Superti-Furga et al, 1996). This affects the transport of sulfate to proteoglycans (mucopolysaccharides), especially chondroitin sulfate B-containing proteoglycans, which is prevalent in cartilage.

## APPROACH TO DIAGNOSIS

Early and precise diagnoses are important for prognosis, optimal immediate and long-term management, and genetic counseling about other possible affected family members. An example is the group of disorders with punctate calcifications (“stippling”) in epiphyses, called chondrodysplasia punctata; there are at least three types, each of which has a different cause and mode of inheritance—autosomal recessive, X-linked recessive, and X-linked dominant (Table 24–2). Multiple factors must be considered—complete physical examination, family history, radiologic studies, and histochemical and/or molecular tests.

Most skeletal dysplasias cause *short stature*, which may be proportionate or disproportionate. In considering a diagnosis, one must know whether the skull, vertebrae (trunk), ribs, or limbs are affected. If the limbs are disproportionately shortened compared with the trunk, there may be segmental (disproportionate) or proportionate involvement of one of the three parts of the limbs: upper arms and thighs (rhizomelic), forearms and legs (mesomelic), and hands and feet (acromelic). Most skeletal dysplasias that manifest at birth involve short limbs. Accurate measurements of length on a rigid board, arm span, and head and chest circumferences must be plotted on standard growth curves.

*Other characteristics* may give important clues for specific disorders:

- Children with achondroplasia and thanatophoric dysplasia have very large heads. Cloverleaf skull deformity is present in thanatophoric and, occasionally, diastrophic dysplasias.

TABLE 24-1

**Most Common Types of Osteochondrodysplasias Detected Prenatally and Perinatally**

Diagnosis	No. Cases (%)	
	Gordienko et al (1996)	Rasmussen et al (1996)
Thanatophoric Osteogenesis imperfecta Type II	3 (8)	5 (20)
Type III	10 (26)	3 (12)
Achondroplasia	5 (13)	2 (7)
Spondyloepiphyseal dysplasia congenita		3 (11)
Campomelic Short-rib polydactyly Type I	2 (5)	2 (7)
Type II	2 (5)	1 (4)
Other diagnoses	2 (5)	1 (4)
No diagnosis	15 (38)	3 (11)
Total no. cases	—	4 (13)
	39	27

- A relatively long chest is seen in asphyxiating thoracic dystrophy.
- The hand in achondroplasia is short and the fingers are trident; in diastrophic dysplasia, there are distinctive “hitchhiker” thumbs.
- Deformations of feet (“clubfeet”) occur in diastrophic dysplasia, Kniest syndrome, spondyloepiphyseal dysplasias, and OI type II.
- Multiple joint dislocations manifest at birth in Larsen and Ehlers-Danlos type VII syndromes as well as atelosteogenesis.

The presence of other abnormalities can be valuable clues to diagnosis, as follows:

- Cleft palate or uvula can occur in campomelic, Kniest, spondyloepiphyseal, short-rib polydactyly (Majewski), atelosteogenesis types I and II, hypochondrogenesis, and diastrophic dysplasias.
- Congenital cataracts occur in chondrodysplasia punctata.
- Congenital cardiac defects occur in short-rib polydactyly dysplasias (conotruncal malformations in type I and transposition of the great arteries in type II).

TABLE 24-2

**Skeletal Dysplasias Manifesting Prenatally or Perinatally**

Dysplasia	Skeletal Features	Nonskeletal Features	Radiographic Features	Inheritance, Gene, Chromosome	Comment(s)
Lethal Thanatophoric	Large cranium, “proptosis,” flat nose bridge, narrow chest, very short limbs (all segments)	Polyhydramnios, hydrocephalus, brain anomalies, congenital cardiac abnormalities	Large calvarium, short base, small magnum foramen, cloverleaf skull; short, splayed, cupped ribs; small, flat, U-shaped vertebrae; short, small, flat pelvis; short, bowed limbs, metaphyseal flare with spike	AD; most are new mutations <i>FGFR3</i> 4p16.3	Same gene as for achondroplasia, hypochondroplasia
Campomelic	Large cranium; small face with flat nose bridge, small chin, (cleft soft palate); small, narrow chest; bowed thighs and legs, with dimple on leg	Polyhydramnios, congenital cardiac abnormalities, female external genitalia in XY males	Large dolichocephalic calvarium with shallow orbits; short and wavy ribs, often 11 pairs; small, flat vertebrae; tall, narrow pelvis; relatively long, thin limbs with bowed femurs, short tibiae	AD; most are new mutations <i>SOX9</i> 17q24.1-q25.1	
Achondrogenesis type IB	Soft cranium; round face; short, round chest; very short limbs	Polyhydramnios	Poorly ossified calvarium; ribs short with fractures (beading); nonossified vertebrae; small pelvis; short broad femurs with metaphyseal spikes, short broad tibiae and fibulae	AR <i>DTDST</i> 5q32-q33	Same gene as diastrophic dysplasia (milder disease) and atelosteogenesis II

TABLE 24-2

## Skeletal Dysplasias Manifesting Prenatally or Perinatally—Cont'd

Dysplasia	Skeletal Features	Nonskeletal Features	Radiographic Features	Inheritance, Gene, Chromosome	Comment(s)
Short-rib polydactyly Types I and III	Hydropic appearance; round flat face; micrognathia; extremely narrow chest; very short limbs; postaxial polydactyly	Cardiac, renal, anal malformations	Normal calvarium; very short, horizontal ribs; flat wide intervertebral disc spaces; small pelvis; short limbs with lateral and medial metaphyseal spurs	AR	
Types II and IV	Hydropic; short face, flat nose, cleft lip $\pm$ palate, low-set ears; narrow chest, protuberant abdomen; moderately short limbs	Cardiac, renal (dysplastic kidneys), respiratory malformations	Very short, horizontal ribs; normal pelvis and vertebrae; short limbs with round metaphyses; premature epiphyseal ossification; polydactyly	AR	
Asphyxiating thoracic dystrophy	Normal face; narrow, long chest; variable limb shortening	Lethal pulmonary insufficiency	Normal calvarium and vertebrae; very short ribs with anterior cupping; short limbs with wide proximal femoral metaphyses; premature ossification of proximal femoral epiphysis	AR	Patients who survive newborn period have renal disease (proteinuria, hypertension). Possibly, a variant of short-rib polydactyly III
Atelosteogenesis Type I (Fig. 24-9)	Flat face with cleft palate, micrognathia; very narrow chest; very short limbs (rhizomelic) with equinovalgus deformities; joint dislocations	Prematurity; stillbirth	Flat vertebrae with coronal and sagittal clefts; scoliosis; short ribs (11 pairs); small pelvis with enlarged sacroscliac notch; short limbs, "drumstick" humeri and femurs; absence of fibulas; short metacarpals, triangular first metacarpals, dysharmonic ossification of hand bones; dislocated knees	AD	Similar to boomerang dysplasia; also known as spondylohumero-femoral dysplasia
Type II	Cleft palate; narrow chest; short limbs with dislocations; equinovarus deformities; gap between first and second digits	Laryngeal stenosis; patent foramen ovale	Occasional coronal and sagittal vertebral clefts; short ribs; normal sacroscliac notch; short "dumbbell" humeri and femurs, small fibulas; large second and third metacarpals; small round midphalanges	AR <i>DTDST</i> 5q32-q33.1	Same gene as for diastrophic dysplasia (milder disease) and achondrogenesis type IB (more severe disease), and multiple epiphyseal dysplasia (MED)

TABLE 24-2

## Skeletal Dysplasias Manifesting Prenatally or Perinatally—Cont'd

Dysplasia	Skeletal Features	Nonskeletal Features	Radiographic Features	Inheritance, Gene, Chromosome	Comment(s)
Dyssegmental (Silverman-Handmaker)	Flat midface, flat orbits, cleft palate, micrognathia; short neck; narrow chest; extremely small limbs	Encephalocele; patent ductus arteriosus	Midface hypoplasia; vertebrae variable sizes with coronal and sagittal clefts; very short, flared ribs; round scapulae with abnormal shape; very short, broad, bowed long bones; small first metacarpals; small, round pelvis	AR <i>PERLECAN</i> 1p36.1	Resembles dyssegmental dysplasia of Roland-Desbuquois (less severe) and Kniest syndrome
Chondrodysplasia punctata, rhizomelic type 1 (RCDP1) (Fig. 24-10)	Face flat; very flat nose bridge and tip; proximal shortening of limbs	Cataracts; joint contractures; skin: ichthyosiform erythroderma	Wide coronal vertebral clefts; short humeri and femurs; stippled epiphyses of long bones and pelvis and periarticular areas; pelvis: trapezoid ilia	AR <i>PEX7</i> 6q22-q24	Patients who survive newborn period can live a few years; severe growth and mental retardation. Biochemical abnormalities: decreased rbc plasmalogens and increased phytanic acid
<b>Nonlethal</b> Chondrodysplasia punctata X-linked recessive	Hypoplasia of the distal phalanges; severe hypoplasia of nose; short stature; congenital ichthyosis			<i>ARSE</i> XR Xp22.3	Milder than X-linked dominant form, CDPX2. Variable clinical severity; neonatal death to longevity and diagnosis in adulthood. Males usually milder than females. (Brunetti-Pierri et al, 1999)
Chondrodysplasia punctata X-linked dominant (Conradi Hunermann Happle syndrome)	Asymmetric rhizomesomelia	Congenital cataracts; ichthyosis; patchy alopecia		<i>ESP</i> 3 $\beta$ hydroxy $\Delta$ 8- $\Delta$ 7 sterol isomerase Xp11.23-11.22	Severe form of disease; usually lethal in males; females vary from stillborn to mild (diagnosis in adulthood); intrafamilial variability
Achondroplasia	Large cranium; bossed forehead, flat nose bridge, prominent chin, short neck; slightly narrow chest; proximal limb shortening, short trident hands; short proximal and middle phalanges; later genu varum; thoracolumbar kyphosis; lumbar lordosis	Hypotonia: delayed motor milestones; spinal stenosis causes spinal compression; small foramen magnum can cause hydrocephalus; short mean adult height: males 131 cm, females 124 cm	Large calvarium, small foramen magnum, short base; diminished lumbosacral interpedicular space, short pedicles; short ribs with anterior cupping; short humeri and femurs; relatively long fibulas; metaphyseal flare; small iliac wings	AD; most cases are new mutations, associated with advanced paternal age <i>FGFR3</i> 4p16.3	Same gene as for hypochondroplasia (milder) SADDAN, and thanatophoric dysplasia (very severe) Hypochondroplasia is usually not apparent until 1-2 yrs

TABLE 24-2

## Skeletal Dysplasias Manifesting Prenatally or Perinatally—Cont'd

Dysplasia	Skeletal Features	Nonskeletal Features	Radiographic Features	Inheritance, Gene, Chromosome	Comment(s)
Diastrophic dysplasia (Fig. 24-11)	Normal cranium; cleft palate, micrognathia; normal chest at birth; very short limbs; thumbs proximally placed and adducted (“hitchhiker thumb”); severe equinovarus of feet; limited movement of many joints	Cystic masses in external ears (“cauliflower ears”) during infancy; deafness due to lack or fusion of ossicles; narrow external canal; scoliosis in childhood	Premature ossification of rib cartilage; narrow L1-L5 interpedicular spaces; scoliosis; short limbs; disproportionately short ulna and fibula (mesomelic); broad flared metaphyses; ovoid first metacarpals; variable symphalangism of proximal interphalangeal joints; irregular delayed epiphyseal ossification except accelerated carpals	AR <i>DTDST</i> 5q32-q33	Intrafamilial variability; normal life span if scoliosis does not impair respiratory function; normal intelligence
Kniest syndrome	Large cranium; flat face with “large” eyes, flat nasal bridge, cleft palate; short limbs with proximal shortening (more severe in lower limbs), enlarged joints, flexion contractures	Infancy: tracheomalacia; childhood: myopia and retinal detachment; hearing loss; delayed motor development; normal intelligence	Frontal and maxillary hypoplasia with shallow orbits; slightly short ribs; flat vertebrae with coronal clefts; anisospondyly (different sizes); small pelvis with irregular acetabular roof; short limbs with broad and flared metaphyses (“dumbbell”), lateral bowing of femurs and upper tibias; slightly short and broad/normal tubular bones of hands and feet; epiphyses at knees not ossified	AD <i>COL2A1</i> 12q13.1-13.2	Same gene as for some spondyloepiphyseal dysplasias, spondyloepiphyseal dysplasia, Stickler syndrome, hypochondrogenesis, achondrogenesis type II (more severe)

- Postaxial polydactyly occurs in short-rib polydactyly and thoracic asphyxiating and chondroectodermal dysplasias; occasionally, preaxial polydactyly also occurs in the short-rib dysplasias.

## TESTS

*Radiographs* of the entire skeleton, including the hands and feet, are essential for accurate diagnosis. If the infant or fetus dies, specimens of cartilage and skin fibroblasts should be obtained for histochemical tests and molecular-gene mutation analysis; if photographs and skeletal radiographs were not obtained premortem, they should be obtained postmortem. Detailed family history and measurements of family members may be helpful; more mildly affected members might have gone undiagnosed.

*Tissue samples* are also needed. Lymphocytes and fibroblasts (from cultured skin) should be obtained in all cases for enzyme and molecular diagnoses. These can be used to make or confirm diagnoses and permit accurate prenatal diagnosis. Even if the molecular or enzymatic basis is not understood at the time, the tissue may be useful in the future.

## OSTEOGENESIS IMPERFECTA TYPES II AND III

OI is characterized by increased bone fragility. As mentioned, it can be classified as either a connective tissue disorder or a skeletal dysplasia. There are four clinical types: Types II and III are the most severe, manifesting prenatally and perinatally. OI type I rarely causes prenatal or perinatal fractures.

### Etiology

OI is caused by abnormalities in type I collagen, which is composed of three polypeptide chains, two  $\alpha$ -1 (I) and one  $\alpha$ -2 (I) fibrils, coiled in a triple helix (Byers, 1993; Byers et al, 1988, 1991). Two genes, *COL1A1* and *COL1A2*, on chromosomes 17q21 and 7q22.1, respectively, encode the chains. Mutations in either of the genes result in abnormal collagen. In OI type I, there is secretion of normal collagen but only half as much as usual, with a milder phenotype. In the other types, the altered procollagen chains are incorporated into the helix, causing 50% to 75% of collagen fibers to be abnormal, resulting in more severe phenotypes (Byers, 1993). Most, if not all, cases of OI are inherited as autosomal dominant traits.

### Presentation

*OI type II (perinatal lethal type)* is estimated to affect 1 in 20,000 to 60,000 infants. Affected infants may be born prematurely, with low birth weight and disproportionately short stature. The limbs are short and bowed with extra, circular skin creases; the hips are abducted and flexed. The head is soft and boggy, and minimal calvarial bone can be felt. The sclerae are dark blue, the nose may be prominent, and the chest is narrow. The infant cries with handling because there are many fractures at different stages of healing. Sixty percent of affected babies are still-born or die during the first day of life, and 80% die by 1 month (Byers et al, 1988). With the growing use of ultrasonography, affected fetuses may be detected in the early second trimester because of short and bowed or angulated limbs and narrow thoraces (Fig. 24-1A).

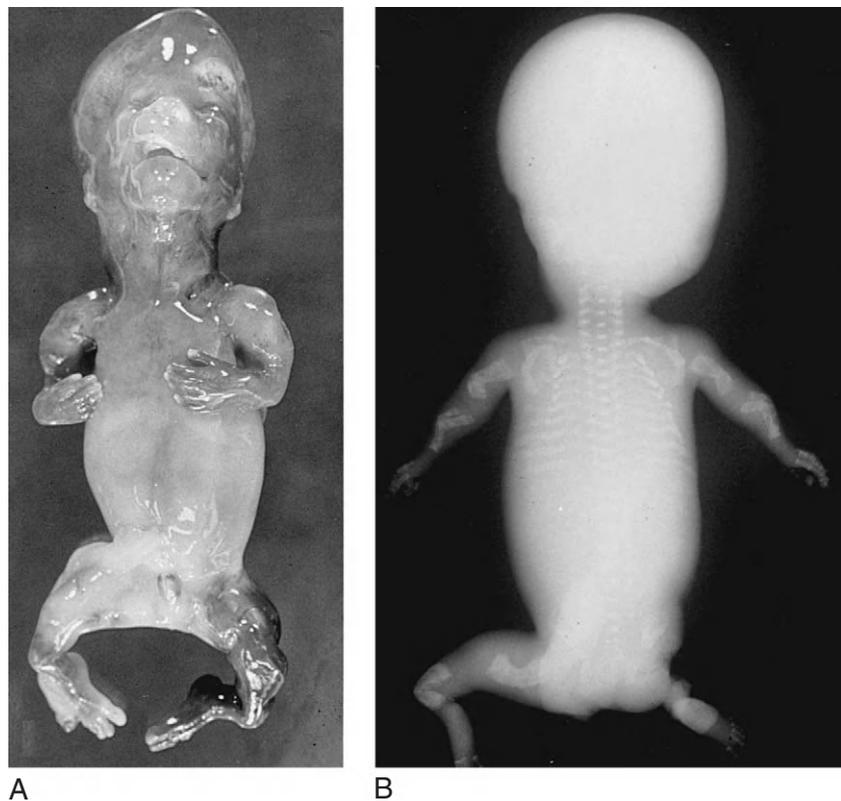

Radiographs show the femurs in OI type II to be short, broad, and “telescoped” or “crumpled”; the tibias are short

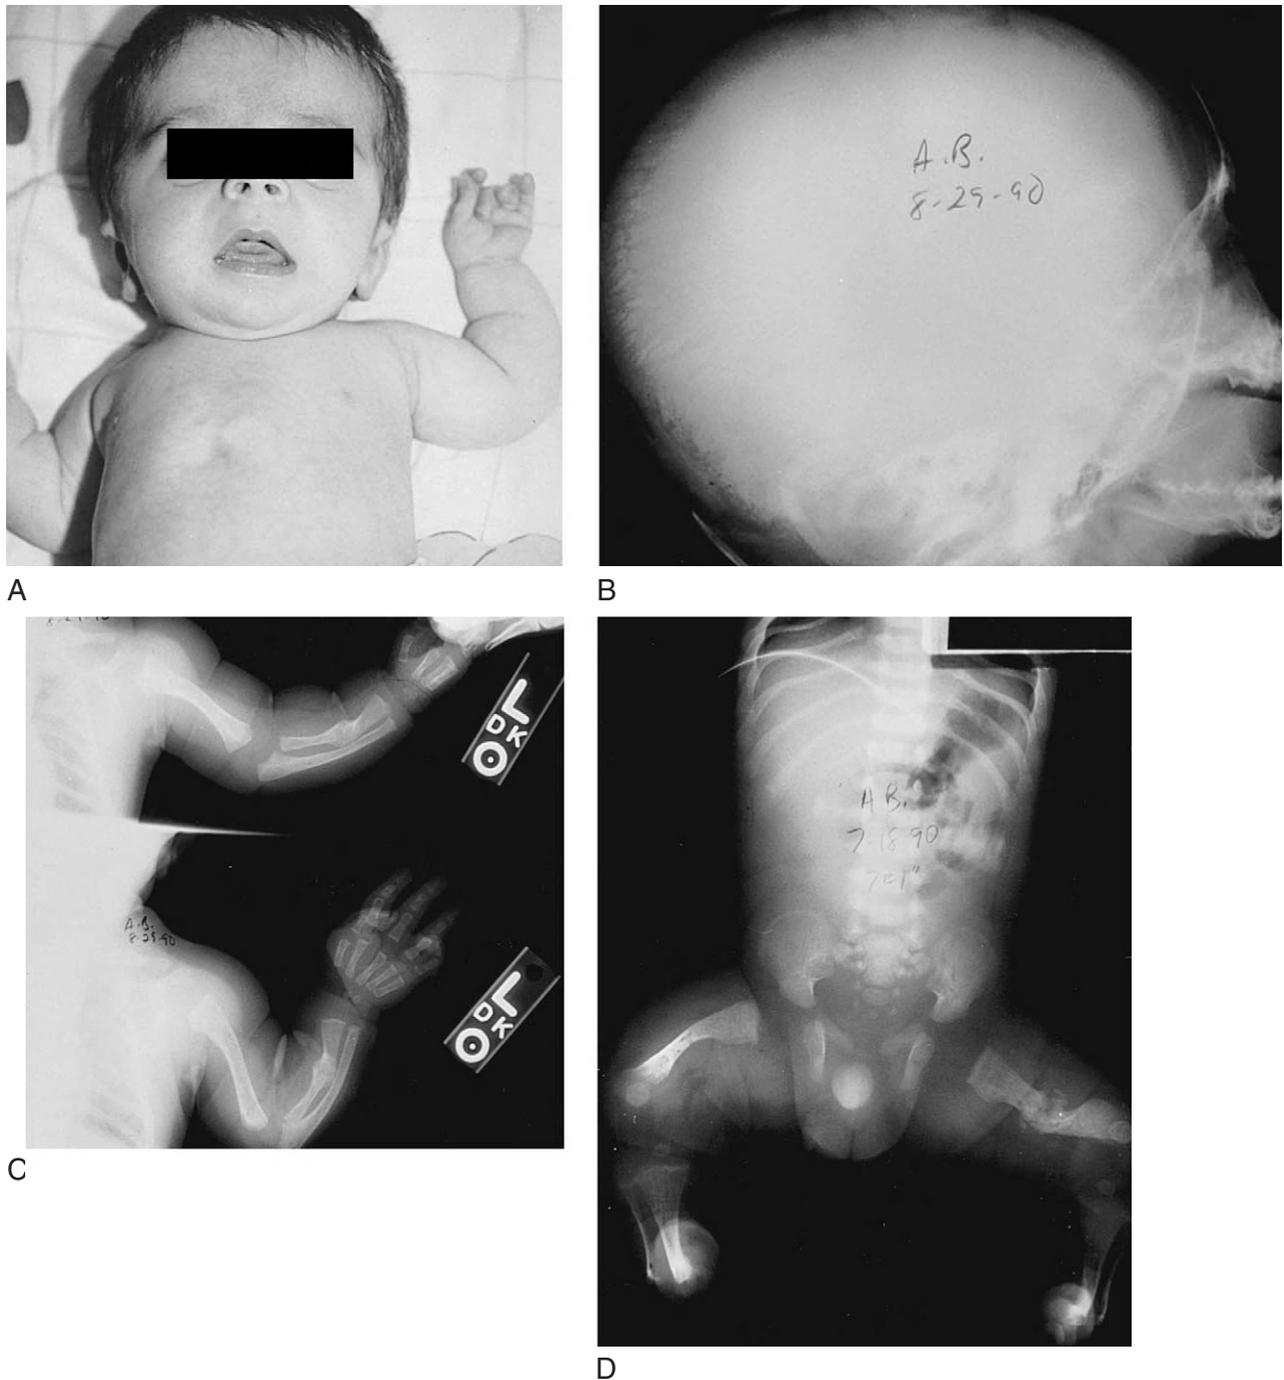

and bowed, and the fibulas may be thin (see Fig. 24-1B). There is minimal or no calvarial mineralization, with occasional wormian bones (small islands of bone in the suture spaces). The vertebrae are very flat (platyspondyly). The ribs are short, wavy, and thin or broad, with “beading” from callus formation.

Prenatal histochemical or molecular diagnosis is possible through analysis of chorionic villi or amniocytes, if a previously affected sibling's mutation is known. The bone deformations in OI type II may be detectable with ultrasonography in the second trimester but may not be 100% accurate.

*OI type III (progressive deforming type)* may manifest prenatally and perinatally as well as in the first 2 years of life (Byers, 1993). Prenatal and perinatal clinical features resemble those in OI type II but are less severe (Fig. 24-2A). Perinatal death is common. If not present at birth, fractures and deformations of the limbs develop in the first and second years. The highest prevalence of fractures in OI, up to 200, occur in type III. Extremely short stature, with adult heights of 92 to 108 cm, may result from microfractures in the growth plates. The head may be large because the calvarium is soft with a large anterior fontanelle. The sclerae may be blue initially but are white by puberty. The head assumes a triangular shape, with bossed, broad forehead and tapered, pointed chin. Later in childhood, dentinogenesis imperfecta and hearing loss may develop. Severe kyphoscoliosis may occur, leading to cardiopulmonary compromise, the major cause of early death. On radiographs, the femurs are short and deformed but not crumpled as in OI type II (see Fig. 24-2B and C). The other long bones are thinner than usual with healing fractures incurred in utero, bowing, and deformations. The calvarium is undermineralized with a large

**FIGURE 24-1.** Osteogenesis imperfecta type II. **A**, 14-week fetus. The calvarium is deformed; limbs are angulated and deformed from multiple fractures. **B**, Radiograph of fetus (14 weeks) showing absence of ossification in calvarium, short telescoped or crumpled humeri and femurs, short and wavy ribs.

**FIGURE 24-2.** Osteogenesis imperfecta type III. **A**, Neonate with normal face, short neck, slightly short limbs. **B**, Radiograph shows that the calvarium is undermineralized with wormian bones. **C**, Radiograph shows the upper limbs, which have bowed humeri and callus in the ulnae. **D**, Radiograph shows lower limbs with moderately short, thick femora and angulated tibiae and fibulae.

anterior fontanelle, and there are many wormian bones (see Fig. 24-2D). The ribs are thin and gracile.

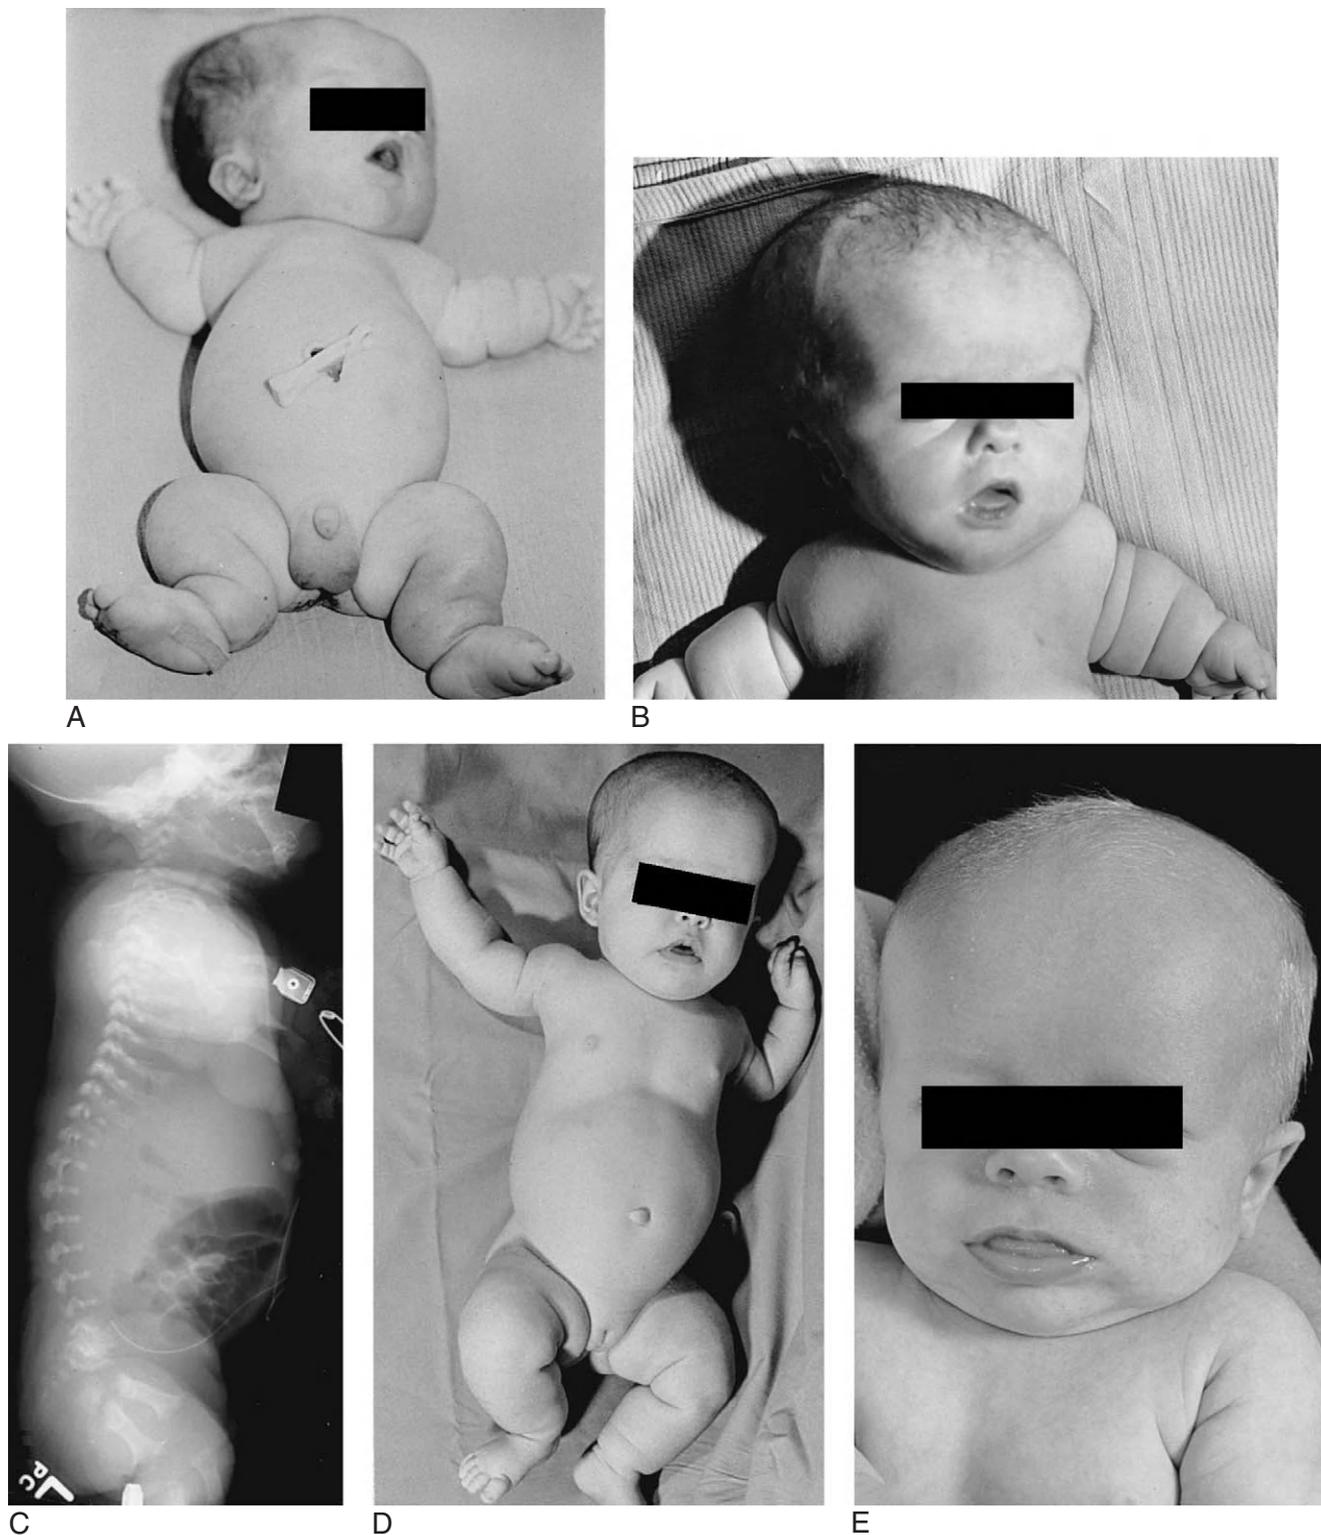

The diagnosis can be confirmed with collagen studies performed on cultured fibroblasts from a skin biopsy. It is difficult to differentiate OI types III and IV histochemically.

#### Differential Diagnosis

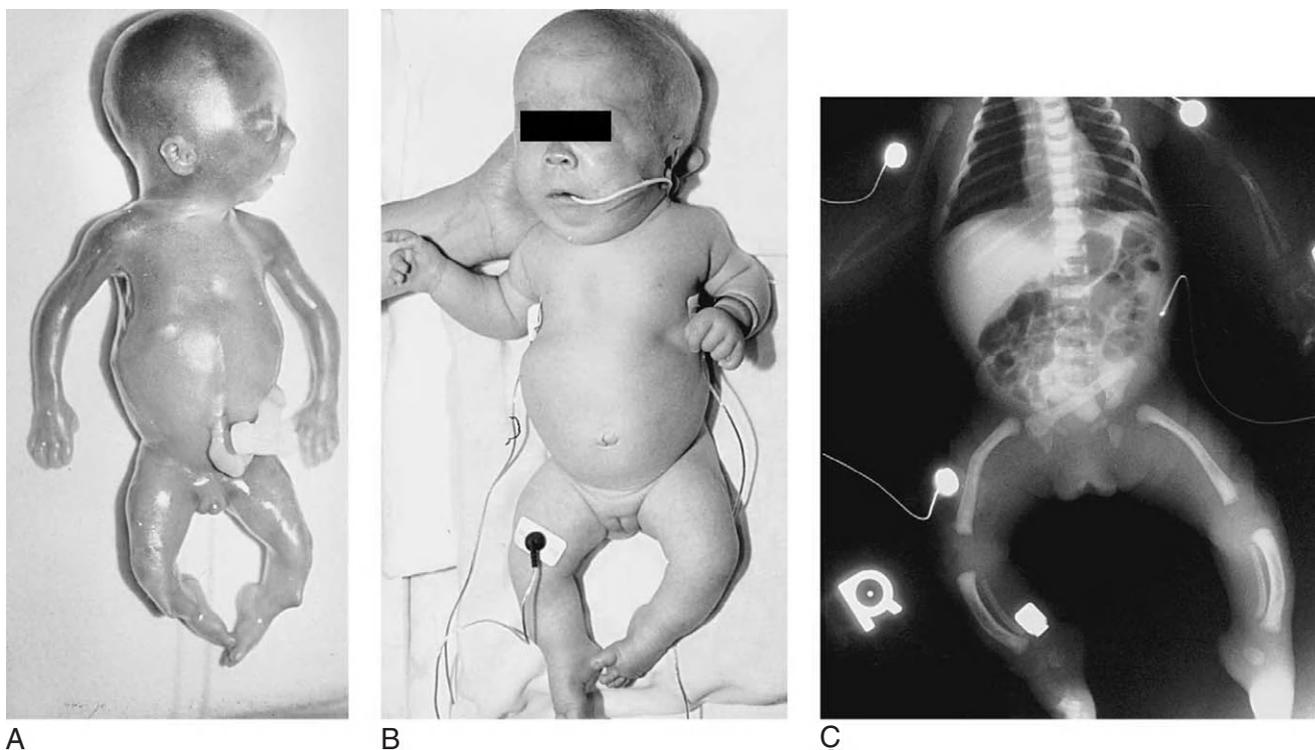

The four lethal skeletal dysplasias below have similar abnormalities to those in OI and can be diagnosed in the

first half of pregnancy by means of ultrasonography. It may be difficult to differentiate the dysplasias; therefore, experienced ultrasonographers are required for accurate diagnoses. These four dysplasias have similar abnormal features in utero on ultrasound examination:

1. Thanatophoric dysplasia (Fig. 24-3; see also subsequent discussion).
2. Campomelic dysplasia (Fig. 24-4; see also subsequent discussion).

**FIGURE 24-3.** Thanatophoric dysplasia (**A** to **C**) and achondroplasia (**D** and **E**). **A**, Neonate with thanatophoric dysplasia has a large head, narrow chest, very short limbs and extra creases on the limbs, short hands with trident fingers, and angulated abducted thighs. **B**, Neonate with thanatophoric dysplasia has a face with bossed forehead, flat nose bridge, short neck, very short limbs with extra creases, and trident fingers. **C**, Radiograph of an infant with thanatophoric dysplasia demonstrates a large calvarium, short ribs with anterior splaying, and short bowed femurs with medial metaphyseal spike. **D**, Infant with achondroplasia has a bossed forehead and proximal limb shortening. **E**, Infant with achondroplasia has a bossed forehead and flat nasal bridge. (**A** and **B**, courtesy Montreal Children's Hospital, Montreal, Quebec, Canada; **D** and **E**, courtesy Charles I. Scott, MD, AI DuPont Institute, Wilmington, DE.)

**FIGURE 24-4.** Campomelic dysplasia. **A**, 46,XY “female” 22-week-old fetus with normal head, long philtrum, micrognathia, low-set ears, mild narrowing of chest, proximally placed thumbs, and bowed or angulated lower limbs resembling those of osteogenesis imperfecta type II but less shortened; the external genitalia are female. **B**, Neonate with the long-limb form of the disorder has a relatively large head, micrognathia, narrow chest, and bowing of lower limbs with characteristic dimpling of lower leg. **C**, Radiograph shows the narrow chest; relatively long, thin limb bones with bowing of the femurs and tibias, and a long, narrow pelvis.

3. Achondrogenesis type IA (Fig. 24-5; see also subsequent discussion).
4. Perinatal hypophosphatasia (see subsequent discussion).

#### Inheritance

A fetus or infant with OI type II or III is usually a sporadic occurrence in a family, but there is a risk of recurrence of approximately 6% in subsequent siblings because the gene mutation might be present in some of a parent’s somatic cells or germline (parental mosaicism) (Byers et al, 1988). The parent is usually asymptomatic but may have minimal manifestations, such as short stature. *Prenatal diagnosis* is possible with ultrasonography and gene mutation analysis.

#### Treatment

If the diagnosis of OI is made prenatally, delivery by cesarean section is recommended to avoid more fractures and intracranial bleeding that could occur with vaginal delivery. The neonate needs careful handling to minimize pain and prevent further fractures. Analgesia alleviates pain. In OI type III, consideration can be given to treatment with bisphosphonates (using intravenous pamidronate), which increase bone density, reduce the frequency of fractures and pain, possibly prevent short stature and deformations, and permit ambulation (Rauch et al, 2002). It is unknown whether the resultant marked decrease in cancellous bone

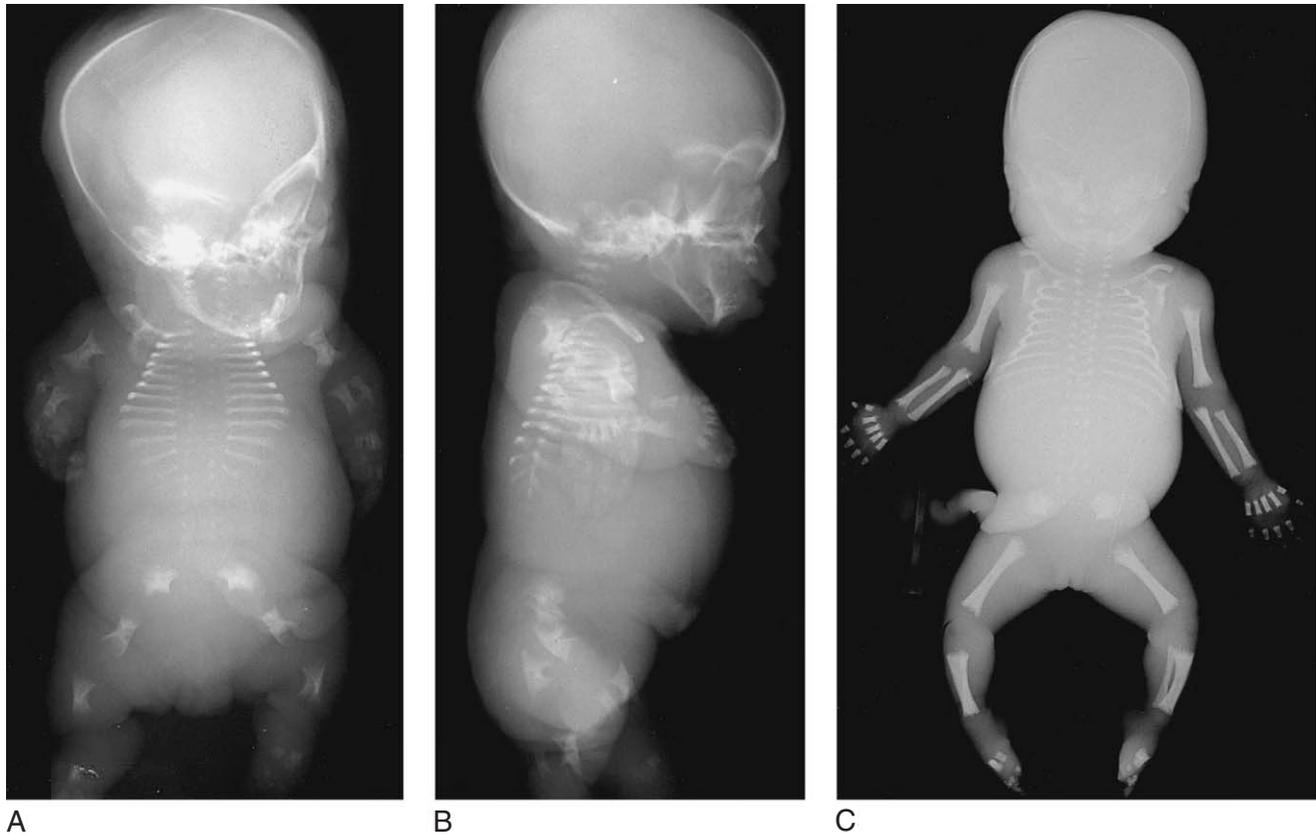

remodeling and the increase in the amount of residual calcified cartilage within secondary spongiosa have sequelae or whether treatment with these agents has other potential adverse effects. It is prudent to treat only severely affected children in whom the clinical benefits outweigh potential long-term effects.

#### Handling an Infant with OI

When changing the diapers of an infant with OI, one should place a hand behind the buttocks with the forearm supporting the legs; similarly, when the infant is lifted, the buttocks and head and neck must be supported. The infant can be laid on a pillow to be carried. To transport the infant, an infant seat that reclines as much as possible and allows easy placement or removal should be used. The seat can be padded with egg crating or 1-inch foam. A layer of foam can be placed between the seat’s harnesses and the child for extra protection. The car seat must always be placed in the back seat. Sling carriers and “umbrella” strollers should not be used for infants with OI because they do not give sufficient leg or head and neck support.

### PERINATAL HYPOPHOSPHATASIA

Perinatal hypophosphatasia is a lethal condition characterized by short deformed limbs, a soft skull, and undermineralization of the entire skeleton, so that many bones

**FIGURE 24-5.** **A** and **B**, Radiographs showing characteristics of achondrogenesis type I: Cervical, thoracic, and lumbar vertebral bodies are not ossified, the sacrum is unossified, the ribs are short, and the limbs are extremely short with medial femoral metaphyseal spikes. **C**, Radiograph showing hypochondrogenesis in a midgestation fetus with underossified calvarium and vertebral bodies (although better ossified than in achondrogenesis), unossified pubis, longer limb bones but irregular metaphyses, short ribs, and a narrow thorax. (Courtesy Elaine Zackai, MD, Children's Hospital of Philadelphia.)

cannot be visualized and may seem on radiography to be absent. In the skull, only the base may be visualized radiologically. There may be rachitic changes and fractures. Seizures that are responsive to pyridoxine may occur. During pregnancy, there is polyhydramnios, and in utero death can occur. The disorder affects approximately 1 in 100,000 live births; neonatal death is usual (Whyte, 1995).

### Etiology

Deficiency of tissue-nonspecific isoenzyme of alkaline phosphatase (TNSALP) causes perinatal hypophosphatasia. The gene for TNSALP is mutant and is located on chromosome 1p34 to p36.1. Many mutations have been linked to severe perinatal hypophosphatasia (Orimo et al, 2001). The serum alkaline phosphatase (ALP) value is very low. Serum values of phosphoethanolamine, inorganic pyrophosphate, and pyridoxal 5'-phosphate, putative natural substrates for TNSALP, may be elevated.

TNSALP acts on multiple substrates: the essential function of TNSALP is in osteoblastic bone matrix mineralization. TNSALP hydrolyzes inorganic pyrophosphate to phosphate, thought to be critical in promoting osteoblastic mineralization. If TNSALP is deficient, there is extracellular accumulation of inorganic pyrophosphate, which inhibits hydroxyapatite crystal formation and mineraliza-

tion of the skeleton. TNSALP is also needed for delivery of pyridoxal-5-phosphate into cells where it is a cofactor (vitamin B<sub>6</sub>).

### Treatment

Treatment of perinatal hypophosphatasia with enzyme replacement has been unsuccessful.

### Inheritance

Perinatal hypophosphatasia is inherited as an autosomal recessive trait; each of a couple's subsequent children has a 25% risk for the disease. Prenatal diagnosis is optimized through the use of ultrasonography, assay of TNSALP activity in amniocytes, DNA mutation analysis if the previously affected child's mutation was known, or a combination of these methods.

## CAMPOMELIC DYSPLASIA

Campomelic dysplasia is characterized by short stature (birth length 35 to 49 cm), large dolichocephalic skull, large anterior fontanelle, high forehead, flat face, widely spaced eyes with short palpebral fissures, low-set ears, cleft soft palate, micrognathia, relatively long, slender

thighs and upper arms, short bowed legs with dimples in the midshaft (in most cases), narrow chest, and kyphoscoliosis. Sex reversal or ambiguous genitalia affects 75% of the chromosomal males; there may be internal and external genital abnormalities (from mild anomalies to complete sex reversal) in XY males (Houston et al, 1983) (see Fig. 24-4A and B). Absence of the olfactory bulbs and tracts as well as heart and renal malformations occur. Death, usually in infancy, results from respiratory compromise. Survivors are usually retarded. A few more mildly affected people without bowed limbs have been reported.

### Radiology

In the second trimester, on ultrasonography, the limbs of a fetus with campomelic dysplasia may appear short, bowed, and angulated, and the disease may be mistaken for OI (see Fig. 24-4C). However, the two disorders are distinguishable because the calvarium in campomelic dysplasia is better ossified, the palate may be cleft, and the chin is small. Specific postnatal abnormalities are very small, bladeless scapulas and hypoplastic pedicles of thoracic vertebrae. Other features are as follows:

- Hypoplastic, undermineralized cervical vertebrae and thoracic pedicles
- Small iliac wings and relatively wide pelvic outlet
- Dislocated hips
- Short phalanges of the hands and feet; talipes equinovarus; anterior bowing of tibia; short fibula; mildly bowed femur
- Absence of ossification of proximal tibial and distal femoral epiphyses
- Ribs may be thin and wavy, with only 11 pairs

### Differential Diagnosis

See osteogenesis types II and III.

### Etiology

The mutant gene, *SOX9* (a transcription factor gene), is located at chromosome 17q24.1 to 25.1 (Tommerup, 1993). *SOX9*, with homology to the *SRY* gene, is involved in both bone formation and control of testis development.

### Inheritance

Campomelic dysplasia is an autosomal dominant trait. Most cases are new sporadic occurrences in a family. Siblings may be affected if there is gonadal mosaicism.

### Management

Chromosome studies to determine gender and ultrasonography to examine internal genitalia should be performed in survivors. Cleft palate may need repair.

## ACHONDROGENESIS TYPES IA AND IB

Achondrogenesis types IA and IB are characterized by short stature, extremely short limbs (with “flipper” hands in type IA), relatively large head with round face, short nose, small mouth, soft skull, and very short neck (Borochowitz et al, 1988). Polyhydramnios during pregnancy, premature

delivery, and hydrops are common. The affected infant is stillborn or dies within hours of birth.

### Radiology

The long bones are extremely short, with square, globular, or triangular shapes and medial spikes in the metaphyses of the femurs (see Fig. 24-5A and B). The calvarium is poorly ossified, the vertebrae are either unossified (type IA) or poorly ossified (type IB), and the ribs are short (with multiple fractures and callus [beading] in type IA).

### Inheritance and Cause

Achondrogenesis type IB is caused by mutations in the *DTDST* gene, which also cause another lethal disorder, atelosteogenesis type 2 (AO2), and two nonlethal disorders, diastrophic dysplasia (DTD) and recessive multiple epiphyseal dysplasia (rMED). The gene product is a sulfate-chloride exchanger of the cell membrane (Superti-Furga et al, 1996).

### Differential Diagnosis

Achondrogenesis type II and hypochondrogenesis are the same condition, caused by different mutations in the same gene for type II collagen but with variable phenotypic expression. The short stature and the limb, calvarial, and vertebral abnormalities are somewhat less severe than in achondrogenesis type I, but there is also hydrops, with stillbirth, or death within hours after birth. Cleft palate may occur in hypochondrogenesis (see Fig. 24-5C).

### Inheritance

The inheritance pattern of achondrogenesis types IA and IB is autosomal dominant, usually a new sporadic mutation.

## ACHONDROPLASIA

Achondroplasia is the most common of the nonlethal chondrodysplasias; it affects 1 in 15,000 live births. It is characterized at birth by short limbs, particularly rhizomelic (proximal) and acromelic (hands) with trident fingers, large head with frontal prominence, flat nose bridge, flat midface, long narrow trunk, and thoracolumbar gibbus deformity (see Fig. 24-3D and E). The lateral cerebral ventricles may be large, but hydrocephalus is not common in affected children, although it is more prevalent than in the general population. The child with achondroplasia is hypotonic; together with the large head, the hypotonia leads to delayed motor milestones.

Most achondroplastic children have normal intelligence. However, development can be impaired if there is hydrocephalus, which can result from perinatal bleeds associated with vaginal deliveries, or impaired respiratory function (Hecht et al, 1991). The foramen magnum and the lumbar spinal canal may be narrow, causing compression of the spinal cord. Compression of the lower brainstem and cervical spinal cord can lead to hypotonia, retardation, quadriparesis, obstructive or central apnea, and sudden death (Pauli et al, 1984). Perinatal or infantile death is unusual (3%); most children die between 2 and 5 months, often during the day, and death may be precipitated by sleeping upright without support for the head.

In the achondroplastic infant who dies suddenly, the head circumference is usually not larger than average for achondroplasia, the neurologic state is not abnormal, and development is average.

Radiologic imaging of the skull and brain is recommended for monitoring; surgical decompression of foramen magnum or lumbar stenosis may prevent neurologic damage. In older persons with achondroplasia, untreated spinal stenosis can cause paresthesias, numbness, bladder and bowel incontinence, and impotence. Standard growth curves for achondroplasia should be used routinely (Horton et al, 1978); deviation from the expected should alert the physician to a possible new complication, such as hydrocephalus. Average adult height in this disorder is 118 to 145 cm (men) and 112 to 136 cm (women) and is diminished because of lumbar lordosis and mild thoracolumbar kyphosis. A controversial surgical technique to lengthen limbs, the Ilizarov method (Ilizarov, 1988), can add as much as 25 cm. It is used in adolescents. Pins are inserted into the limbs on either side of the epiphyses or fractured bone with callus formation, and the areas are stretched by millimeters daily.

### Radiology

The proximal long bones, the humeri and femurs, are short, especially the femoral neck. Fibulas are longer than tibias. There is metaphyseal flaring. The hand is short and trident with short proximal and midphalanges. The calvarium is large with a small foramen magnum and a short base. Vertebrae are small and cuboid with short pedicles and anterior beaking of the first or second lumbar vertebrae; there is progressive narrowing of interpedicular distance in the lumbar vertebrae. The pelvis has small, round iliac wings, a narrow greater sciatic notch, and flat acetabular roofs.

### Inheritance

The inheritance pattern in achondroplasia is autosomal dominant. Approximately 90% of cases are sporadic occurrences in a family, representing new mutations. Many cases are associated with advanced paternal age, with molecular confirmation that the new mutations are of paternal origin. Affected individuals are fertile, and achondroplasia is transmitted as a fully penetrant autosomal dominant trait, meaning that each person who inherits the mutant gene will show the condition.

### Etiology

The cause of achondroplasia is a mutation of the gene for *FGFR3* (fibroblast growth factor receptor 3), a membrane-spanning tyrosine kinase receptor. *FGFR3* is encoded on chromosome 4p16.3. More than 97% of persons with achondroplasia have a mutation in the transmembrane domain of the *FGFR3* gene, in which glycine is substituted by arginine, Gly380Arg (Shiang et al, 1994). The same gene is mutated, at different sites, in hypochondroplasia, thanatophoric dysplasia, SADDAN, Muenke craniosynostosis, and Crouzon craniosynostosis syndrome with acanthosis nigricans (Vajo et al, 2000). Histopathologic examination demonstrates a defect in

the maturation of the cartilage growth plates of long bones.

### Differential Diagnosis

The differential diagnosis for achondroplasia includes the following disorders:

1. SADDAN (Vajo et al, 2000). Affected infants have seizures and hydrocephalus. This disorder represents the part of the spectrum between lethal thanatophoric dysplasia (see later) and achondroplasia, with survival past infancy into young adulthood without prolonged ventilatory assistance. Some infants with SADDAN have the same Lys650Met mutation as some infants with thanatophoric dysplasia type I yet have skeletal abnormalities different from both thanatophoric dysplasia types I and II. These include absence of craniosynostosis or cloverleaf skull anomaly and only moderate bowing of the femurs with reverse bowing of the tibia and fibula.
2. Hypochondroplasia (usually not apparent at birth, as the face is normal). Although limbs are usually short, there is no rhizomelia, mesomelia, or acromelia, and final height is greater than in achondroplasia. There may be mild metaphyseal flaring, brachydactyly, and mild limitation of elbow extension. Hypochondroplasia may be genetically heterogeneous, because not all affected people have *FGFR3* mutations; those who do often have an Asn540Lys mutation.

### Management in the Newborn Period

Development of thoracolumbar kyphosis in a patient with achondroplasia is associated with unsupported sitting before trunk muscle strength is adequate. Infants should not be carried in flexed positions (including soft sling-carriers, “swingomatics,” “jolly jumpers,” and “umbrella” strollers), which may increase the risk for gibbus. Unsupported sitting should be avoided. Car safety seats should always be used.

Hydrocephalus may develop during the first 2 years, so the head circumference should be carefully measured monthly during the first year and plotted on achondroplasia growth charts. A disproportionate increase may indicate development of hydrocephalus.

Parents should be counseled about the clinical and hereditary aspects of the disorder and given a copy of the guidelines for health supervision of children with achondroplasia issued by the American Academy of Pediatrics (Health supervision, 1995).

## THANATOPHORIC DYSPLASIA

Thanatophoric dysplasia is one of the most common lethal dysplasias (Rimoin and Lachman, 1996; Spranger and Maroteaux, 1990), occurring in 1 in 35,000 births. It is characterized by extremely short limbs, long narrow trunk, large head with bulging forehead, prominent eyes, flat nose bridge, wide fontanelle, and, occasionally, cloverleaf skull deformity (see Fig. 24–3A). It is differentiated into types I and II on the basis of radiologic features. Death occurs in the neonatal period from respiratory insufficiency. Polyhydramnios is common during pregnancy.

Radiography shows that the femurs are short, flared at the metaphyses, with a medial spike, bowed (type I) or straight (type II); other long bones are also short and bowed (see Fig. 24–3B and C and Table 24–2). The calvarium is large with a short base and small foramen magnum; cloverleaf skull is sometimes present in type I thanatophoric dysplasia and is severe in type II. Vertebrae are flat with notching of superior and inferior aspects on lateral views; lumbar vertebrae have an inverted-U appearance on anteroposterior views. Ribs are short, cupped, and splayed anteriorly (Tavormina et al, 1995). A subtype of thanatophoric dysplasia type I is the platyspondylic San Diego type, in which there are metaphyseal spikes, better-preserved growth plates, and large inclusion bodies in the rough endoplasmic reticulum.

### Differential Diagnosis

The differential diagnosis for thanatophoric dysplasia consists of the following disorders:

1. OI types II and III
2. Achondroplasia (see earlier discussion)
3. Achondrogenesis and hypochondrogenesis

### Etiology

Thanatophoric dysplasia types I and II are caused by distinct mutations in the gene for *FGFR3*. In thanatophoric dysplasia type I, most mutations have been in the extracellular domain, with single amino acid substitutions by cysteine (Rousseau et al, 1995; Tavormina et al, 1995; Wilcox et al, 1998). In most European, North American, and Japanese studies, the most common mutation has been Arg248Cys. In all studied cases of thanatophoric dysplasia type II, the lysine at amino acid 650 has been substituted by glutamate (Lys650Glu) (Tavormina et al, 1995; Wilcox et al, 1998). More than 98% of studied cases of achondroplasia have substitution of the same amino acid, glycine, by arginine (Gly380Arg) (Shiang et al, 1994). In several patients with hypochondroplasia, mutations have been found at one specific nucleotide coding for asparagine, which has been substituted by lysine (Asp540Lys) (Bellus et al, 1995a and 1995b).

### Inheritance

Most cases of thanatophoric dysplasia, as with achondroplasia and hypochondroplasia, occur sporadically, resulting from new autosomal dominant mutations. Nevertheless, there is a small risk of recurrence in siblings of the patient with a sporadic case, because of possible parental mosaicism.

## CONGENITAL (NEONATAL, INFANTILE) MARFAN SYNDROME

Congenital Marfan syndrome (cMFS), the most severe form of Marfan syndrome, is caused by mutations in the same gene associated with classic Marfan syndrome (Dietz et al, 1991). The affected neonate has a long, thin body with an aged appearance because of a lack of subcutaneous tissue and wrinkled, sagging skin (cutis laxa) (Morse et al, 1990) (Fig. 24–6A). The characteristic

facies has dolichocephaly, deep-set eyes with large or small corneas (and occasionally cataracts), high nose bridge, high palate, small pointed chin with a horizontal skin crease, and large simple or crumpled ears (see Fig. 24–6B and C). The fingers and toes are long and thin (arachnodactyly). Some joints are hyperextensible, and others have flexion contractures, causing equinovarus or equinovagus, dislocated hips, or adducted thumbs. The infant tends to be hypotonic, with low muscle mass. Occasional features are diaphragmatic or inguinal hernias and retinal detachment. Lenses are usually not subluxated at birth. The most important cause of morbidity and mortality is severe cardiovascular disease, which affects almost every neonate with cMFS, namely, mitral and tricuspid valve prolapse and insufficiency and aortic root dilation. The ascending aorta may be dilated and tortuous. Congestive cardiac failure associated with mitral and tricuspid regurgitation develops; most infants die in the first year. Survivors have continuing hypotonia and contractures, are unable to walk, and require many surgical procedures.

### Inheritance

Marfan syndrome is an autosomal dominant disorder. Most neonates with cMFS are sporadic occurrences in a family (Dietz et al, 1991; Godfrey et al, 1995; Morse et al, 1990). However, there is one well-documented neonate with cMFS whose father had classic Marfan syndrome except for average height (Lopes et al, 1995). Routine ultrasonography at 34 weeks of gestation showed oligohydramnios and cardiomegaly. Fetal echocardiography demonstrated the typical severe features and pleural effusion.

### Etiology

Congenital MFS is caused by abnormalities of a connective tissue, fibrillin, which is encoded by the gene fibrillin 1 (*FBNI*) on the long arm of chromosome 15 (15q21.1) (Dietz et al, 1991; Godfrey et al, 1995). Fibrillin, together with other proteins (microfibril-associated glycoproteins), is a component of microfibrils, which form linear bundles in the matrices of many tissues, such as aorta, periosteum, perichondrium, cartilage, tendons, muscle, pleura, and meninges. Microfibrils have the following functions: (1) as scaffolding onto which elastin is deposited, for example, in the tunica media of the aorta, (2) as scaffolding for nonelastic tissues, for example, the ciliary zonule of the eye, periodontal ligament, and mesangium of renal glomeruli, and (3) as connections between elastin and other matrix components, for example, in the skin between elastin bundles and the dermoid-epidermoid junction.

There is a region of two “hot spots” in *FBNI* in which mutations causing congenital Marfan syndrome occur. These are missense mutations (mainly), small deletions or insertions and one exon skipping mutation in exons 24 to 27, and exon skipping mutations affecting exons 31 and 32 (Booms et al, 1999). It is possible that exon skipping mutations could cause very severe disruption of microfibril assembly by interfering with the exact lateral alignment of fibrillin monomers that must be incorporated into polymeric microfibrils.

**FIGURE 24-6.** Congenital Marfan syndrome. **A**, Neonate with long thin trunk and limbs (particularly the feet), lack of adipose tissue, and multiple skin creases giving an aged appearance. The ears are large and simple, and the chin is small with a horizontal crease. There are flexion contractures at the joints. **B**, Neonate's face shows laxity of skin, typical horizontal chin crease, and pointed chin. The fingers are long with adduction contractures of the thumbs, which extend past the edge of the palm, and floppy wrists. **C**, Lateral view of the neonate's head showing simple "large" ears and redundant skin on the neck.

### Tests

Blood and skin should be obtained for gene mutation studies in lymphocytes and skin fibroblasts, although it has not been possible to detect the mutation in each case.

### Prenatal Diagnosis

Recurrences of congenital Marfan syndrome are not usual, but, if parents want assurance, prenatal diagnosis by chorionic villous biopsy and amniocentesis is feasible if the gene mutation is known. Prenatal detection by ultrasonography is possible in the second half of pregnancy. It is not known whether the cardiovascular and joint abnormalities are detectable before 20 weeks of gestation.

### Differential Diagnosis

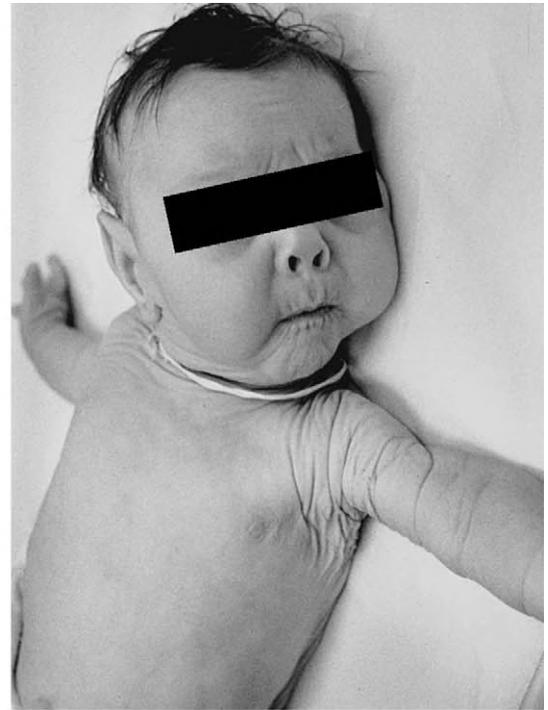

The differential diagnosis for cMFS includes the following disorders.

1. Beals syndrome, or congenital contractural arachnodactyly (CCA), is characterized by a similar thin, wasted appearance with minimal muscle and fat mass and contractures of the large and small joints (Fig. 24-7A). Cardiovascular involvement is usually limited to mitral valve prolapse, contractures improve to some degree with time, and life span is normal. CCA is an autosomal dominant condition caused by mutations in the fibrillin 2 (*FBN2*) gene on chromosome 5 (5q23-31).

A

**FIGURE 24-7.** A, Congenital contractural arachnodactyly (Beals syndrome). This infant has a long, thin trunk and limbs, contractures of joints, and crumpled ears. B, Cutis laxa. (Courtesy Montreal Children's Hospital, Montreal, Quebec.)

B

- The autosomal recessive form of cutis laxa syndrome is severe and can manifest at birth with loose, sagging skin, pulmonary emphysema, and gastrointestinal and urinary tract diverticula (Fig. 24-7B). The cardiovascular abnormality seen in Marfan syndrome does not occur in cutis laxa.

### WILLIAMS SYNDROME

Williams syndrome is difficult to diagnose in the newborn period, but the astute clinician notes an irritable infant with a coarse “swollen” face with periorbital fullness and thick lips who may have a cardiac murmur (Morris et al, 1988) (Fig. 24-8A and B). Supravalvar aortic stenosis and peripheral pulmonic stenosis may manifest in the newborn period, with occasional atrial or ventricular septal defects and, rarely, coarctation of the aorta. The presence of such an unusual vascular lesion, supravalvar aortic stenosis, should bring to mind the possibility of either isolated autosomal dominant supravalvar aortic stenosis or Williams syndrome. Supravalvar aortic stenosis affects more than 50% of children with Williams syndrome. Gestational age is usually approximately 42 weeks, with birth weight and length in the lower half of or below the normal growth curves. The facies in infancy may be coarse or fine, with periorbital fullness, medial flare of the eyebrows, common blue irises with a stellate pattern, epicanthic folds, flat nose bridge with full nasal tip and anteverted nares, long or undefined philtrum, chubby “low-set” cheeks, small chin, and large ears (see Fig. 24-8C

and D). The lips may be thick at birth or may thicken later; the “Cupid’s bow” is diminished or absent. The head may be dolichocephalic (increased anteroposterior diameter), and the hair curly.

Clinodactyly (incurving) of the fifth fingers is common. The skin is very soft, with fine creases on the palms, and ages prematurely. There is occasional inability to pronate and supinate the forearm. The limbs are short compared with the trunk but this characteristic may not be obvious in the newborn period. Mild hypotonia is common. Frequent vomiting starts soon after birth, and it is not unusual for the infant to scream most of the day and to refuse feedings. This behavior may be due to gastroesophageal reflux, causing esophagitis, or to hypercalcemia. The irritability can persist for most of the first year.

Moderate global developmental delay with a specific pattern of strengths and weaknesses is usual; rare individuals have normal IQ or severe retardation. Strengths include good expressive language, recognition of faces, friendliness (which may be inappropriate), and, sometimes, short-term memory. These qualities can hide or mask for the casual observer the patient’s difficulties with visuomotor abilities such as writing and drawing figures, mathematical reasoning, understanding money, and subtle social interactions. The voice is deep and hoarse. Hyperactivity is common and can be controlled with methylphenidate and similar drugs, thereby improving learning and performance (Power et al, 1997).

In addition to supravalvar aortic and peripheral pulmonic artery stenoses, narrowing (stenosis or coarctation) of other vessels, including the aortic, renal, and cerebral

**FIGURE 24-8.** Williams syndrome. **A**, Neonate with a coarse face, periorbital fullness, wide mouth, and thick lips with decreased Cupid's bow. **B**, Neonate profile showing periorbital fullness, flat nasal bridge with full tip, and prominent cheeks. **C**, This infant has periorbital fullness, flat nasal bridge, thick lips with decreased Cupid's bow, pouty lower lip, and "low-set" full cheeks. **D**, Infant profile showing dolichocephaly (increased anteroposterior diameter of head), higher nasal bridge than in neonate, full nasal tip, pouty lower lip, long neck, sloping shoulders, and part of pectus excavatum.

arteries, may occur (Kaplan et al, 1995). Hypertension may develop because of arterial stenosis or renal disease. Life span may be shortened by cardiac or renal failure. Cardiac failure is less common than a decade ago because of earlier diagnosis and cardiac intervention with medications or surgery. Diverticulosis of the bowel (associated with chronic constipation) and bladder (associated with chronic dys-synergia of bladder emptying) may develop in adolescence or adulthood (Schulman et al, 1996). Con-

tractures can impair daily function (Kaplan et al, 1989). Rarely, renal failure develops (Pober et al, 1993).

#### Etiology

Williams syndrome is a contiguous gene deletion syndrome resulting from a deletion at 7q11.23 on one chromosome 7 only (Ewart et al, 1993). Many genes have been deleted, including elastin (Ewart et al, 1993) and

replication factor C subunit 2 (Peoples et al, 1996), and LIM-kinase 1 (Frangiskakis et al, 1996). The function of all the deleted genes has not yet been elucidated. The lack of elastin accounts for many features, such as arterial narrowing, diverticula, skin and joint problems, some facial characteristics, and deep voice. The replication factor may be important for cell growth. The LIM-kinase has been linked to the visuomotor dysfunction in one series (Frangiskakis et al, 1996), but this finding is not substantiated in other series. The frequency of deletion in chromosomes of maternal and paternal origins is the same. The deletion can be demonstrated with fluorescent in situ hybridization (FISH) with use of a probe that includes the elastin gene and extends beyond the 3' and 5' borders.

### Inheritance

Most cases of Williams syndrome are sporadic occurrences in a family. There are reports of several sibling pairs with Williams syndrome with neither parent affected (Karamostefa et al, 1999; CI Scott Jr, personal communication, 1997). This occurrence could be due to germline mosaicism in one parent; the risk for recurrence in a sibling of a sporadic case is approximately 5%, on the basis of experience in other disorders (Byers et al, 1988). Each child of a person with Williams syndrome has a 50% chance of inheriting the chromosome 7 with the deletion and manifesting the disorder (Morris et al, 1993); there are known families in which a parent and a child have Williams syndrome.

### Prenatal Diagnosis

Prenatal diagnosis of Williams syndrome is established with FISH of chorionic villus cells and amniocytes.

### Differential Diagnosis

The differential diagnosis of Williams syndrome in a newborn consists of the following disorders:

1. Lysosomal storage disease, particularly G<sub>M1</sub> gangliosidosis or mucopolipidosis type II (I-cell disease), may cause coarse facial features and joint contractures in the newborn period. There may be cardiomyopathy but not arterial narrowing and other features.
2. Noonan syndrome may cause coarse features and valvar pulmonic stenosis but not usually peripheral pulmonic stenosis.
3. Autosomal dominant supravalvar aortic stenosis is not associated with all the other features of Williams syndrome. Often there are other affected family members.

### Management

A multispecialty team approach is needed for the life of a person with Williams syndrome. However, in the newborn period, the most immediate problems are the feeding difficulty, hypotonia, and narrowing of the great vessels (Kaplan, et al, 2001). The infant may be irritable, crying constantly, and refusing to feed. Recognition and treatment of contributory factors, as follow, will help:

- Sucking may be weak because of hypotonia; breast-feeding may not be feasible.
- Swallowing may be incoordinated.

- Gastroesophageal reflux causes profuse vomiting and pain from esophagitis.
- Idiopathic hypercalcemia adds to the vomiting and irritability and causes constipation; the ionized calcium value should be measured, and a low-calcium formula may be needed.
- Stenoses of the great vessels impair energy; an echocardiogram should be performed.

## EHLERS-DANLOS SYNDROMES

There are at least eight types of Ehlers-Danlos syndrome, which are characterized by varying degrees and extents of joint and skin hypermobility, excessive bruising, thin wide scars, and fragility of tissues (Steinmann et al, 1993). Ehlers-Danlos syndrome types I and VII are the most likely to manifest in the newborn period. Type I is characterized by premature delivery of a fetus with Ehlers-Danlos syndrome as a result of rupture of the amniotic membranes. The infant may be floppy and in breech position. There may be joint laxity and instability. In type VII, the major involvement is in the ligaments and joint capsules. Large and small joints are hypermobile and dislocatable; severe congenital dislocation of hips occurs. Dislocations are recurrent.

In type IV Ehlers-Danlos syndrome, the greatest danger is to the pregnant affected woman, for whom there is a high risk of uterine rupture. Although there is a 50% risk that the fetus will be affected, the problems of blood loss and prematurity are more important in the newborn period than the disorder itself.

### Etiology

Collagen type V has been implicated in causing (some) cases of Ehlers-Danlos syndrome types I and II (Burrows et al, 1996; De Paepe et al, 1997). Type IV of the syndrome is caused by mutations in collagen type III. Type VII is caused by a deleted exon 6 in the  $\alpha$ -1 (COL1A1) or  $\alpha$ -2 chain (COL1A2) of type I collagen.

### Inheritance

The types of Ehlers-Danlos syndrome discussed here are inherited as autosomal dominant traits. Each child of an affected person has a 50% chance of inheriting and manifesting the disorder.

### Prenatal Diagnosis

If the molecular defect has been characterized, chorionic villus sampling or amniocentesis is feasible. This had been difficult for type I, because the connective tissue was not known. However, amniocentesis in a fetus affected with Ehlers-Danlos syndrome type I may cause amniotic tears and fluid leaking.

## OTHER SKELETAL DYSPLASIAS

For information on atelosteogenesis (Fig. 24-9), chondrodysplasia (Fig. 24-10), and diastrophic dysplasia (Fig. 24-11), see Table 24-2.

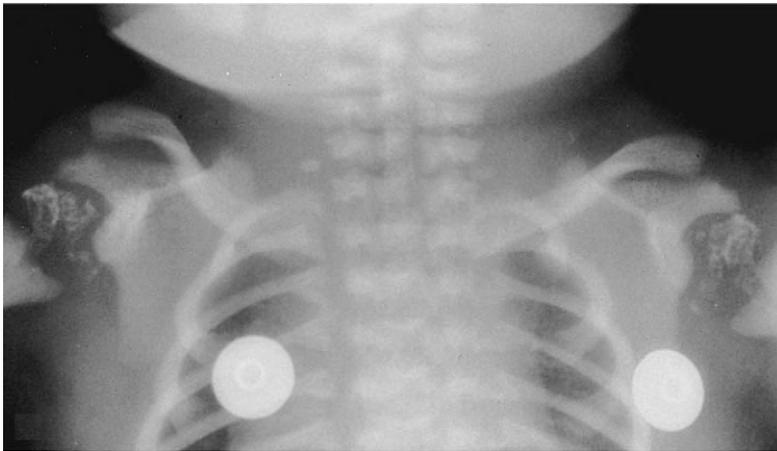

**FIGURE 24-9.** Atelosteogenesis (see Table 24-2). **A** and **B**, Infant with proximal limb shortening and equinovalgus deformities of the hands and feet. **C**, Radiograph of the upper limb showing distal tapering of humerus; metacarpals and phalanges are short and broad or irregular. **D**, Radiograph of the lower limb showing “clubbing” of foot; fibula is not visualized and may be hypoplastic or absent. (Courtesy Charles I. Scott, MD, AI DuPont Institute, Wilmington, DE.)

# EVALUATION AND CARE OF THE NORMAL NEWBORN

Editor: H. WILLIAM TAEUSCH

## CHAPTER 25

### Initial Evaluation: History and Physical Examination of the Newborn

Susan Sniderman and H. William Taeusch

Most newborn infants are normal, that is, free from disease and birth defects. Most are able to adapt easily to extrauterine life. Most parents, although having some degree of ambivalence, are excited by their newborn child and are able to care for the infant. When this scenario pertains, physicians must offer parents support and information about the major issues, risks, and achievements that they can expect for their infant over the next few months.

When an infant is born prematurely or is found to have anomalies or illnesses, the history and physical examination may have to be performed at the same time as the parents are informed of the infant's problems and likely course.

Specifics of the examination of various systems are given throughout this book. Therefore, the points relevant to newborns, particularly sick and anomalous infants, are emphasized in this chapter.

#### EMERGENCY ASSESSMENT

Assessment of the newborn ranges from routine evaluation of a healthy full-term infant nearing the time of discharge to the emergency assessment of a gray, evidently lifeless, 500-g newborn in the delivery room. The impressions gained in the first seconds to minutes often dictate the speed with which further assessment and treatment must occur. A rapid assessment, including both a brief history and physical examination, is warranted whenever an infant has an acute change in status. The evaluation should not impede attention to the infant's immediate needs. It is a novice's mistake to suspect overwhelming sepsis, then to take several hours to obtain the history and perform the physical examination and a leisurely lumbar puncture before ensuring that antibiotics have been given to the infant. Another mistake is to wait for a chest radiograph to

be obtained for an infant with hypotension and a clinically evident tension pneumothorax. A third mistake is to allow an infant to suffer thermal and oxygen insufficiency while hidden under sterile drapes during a protracted insertion of an umbilical artery catheter. A list of perinatal and postnatal conditions necessitating emergency assessment is given in Table 25-1. Delivery room assessment and resuscitation are discussed in Chapter 28.

#### HISTORY

The first interview with the parents should occur, if possible, before birth. With rapidly expanding genetic diagnostic capabilities and identification of high-risk fetuses with prenatal ultrasonography, the need for pediatricians to meet with the parents before birth is increasingly common.

The first evaluation of the newborn infant is often said to be the most important routine examination that a person receives in his or her lifetime. If the infant is sick or has anomalies, this statement is particularly pertinent. However, for well infants, remarkably few studies have examined which elements of the initial history and physical examination are most important and which professional personnel should conduct them. If the infant is born at term with no complications, the parents are delighted with the good news. If the infant needs intensive care (approximately 3% of live births), the tendency to focus on ventilators, monitors, laboratory tests, radiographs, and ultrasonography makes it difficult for the parents to focus on the more mundane but possibly very important and pertinent medical history.

Frequently, infants enter the neonatal intensive care unit (NICU) without the parents having been able to anticipate this occurrence. When the parents first visit the NICU, they confront a strange environment in which the life of their infant is entrusted to nurses and doctors not known to them. Both parents may be exhausted and anxious in the hours after the delivery, at the time they become aware that the infant is seriously ill. Some parents are fatalistic and accept opinions about diagnosis and prognosis less out of trust than from a belief that they have little effect on events. Others attempt to exert control over the caregivers in the belief that their infant's plight can be fixed only if they (the parents) determine the correct decisions and treatments to be made.

Therefore, the style with which the initial interview is conducted must be adapted to the parents' as well as the infant's needs. The interview serves several purposes. First, it allows the collection of information that affects the management of the infant. Second, a therapeutic bond may be

**TABLE 25-1****Neonatal Conditions Requiring Emergency Assessment**

Probably lethal conditions	Anencephaly, hydranencephaly, severe hydrops with hypoplastic lungs, extremely low birth weight (previability), nonresponsiveness to resuscitation
Respiratory conditions	
Airway obstruction	Mucus, meconium, kinked endotracheal tube, webs, cysts, large tongue, stenosis, tumors, vascular rings
Space-occupying lesions	Pneumothorax, pleural effusions, tracheoesophageal fistula, diaphragmatic hernia, adenomatoid malformation, tumors
Insufficient respiratory drive	Immaturity, asphyxia, maternal drugs, central nervous system depression, neuromuscular disease
Parenchymal disease	Respiratory distress syndrome, meconium aspiration pneumonia, infectious pneumonitis, hypoplastic lungs
Cardiovascular conditions	Hypovolemia, hypotension, bradycardia or other arrhythmia, hydrops, congestive heart failure, decreased pulmonary blood flow due to structural cyanotic congenital heart disease or persistent pulmonary hypertension, anemia, hyperviscosity

formed with the parents, the first stage in enlisting them as allies rather than adversaries in the days, weeks, and possibly months ahead while the infant is in the NICU. Third, the clinician can make an initial assessment of the adequacy of the home and the parents with regard to the care of the infant. Fourth, the interview gives the parents an opportunity to receive an initial report on the status of the infant.

If the infant is being transferred to another hospital, giving the mother a “belonging” of the infant (e.g., a bracelet or Polaroid picture) can help her contend with the birth and immediate separation (to the NICU) from her infant. Realistically allaying the parents’ anxiety about their infant’s condition is often not possible at the first interview, but the manner and conduct of the history-taking can help the parents feel that their infant will receive competent care. Frightening though the illness or anomaly may be, the parents’ concept of their infant’s problem may be even more frightening; thus, some reassurance can be offered in most cases, especially after the parents have seen the infant. Novice caregivers, as a symptom of their own insecurity, may emphasize data in these discussions. This tactic, particularly at the first meeting, usually does more harm than good. The error of the opposite approach is to patronize the parents in an abbreviated interview. The worst mistake is to minimize contact with the parents altogether.

Usually, parents are justly intolerant of the professional who waits until after all history-taking, examinations, and

laboratory data are in hand before giving them any notion of the problems. It may be wise to start an interview with an overview and follow with the history-taking. At the conclusion of the interview, the clinician should outline the next steps (diagnostic and therapeutic), describe real and potential problems, seek questions from the parents, and close with plans for the next contact.

The initial history and physical examination are screening tools. All systems and areas of the body are evaluated in a feed-forward mode; that is, if the initial screening result is positive (e.g., a problem with the heart or lungs), then that system immediately receives a more thorough evaluation, not only through the physical examination but also through expansion of the history and laboratory examinations. The equally weighted and relentlessly thorough history and physical examination performed by the compulsive novice are rightfully replaced by a balanced examination suitable for the individual circumstances of the infant.

The examiner, throughout the history and physical examination, seeks answers to a series of questions, the first and most important of which is whether the infant is acutely ill. Next, the examiner seeks whether there are problems with regard to the following aspects of the infant:

- Any specific organ system
- Infection
- Inadequate oxygen or nutrients (acute or chronic)
- Abnormal in utero environment
- Growth
- Anomalies or genetic disease
- Trauma
- Maturity
- Transition from in utero existence
- Home environment

The history, physical examination, and laboratory evaluations are never complete for sick infants in an intensive care setting. Information is constantly being compiled from diagnostic studies, physicians, nurses, respiratory therapists, family members, and so forth. Integration of these data with clear and appropriate communication in interviews with parents is one of the hardest tasks to learn. One of the best techniques is the use of careful, succinct, system- or problem-oriented, dated, and timed notes in the infant’s hospital chart, including information about what has been told to the parents as well as their particular concerns.

## MATERNAL HISTORY

The history of the newborn is principally the history of the mother’s pregnancy, general health, and previous pregnancies. Table 25-2 outlines the array of maternal conditions that can affect the newborn. Maternal influences on the fetus are thoroughly reviewed by Creasy and Resnik (2004).

The major problem of newborns throughout the world is low birth weight with prematurity. The complex and interrelated risk factors for low birth weight are summarized in Table 25-3. Each of these factors is important. If any of these factors is present in the maternal history, their relative weights must be individualized, because none of the items listed is necessarily associated with preterm delivery.

**TABLE 25-2****Maternal History****Social, educational, and economic factors**

Age, race, primary language, work stress, education, religion, reasons for becoming pregnant, preparation for infant care, home support, health care access, history of child abuse

**Behavioral factors and habits**

Smoking, drugs, alcohol, exercise (duration and amount)

**Exposure to toxins or teratogens**

Radiation, radiochemicals, hormones (including diethylstilbestrol), thyroid suppressants, aminopterin, anticancer agents, mercury, chlorobiphenyls and other organic substances, hydantoins, anticoagulants, isotretinoin

**Nutrition**

Diet, vitamin and mineral supplements, weight gain

**Genetic/familial disorders**

See Table 25-4

**Chronic medical problems predating pregnancy, and outcome(s) of prior pregnancy(ies)**

Fetal death, twins, prematurity, blood group incompatibilities, birth weight or gestational age of previous child(ren)

**Prenatal care**

Number of visits, trimester of first visit, ultrasonography

**Problems of current pregnancy\***

Central nervous system or psychiatric

Endocrine: diabetes, thyroid status, thyroid medication

Metabolic: cholestasis

Cardiopulmonary: mitral insufficiency or asthma

Hypertensive disorder, preeclampsia

Hematologic: anemia, Rh incompatibility, idiopathic or alloimmune thrombocytopenia

Third-trimester bleeding: placenta previa, abruptio placentae, ruptured uterus

Immunologic: systemic lupus erythematosus

Surgery or trauma

Infectious

Medications: tocolytics, glucocorticoids, antibiotics, antihypertensives

Renal

Neoplastic

Reproductive: incompetent cervix, hydramnios, oligohydramnios, in vitro fertilization

**Special tests during pregnancy**

Ultrasonographic examinations, karyotyping, alpha-fetoprotein testing, chorionic villus biopsy, percutaneous umbilical blood sampling of the fetus, stress and nonstress testing, amniotic fluid testing for bilirubin, fetal maturity assessment, biophysical profile

**Infection screening**

Rubella, syphilis, acquired immunodeficiency syndrome, toxoplasmosis, herpes, hepatitis B and C, cytomegalovirus, tuberculosis, gonorrhea (for close contacts as well as the mother)

**Onset and events of labor**

Fetal heart rate monitoring, fetal scalp pH, meconium, rupture of membranes, amnioinfusion, fever, maternal oxygen, vena caval compression, blood pressure, ventilation, analgesia or anesthesia, other medications, duration of stages of labor,<sup>1</sup> mode of delivery

\*Pregnancy-associated diseases and fetal exposure to tobacco, marijuana, alcohol, or illicit drugs are included on the U.S. Standard Certificates of Live Birth and Fetal Death (Freedman MA, Gay GA, Brookert JE, et al: The 1989 revisions of the U.S. Standard Certificates of Live Birth and Death and the U.S. Standard Report of Fetal Death. *Am J Public Health* 78:168, 1988.)

<sup>1</sup>Stage 1 = onset to full cervical dilation; stage 2 = dilation to delivery of fetus; stage 3 = delivery of fetus to delivery of placenta.

**Prenatal Care**

The reasons that only some women receive prenatal care are of vital interest. Even though birth weight-specific mortality in the United States is among the world's lowest, the high neonatal mortality rate is directly related to a high rate of low-birth-weight deliveries. Deficiency or absence of prenatal care is associated with an increased risk of prematurity. All people who care for mothers and infants share a respon-

sibility for disseminating these facts and uncovering and correcting the causes of lateness or absence of prenatal care.

**Duration of Pregnancy**

Estimates of the length of gestation should be obtained from (1) the date of the mother's last menstrual period, (2) the date of quickening, that is, when the mother first

TABLE 25-3

**Principal Maternal Risk Factors for Low Birth Weight Infants**

Demographic risks	Age (<18 or >35 yrs) Ethnicity Low socioeconomic status Unmarried Low level of education
Medical risks predating pregnancy	Parity (0 or >4) Low weight for height Genitourinary problems, renal insufficiency, or uterine surgery Selected diseases, e.g., diabetes and hypertension Poor obstetric history, including previous low-birth-weight baby or multiple abortions Genetic factors, e.g., the mother herself was a low-birth-weight infant
Medical risks in current pregnancy	Multiple pregnancy Poor weight gain Short interpregnancy interval Hypotension Hypertension, preeclampsia, or toxemia Infections, e.g., rubella, symptomatic bacteriuria, or cytomegalovirus infection First- or second-trimester bleeding Placental problems, e.g., placenta previa, abruptio placentae Hyperemesis Oligohydramnios or polyhydramnios Anemia or abnormal hemoglobin level Isoimmunization Fetal anomalies Incompetent cervix Spontaneous premature rupture of membranes
Behavioral and environmental risks	Smoking Poor nutritional status Alcohol and other substance abuse, particularly cocaine Diethylstilbestrol exposure and exposure to other toxins High altitude
Health care risks	Insufficient prenatal care Iatrogenic prematurity
Other possible correlates of premature labor	Physical and psychosocial stress or abuse Uterine irritability Cervical changes before labor Infections, e.g., with <i>Mycoplasma</i> and <i>Chlamydia</i> Immune interactions between the mother and fetus

Adapted from the Institute of Medicine Committee to Study the Prevention of Low Birthweight: Preventing Low Birthweight. Washington, DC, National Academy Press, 1985.

feels the fetus move (16 to 18 weeks), (3) the first occurrence of fetal heart sounds (14 to 16 weeks with a fetoscope), and (4) ultrasonographic measurements. Nägele's rule is used to estimate the time of term delivery; with this rule, 3 calendar months are subtracted from the first day of the last menstrual period, and 7 days are added to the result. The uterine fundus is usually at the umbilicus by the fifth month after the last menstrual period.

**Genetic and Familial Factors**

A history of genetic and familial disorders is becoming increasingly important as the diagnosis of genetic disease of the fetus during pregnancy becomes more widely available (see Part V of this text). Table 25-4 contains a list of maternal genetic screening questions adapted from the one recommended by the American College of Obstetricians and Gynecologists.

**Complications of Pregnancy**

Complications of pregnancy (e.g., gestational diabetes mellitus, preeclampsia) may put the fetus at risk for specific abnormalities after birth, such as hypoglycemia and intrauterine growth restriction. Medications used to treat other complications may be important because they may have certain effects on the fetus (e.g., hydantoin causes dysmorphic features; diuretics may cause fetal thrombocytopenia). Even though they may be subclinical in the mother, infectious illnesses may lead to the birth of an infant with evidence of chronic in utero infection.

TABLE 25-4

**Maternal Prenatal Genetic Screening Questions**

1. Are you more than 34 years of age?
2. Has anyone in your family or the father's family had: Down syndrome ("mongolism"), chromosome problems or abnormalities, back (midline) defects at birth or later in life (spina bifida), prolonged or excessive bleeding (hemophilia), muscle weakness problems (muscular dystrophy), or childhood lung problems (cystic fibrosis)?
3. Do you or does the baby's father have a birth defect? Do any members of your or the father's family have birth defects of any kind?
4. Have any members of your family or the father's family, or any of your prior infants, had problems that were inherited or "passed down" through family members to their children?
5. Do you or the baby's father have any close relatives with mental retardation or learning disabilities in school?
6. Have you or the baby's father ever been tested for these genetic problems (relevant to specific ethnic group): Tay-Sachs disease, sickle cell trait or disease,  $\beta$ -thalassemia?
7. Have you lost any early pregnancies (had any miscarriages)?

Adapted from the American College of Obstetricians and Gynecologists: Antenatal Diagnosis of Genetic Disorders. ACOG Technical Bulletin No. 108. Washington, DC, ACOG, 1987, p 3.

## General Health of Mother

In the same way, chronic diseases in the mother may have important consequences for her infant. A mother with systemic lupus erythematosus may have certain antibodies that may cause heart block in the fetus, or a mother with long-standing renal disease may have a growth-retarded infant. Maternal diabetes mellitus with elevated glucose levels in the first trimester is associated with at least a five-fold increase in serious congenital anomalies including congenital heart disease, caudal regression syndrome, and left microcolon. Even diseases that have resolved in the mother (e.g., Graves disease and idiopathic thrombocytopenic purpura) may continue to affect the fetus because of the presence of serum factors that persist and cross the placenta, causing problems in the fetus and newborn infant.

## Onset and Events of Labor

The timing of the onset of labor and the events that occur around it are important. Examples are an automobile accident, premature rupture of membranes, and sharp, near-continuous low back pain with vaginal bleeding. Indications for risk of acute infections in the fetus should be sought. Has the mother had a recent infection? Did she have a fever around the time of delivery? The diagnosis of maternal chorioamnionitis has been associated with a high risk of neonatal encephalopathy and cerebral palsy. Has the mother received antibiotics? How long did labor last, and how long were the membranes ruptured before delivery?

The fetal heart rate in conjunction with uterine contractions is the best signal during labor of the condition of the fetus (see Chapter 13). Adjuncts include the use of fetal scalp pH monitoring.

The presentation of the fetus in the birth canal and the route of delivery are of obvious importance. Breech position occurs in 8% of women in labor. In approximately 25% of breech deliveries, conditions such as placenta previa, malformations of the fetus or uterus, twinning, and premature labor may coexist. Risks of vaginal delivery for the fetus in the breech position include prolapse of the cord, trapping of the head at the level of the cervix, asphyxia, trauma, and congenital hip dysplasia.

## Amniotic Fluid

The infant at term is immersed in about 1 L of amniotic fluid. Sources of this fluid are fetal urine, lung secretions, and transudate from surrounding membranes. Before birth, ultrasonographic assessment of amniotic fluid volume is part of the biophysical profile. Although standards vary, normal volumes are associated with the presence of one or more pockets of fluid with a total vertical diameter greater than 4 cm. Oligohydramnios is indicated by less than 500 mL of fluid. Polyhydramnios indicates more than 2 L of fluid at birth. Near term, the fetus drinks approximately 125 mL/kg body weight of amniotic fluid per day (equivalent to the volume of postnatal milk intake). The fluid has a pH of 7.2 and is alkaline with respect to vaginal fluid. Therefore leakage of amniotic fluid from the vagina can be tested for by checking the pH of the vaginal fluid.

Oligohydramnios or polyhydramnios is most common when fetal swallowing or micturition is increased or decreased. Either condition can be a matter of degree and is best assessed with fetal ultrasonography. Phelan and colleagues (1987) have described the simplest method, in which the largest pockets of fluid visualized on ultrasonography in each of four uterine quadrants are summed. If the sum is less than 6 cm, oligohydramnios is diagnosed. Causes of oligohydramnios include conditions in which there is decreased urination (e.g., bilateral cystic dysplastic kidneys, posterior urethral valves, maternal use of indomethacin), severe placental insufficiency, and chronic leaking of amniotic fluid resulting from premature membrane rupture. The consequences of oligohydramnios are joint contractures and limb deformities, lung hypoplasia, and Potter facies. Conditions listed in Table 25-5 are associated with polyhydramnios. High intestinal obstruction and anencephaly (presumably caused by decreased clearance of amniotic fluid by swallowing) are the most common.

## Timing of Umbilical Cord Clamping

Many events affect the relative volumes of blood left in the newborn and the placenta after birth. Prenatal asphyxia shifts blood from the placenta to the fetus, and, in these cases, because of the need to suction meconium and resuscitate the infant, no delay in cord clamping appears to be useful. If the cord of a normal infant is clamped within 5 seconds of delivery, before a contraction compresses the placenta, and if the infant is held well above the mother's introitus before cord clamping, the infant may be hypovolemic. In contrast, if the obstetrician zealously "strips" the cord toward the infant and delays clamping it, the resulting shift of blood volume from the placenta to the newborn may result in polycythemia, delayed absorption of lung fluid, and hyperbilirubinemia.

**TABLE 25-5**

### Conditions Associated with Polyhydramnios

Agnathia
Anencephaly and other central nervous system defects
Beckwith-Wiedemann syndrome
Chylothorax
Conjoined twins
Cystic adenomatoid malformation of the lung
Diaphragmatic hernia
Fetal akinesia
Fetal death
Hydrops
Gastroschisis
Hemangioma
Maternal diabetes
Teratoma
Trisomies
Tumors of the lungs, placenta, or ovaries
Umbilical cord compression
Upper gastrointestinal obstruction (e.g., duodenal atresia)
Werdnig-Hoffmann disease

Despite years of research, there is little consensus on the optimal timing of cord clamping. In the absence of asphyxia and isoimmunization, 30 to 45 seconds is a reasonable period to allow to lapse while the infant is held at the level of the introitus. This interval usually allows for an inspiratory gasp on the part of the newborn and a uterine contraction on the part of the mother. Both occurrences favor transfer of blood from the placenta to the newborn (Table 25–6). The obstetrician can suction the nares and oropharynx during this time. Few pediatricians and obstetricians note the timing and nature of the separation of the newborn infant from the placenta, although such information would be helpful in infants with anemia or polycythemia.

Blood volumes are between 85 and 100 mL/kg of body weight in term infants and up to 110 mL/kg in preterm infants. Values can be 35% higher with large shifts of blood volume from the placenta. At term, 75 to 100 mL (20 to 35 mL/kg) of blood is available to the newborn from the placenta.

### PLACENTA AND UMBILICAL CORD

The problems of the placenta are discussed in Chapter 4. The placenta at term (cord and membranes excised 2 cm from the insertion) weighs between 400 and 500 g, with approximately 50% of the weight representing maternal blood and approximately 15% composed of fetal blood. A fetal-placental weight ratio at birth greater than 10 implies that nutrient delivery and gas exchange may have been suboptimal. The cord may demonstrate one umbilical artery (0.7% of live births), true knots, evidence of vascular rupture, compression, hematoma, or edema. In some infants with intrauterine growth restriction, the cord and chorionic plate may be stained greenish brown, the cord may be long and thin, and diminished Wharton jelly may be present. The insertion of the cord may be central or marginal, or it may be incorporated into the membranes

(velamentous), sometimes with vasa previa (splitting of the vessels in the membranes before insertion into the placenta). The umbilical cord is usually longer than 40 cm at term, and a shorter cord may indicate relative fetal akinesia from a variety of causes, the inference being that fetal activity contributes to lengthening of the cord. Amniotic membranes may show evidence of banding or thickening, often in association with amniotic fluid infection. In twins, there may be no membrane between cord insertions (monochorionic monoamniotic), a thin transparent membrane (monochorionic diamniotic), or a thick but separable opaque membrane (dichorionic diamniotic). About 20% of all monochorionic diamniotic twin pregnancies have placental vascular anastomoses with the risk of twin-twin transfusion syndrome (see also Chapter 4).

### PHYSICAL EXAMINATION

The examiner always faces the dilemma of needing to be thorough while needing to be gentle and quick so as not to destabilize the smallest and sickest infants. The physical examination of newborn infants is tailored to fit both the gestational age and the postnatal age of an infant. The evaluation in the delivery room of a gasping 25-week premature infant is different from the routine examination at 12 hours of age of a full-term infant in the well baby nursery. (Compare Figures 25–1, 25–2, and 25–3 with the full-term infants in subsequent figures; then look at Figure 25–4.)

Ideally, the neonatal examination should take place with the infant under a radiant warmer. The clinician needs patience to be able to return frequently to resume performing parts of the examination, so as to stay within the limits of an infant's tolerance. It is fruitless to examine the abdomen of an infant who is crying and risky to do so in one who has just had a full feeding. At the same time, it is embarrassing to miss an imperforate anus or extra digits in an infant whose respiratory problems have captivated the examiner's initial interest. Table 25–7 outlines the elements of a complete history and physical examination for a newborn infant.

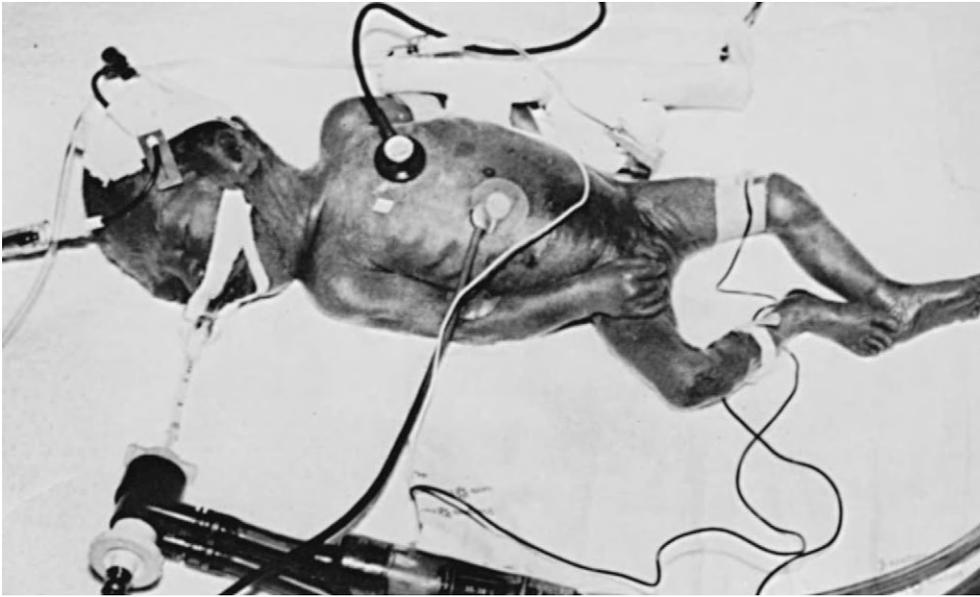

### Nosocomial Infection

Before one touches an infant for any purpose, he or she should perform hand-washing after removing rings and watches. The hand-washing should be done immediately before and immediately after the examination. A “low level of mysophobia” is prevalent among nursery personnel, no doubt contributing to the nosocomial infection rate approaching 50% for small sick infants who have spent more than several months in a NICU. If the prevalence of hand-washing is suboptimal in most nurseries, the use of insufficiently cleaned stethoscopes and other equipment is ever present. With concern provoked by the prevalence of acquired immunodeficiency syndrome (AIDS), many nurseries use universal precautions, meaning that a fresh gown and gloves are used for each direct contact with each patient, whether or not bodily fluids are directly handled. Reason dictates that patients should receive at least the same protection against common nosocomial bacteria as caregivers afford themselves against the much smaller risk of AIDS.

**TABLE 25–6**

#### Factors Determining Neonatal and Placental Blood Volumes

Prenatal drugs (e.g., ergot derivatives)
Maternal vascular disease (preeclampsia or diabetes)
Placental and fetal sizes
Maternal hypotension
Fetal asphyxia or placental insufficiency
Rate of umbilical artery constriction
Position of fetus relative to placenta
Uterine contractions (frequency, amplitude, duration, and baseline)
Time of cord clamping
Neonatal cardiac output
Fetal blood volume (hydrops)
Time of placental separation
Route of delivery
Cord compression
Timing of first breaths relative to cord clamping

**FIGURE 25-1.** The problems of physical examination are illustrated by comparing this 25-week, 710-g infant, A.W., with respiratory distress syndrome with the full-term newborn shown in Figure 25-5. The story of this premature infant is the subject of a book entitled *Born Early*. (From Avery ME, Litwack G: *Born Early: The Story of a Premature Baby*. Copyright © 1983 by Mary Ellen Avery, MD, and Georgia Litwack. By permission of Little, Brown and Company.)

### Vital Signs

Vital signs are usually assigned the first place in write-ups of the physical examination. For small sick newborns, single measurements are less important than trends, which

can be recorded as such. For example, “Axillary temperature was 34° C at 20:05 on arrival in the NICU and was 36.8° C after 2 hours in the servo-controlled overhead warmer supplemented with heat lamps.” Without a good indication of the times of the measurements, vital sign

**FIGURE 25-2.** The infant A.W. is shown after the first week of life. Note the size of the skull relative to the adult hand supporting the head. Abundant lanugo is evident. (Courtesy of G. Litwack.)

**FIGURE 25-3.** The infant A.W. at 6 weeks of age and 850 g. She required 33 days of ventilator support and underwent surgical ligation of a patent ductus arteriosus. With the head to the right, the infant manifests a strong spontaneous tonic neck reflex posture. She needed an incubator for temperature control but is shown here during a weight measurement. (Courtesy of G. Litwack.)

A

B

**FIGURE 25-4.** A, A.W., at 5 years of age, is thriving. B, A.W. at 15 years of age. She excels in academic studies and in athletics. (Courtesy of G. Litwack.)

data for newborns have little meaning. Temperature for the most part is measured in the axilla with electronic thermometers with disposable tips (see Chapter 29). Rectal temperatures, because of the greater risk of trauma or perforation associated with obtaining them, are useful only when core temperature may be in question. When the infant's temperature is more than  $37.5^{\circ}\text{C}$ , it is important to assess whether this elevation is a fever associated with infection or is related to an overly warm environment or excessive bundling. If the core temperature is elevated but the extremities are cool, sepsis is likely. When the extremities are warm, the cause is likely to be environmental or, rarely, "warm shock."

For all spontaneously breathing infants, term and premature, respiratory rates normally fall within a range of 40 to 60 breaths/min by 1 hour of age. Rarely, a term infant has a persisting respiratory rate of 100 breaths/min on the second day of life with no evident clinical, radiographic, or laboratory abnormality. In these cases, the respiratory rate becomes normal by the end of the first week. Persistent bradypnea is rare, seen only in extremely premature infants who are ill, infants whose respiratory drive is depressed from maternal narcotic administration, and infants with persisting central hypoventilation (Ondine's curse). Apneic episodes and periodic breathing should be described. In recorded observations, description rather than opinion is preferable; for example, "The infant had about six respiratory pauses of 4 to 7 seconds each without bradycardia or evident desaturation during a 5-minute period while lying undisturbed in apparent REM sleep."

Blood pressure is not usually measured routinely in well infants, and the cost-to-benefit ratio of this proce-

dure for normal infants is unknown. For sick infants, blood pressure is assessed, for example, by direct intra-arterial measurement, oscillometry, auscultation, and Doppler flow. Intra-arterial catheters permit continuous blood pressure monitoring as a matter of routine. In infants being evaluated for a heart problem, blood pressure should be measured in all four extremities, primarily to check for problems of juxtaductal coarctation and left ventricular and outflow tract hypoplasia. Blood pressure correlates directly with gestational age and birth weight. In general, hypotension must be considered when mean blood pressure is less than gestational age. In the smallest, sickest newborns, blood pressures are usually measured intra-arterially with transducers that often receive suboptimal calibration. The transducer must be at the level of the ventricles, and with lower blood pressures, errors of leveling may cause large errors in blood pressure readings. Trends in blood pressure, skin perfusion, recent clinical events, urine output, and arterial pH are essential data for the diagnosis of clinically significant hypotension. Hypertension is a consideration with mean pressures of more than 50 to 70 mm Hg in preterm or term infants.

### Weight, Length, and Head Circumference

Weight should be measured in grams for greatest accuracy. For infants with birth weights between 500 and 800 g, differences of only 100 g are associated with differences in mortality of 50%. Length is more easily measured with an inflexible meter rule laid beside the baby rather than with a flexible measuring tape. Measurements of length carried out by one person using a measuring tape on a

squirming infant are commonly inaccurate by several centimeters. The tonic neck reflex can occasionally help in straightening the leg during the measurement. The ponderal index (multiply the weight in grams by 100, then divide by the length in centimeters) may be useful in identifying the occasional baby who is underweight for length and therefore small for gestational age, who nonetheless is not so identified by standard weight, gestation, and length norms. Head circumference is determined by placing a soft tape measure just above the eyebrows and finding the largest circumference over the occiput (Fig. 25-5).

**FIGURE 25-5.** Positioning of tape for head circumference measurement.

### Gestational Age Assessment

Gestational age assessment is best achieved by recording all the available data, that is, by recording duration of gestation based on last menstrual period, prenatal ultrasonographic estimates, and, after birth, the gestational age that matches the 50th percentile for the child's head circumference, length, and weight, and the estimate of gestational age based on physical characteristics. These indicators can be combined to give "obstetric" duration and "pediatric" estimates of gestation that can be combined into a "clinical" estimate. We believe that the physical assessments of gestational age have been overemphasized because the skin and the central nervous system, which contribute the most to the score, can be affected by factors other than the duration of gestation, such as respiratory distress, asphyxia, and antenatal steroid therapy. The scoring examination by Ballard and associates (1991) is one of the simplest and should be consulted for detailed assessments. In terms of weight, as a rule of thumb, 24-week infants are about 600 g (the usual limit of viability), 28-week infants are 1200 g ( $600 \times 2$ ), and 33-week infants are 1800 g ( $600 \times 3$ ).

### Overall Appearance

Observing the infant is the most important aspect of the physical examination. It is best performed with the infant quiet and nude. Occasionally, these two states are incompatible, in which case the infant can usually be quieted by being rocked to and fro while the examiner makes faces and babbles. This time-honored method usually catches the surprised attention of the infant (and other personnel who happen by). The state of alertness, the muscle tone, the activity, obvious anomalies or injuries, respiratory pattern, and the skin are assessed during inspection. The infant may appear sick or well, responsive or lethargic. The muscle tone in a term infant should be sufficient for the hips, knees, and elbows to be flexed while the infant is lying supine or prone. Some spontaneous movements should be evident, and the well infant should appear alert

at some point during the examination, unless the examiner is an extraordinarily boring person. The color should be pink rather than sallow or pale or blue. Cyanosis may be generalized or may be limited to the distal extremities or to the lower part of the body, as is seen occasionally with massive right-to-left shunting through a still patent ductus arteriosus. When only the hands and feet are blue, the infant may be cold with resulting peripheral vasoconstriction; this appearance is called acrocyanosis.

The appearance of the small premature infant after stabilization is different from the preceding description. The 900-g infant with respiratory distress syndrome may be intubated or ventilated and may have an arterial line or peripheral intravenous lines in place. Usually, a thermistor for temperature regulation and leads for cardiac and respiratory monitoring are also attached. Such an infant may also be sedated or paralyzed by muscle relaxants. Regardless, the infant is usually flaccid and minimally responsive. The infant may be covered in various ways to minimize heat loss and restrained to maintain the vascular lines. Stimulation during the examination may cause arterial desaturation, silent crying attempts around the endotracheal tube, decreased blood pressure, tachycardia or bradycardia, and decreased skin perfusion. In these cases, continual information on gas exchange, blood pressure, temperature, ventilation, and heart rate is gained at the price of access to the infant, which in any case can be harmful, especially if the examination is lengthy, inept, or both. Nonetheless, a careful head-to-foot examination can be gently and quickly carried out by one or two (not four or five) examiners. The cardiac and pulmonary examinations are often difficult because of ventilator noise (water accumulation in the inspiratory tube) and because of difficulties obtaining a good seal on the chest of premature babies with stethoscope bells designed for larger babies. The examination of the abdomen with a single index finger is often easier than the examination of full-term infants because of the thinness and diminished tone of the anterior abdominal wall.

Anomalies and birth injuries are often apparent on inspection. When observing the infant, one must look carefully at the facial features and the shape of the ears and head for any obviously dysmorphic or malformed features. Are there any obvious anomalies? Is the infant well proportioned or are the limbs short or long compared with the trunk? If any anomaly or dysmorphic feature is noted, a search should begin for other major or minor abnormalities that may help lead to diagnosis of isolated malformations, a malformation sequence or syndrome, or a deformation or disruption caused by external environmental factors. Malformations, deformations, and chromosome problems are discussed in Part V of this text. The most common anomalies are listed in Table 25–8. Birth injuries are often signified by lack of motion or asymmetries of movement of the limbs or face. There may be obvious pain when an extremity or clavicle is palpated, and bruising may be apparent after a few hours of life. Birth injuries occur with greater frequency in breech deliveries and other abnormal presentations. The most common birth injuries are listed in Table 25–9.

The chest should be inspected for symmetry. A prominent left chest may indicate cardiac hypertrophy from an

**TABLE 25–8****Most Common Anomalies Noted on the Initial Examination of a Newborn**

Anomaly	Frequency (per 1000 live births)
Skin tags	10-15
Polydactyly	10-15
Cleft lip or palate	1-4
Congenital heart defects	1-4
Congenital hip dislocation	1-4
Down syndrome	1-4*
Talipes equinovarus	1-4
Spina bifidas, anencephaly, or encephalocele	1-4/10,000 live births

\*Frequency increases with maternal age greater than 33 years.

obstructive lesion. A visible cardiac impulse may indicate a patent ductus arteriosus with left-to-right shunt. A small chest in an infant manifesting respiratory distress or failure may indicate pulmonary hypoplasia or, in a more severe form, asphyxiating thoracic dystrophy.

Much information is obtained by watching the infant breathe. Regular respiratory movements of less than 60 breaths/min without suprasternal, intercostal, or subcostal retractions make pulmonary disease unlikely. Apneic spells and periodic breathing can also be observed.

### Inspection by System

After gaining a general impression of the infant's status and being convinced that emergency intervention (intubation, relief of pneumothorax, or transfusion) is unnecessary, the clinician may continue observation of the infant by system, usually starting at the head and working caudad. Then the examination is repeated with palpation, auscultation, reflex testing, the shining of lights into various orifices, and, finally,

**TABLE 25–9****Most Common Birth Injuries and Insults**

Decreased gas exchange: placental insufficiency, prolapsed cord, premature placental separation*
Broken clavicle
Facial palsy
Brachial plexus injuries (especially Erb palsy)
Fractures of the humerus or skull
Ruptured internal organs
Testicular trauma
Fat necrosis
Lacerations or scalpel injury
Cephalhematoma and subgaleal hematoma
Scalp lesions from fetal scalp electrode or forceps
Umbilical cord accidents

\*Acute parturient asphyxia of sufficient duration and severity to be associated with hypoxic-ischemic encephalopathy. The incidence for each of these conditions is roughly 1-3 per 1000 live births.

range of motion. Auscultation and abdominal examination require a quiet if not cooperative infant. The hip examination and the Moro reflex testing should be the finale, because these assessments frequently leave the infant displeased with the whole concept of being examined.

### The Cry

As the clinician performs various parts of the newborn examination, he or she should listen for the infant's cry. Is it husky, loud, and sustained or is it shrill and high-pitched, indicating a possible central nervous system abnormality? The cry may be low pitched and husky in hypothyroidism, or hoarse with vocal cord injury or recurrent laryngeal nerve palsy. A weak whimper may indicate overwhelming sepsis or neuromuscular disease. Inspiratory stridor from airway obstruction may be heard only when the infant is crying. Complete aphonia usually indicates bilateral vocal cord injury or paralysis.

### Skin

Vernix usually covers the skin, especially in the skinfolds of the axillas, neck, and groin at birth. Post-term infants characteristically have little vernix, and their skin is dry, cracked, and wrinkled. The texture of the skin is evaluated with regard to scaliness, elasticity, thickness, and local or generalized edema. Hemangiomas, nevi, and urticarial, pustular, vesicular, or nodular rashes are sought. Particularly in infants with vascular catheters, evidence of partial or complete arterial or venous obstruction should be sought at regular intervals. Dermal sinuses occur in the midline of the back from occiput to coccyx and near the ears and in the neck. Dimples, sinuses, hirsute areas, or cystic swellings suggest the presence of cranial or vertebral sinuses or underlying defects. Preterm infants may have fine downy hair (lanugo) over the shoulders, back, thighs, forehead, and ears. The lanugo regresses as they mature over weeks.

Ecchymoses or petechiae may relate to birth trauma and may herald a higher than normal hyperbilirubinemia as the blood products break down and are absorbed over 24 to 36 hours. Generalized and recurring petechiae, especially those not on the head and neck region, may signify serious infectious or hematologic problems.

Common findings include milia, white papules less than 1 mm in diameter that are scattered across the forehead. These and white vesicles with a red base (erythema toxicum) are transient and benign. In black infants, a similar but more dramatic benign condition is transient neonatal pustular melanosis. These conditions at times are impossible to differentiate on inspection from infectious pustules. Jaundice in the third day of life or later is common, but jaundice that is evident on the first day of life is unusual and needs laboratory investigation.

### Head

The most common findings after birth are caput succedaneum and cephalohematoma. Caput succedaneum is edema of the scalp skin and crosses suture lines. Cephalo-

hematomas are subperiosteal and therefore do not cross suture lines. Frequently, the clinician gains the impression of a depressed skull fracture while palpating the rim of a cephalohematoma. This (false) perception is so common that we do not routinely obtain skull radiographs of an infant with a cephalohematoma unless other worrisome signs are present as well. Rarely, subgaleal hemorrhage may occur, especially after a birth assisted with vacuum extraction. The hemorrhage is under the aponeurosis of the scalp but above the periosteum. The swelling crosses suture lines and can be differentiated from a caput succedaneum on the basis of its firmness and other signs of loss of blood from the intravascular space.

On the first day of life, molding of the head from descent through the birth canal may be present, and the skull plates are overriding. After a few days, the clinician can better estimate the size of the fontanelles, their flatness, fullness, or tenseness, and the width of suture lines (Faix, 1982; Popich and Smith, 1972). Fontanelles may tense normally with vigorous crying. A bulging or tense fontanelle has a feel on palpation nearly equivalent to that of bone. In contrast, a full fontanelle may be normal and is easily distinguished from bone on palpation. The clinician may note the fusion of the sagittal, metopic, or coronal sutures as either total, partial, or unilateral. Large fontanelles and split sutures are most often a normal variant, but they can be associated with increased intracranial pressure or conditions that impair bone growth. Likewise, small fontanelles and overriding sutures are generally of little significance but may be associated with conditions in which brain growth has been retarded (Table 25–10). A small (third) fontanelle anterior to the posterior fontanelle is occasionally found and is associated with Down syndrome and hypothyroidism. Unusual whorls or other hair patterns and asymmetries of the skull may indicate problems in global or regional brain development.

### Skull Defects

Craniotabes is a demineralized area or softening of the skull. The skull bone can be indented with gentle pressure like a table tennis ball. When this finding is appreciated to a mild degree near the suture lines in newborn

**TABLE 25–10**

#### Disorders Sometimes Associated with Abnormal Fontanelles

Fontanelles too large	Skeletal disorders (e.g., hypophosphatasia, osteogenesis imperfecta) Chromosome abnormalities Hypothyroidism Increased intracranial pressure, hydrocephalus
Fontanelles too small	Hyperthyroidism Craniosynostosis Microcephaly
Third fontanelle	Down syndrome Hypothyroidism

infants, it is commonly a normal variant. When present over most of the skull, craniotabes may be associated with conditions in which calcification has been deficient (e.g., syphilis, osteogenesis imperfecta). By contrast, craniosynostosis is a condition wherein sutures are fused, thereby constraining brain growth.

Transillumination is useful for detecting severe hydrocephaly and hydranencephaly before obtaining an ultrasonographic evaluation. The heads of premature infants normally have a greater degree of transillumination than the heads of term infants.

### Eyes

Eyes are difficult to examine in the newborn, especially when instillation of silver nitrate has occurred. The use of this substance, which is currently not preferred over other antibacterials, is associated with swelling and conjunctivitis during the first 36 hours of life. Often, an infant soothed with to-and-fro rocking, during which the head is elevated, spontaneously opens the eyes, allowing their inspection and as well as assessment of visual tracking of the examiner's face or a bright object as it moves from side to side (Fig. 25-6).

Gross vision can also be assessed by observing whether the infant turns to light. Pupils should be equal in size, reactive to light, and symmetrical. The corneas should be clear. The pupil can be inspected with a light, and the pink retina (red reflex) discerned to rule out lenticular, anterior, and posterior chamber opacities. (With the ophthalmoscope about 6 inches from the infant, the clinician uses the +10 diopter lens.) Fixed strabismus should be absent, and the eye movements for the most part should be coordinated. The examiner can assess eye movements by checking for oculovestibular nystagmus, which consists of holding the infant under the axillas facing the examiner while the examiner turns in a circle. The infant's eyes should slowly

**FIGURE 25-6.** Head turning to follow a ball. (Courtesy of Dr. B. Brazelton.)

deviate in the direction of spin with quick movements in the opposite direction. If other disease is present or a more complete examination is indicated, the pupils should be dilated for a complete retinal examination.

### Ears

The ears are examined for placement and deformation. Low-set or posteriorly rotated ears may be associated with other more major anomalies. Usually, the tips of the ears are cephalad to an imaginary circumferential line drawn around the skull through the inner and outer canthi of both eyes. Gross hearing is often inaccurately assessed by observing whether the infant blinks in response to a loud noise. More formal hearing screening for all newborns has now been recommended (see "Laboratory Screening"). In the immediate newborn period, the ear canals are usually occluded by vernix and are not routinely examined.

### Mouth and Lower Face

The lips may be good indicators of whether the infant is cyanotic. Retention cysts on the alveolar ridge may look like teeth; natal teeth occur rarely and are usually shed in a few days. Retention cysts, also called Epstein pearls, disappear in a few weeks. The frenulum, which in years past was occasionally cut to prevent "tongue-tie," can usually be ignored. The palate is examined for cleft, the tongue for size, and the sublingual area for masses. The two corners of the mouth should move symmetrically when the infant cries or grimaces; asymmetry is most usually caused by a seventh cranial nerve palsy. A long philtrum, thin upper lip, cleft lip, cleft palate, and small jaw are other significant findings associated with abnormal fetal development sometimes caused by chromosome abnormalities, alcohol, or other fetal toxins.

### Nose

Patency of each naris can be checked by holding a wisp of cotton at the orifice while occluding the other naris with the mouth closed. Newborn infants breathe preferentially through the nose, so bilateral choanal atresia may cause severe respiratory distress. Flaring of the nostrils occurs whenever respiratory effort is increased regardless of cause.

Almost half of all infants have nonfunctional nasolacrimal ducts for 1 to 5 days. Swelling is common at the inner canthal region, but infection (dacryocystitis) is rare. In more than 80% of cases, the ducts open spontaneously by age 3 months.

### Neck

The neck of the newborn always seems short. A very short, webbed neck may be associated with Klippel-Feil or Turner syndrome. The neck is palpated for cysts or masses. A thyroglossal duct cyst is usually palpable in the midline and retracts with tongue protrusion. The infant may have congenital muscular torticollis with or without a fibrous

mass in the sternocleidomastoid muscle, associated with head tilt. A cystic hygroma is a spongy mass that may increase with increased intrathoracic pressure and may transilluminate. Hemangiomas are similar to hygromas to palpation but are commonly associated with skin discoloration. Branchial cleft cysts may have associated fistulas. They are palpable anterior to the sternocleidomastoid and may retract with swallowing. Thyroid masses are usually visible and are easily palpable with the head extended.

### **Chest and Lungs**

The circumference of the chest of the newborn is roughly equivalent to that of the head. Continued inspection of the chest may show a protruding xiphisternum (pectus carinatum), which is usually a normal variant. In contrast, a pectus excavatum deformity may be present at birth or may be associated with prolonged low-compliance respiration. While the infant is breathing, nasal flaring may be present along with retractions and “grunting,” which is partial glottic closure during the first part of expiration. Suprasternal retractions and gasping, as opposed to substernal retractions, may indicate upper airway obstruction; in an infant with this finding, laryngoscopy should be performed rapidly. Almost any cardiopulmonary disease in the newborn period reduces lung compliance and is associated with subcostal retractions. The appearance of flaring, grunting, tachypnea, and retractions is called respiratory distress. Respiratory distress may be associated with pneumonia, delayed resorption of lung fluid, respiratory distress syndrome, or any number of cardiorespiratory problems.

Asymmetry of the chest may indicate fetal obstructive cardiac anomalies, a tension pneumothorax, or other forms of air trapping or mass lesions.

The nipples and underlying breast tissue are usually 1 cm in diameter in term infants, both boys and girls, and may be asymmetric. Under maternal hormonal influence, the breast bud may become as large as 3 to 4 cm in diameter and may excrete a watery whitish fluid for a few days or weeks (“witch’s” milk). The enlargement occurs in both sexes and is usually symmetric. Redness or asymmetry indicates probable infection, which requires the administration of antibiotics. Widely spaced nipples and accessory nipples should be noted.

Single-finger percussion can be useful for detection of consolidated pneumonias or pleural effusions. Suspicion of clinically significant pneumothorax should lead to instant confirmatory checks of blood pressure, transillumination, and chest radiographs. Transillumination is carried out with high-energy fiberoptic transillumination devices in a darkened room. Some practice is necessary before the examiner can clearly distinguish the normal from excessive coronas of pink transillumination around the closely applied light source.

Auscultation of the lungs is best carried out with a cleaned and warmed stethoscope bell. Rhonchi can be inspiratory or expiratory. Inspiratory stridor implies large-airway obstruction, and expiratory prolongation indicates small-airway obstruction. Rales are moist crackling sounds emulated by licking a thumb and forefinger and separating them close to one’s ear. The burst of fine crackles on

separation of the thumb and forefinger is of the same quality and intensity as rales in the newborn. Gurgling and bubbling sounds come from secretions in large airways and often indicate the need for tracheal suctioning. Harsher bubbling sounds may be from water accumulating in the tubing of a ventilator. Listening alternately in the right and left axillas may indicate diminished breath sounds on one side. These asymmetries may indicate unilateral pneumothorax or that an endotracheal tube has inadvertently advanced into the right main bronchus. Rarely, bowel sounds may be heard high in the chest in the absence of breath sounds. If so, diaphragmatic hernia is possible, and emergency radiologic examination and surgical consultation are necessary. Meanwhile, a nasogastric tube should be inserted to prevent distention of the stomach and bowel within the chest cavity.

### **Heart and Vascular System**

The most common cardiac conditions in the newborn period are perinatal adaptations involving the ductus arteriosus (see Chapter 56), with right-to-left shunting through the ductus arteriosus of term infants with persistent pulmonary hypertension and left-to-right shunting through the ductus arteriosus of premature infants. Significant structural heart anomalies are diagnosed in the first week of life in about 1% of live-born children. The most common serious anomalies recognized in the first week of life are ventricular septal defects, patent ductus arteriosus, transpositions, hypoplastic left heart syndromes, tetralogy of Fallot, and coarctations.

The most common findings for an infant with heart disease in the newborn period are tachypnea, cyanosis, or both with an increased O<sub>2</sub> requirement. These findings are observed in the most common pathophysiologic conditions associated with congenital heart disease—low cardiac output, congestive heart failure from left-to-right shunts, obstruction to outflow, and insufficient pulmonary blood flow. The general appearance can often signal a cardiac problem, for example, the shocky underperfused infant on the third day of life with a hypoplastic left ventricle versus the contented cyanotic infant in no distress with transposition of the great vessels. Other aspects of heart disease detectable on general inspection are markedly increased precordial activity, hypertrophy of the left chest, and, rarely, venous engorgement (e.g., in an infant with thrombosis of a central venous line leading to a vena cava syndrome).

### **Auscultation**

The clinician should listen for cardiovascular problems first in “noncardiac” areas, such as the axilla (peripheral pulmonic stenosis), the neck (aortic obstruction), and the head and liver (arteriovenous malformations). Timing of the onset of murmurs is important. Frequently, murmurs that depend on pulmonary vascular tone (e.g., left-to-right shunt through a patent ductus arteriosus) may not be heard until pulmonary vascular resistance has decreased in the second to third day of life in an infant with respiratory distress syndrome or within 12 hours of birth in a normal full-term infant. The murmur of tricuspid insufficiency

associated with a dilated heart after severe perinatal asphyxia may be present only in the first hours of life. Obstructive murmurs characteristically are heard from birth unless low cardiac output is present. Other characteristics that are important to note are the site where the murmur is heard best, the timing of the murmur with regard to systole and diastole, the quality, and the loudness. The murmurs that are of low intensity, that occur near the sternum or only in noncardiac areas, and that occur early in systole are often innocent.

A detailed history and physical examination, including four-extremity blood pressures, a chest radiograph, blood gas analysis, pre- and post-ductal oxygen saturation, and electrocardiogram, and ultrasonography, are usually sufficient to clarify whether congenital heart disease is present. Neonatologists and pediatricians who commonly care for newborns should be able to evaluate the heart using chest radiography, electrocardiography, and auscultation.

Irregularities in heart rhythm may also be auscultated. Sinus arrhythmia sounds like a periodic slowing and then speeding up of the heart rate, whereas premature atrial and ventricular contractions make the heart rhythm sound very irregular.

#### CASE STUDY 1

Baby B was transferred to the NICU at 6 hours of age because of tachypnea. The history of pregnancy and delivery was unremarkable. Physical examination showed the patient to be a well-formed, full-term infant breathing at a rate of 78 breaths/min. Lungs had occasional rales. The heart rate was 180 beats/min. A gallop rhythm was heard, but no murmurs. The liver was palpable 4 cm below the costal margin and was thought to be enlarged. The physical findings suggested heart failure, which was confirmed by a chest radiograph that showed an enlarged heart and pulmonary congestion. Arterial blood gas analysis on a specimen collected while the baby was receiving 30% oxygen showed a PaO<sub>2</sub> of 68, a PCO<sub>2</sub> of 48, and a pH of 7.2 with a base deficit. An electrocardiogram indicated a modest reduction of voltage in all leads. Ultrasonography of the heart showed that the organ was large with poor contractility. A number of diagnoses were considered including various cardiomyopathies, pericardial effusion, and anomalous pulmonary venous drainage with obstruction. The infant underwent cardiac catheterization, by which a large and inoperable arteriovenous malformation of the brain was diagnosed after injection of dye for cardiac angiography. After the infant returned to the unit, a large bruit was easily heard with the stethoscope applied to the anterior fontanelle or to the skull lateral to the eyes.

This case serves as a reminder that heart failure may occur from arteriovenous fistulas anywhere in the body.

#### Abdomen

The abdomen is assessed by inspection and palpation for organomegaly, masses, inflammation, and distention. Unusual flatness or a scaphoid shape to the abdomen may be associated with congenital diaphragmatic hernia. Examination by inspection, palpation, auscultation, transillumination, and ultrasonography can usually discriminate between air within or outside the gastrointestinal tract and enlarged viscus or viscera, and a cystic or solid

tumor. Normally, the examiner palpates a 1- to 2-cm liver edge below the right costal margin, a spleen tip overlying the stomach, and the lower pole of the left kidney in the pelvic gutter (Fig. 25-7). The examiner also looks for dilated veins on the abdominal wall indicating venous distention. Visible gastric or bowel patterns may be considered a certain sign of ileus or other obstruction. The umbilical stump should be examined for bleeding, abnormal vessels, increased or decreased Wharton jelly, meconium staining, polyps, granuloma, exudative discharge, or other evidence of inflammation (redness, tenderness, edema of abdominal wall, induration) or abnormal communication with intra-abdominal viscera. Omphaloceles and gastroschisis are readily apparent, but small umbilical hernias and diastasis recti abdominis may be less so.

Abdominal masses occur in approximately 1 of 1000 live births (Table 25-11). Evaluation is carried out by history, physical examination, ultrasonography, and radiography. Some masses are transitory and of little significance (e.g., intraluminal stool, gaseous dilation of the stomach or colon, distended bladder, or large but normal kidneys) (Table 25-12).

#### Genital System

Maturation of the genitalia is apparent over the last 3 months of gestation, and the changes serve as one index on the scoring of physical attributes for gestational age

**FIGURE 25-7.** Abdominal palpation is carried out using counter-pressure in the flank with one hand. The lower pole of each kidney is usually palpable with this technique in the first days of life, before abdominal muscle tone increases. Note the bilateral clubfoot.

TABLE 25-11

**Most Common Congenital Abdominal Masses**

Renal (55% of total abdominal masses)	Hydronephrosis Multicystic or polycystic kidneys Renal malformations Renal vein thrombosis Renal neoplasms
Genital (15%)	Hydrometrocolpos Ovarian cyst
Gastrointestinal (15%)	Obstructions Cysts or tumors Duplications
Liver and biliary (5%)	Cysts Tumors
Retroperitoneal (5%)	Solid tumors Anterior meningocele
Adrenal (5%)	Hemorrhage Neuroblastoma

Data from Griscam NT: The roentgenology of neonatal abdominal masses. *AJR AM J Roentgenol* 93:447, 1965, and Kirks D, Marten DE, Grossman H, Bowie JD: Diagnostic imaging of pediatric abdominal masses: An overview. *Radiol Clin North Am* 19:527, 1981.

TABLE 25-12

**Common Findings in the Neonate that are of Little Clinical Significance\***

Head	Caput succedaneum, cephalohematoma, asymmetries, bony protrusions, molding
Ears	Skin tags
Eyes	Position (close-set), conjunctival hemorrhage
Nose	Asymmetric nares
Mouth	Ranula, sucking calluses, epulis, frenulum, natal teeth, Epstein pearls
Face	Unusual features not consistent with known syndromes
Skin	Sparse petechiae on the head, erythema toxicum, mongolian spot, nevus flammeus, telangiectasia, nevi, inclusion cysts, bruises, prominent lanugo or vernix, milia, miliaria, dark pigmentation over genital skin, mild jaundice after 2nd day, peeling of skin, skin tags, sacrococcygeal dimple
Neck	Relative absence
Chest	Nipple spacing, extra nipples, breast hypertrophy, witch's milk
Umbilicus	Erythema or umbilicus cutis
Abdomen	Evanescent masses
Heart	Evanescent murmurs and adventitious sounds
Genitalia	Mild hypospadias, prominent labia, mucous secretion, transient vaginal blood, phimosis
Extremities	Extra digits, syndactyly, hips tight to abduction, neck in extension after breech delivery
Neurologic system	Transient tone asymmetries or abnormality, jitters, sudden jerky movements

\*Some of the items on this list may be associated with significant disease (e.g., jitteriness may be associated with metabolic problems or drug withdrawal). However, when findings on this list are mild and transient, they are most commonly not associated with significant disease. If the significance of a finding is in doubt, it is prudent to ask for another opinion and to follow up.

assignment. The spectrum of differences that nonetheless fall within the normal range are surprising. For a discussion of ambiguous genitalia, see Chapter 91.

Penile length and clitoral size are assessed. A clear white mucus is often present in the vagina of term infants for the first few days as a result of estrogens from the mother. The location of the urethral meatus and the presence or absence of palpable gonads are noted, and inguinal hernias are sought. Most "congenital" hernias are apparent only after a month or two, and these are most common in premature infants. The anus should be checked for patency and distance from the genitalia. The perineum should be checked for palpable masses. Rarely, with variants of imperforate anus with fistula, stool exudes from the vagina.

**Musculoskeletal System**

The musculoskeletal system is assessed by observation and palpation for obvious trauma, inflammation, and malformation. The most common alterations in the musculoskeletal system are deformations caused by adverse mechanical forces in utero. Oligohydramnios that limits fetal movement and neuromuscular problems of the fetus can both be associated with multiple contractures known as *arthrogryposis*. Most positional deformities are mild and resolve with time. The hips deserve special attention because the physical examination is the only method of detecting hip problems before permanent damage has occurred by 1 year of age or so. Examination of the hips should be undertaken repeatedly in the first year of life, because a dislocation may not be demonstrable for several months after birth (Place et al, 1978).

Developmental dysplasia of the hip (DDH) occurs in about 1 of 800 live births, more commonly in white infants and girls. During pregnancy, circulating maternal hormones may contribute to joint capsule laxity, particularly in the female fetus. The condition represents a spectrum of conditions from the dislocatable hip found in approximately 5 of 100 live births to the fixed dislocation that may occur in the second trimester in association with some forms of arthrogryposis. It is found more commonly in infants delivered in breech position and in those with a positive family history for DDH. In utero conditions that limit hip movement as well as specific syndromes and chromosome disorders may be associated with hip dislocation. Such dislocation is often unilateral, occurring more commonly in the left hip for reasons that are unclear.

There are two major tests (with a number of variations) for determining whether the femoral head is fixed in the acetabulum (Fig. 25-8). The Barlow test determines whether the femoral head can be dislocated posteriorly. As the knees are brought together (adducted) or held in midabduction, the examiner pushes laterally on the upper inner thigh (lesser trochanter). A click or clunk indicates that the femoral head is slipping over the lateral ridge of the acetabulum during this maneuver. With the fingers on the greater trochanter, the examiner can alternately push the hip into and out of the acetabulum by alternating pressure with the thumb and the fingers. The Ortolani test is carried out by abducting the flexed hips while pushing upward on the posterior proximal femur. The hips are

A

B

C

**FIGURE 25-8.** **A**, The hips are checked with the Ortolani maneuver. The examiner's second and third fingers press up against the heads of the femurs, and the hands press the shafts of the femurs toward the mattress while simultaneously abducting the hips. A palpable clunk during this maneuver indicates that the femoral head has slipped over the lip of the acetabulum and is dislocatable. **B**, Full abduction. **C**, For the Barlow maneuver, the examiner stabilizes the pelvis with the left hand and attempts to move the shaft of the femur upward and downward without flexing the hip. This maneuver checks whether the femoral head can be displaced posteriorly out of the acetabulum; instability of the femoral head is palpable during this maneuver in infants with congenitally dislocated hips (see Chapter 94).

adducted and flexed to 90 degrees; downward pressure is exerted on the knee while the hips are simultaneously abducted. A positive result consists of a click or clunk as the laterally dislocated femoral head is pushed over the acetabular ridge into the acetabulum. A modification of the Barlow test is to move the thigh anteriorly and posteriorly while holding the midthigh firmly with one hand and stabilizing the pelvis with the other. With this maneuver, the femoral head can alternately be dislocated and relocated, and in our experience, this test has been successful when the Ortolani maneuver has not (see Fig. 25-8).

Fixed dislocations that occurred early in fetal life often cannot be detected by the tests described because the femoral head is locked outside of the acetabulum as a result of joint capsule contractures. The diagnosis is made from palpation of the femoral head in a posterior location and by detecting limitation of hip mobility, in association with other problems, such as spina bifida and arthrogryposis. The sine qua non for diagnosis of DDH is real-time ultrasonography (Aronsson, 1994). (For a fuller discussion of DDH, including a discussion of Galeazzi and Klisic signs, see Morrissy, 1990.)

The four extremities should be checked for fractures, and the joints for hypermobility and hypomobility. A hypotonic arm or wrist drop implies brachial palsy on the affected side. The digits should be examined for polydactylism, syndactylism, edema, unusual skin ridge whorls

and creases, nail growth, and unusual digit placement or contractures. Amputations or other evidence of amniotic bands may be present.

A variety of malformations of the lower extremities is common. Genu recurvatum is characterized by abnormal hyperextensibility of the knee joint. This condition affects females significantly more commonly than males. Genu recurvatum is associated with the breech position. The disorder may also be a feature of a number of disorders, such as the Ehlers-Danlos, Marfan, Klinefelter, and Turner syndromes, but it usually occurs as an in utero deformation not associated with other conditions. The extended leg or legs describe a concave arc when hyperextended at the knee. Hyperextensibility is mild or severe; that is, the arc is shallow or deep. In severe cases, there may be actual posterior dislocation of the knee. Nothing need be done for cases of mild or moderate severity. Posterior splinting or, rarely, casting for 2 to 4 weeks is indicated for the most severe forms.

Pes calcaneovalgus is the absolutely flat and sometimes slightly convex foot that often lies at rest dorsiflexed at an acute angle to the foreleg. When gentle pressure is applied to the sole of the foot, dorsiflexion increases easily until its dorsal surface lies in contact with the shin. Such feet should be casted in the equinovarus position for 4 to 6 weeks, and this therapy should be repeated several times if necessary. Continued treatment may be needed for several years.

In pes metatarsovarus, the heel and posterior half of the foot appear normal, but the forefoot angulates sharply inward. Thus, the outer border of the foot is convex, whereas its inner border is concave. If the foot can be straightened by gentle traction, with the examiner's thumb held firmly over the apex of the convexity, no immediate treatment is needed. If, however, the angulation is difficult or impossible to overcome, casting is probably indicated. Later use of corrective shoes may or may not be necessary.

Pes equinovarus is the classic clubfoot with sharp and tight hyperextension and in-curving of the entire foot. It is often a solitary defect, but not infrequently, it is associated with congenital dislocation of the hip, myelomeningocele, arthrogryposis, or other defects. It requires immediate and long-term orthopedic care. Most cases can be corrected by casting and subsequent shoe corrections. A few cases require open operation.

### Neurologic System

The neurologic examination is discussed in detail in Chapter 61. For most infants, the aim is to find whether a neurologic problem exists (Table 25-13); if so, the examination can be expanded to fully describe the findings. For a paralyzed 800-g infant undergoing mechanical ventilation, a complete neurologic examination is impossible. Nonetheless, neurologic assessment should not be deferred altogether. For example, attention to head size, shape, and possible abnormality, fontanelle size and pressure, pupil size and equality, lability of blood gases and blood pressure, variability of heart rate, and limb muscle mass are all available information about an infant's central nervous system status.

The quality and quantity of spontaneous movements are the best indicators of neuromuscular function and are assessed by inspection. Decreased tone may be one of the first detectable abnormalities in a full-term infant with sepsis. Tone is gestation and illness dependent, with smaller and sick infants having decreased tones. Tone may also vary in different muscle groups. The examiner checks the range of passive rotation of the neck by turning the infants' head

to the left and right. He or she assesses flexor tone in the neck and arms by pulling the infant to a sitting position (Fig. 25-9), and extensor tone in the neck by holding the infant prone. Shoulder tone is assessed by an examiner either holding the infant in a vertical sling, that is, under the axillas, or performing the scarf maneuver (Fig. 25-10). Tone in the lower extremities is checked by the hip examination and with the heel-to-ear maneuver.

An array of primitive reflexes is present in the term newborn infant, but its expression is highly dependent on state—the most optimal being an awake alert state. Premature infants have diminished responses with decreasing gestational age, although this belief may be confounded by the growing frequency of illness with decreasing gestation and by the fact that sick infants respond poorly to elicitation of these reflexes. The Moro and tonic neck reflexes disappear by 6 months of age, but others (e.g., the parachute and Landau reflexes) make their appearance as these wane.

The most obvious primitive reflex of the newborn is the Moro. The infant can be supported behind the upper back by the examiner's hand, then dropped back 1 cm or so to the mattress. The arms are flung open followed by a flexion and an adduction (i.e., an "embrace"). The eyes open, as if in surprise, and the baby commonly emits a lusty cry, making this reflex a good stopping point for the examination. The examiner can elicit the grasp reflex in both hands and feet by placing a thumb on the infant's palm. With palmar pressure, the infant may open the mouth and yawn (palmar-mental reflex). When the examiner stimulates the dorsum of the foot, the infant lifts the stimulated foot and places it on a surface (placing). When the examiner allows the plantar surface of the other foot to contact a table top, the infant makes crude sequential walking movements (stepping). To obtain the tonic neck reflex, the examiner rotates the infant's head to the right or left while keeping the supine infant's shoulders flat.

**TABLE 25-13**

#### Outline of Neurologic Screening Examination

Appearance
Behavior, state, cry, abnormal movements
Visual responses
Hearing responses
Head size and shape
Active and passive tone of major muscle groups:
Neck shoulders and upper extremities (pull to sit—traction response, vertical sling)
Trunk (horizontal suspension)
Lower extremities
Cranial nerves
Primitive neonatal reflexes (grasp, root, suck, Moro, withdrawal, tonic neck)
Deep tendon reflexes

**FIGURE 25-9.** Tone of the neck flexors is assessed by pulling the infant off the mattress by both hands. In this infant, marked head lag is present.

**FIGURE 25-10.** The infant is held in a vertical sling. Muscle tone of the shoulder girdle is assessed with this maneuver. Extensor tone of the neck is checked. The infant may “follow” the face of the examiner. In older infants, “scissoring” of the lower extremities is suggestive of increased tone. With the infant held in this position while the examiner turns in a circle, oculovestibular nystagmus can be assessed.

The arm and leg to the side of the occiput flex, and the other arm and leg extend (fencer's stance). When the infant is supported prone by the examiner's hand, tickling the area of the lateral spine causes the buttocks to swing to the side of stimulation (trunk incurvation reflex). Holding the infant in the same position and running a finger from the base of the spine toward the neck elicits spinal extension and, with a full bladder, micturition. Light pressure applied with the examiner's fingers to the soles of the feet causes the legs to extend (magnet reflex). Extending one of the infant's legs while the infant is supine and stimulating the plantar surface of the same foot causes the contralateral leg to flex, adduct, and extend (crossed extension reflex).

The examiner can best assess the infant's deep tendon reflexes by tapping with an index finger.

Other physical findings of clinical significance are listed in Table 25-14. Table 25-15 summarizes the various

evaluations and issues for a “typical” high-risk premature infant during hospitalization.

## ULTRASONOGRAPHY

Whenever a problem is defined that consists of anomalies or involves the head, heart, abdomen, or kidneys, the physician should conduct a screening ultrasonographic examination. Although the physician of newborns may not be an expert in imaging techniques, he or she should be capable of performing a screening examination in the same way that one carries out auscultation of the heart even if one is not a cardiologist. Obstetricians subspecializing in perinatology have surpassed neonatologists in their proficiency with ultrasonography screening. Using a 5-MHz sector scanner, the examiner can gain useful information by manipulating only gain and depth controls (Walther and Leighton, 1996).

### Head

The head is examined in the coronal and parasagittal planes through the anterior fontanelle. Ventricular size and the presence or absence of paraventricular and intraventricular blood are noted. Severe ventricular enlargement can be appreciated even by the relatively untrained examiner.

### Heart

The examiner should be able to identify all four chambers of the heart by aiming the probe, held in a transverse plane, cephalad from the substernal area. The atria are smaller than the ventricles and are symmetrical. At birth, the ventricles appear to be of equal size. Good contractility can be appreciated. Pericardial fluid may be signified by the presence of an echo-free area around

**TABLE 25-14**

#### Common Physical Findings that are of Clinical Significance in the Neonate

Apnea
Tachypnea
Grunting
Bradycardia
Cyanosis
Hypotonia
Decreased breath sounds
Heart murmurs
Organomegaly
Evident anomalies other than of ears and digits
Jaundice
Plethora or pallor
Diffuse petechiae

TABLE 25-15

**Changing Issues During Hospitalization of a “Typical” High-Risk Premature Infant**

Evaluation Initial	Pertinent Issues Major malformations Severe cardiopulmonary conditions Viability Postasphyxial complications Hypotension Intrauterine growth and length of gestation Meeting with parents
Midweek	Patent ductus arteriosus Intraventricular hemorrhage Pneumothoraces and air leaks Jaundice Culture reports Meeting with parents
First week	Metabolic Renal Gastrointestinal (necrotizing enterocolitis) Intraventricular hemorrhage Meeting with parents
First month	Chronic lung disease Cystic periventricular lesions or ventricular enlargement Retinopathy Nutritional status Nosocomial infection Meeting with parents
Second and third months	Parental issues Anemia Feeding Hydrocephalus Growth Chronic central nervous system disability Apnea
Before discharge	Meeting with parents Special (e.g., home oxygen) Primary care vs. special medical follow-up planning Other support services Review of hospital course and global follow-up plans

the heart that is surrounded by the echo-dense pericardium.

### Renal System

The paravertebral areas and the locale of the bladder are examined. Size, shape, and presence of large cysts or dilated collection systems are noted. The bladder can be visualized if filled with urine.

### LABORATORY SCREENING

At the time of the initial history and physical examination, the infant should be screened for a number of conditions, the precise nature of which depend on the characteristics

of the population being served. For example, in an inner-city population, we tend to screen particularly for the conditions described in the following sections.

**Hematocrit, Rh, Blood Type, and Direct Antiglobulin Test (DAT, Direct Coombs’ Test).** We collect heelstick blood specimens from all live-born infants. In our inner-city population, in which there is a greater risk of poor placentation and less than optimal use of prenatal care, we find about a 4% risk of clinical polycythemia (one venous hematocrit value >65% in an infant with symptoms or >70% in an infant without symptoms).

**Hearing Screening.** Only 50% of infants with significant hearing loss have identifiable risk factors. Fifty percent of hearing loss in newborns is genetic, with over half of cases being autosomal recessive traits. Nongenetic causes of hearing loss include fetal infection, teratogens, maternal disease, and perinatal events such as asphyxia, hyperbilirubinemia, and meningitis. Behavioral testing of hearing is crude in the newborn. Therefore, we follow the American Academy of Pediatrics (AAP) recommendation to screen all newborns with automated auditory brainstem response (ABR), a technique using three scalp electrodes that record brain waves and wave-form responses to auditory stimulation, thereby providing information on pathways from the outer ear to the cortex. Sensitivity is 100%, and specificity is 96%. Depending on the cause and extent of hearing loss, language acquisition may be improved by fitting a newborn with a hearing aid as early as 1 to 3 months. (Eilers and Oller, 1994; Joint Committee on Infant Hearing, 1995; Kuhl, 1993; J Stewart, Codirector, Newborn Hearing Screening Program, Beth Israel Deaconess Medical Center, Boston: Personal communication, 1997).

**Syphilis.** Standard immunologic tests for syphilis are a routine part of prenatal care in the United States. Because it is possible for exposure to *Treponema pallidum* to occur between the first trimester and delivery, mothers or infants in high-risk populations should be screened at delivery as well.

**Human Immunodeficiency Virus.** We offer testing for the human immunodeficiency virus (HIV) antibody to the newborn of any mother who has not been tested for HIV during pregnancy. Risk varies widely in different geographic areas.

**Hepatitis B.** We screen all mothers for hepatitis B, giving greater attention to those at special risk—for example, women who are involved in prostitution, who are from high-risk areas (Asia, Africa, Pacific islands, and inner cities of the United States), who have occupational exposure to blood products, who have been rejected for blood donation, who have received multiple frequent blood transfusions, who use intravenous drugs, who have had no prenatal care, and who have a history of liver disease or live with family members who have liver disease or are undergoing dialysis. Current risk estimates for infants born in Los Angeles are approximately 3 per 1000 live births (hepatitis data courtesy of L. Mascola, Los Angeles Department of Health Services). We administer hepatitis vaccine to all

newborns according to current AAP recommendations. If the mother is hepatitis B positive, then hepatitis immune globulin is administered in addition to the vaccine.

**Drug Abuse.** Toxicology screening tests are performed on the urine of newborns whose mothers have a history of illicit drug use or who received little prenatal care, and (for our inner-city population) all infants admitted to the NICU. The screen used in our hospital identifies metabolites of amphetamines, phencyclidine (angel dust), opiates, and cocaine. It does not identify alcohol or cannabis. Approximately 12% of inner-city infants admitted to NICUs test positive for illicit drugs (see Chapter 12).

**Tuberculosis.** Mothers in groups at high risk for tuberculosis should undergo skin testing near delivery, and those who have positive results should be followed up with a chest radiograph and a careful history to look for active tuberculosis which requires treatment.

**Metabolic Diseases.** All states screen newborns for phenylketonuria and hypothyroidism (although different screening tools are used for hypothyroidism). Most states screen for galactosemia and hemoglobinopathies (such as sickle cell disease). Less than half the states screen for branched-chain amino acidemia, biotinidase deficiency, congenital adrenal hyperplasia, and homocystinuria. Only a few states currently screen for cystic fibrosis and toxoplasmosis (Stoddard and Farrell, 1997).

## WELL-BABY CARE

The principles of routine care for normal infants are screening for disease, prophylaxis for common problems (eye care and vitamin K<sub>1</sub> oxide), parent education when needed about infant care, and anticipatory guidance. These are discussed in the next chapter. The initial and discharge histories and examinations are truncated versions of complete procedures.

A welcome current trend “demedicalizes” routine delivery and postpartum care. This concept means delivery in a “homey” rather than operating room setting. More choices are offered to the parents concerning issues of childbirth, such as anesthesia and route and timing of delivery. The infant and mother are kept together as much as possible after birth. Fathers are often present during delivery, and liberal visiting policies that allow children to see their mother and new sibling are encouraged. Both before and after birth, nonmedically oriented classes are offered for discussing problems of both the mother and the infant. Forces in favor of these trends come from parents and (with regard to shorter hospital stays) financial considerations. Forces against these trends stem from administrative difficulties in handling the desires of parents and concerns about cross-infection.

How long should a mother and newborn stay in the hospital after delivery? Nobody knows. Since the last edition of this book, managed care has, to a growing extent, replaced fee for service as a medical reimbursement scheme in the United States. This change has provided a new impetus to find ways of reducing medical costs. Discharging mothers and newborn infants sooner after delivery is believed to be one way of achieving this goal. In California, the current norm is a hospital stay of 48 hours

for a mother and infant after a vaginal delivery, and 4 days after a cesarean section. Although the benefit for cost savings in the short term appears obvious, it is not known whether this practice carries significant increased risk, especially for inner-city women and their infants (Braveman et al, 1995). Lee and associates (1995) found that readmission rates for infants nearly doubled after the duration of hospital stay after delivery was halved. Readmissions were largely for jaundice and poor milk intake.

Table 25–16 lists questions for which answers are needed before discharge of the mother and infant. The length of the list illustrates the difficulties presented by discharge of the mother within 24 hours of delivery.

In the delivery rooms of most U.S. hospitals, every newborn's eyes are instilled with erythromycin or 1% silver nitrate drops from single-use containers for prophylaxis of gonococcal eye infection. Vitamin K<sub>1</sub>, 0.5 to 1.0 mg, is given intramuscularly to prevent hemorrhagic disease of the newborn. The infant is then bathed with a nonmedicated mild soap. No antiseptic is routinely applied to the umbilical cord stump.

**TABLE 25-16**

### Pre-Discharge Screening Questions for Newborns

1. Is the infant at least 35 weeks of gestation at time of discharge?
2. Is the infant feeding well? If the mother is breastfeeding, does she know how to get support or where to call if she is having problems?
3. Has the infant been voiding and stooling appropriately?
4. Has the infant been able to maintain normal body temperature in a regular crib?
5. Does the infant have any significant anomalies or medical problems that need further investigation and/or follow-up and have the appropriate visits been scheduled?
6. Is the infant at risk for hyperbilirubinemia and has appropriate follow-up been arranged?
7. Has it been at least 5 days since the last episode of apnea that required stimulation?
8. Do parents want the infant to be circumcised prior to discharge?
9. Do the parents have a medical home for the baby?
10. Does the family have health insurance for the infant or does it need help with this issue?
11. Has the mother recovered from her childbirth experience well enough to adequately care for her infant? Does she have help or support at home?
12. Is the family able to contend with minor problems that may arise soon after discharge?
13. Is the family aware of the customary newborn prophylaxis and screening that their infant has received (e.g., eye prophylaxis, Vitamin K, state screening for metabolic errors, hearing screening, hepatitis B immunization)?
14. Have the parents received anticipatory guidance and instruction with regard to feeding problems, jaundice, signs of infection, use of infant car seats, immunizations, well-baby visits, sleeping position on the back to reduce sudden infant death syndrome (SIDS)?
15. Is the initial maternal-infant interaction appropriate?
16. Have the parents had an opportunity to discuss questions and concerns with hospital caregivers?

## DISCHARGE PLANNING

Discharge of a premature infant from the intermediate care unit can take place when the parents have made adequate preparations (actual and psychological) for the care of the infant. Meeting this need may take weeks of preparation on the part of the staff and may include arranging in-home support and equipment, teaching feeding and medication techniques, and providing anticipatory guidance. Other criteria for discharge are adequate feeding and weight gain and physiologic stability (e.g., absence of apnea and steady body temperature).

Detailed recording of the major events of the infant's stay—diagnoses, results of meetings with parents and case conferences, most recent evaluations, medications, and future needs—all should be summarized, and the information disseminated appropriately. Most importantly, the primary physician should know the parents and the infant well by the time of discharge, so that trust and confidence exist on both sides.

## Discharge Summary

An array of computerized data collection systems is available that should soon permit vastly improved transfer of information, freeing physicians from the tyranny of the handwritten medical record. We currently use a custom-programmed computerized database for data entry and retrieval, which deals with daily hospital notes for a hospital delivery service of 1700 inner-city births per year, including well babies, intermediate care babies, and babies requiring intensive care.

## FOLLOW-UP CARE

A variety of support groups is available for parents of infants with special problems. Pediatric follow-up care for normal infants is detailed in the *Guidelines for Health Supervision* published by the American Academy of Pediatrics and available in standard pediatric texts (Avery and First, 1989). California has also published detailed infant and child health assessment guidelines (Children's Medical Services, 1997). Follow-up care of high-risk infants is described in detail by Ballard (1988) and by Tausch and Yogman (1987). Current changes in immunization recommendations can be ascertained through the Centers for Disease Control and the latest Academy of Pediatrics listing.

## Routine Newborn Care

Carol A. Miller and Thomas B. Newman

The normal newborn nursery has a unique position within the hospital. It is probably the only inpatient unit focused on the care of the relatively well patient. It is also a unit where care of the patient is intimately connected to care of the mother. The mother-newborn dyad should be treated as an integral unit, promoting bonding and developing the mother's expertise as her infant's caregiver. With this goal in mind, many units are designed for the rooming-in of mother and infant and encourage physicians and nurses to give routine care to newborns in those locations rather in the nursery, as was previously practiced (Kennell and Klaus, 1998; Klaus, 1998; Prodromidis et al, 1995). The mother then becomes an important observer of her infant's behavior and a relevant member of the infant's care team. Some practitioners may find practicing this way a challenge and a bit awkward but with time may come to prefer the chance to include the mother in their assessment and care of her baby.

The shortening of the length of hospital stay for both mothers and newborns was an additional change that raised concern regarding the ability to adequately follow the newborn's successful transition to the outside world (Boodman, 1995). Current average stays for the healthy newborn range from about 24 to 48 hours after a vaginal delivery and from 72 to 96 hours after cesarean section (National Center for Health Statistics, 1999). Reliable assessment tools that can help identify which infants might eventually require intervention for problems such as breast-feeding or hyperbilirubinemia and reasonable strategies for prevention are obvious areas for future research. Fortunately, despite these challenges, most healthy infants born at term or close to term proceed through transition smoothly, are stable at discharge, and continue to be so at home (Escobar et al, 2001).

Nevertheless, care of the normal newborn within the hospital setting remains an important aspect of pediatric care and requires expertise and training. Routine procedures should be re-evaluated continually for efficacy and efficiency. Uncomfortable interventions should be minimized, as should practices that disrupt the mother's close contact with her baby. Pediatricians and other care providers should keep abreast of new technologies that might enhance the ability to deliver high-quality care in the least intrusive manner possible.

This chapter focuses on current routine newborn care practices. The physical examination assessment as well as the delivery room care are covered in detail in Chapters 25 and 27. In areas of controversy, we attempt to explore all sides of the issues and present national consensus

when available. The reader is encouraged to view this material as we do—as a work in progress subject to change because of new research and experience.

### ROUTINE ASSESSMENT AND SCREENING TESTS

#### Initial Assessment, Vital Signs, and Monitoring

A major goal of the initial care of the newborn is to identify potentially serious problems at an early stage while taking pains to minimize any maneuvers that cause discomfort to the infant or require separation from the mother. The initial assessment is made in the delivery room (see Chapter 25), including review of the mother's history with particular attention to risk factors for infection (see Chapter 39), a cursory examination of the infant, and assignment of Apgar scores. The purpose of this first assessment is to determine whether there is any reason to take the infant to the nursery for medical attention rather than placing him or her "skin to skin" on the mother's chest, the preferred place for infants to begin life after birth (Kennell and Klaus, 1998; Sinusas and Gagliardi, 2001). Most infants with good Apgar scores should be able to stay skin-to-skin with their mothers for at least the first hour or so, and given the opportunity to find their way to the breast and begin nursing (Righard and Alade, 1990). This important time should not be disturbed without sound medical justification, because the early contact facilitates bonding between mother and infant. Randomized trials have shown that this initial close contact enhances the relationship between mother and infant (Anisfeld and Lipper, 1983) and may increase the likelihood of successful breast-feeding (Renfrew et al, 2000; Sinusas and Gagliardi, 2001). For these reasons, the routine procedures discussed here (e.g., eye prophylaxis, vitamin K administration) should be deferred until the baby has spent at least the first hour with the mother.

Although the infant should spend much of the first few hours with the mother, he or she should be assessed frequently. Many infants with significant illnesses have good Apgar scores and appear fine initially, only to deteriorate over the first 12 to 24 hours after birth. For this reason, the newborn's vital signs, tone, color, perfusion, and level of activity and consciousness should be monitored and recorded at least every 30 minutes until stable for 2 hours (American Academy of Pediatrics [AAP], 1997), and at least every 6 hours thereafter for the first 24 hours. Many normal infants have some initial respiratory distress soon after birth, which improves rapidly over the first 4 hours. Frequent assessments are necessary to determine whether the infant's status is deteriorating rather than showing the expected improvement.

The highest priority of the complete physical examination of the newborn infant is to identify abnormalities likely to have significant health consequences, particularly those for which early treatment has been demonstrated to improve outcome. However, another important reason for the physical examination is to anticipate and answer parents' questions. Performing the physical examination with the parents present facilitates this process. Many findings that do not require intervention but may be unfamiliar to

parents, such as subconjunctival hemorrhages, the Moro reflex, and Mongolian spots, can be demonstrated and named; see Chapter 25.

## Routine Laboratory Testing

### Glucose and Hematocrit

The performance of routine laboratory tests in the first several hours after birth is controversial. A spun hematocrit and a glucose measurement using a chemical strip on a heelstick blood specimen are routinely done at 2 to 4 hours of age in some hospitals. The rationale for screening is that both hypoglycemia and polycythemia can be asymptomatic, both are associated with increased risk of adverse neurologic outcome, and both can be treated—the former with supplemental glucose and the latter by partial-exchange transfusion, in which aliquots of the infant's blood are withdrawn and replaced with saline solution.

However, the Committee on the Fetus and Newborn of the AAP does not recommend routine screening of infants for these entities, because there is no evidence that identifying and treating asymptomatic infants with polycythemia or hypoglycemia improves their outcome (Committee on Fetus and Newborn, 1995). That is, although low plasma glucose levels can be raised with supplemental glucose and high blood counts can be reduced by partial-exchange transfusion, and although it makes sense that this approach might benefit the infant, there are no randomized trials showing that this is the case. Proponents of screening argue that our understanding of the body is sufficient to project that screening and intervention will be beneficial; opponents favor obtaining evidence of benefit before screening and intervention in asymptomatic people. One dilemma proponents of screening have is that in the absence of randomized trials, it is hard to know the level of asymptomatic laboratory abnormality at which treatment should be initiated. Thus different nurseries not only have different protocols for screening, they have different ranges for what constitutes the lower limit of normal and different protocols for treatment (Bonacruz et al, 1996; Koh and Vong, 1996). Given the lack of data on these tests, a wide range of clinical practices is acceptable, and parental preferences for more or less screening and intervention should be respected.

### Routine Metabolic Screens

Newborn metabolic screening for rare diseases like hypothyroidism and PKU is discussed in Chapter 27. Requirements for screening vary from state to state and over time. In general, there has been a trend toward screening for more diseases as new tests have become available. Unfortunately, in many cases the ability to diagnose metabolic diseases has preceded studies demonstrating the benefits of early intervention. Because of the low prevalence of the diseases being screened for, even with very specific tests most positive results will turn out to be falsely positive. Nonetheless, the incremental cost of testing for additional diseases is low and early results with a

new technique called tandem mass spectrometry are promising, suggesting the ability to diagnose a wide range of metabolic disorders, with a retest rate of only about 1 in 1000 and a positive predictive value of about 10% (Wiley et al, 1999; Zytovicz et al, 2001).

In order to avoid unnecessarily alarming families with these falsely positive results, it may be helpful to explain to families at the time the test is being drawn that the testing is for very rare diseases, that there are occasional false-alarms and inadequate specimens, and that therefore they should not panic if they are asked to bring the infant back for a repeat test.

### Hearing Screening

The rationale for newborn hearing screening comes from evidence that early detection and intervention in hearing-impaired children lead to improved language development (Moeller, 2000; Yoshinaga-Itano et al, 1998) and that in the absence of screening many children with hearing loss are not identified until 2 or 3 years of age. Although the data relating early intervention to improved outcome are from observational studies, rather than experiments, the strength and consistency of the association, the biologic plausibility, and the lack of another equally plausible explanation suggest that the relationship is causal.

The development of objective physiologic measures of hearing in newborns has made universal newborn hearing screening possible. Two technologies commonly used are measurements of otoacoustic emissions (OAE) and auditory brainstem responses (ABR). OAEs are *sounds* generated by the outer hair cells of the cochlea that can be measured by sensitive microphones. OAEs are not necessary for hearing, but are an indirect measure of the integrity of the cochlea (Folsom and Diefendorf, 1999). Measurements of OAEs will be abnormal in the face of conductive hearing loss due to obstruction of the external auditory canal or due to middle ear disease. Conversely, because OAEs only measure cochlear function, they will be normal in infants with neural but not sensory hearing loss (Joint Committee on Infant Hearing, 2000). Measurement of ABRs involves averaging electroencephalographic responses to multiple clicks. By subtracting baseline brain wave activity from the signal just after the clicks, brainwaves related to hearing can be separated and displayed, including the cochlea, auditory nerve, and auditory brainstem pathways. Because the clicks used include mainly mid- to high frequencies (2000 to 8000 Hz), low frequency hearing loss and steeply downsloping high frequency hearing loss (i.e., severe hearing loss at 8000 Hz with normal hearing at 2000 Hz) can be missed.

Although there are likely to be benefits from early identification of infants with hearing loss, they do not come without costs. Because the prevalence of hearing loss in newborns is low—only about 1 per 1000—(Fortnum et al, 2001) and the tests have imperfect specificity, most infants that fail the hearing screens will subsequently be found to have normal hearing. If the referral rate is 4% (the upper limit of what is recommended) (Joint Committee on Infant Hearing, 2000), this means that only about 1 in 40 referred infants (2.5%) will actually have hearing loss. Opponents of

universal hearing screening suggest that we need data that the benefits of early detection of hearing loss in the true positives exceed the potential but largely unstudied adverse effects on the much more numerous false positives. These include expense (which may not be covered by third-party payers), parental anxiety, and possible adverse effects on the parent child relationship related to additional testing (Paradise, 1999).

Clinicians caring for newborns should take steps to minimize adverse effects in infants failing newborn hearing screening tests. The easiest step is simply repeating the test before discharge. Clemens and Davis (2001) reported that this reduced the number of referrals by 80%. For those still testing positive, the most important step is to provide accurate information to the parents. If the “refer” rate for the screening test used on the infant is known, a ball-park estimate for parents of the chance that their child truly has hearing loss is simply the prevalence of the disease (in this instance, 1 per 1000) divided by that referral rate. For example, a referral rate of 2% = 20 per 1000 means that the chance that a positive screen is truly positive is about 1 in 20.

Infants still failing the screen on retesting should receive confirmatory audiologic testing and medical evaluations before 3 months of age. Because the goal of screening is not only early identification but early treatment of affected infants, it is important that resources be available for further diagnosis and treatment of infants testing positive. If resources and expertise to provide these services at an affordable cost to families are not available, screening could do more harm than good.

## ROUTINE AND COMMON MEDICAL TREATMENTS

For any therapy given routinely to all infants, there must be compelling evidence that the benefits exceed the risks. Parents who question the need for these therapies should be supported for their interest in protecting their infant from unnecessary medical intervention, and treated with respect, not condescension or antagonism. Certainly the history of medicine provides ample justification for a skeptical attitude about conventionally accepted medical interventions. A collaborative approach to helping parents make informed decisions is likely to be more helpful than one that is overly directive or dogmatic. Such an approach requires clinicians caring for newborns to be familiar with the risks and benefits of common therapies, in order to help interested parents make informed decisions about providing or withholding them.

### Prevention of Ophthalmia Neonatorum and Conjunctivitis

Severe conjunctivitis in the newborn (“Ophthalmia neonatorum”) was a major cause of blindness until the prophylactic instillation of antibiotic eye drops or ointment to newborns became routine. It is now required by law in most states. The most severe cases leading to risk of blindness are due to *Neisseria gonorrhoea*, but other organisms, including *Chlamydia trachomatis*, *Hemophilus influenzae* and *Streptococcus pneumoniae* also cause con-

junctivitis in the first few months after birth (Krohn et al, 1993). Among patients with good prenatal care that has included cervical cultures for gonorrhea, the risk of gonococcal conjunctivitis is low. For this reason, some of these patients may question the need for prophylaxis, because of concerns about causing chemical conjunctivitis. However, Bell and colleagues (Bell et al, 1993) in a randomized trial of such low-risk infants, found that either 1% silver nitrate drops or 0.5% erythromycin ointment reduced the total risk of conjunctivitis (both infectious and noninfectious) compared with no treatment. Most of the cases in all 3 groups were mild, and all of the benefit was in the first two weeks. The rates of conjunctivitis were 15% with no treatment, 8% with silver nitrate ( $P = .03$ ), and 9% with erythromycin ( $P = .05$ ), for a risk difference favoring treatment of 6%-7% and the number needed to treat to prevent one case of conjunctivitis, about 15.

Isenberg et al (1995) performed a randomized trial in Kenya, comparing 2.5% povidone-iodine solution with 1% silver nitrate solution and 0.5% erythromycin ointment. They reported that povidone-iodine was less expensive and slightly more effective at preventing both infectious (risk difference 2%-4%) and noninfectious (risk difference about 4%) conjunctivitis in newborns. However, 2.5% povidone-iodine ophthalmic solution has not been approved by the U.S. Food and Drug Administration for this indication.

## Vitamin K

Vitamin K is routinely administered to newborns to prevent vitamin K deficiency bleeding (VKDB; Chapter 76). Vitamin K deficiency beyond the newborn period is usually associated with fat malabsorption, because intake is generally adequate from the diet and from synthesis of vitamin K by intestinal flora. Newborns are at risk of vitamin K deficiency, and hence of prolonged clotting times and hemorrhage, because vitamin K is poorly transferred across the placenta, is present only at low levels in breast milk, and because their intestines have not yet been sufficiently colonized to make vitamin K.

Vitamin K deficiency bleeding is divided into three categories: early (first 24 hours), classic (1 to 7 days), and late (>7 days). Early VKDB is most often associated with maternal use of anticoagulants or other drugs that interfere with vitamin K metabolism, and is not prevented by prophylactic vitamin K administration. Classic VKDB, most often from the skin, gastrointestinal tract, or circumcision site, was reported to occur in about 1% of unsupplemented infants (Lane et al, 1985) and can be prevented by either oral or parenteral Vitamin K (Zipursky, 1999). Late VKDB is much less common, occurring in only about 5-10 per 100,000 untreated infants (McNinch and Tripp, 1991; Schubiger et al, 1999), but is much more serious, with about half the cases presenting with CNS bleeding, leading to death or serious neurologic sequelae (Bor et al, 2000; Brousson, 1996).

Late VKDB is more effectively prevented by intramuscular (1 mg, about 95% effective) than by oral vitamin K (e.g., 1 mg per week; about 80% effective) (Cornellissen et al, 1997), partly because compliance with oral vitamin K is incomplete and because some children with undiagnosed liver disease will fail adequately to absorb the oral

vitamin K (Schubiger, 1999). Thus, the excess risk of late VKDB after oral vitamin K, compared with parenteral vitamin K is about 1-2/100,000.

A clear advantage of oral compared with intramuscular vitamin K is that it is not painful for the infant. A more controversial advantage is that it has not been associated with an increased risk of childhood cancer (particularly leukemia), as has intramuscular vitamin K. This association was initially suggested from two studies in Bristol, England, mostly of children born in the 1970s, which found the risk of childhood cancer was more than doubled among those that had received intramuscular vitamin K (Golding et al, 1992). Many subsequent studies in other populations have failed to confirm the association (Ekelund et al, 1993; Klebanoff et al, 1993; McKinney et al, 1998; von Kries et al, 1996), and childhood leukemia incidence did not increase in the years following intramuscular vitamin K (Miller, 1992; Olsen et al, 1994). Thus, an association of anywhere near the magnitude suggested by the initial studies from Bristol has been effectively ruled out. However, the issue has not entirely been put to rest because point estimates for the relative risk of leukemia in several studies, although not statistically significant, have been in the range of 1.2 to 1.3 (Ansell et al, 1996; McKinney et al, 1998; Parker et al, 1998; Passmore et al, 1998) and even a 10% increase in leukemia risk would be clinically relevant because leukemia is more than ten times as common than severe VKDB (Golding et al, 1992; Hey, 1999; von Kries, 1998). Because current studies have not had the power or consistency of results to rule out a small increase in risk of cancer following IM Vitamin K, vitamin K is given orally, rather than parenterally in some European countries. Unfortunately, there is currently (2001) no oral vitamin K preparation approved by the U.S. Food and Drug Administration for prophylactic use in newborns. When parents decline intramuscular vitamin K, the parenteral preparation (Aquamephyton) can be given orally. However, gagging and vomiting due to its bad taste are common, and it is not clear that oral use of the parenteral preparation is as effective as the oral preparations that have been studied in Europe. The American Academy of Pediatrics has recommended continuing to give vitamin K intramuscularly, while encouraging the licensing of an oral vitamin K preparation in the United States (American Academy of Pediatrics Ad Hoc Task Force, 1993).

## Circumcision

Few medical treatments generate as much heated debate as circumcision of newborn boys. Many parents will have already made a decision about circumcision by the time their son is born, and they may not wish to discuss the risks and benefits. Others, however, will request medical information on the medical risks and benefits, in order to make an informed decision. Unfortunately, misinformation abounds, particularly on the Internet, and the biases of authors color what looks to parents like objective information. The authors of this chapter are neither strong proponents nor opponents of circumcision, but like the American Academy of Pediatrics (1999) and the American College of Obstetrics and Gynecology (2001) we strongly oppose circumcision without anesthesia and we believe

parents should be informed of the risks and benefits so that they can make the decision based upon accurate information (Learman, 1999).

The principal risks of circumcision include bleeding, infection, pain, and an unsatisfactory cosmetic result. The risks are probably operator dependent and also depend on the method used. The three most commonly used methods are the Mogen and Gomco clamps and the Plastibell device. Studies of circumcision complications have been case reports or retrospective series, likely underestimating minor complications. The Mogen clamp is the fastest method, but carries a low but poorly quantified (perhaps 1 in 5,000-10,000) risk of partial amputation of the glans (Strimling, 1996). The Plastibell device leads to ischemic necrosis and eventual sloughing of the foreskin. Plastibell circumcision has been associated with a slightly higher risk of infection than Gomco circumcision (.72% vs .14% in one series) (Gee and Ansell, 1976) and necrotizing fasciitis has been reported only with Plastibell circumcision (Bliss et al, 1997; Woodside, 1980). The risk of bleeding with either the Gomco or Plastibell devices is about 1%; this usually responds to local measures (Amir et al, 2000; Gee and Ansell, 1976). "Degloving" injuries that required skin grafting have been reported following Gomco circumcision (Patel et al, 2001). Infections related to neonatal circumcisions occur rarely. A recent study of over 130,000 circumcised neonates reported only 2 infections (Christakis et al, 2000). The risk of pain from circumcision can be minimized with anesthesia. A ring block or dorsal penile nerve block is easy to learn and more effective than topical anesthesia at reducing crying and physiologic pain responses (Butler-O'Hara et al, 1998; Lander et al, 1997). In addition, a few drops of a concentrated (~35%) sucrose solution on a pacifier help reduce apparent pain (Blass and Hoffmeyer, 1991; Herschel et al, 1998). The pain from circumcision with inadequate anesthesia may have consequences beyond the neonatal period. Taddio and colleagues have shown that boys circumcised without anesthesia cried longer following routine vaccinations at 4 and 6 months than uncircumcised boys or those circumcised with anesthesia (Taddio et al, 1997).

Data on satisfaction with the cosmetic result are sparse, of questionable generalizability, and probably subject to publication bias, as authors might be less eager to report on a high prevalence of dissatisfied patients. In one study of Gomco circumcisions, 99.7% of parents were satisfied with the result (Amir et al, 2000). Parents of uncircumcised infants in another study were more likely to be dissatisfied with their decision than were parents of circumcised infants (27% vs. 14%) (Adler et al, 2001). This is not an argument in favor of circumcision, however, because dissatisfaction with circumcision (i.e., wishing it had not been done) is less easily remedied than dissatisfaction with lack of circumcision, which presumably can be remedied (albeit expensively) with later circumcision. It does, however, suggest that information about circumcision and care of the intact foreskin should be provided to all families, not just those requesting circumcision.

The benefits of circumcision include reduced risk of foreskin problems, including infections and irritations, phimosis and paraphimosis; reduced risk of human immunodeficiency virus (HIV) and other sexually transmitted diseases, reduced risk of penile cancer, and

reduced risk of urinary tract infections. The reduced risk of HIV infection was particularly compelling in a recent study of couples in sub-Saharan Africa discordant for HIV infection (Quinn et al, 2000). Over a follow-up period of about 2 years, seroconversions occurred among 40 of 137 uncircumcised men (29%) and none of 50 circumcised men ( $P < 0.001$ ). Opponents of circumcision argue that most uncircumcised males will not have any of these problems, that they could be prevented by good hygiene and safer sexual practices, and that men wishing the benefits of reduced risk of sexually transmitted diseases or penile cancer may undergo elective circumcision at a later age, when they are old enough to provide their own consent. Unlike the other benefits, the approximately 10-fold reduction in risk of urinary tract infections (from 1%-2% to 0.1%-0.2%) (Schoen & Fischell, 1991) is mainly a benefit from circumcision in the neonatal period. Although most urinary tract infections have a benign course, even in infancy bacteremia accompanies UTI in about 10% of cases under 3 months, thus not surprisingly meningitis and death from UTI in infancy have been reported (Bergstrom et al, 1972; Wiswell and Geschke, 1989).

A recent task force of the American Academy of Pediatrics (1999) concluded that there were both risks and “potential medical benefits” of circumcision. This unfortunate phrasing has been widely misinterpreted. The medical benefits of circumcision are established beyond any reasonable doubt. They are “potential” only in that the most uncircumcised males will not develop conditions circumcision would have prevented, just as most infants immunized against meningitis would not have developed meningitis anyway. Routine immunization to prevent meningitis is recommended while circumcision is not, because the risks, irreversible changes, and nonmedical significance of circumcision are much greater than those associated with immunization (Newman, 2001).

## ONGOING CARE

### Infant Security Systems

Sentinel events, such as the switching of babies in the hospital, kidnappings from newborn nurseries, and liberal rooming-in policies heightened awareness that hospital systems were needed to accurately identify newborns throughout their hospital stay and to prevent unauthorized persons from gaining access. Accreditation agencies are encouraging that newborn security systems be put in place beyond those set up for the general hospital. Infant identification systems include immediate banding of newborns and their mothers before they leave the delivery room with the infant’s name and medical record number along with the mother’s name and medical record number. Every time a newborn is separated and subsequently reunited with the mother, banding checks should be made to confirm the correct match-up of mother and baby. Generally one other person, specified by the mother is also banded, allowing that person independent access to the newborn (Appelbaum, 2000-2001; Rabun et al, 1992).

The newborn’s band is generally attached to a sensor that will alert unit staff and hospital security personnel

when passage near or through exits occurs. These alerts are tied to immediate response procedures (i.e., “Code Pink”) designed to prohibit the infant’s unauthorized removal from the hospital. There are several such systems available with many of the newer ones attached to computer programs that will identify the exact location of the infant at the time the alert is sounded (Secure Care Systems of Virginia, [www.securecaresystems.com](http://www.securecaresystems.com)).

Infant security systems, while well-intentioned are not yet perfect and are troubled by false alarms, often because someone mistakenly takes the infant down the wrong corridor and passes a sensor. Sometimes there are mechanical problems, temporarily disabling the system. Additionally, as the newborn normally loses weight after birth, bands become loose and frequently fall off the legs or arms. Data assessing the effectiveness of electronically tracking newborns are currently unavailable and it will probably take some time before measurable change can be documented as these are uncommon though frightening events. Until the perfect electronic system is developed, mothers should be instructed regarding precautions they can take to safeguard their babies.

### Temperature and Bathing

Monitoring the newborn’s ability to thermoregulate and maintain body temperature within normal range should be as simple as taking the temperature and comparing the reading with a norm. However, there are many questions that can complicate such a seemingly simple procedure, such as how and at what body site to take the temperature and, more importantly, what the normal temperature for a newborn is? Generally, comparing and noting trends of repeated measurements on the same baby gives much more valuable information than a single value at a single point in time.

Temperatures taken either axillary or rectally are common practices. The time required to obtain a stabilized reading using a digital thermometer is about 30-45 seconds at either site. Placement of the thermometer for axillary temperatures should be with the tip at the apex of the axilla midway between the anterior and posterior axillary borders. For rectal (not deep rectal) temperatures insert the thermometer gently to about 1 cm (May and Mahlmeister, 1994). Comparison studies show that temperatures taken rectally range between 0.1-0.3° C higher than those taken axillary. Results from both sites are about 0.2-0.5° C lower than core rectal temperatures. The advantage of using the axillary site is its’ relative safety. Taking temperatures rectally has been associated with rectal perforation (Frank and Brown, 1978; Young, 1979).

There is no consensus as to what should be considered the normal temperature of a term healthy newborn. Studies of newborn thermoregulation most often focus on the newborn’s response to extreme ambient conditions and seldom attempt to define what the normal range should be for clinical use. Mayfield and colleagues (1984) recommended core (deep rectal) temperatures between 36.5° C and 37.5° C as normal. The American Academy of Pediatrics Policy Statement of 1995 has set 36.1° C-37.0° C taken axillary as a discharge criteria (American Academy of

Pediatrics Committee on the Fetus and Newborn, 1995). Maternal fever (Takayama et al, 2000), birth weight (Takayama et al, 2000), bundling (Strothers et al, 1977), environmental temperature (CDC, 1988), and sleep state can alter (sometimes only temporarily) newborn temperature (Nako et al, 2000). For clinical use, interpreting trends over several hours rather than a single value in asymptomatic healthy newborns before instituting aggressive interventions such as septic work-ups seems prudent.

Bathing newborns within the first 24 hours of life continues to be common practice while daily bathing routines have been eliminated. Bathing to remove the blood and maternal body fluids is in keeping with universal precautions against blood borne pathogens such as hepatitis C and HIV (CDC, 1988). Proponents of no bathing cite preserving vernix for as long as possible because of reported infection protection properties, avoiding the disruption of mother-infant contact (which might adversely affect bonding and breast-feeding), and risk of hypothermia as their reasons. Bathing using a mild pH neutral soap or cleanser after the infant's temperature has reached 36.5°-36.8° C, followed by drying with a warm towel, results in very little change in temperatures (Nako et al, 2000). Babies do not need to be placed under radiant warmers routinely after their baths (Anderson et al, 1995). Having the mother give the first bath under supervision is an opportunity to teach this skill as well as encourage intimate touching by the mother and enhancing her attachment to her infant (Karl, 1999).

### Cord Care

Care of the umbilical cord is aimed at preventing or lowering the risk of omphalitis and sepsis. Cord care routines include simple cleaning, applying antiseptics, or antibiotics. The 1999 Cochrane review of randomized or quasi-randomized trials found no reported infections or deaths regardless of the method used (Zupan and Garner, 1999). The length of time to cord separation did vary. With cleaning only, the time to cord separation was about 8 days compared with 10 days after alcohol and 12 days with antibiotics (Zupan and Garner, 1999). One study found significantly higher maternal satisfaction with alcohol versus no care. Antibiotic use does lower the bacterial count significantly more and may be preferable to use under conditions when bacterial contamination of the cord might be higher such as out-of-hospital births (Zupan and Garner, 1999). Practitioners who choose to recommend no cleaning (Dore et al, 1998) at all should remember to advise the mother of the expected odor and unsightliness.

### Feeding

Breast-feeding is highly recommended for newborns. Few would dispute the Academy of Pediatrics statement in 1997 that "human milk is the preferred feeding for all infants, including premature and sick newborns with rare exceptions" (American Academy of Pediatrics, 1997). The benefits ascribed to breast milk include nutritional (Fomon, 1993), enhancement of bonding associated with early contact (Klaus, 1998), infection protection (Lawrence, 1994), diminished risk of serious atopic disease (Saarinen and

Kajosaari, 1995), and economic (Weimer, 2001). Enhanced cognitive development has been suggested by some including a recent Norwegian study (Angelsen et al, 2001) finding of higher MDI scores at 13 months and higher WPPSI-R scores at 5 years of age with breast-feeding duration of 6 months compared with three months, despite correcting for significant confounders such as maternal age, intelligence, and smoking. Lowered risk of chronic bowel disease may also be a benefit (Corrao et al, 1998). Regarding childhood cancer, a weak association with reduced risk was found by the UK Childhood Cancer Study Investigators which was a consistent trend in other smaller studies reviewed by the same group (Beral et al, 2001).

The protective effect of breast-feeding against sudden infant death syndrome (SIDS) is not as clear as was once thought from earlier studies. Sullivan's review of SIDS risk factors includes an analysis of several large studies from several countries. Although the two- to threefold decreased risk was a consistent finding among the studies, the magnitude of difference compared with bottle feeding lowers considerably when strong confounding factors such as maternal smoking, maternal age, and socio-economic levels were removed (Sullivan and Barlow, 2001). Nevertheless, even after rigorous analysis and care to remove the confounders, the association of breast-feeding with lowered risk for SIDS remains. Because breast-feeding moms tend to be nonsmoking, older age (i.e., non-adolescent), and of higher socio-economic level, breast-feeding may be a marker of lifestyle practices protective against SIDS. By promoting breast-feeding, practitioners potentially could introduce other healthy practices such as smoking cessation while encouraging more mothers to adopt "breast is best."

Earlier reports of decreased risk of insulin dependent diabetes mellitus (Gerstein, 1994; Mayer et al, 1998) have not been supported by more recent reports (Dahlquist and Mustonen, 2000; Jones et al, 1998; Norris et al, 1996). Jones and associates reported data from the Oxford Record Linkage Study of 311 diabetic children and found no association (Norris et al, 1996). The DAISY study in Colorado (Jones et al, 1998) as well as The Swedish Childhood Diabetes Study Group (Dahlquist and Mustonen, 2000) failed to find an association between breast-feeding and risk of developing diabetes.

Benefits of breast-feeding are not limited to the infant but extend to mothers by improving postpartum recovery, partial birth control, reduction in postmenopausal hip fractures, and reduced risk of ovarian and breast cancers. For these reasons and others, breast-feeding through the first six months of life and continuing at least until twelve months of life continues to be strongly recommended (American Academy of Pediatrics, 1997).

If such an ambitious recommendation is to be successfully accomplished, breast-feeding should be encouraged and supported prenatally, perinatally, and postnatally. The message should be consistent from physicians, nurses, dietitians, other health care providers, family, friends, the community, and the media. Current rates of both initiation of breast-feeding as well as continuation among mothers in the United States are disappointingly low. Ryan reported 1995 newborn breast-feeding rates (both exclusive as well as in combination with formula) of about 59%. By six months only 21.6% of mothers were still breast-feeding

and many were supplementing feeds with formula (Ryan, 1997). By 2001 there has been only slight improvement with 64% of mothers initiating breast-feeding and 29% still breast-feeding at 6 months (Weimer, 2001).

The international community's interest in promoting breast-feeding worldwide comes as no surprise when the challenges of access to good nutritional sources, poverty, adequate sanitation, clean water sources, and infection control are prevalent and especially life-threatening to infants in developing countries. However, tangible benefits to developed countries, including the tremendous cost savings, justifies worldwide attention. Focusing on the United States, the U.S. Department of Agriculture issued its 2001 report analyzing the economic benefits if the Surgeon General's goal of early postpartum breast-feeding rates of 75% and 29% continuing at six months were achieved. This analysis only considered the reduction in incidence, medical care, and lost parental wages associated with three infectious diseases: otitis media, gastroenteritis, and premature deaths associated with necrotizing enterocolitis (Weimer, 2001). By the investigators' estimation, an impressive \$3.6 billion per year would be saved. By inference, if the same analysis was applied to all the recognized benefits of breast-feeding the dollar amount would be staggering.

Recognizing the important role of newborn care providers and hospitals in the initiation of breast-feeding and that many hospital practices actually presented barriers to successful breast-feeding, the Baby-Friendly Hospital Initiative as an international approach was put forth. Presented in the 1989 joint statement by the World Health Organization (WHO) and United Nations Children's Fund (UNICEF), ten steps to successful breast-feeding were delineated (Joint WHO/UNICEF Statement, 1989). World recognition as a designated Baby-Friendly Hospital is given to those hospitals successfully completing the ten steps (Table 26-1). Accomplishing these ten steps requires cooperation between physicians, nurses, lactation specialists, hospital administration, and other key hospital departments.

### Obstacles to Breast-Feeding

Obstacles to the establishment of breast-feeding include inadequate prenatal education and promotion, physician under-education and lack of support, cultural views, promotion of commercial formula, hospital practices, and lack of timely post-discharge follow-up (Weimer, 2001). Numerous studies have documented the lack of physician knowledge about breast-feeding. Two recent representative studies are those of Schanler and colleagues (1999) and Lee and associates (2000). Both studies involved surveying factual knowledge using a questionnaire which included clinical scenarios where physicians would be asked their advice regarding breast-feeding. Schanler in Texas found that whereas 65% of physicians recommended breast-feeding exclusively in the first month of life, only 37% followed the AAP guideline, recommending breast-feeding for the first twelve months. Many advised against breast-feeding for medical conditions known to be compatible with breast-feeding. Most were unaware of the Baby-Friendly Hospital Initiative. Nursing staff's lack of support for breast-feeding

**TABLE 26-1**

### Ten Steps to Successful Breast-feeding

1. Have a written breast-feeding policy that is routinely communicated to all health-care staff.
2. Train all health-care staff in the skills necessary to implement the breast-feeding policy.
3. Inform all pregnant women about the benefits and management of breast-feeding.
4. Help mothers initiate breast-feeding soon after birth.
5. Show mothers how to breast-feed and how to maintain lactation even if they are separated from their babies.
6. Give newborn infants no food or drink other than breast milk, unless medically indicated.
7. Practice rooming-in, allowing mothers and infants to remain together 24 hours a day.
8. Encourage breast-feeding on demand.
9. Give no artificial teats or dummies to breast-feeding infants.
10. Foster the establishment of breast-feeding support groups and refer mothers to them on discharge from the hospital or clinic.

has been identified as influential in mothers' decision not to breast-feed. One study found a correlation between nurse attitude and behavior with their level of knowledge and personal experience. Those with more lactation knowledge and who had breastfed themselves were more likely to promote breast-feeding to their patients (Patton et al, 1996).

Cultural attitudes reflective of ethnicity, maternal age (adolescents), socio-economic level, and family have been identified as obstacles to successful breast-feeding. Forste and colleagues (2001) reported a strong relationship between race and the decision to breast-feed. In their analysis of data on 1088 women from the National Survey of Family Growth, they found that after correcting for confounders, African-American mothers were still 60% less likely to breast-feed as were non-African-American mothers. They went on to suggest that the gap in breast-feeding largely explains the higher rates of infant mortality and low birth weight among African-Americans. The reason given by these women for choosing not to breast-feed most often was "preferred to bottle-feed" without further elaboration. Adolescents' decision to breast-feed closely aligns that of peer and family influences and breast-feeding knowledge. Lizarraga and associates (1992) found a positive correlation between teens who had been breastfed themselves and their intent to breast-feed. A study comparing Japanese students in Japan with those in Michigan found that significantly more Japanese students perceived their mothers to have positive attitudes about breast-feeding as did the students themselves compared with the Michigan girls (Yeo et al, 1994). A study of African-American and Latina teen women by Hannon and colleagues (2000) identified fear of pain, embarrassment with public exposure, and unease with the act of breast-feeding, as well as concern for excessive attachment between mother and baby as reasons to not breast-feed.

Differences in socio-economic levels continue to be associated with differing rates of breast-feeding independent of race. Review of data presented in the Healthy People

2000 Final Review (National Center for Health Statistics, 2001) clearly illustrates the disparity between low-income women and those in higher income brackets despite targeted efforts to increase breast-feeding over the past ten years. Target goals for all women were 75% breast-feeding in the early postpartum period and 50% still breast-feeding by 6 months. Actual figures in 1999 showed 67% of mothers initiated breast-feeding and 31% were breast-feeding at 6 months. For low-income women, while progress was made, the comparable rates were 49% in the early postpartum period and 20% at 6 months. Possible reasons are suggested in two studies (Guttman and Zimmerman, 2000; Humphreys et al, 1998) and include lack of social support from peer groups, interference with working, breast-feeding experience, and perceived public disapproval.

Additional barriers to breast-feeding include parental educational level and knowledge about breast-feeding (Susin et al, 1999), partner's attitude (Arora et al, 2000), maternal employment (Gielen et al, 1991), commercial formula promotion (Henderson et al, 2000; Howard et al, 2000), and hospital practices (Perez-Escamilla et al, 1994; Snell et al, 1992; Zimmerman and Bernstein, 1996). Identifying obstacles to breast-feeding has resulted in multi-targeted approaches to the promotion of breast-feeding. Examples include the Baby-Friendly Hospital Initiative and its associated ten steps as discussed above. Studies have shown that even accomplishing some of the recommended changes results in demonstrable increases in breast-feeding rates in both the initiation and duration (Cattaneo and Buzzetti, 2001; DiGirolamo et al, 2001; Phillipp et al, 2001). Powers and colleagues (1994) reviewed 16 hospital practice changes friendly to the establishment and support of breast-feeding. These included educating and training of staff, allowing a close companion continuous access to the laboring mother, putting the baby to breast as soon after birth as possible (i.e., in the delivery room), rooming-in, encouraging frequent feedings, minimizing procedures that disrupt mother-infant closeness, discontinuing the dispensing of commercial gift packs containing formula, trained staff readily available to monitor progress and offer helpful instruction, and arranging for early post-discharge visits.

### **Contraindications to Breast-Feeding**

There are few conditions under which breast-feeding would not be advisable because of the adverse effects on the infant. These include illegal drugs of abuse, maternal HIV infections, untreated maternal tuberculosis, and galactosemia (American Academy of Pediatrics, 1997; American Academy of Pediatrics, 2001; Mbori-Ngacha et al, 2001). Use of some medications may require temporary cessation of breast-feeding. In these situations, extra education and support should be given to the mother to reduce any anxiety regarding returning to breast-feeding when safety has been restored. These medications include cancer chemotherapy, radioactive isotopes, and antimetabolites. When maternal medications have been prescribed and there is not enough information to determine clearly the effects on the newborn, parents should be given the best available information to aid in their decision-making regarding breast-feeding. Smoking, while not a contraindication to breast-feeding

should be discouraged. Around the time of the birth of a new baby, mothers who smoke may be receptive to smoking cessation interventions. It is appropriate to offer these interventions to women and to encourage the use of local resources to aid in stopping or at least decreasing cigarette use.

### **Hepatitis C and Breast-Feeding**

The current data are inconclusive regarding the clinical risk to the breast-feeding infant whose mother is infected with hepatitis C virus. Studies have recovered virus in samples of breast milk, however, no documented transmission has been reported. At this time the AAP recommends informing mothers of available information regarding the risk and support their decision to breast-feed or not (American Academy of Pediatrics, 1998; European Pediatric Hepatitis C Virus Network, 2001). Regardless of the breast-feeding decision, some pediatric hepatologists (for example, Rosenthal) advise PCR testing for hepatitis C virus be done shortly after birth and again between 9-12 months of life to assess the infant's infection status. PCR is recommended rather than antibody (ELISA) testing to avoid misinterpretation due to the presence of passively transferred maternal antibody.

The anatomy, physiology, and biochemistry relevant to lactation are well described in a textbook by Ruth A. Lawrence and will not be reviewed in this chapter (Lawrence, 1994).

### **Bottle Feeding**

For those infants whose mothers choose formula feeding, the standard 20 calorie per ounce, iron-fortified cow's milk based formulas are recommended (American Academy of Pediatrics, 1998). Feedings are usually begun within the first 4-6 hours of life after an initial sterile water feeding is given to test the integrity of the sucking and swallowing competency of the infant and to reduce the likelihood of formula aspiration into the lungs should a defect such as tracheo-esophageal fistula exist. The intake of term newborns on the first day of life, feeding and libitum, averages about 10-30 cc/kg/day and about twice this amount on day 2 (Dollberg et al, 2001). As the volume is considerably larger than the intake of breastfed newborns during the first 2 days, the percentage of weight loss of formula fed newborns is lower and may not reach the 7%-9% decrease from birth weight common with exclusive breast-feeding.

### **Sleep Position**

The importance of sleep position and the prevention of SIDS has clearly been demonstrated. Following the AAP's 1992 statement (American Academy of Pediatrics, 2000) strongly recommending supine sleeping position for infants, along with the "Back to Sleep" campaign, a greater than 40% reduction in the incidence of SIDS in the United States between 1992 and 1998 was achieved (American Academy of Pediatrics, 2000) Anticipatory guidance to educate parents and increase the likelihood of acceptance of this practice as routine should begin prenatally and continue

throughout the postpartum hospital stay. Talking to parents, giving them appropriate informational material to read, as well as directing them to other informational sources such as the Newborn Channel (a 24-hour closed-circuit television channel on newborn care) are all helpful strategies (U.S. Public Health Service, 1994; Newborn Channel, [www.newborn.com/about.html](http://www.newborn.com/about.html)). Especially powerful is modeling behavior. Hospitals should examine their own sleep position practices and change to that of supine positioning (Braveman et al, 1995).

Parents should be instructed to avoid placing soft objects, pillows, or loose bedding under or in the infant's crib. If blankets are to be used, safe ways to wrap the infant to avoid obstructing the nose and mouth should be demonstrated. Education of staff may be needed to ensure consistency of complying with hospital policy. Special efforts to educate and address myths common in cultural groups with longstanding prone positioning practices may be necessary. African-Americans have been identified as one group where the acceptance of supine sleep positioning has lagged behind. SIDS rates for African-Americans, while lowered over the past ten years, remain disproportionately higher than for Caucasians (American Academy of Pediatrics, 2000). Special efforts to educate and encourage change in practice are clearly needed to reduce this continuing disparity.

### Anticipatory Guidance

The postpartum period presents an opportune time to begin anticipatory guidance. To avoid overloading the mother with information at a time when she is mentally and physically recovering from labor and delivery, trying to establish breast-feeding, and trying to connect with her new infant, staff and physicians should consider carefully and prioritize the information delivered. One approach might be to consider what the mother is most likely to encounter during the first 2-4 weeks (2 weeks if she appears especially inexperienced) at home with her infant. Easily readable handouts in the mother's primary language are helpful aids. Topics related to benign newborn skin findings, common behaviors such as snorting noises, sneezing hiccups, spitting-up, brief jerks while sleeping and facial grimaces, urate crystals, breast enlargement, pseudomenses, and crying responses are some examples. General care guidance should include bathing, appropriate clothing and how much, diapering, skin care, optimal environmental temperature, crib and bassinet use, care of circumcision site, and expected feeding, stooling, and voiding patterns. Family adjustment concerns should be addressed as well, especially sibling acceptance and house-pets as well as postpartum depression or the "blues." Safety items might include proper sleeping surfaces, the pros and cons of co-bedding, passive exposure to smoking, safe carryalls, and car seats. Warning signs of illness and how to respond should be reviewed (Table 26-2). Phone numbers and names of available resources should be provided.

### Discharge and Follow-up

The optimal length of hospital stay has not been determined (Braveman et al, 1995). Over the past two decades the average length of stay has decreased, initially driven by

**TABLE 26-2**

#### Newborn Warning Signs of Illness for Parents

- Refusal of feedings two or more times in a row. Breast-fed newborns generally feed every 2-3 hours and formula fed newborns feed every 3-4 hours
- Fewer than six wet diapers per day
- Fewer than two stools per day
- Difficulty waking baby for feedings (lethargy)
- Persistent difficulties with breast-feeding technique, such as inadequate latch, no let-down, inadequate suck/swallow pattern, and persistent pain with feedings
- Yellow coloring (jaundice) of the eyes or skin, especially if it extends to or beyond the belly button (umbilicus)
- Blue color or pale skin
- Repeated projectile vomiting
- Distended, tight abdomen
- Redness, swelling, or discharge from the eyes or umbilicus

parents seeking to de-medicalize the birthing experience and finding the hospital's highly technical environment inconsistent with an experience that could include family members, individual comforting practices to be used during labor, and close contact with their infants. As labor, delivery, postpartum, and nursery practices responded to these requests, discharge timing became less driven by patient preferences and more driven by third party payor reimbursement policies. The medical backlash to early newborn discharge included reports of sentinel events such as kernicterus from extreme hyperbilirubinemia (Sola, 1995), inadequately established feedings resulting in readmission for severe dehydration and hypernatremia (Cooper et al, 1995), missed congenital heart defects (Kuehl et al, 1999), and general dissatisfaction by both the patients and doctors because of the interruption of the time honored practice of physician-directed timing of discharge. Federal and state legislation was passed modulating this behavior, requiring that minimal lengths of stays of 48 hours and 96 hours for uncomplicated vaginal and cesarean section deliveries of healthy term infants be financially covered. The AAP policy statement issued in 1995 emphasized the need to time discharge according to the stability of the mother and infant. The statement details minimal medical and psychosocial criteria which should be met before consideration for discharge. The importance of specifying an identified and timely follow-up plan before discharge is emphasized (American Academy of Pediatrics, 1995). Table 26-3 summarizes these criteria.

### Car Seats

Promoting the safe and proper use of car seats can be appropriately addressed as a part of discharge teaching. Hospital policy might also include having trained hospital personnel observe and assist the parents in positioning the infant in the car seat and securing it properly in the vehicle prior to discharge. Infants are most safe if placed in a rear-facing seat installed in the back seat of the vehicle (American Academy of Pediatrics, 2002). Some hospitals support programs providing car seat purchasing and/or rental programs

**TABLE 26-3****Criteria for Newborn Discharge**

- Uncomplicated antepartum, intrapartum, and postpartum courses
- Vaginal delivery
- Singleton birth at term gestation and appropriate for gestational age
- Vital signs within normal ranges and stable for 12 hours before discharge
- Spontaneous voiding and stooling at least once
- Completion of two successful feedings
- Physical findings within normal ranges
- Circumcision site free of excessive bleeding for 2 hours
- Jaundice appropriately evaluated
- Mother demonstrating competency in providing adequate care for her baby
- Adequate support readily available to mother after discharge
- Laboratory data reviewed and screening tests performed
- Hepatitis B vaccine administered appropriate to the newborn's risk status
- Completion of hearing screening
- Identification of post-discharge continuing medical care
- Family, environmental, and social risk factors assessed
- Follow-up within 48 hours of discharge possible

for families who are unprepared at the time of discharge. The AAP recommends that parents purchase a car seat that meets federal safety standards, is the right size for the child, fits the vehicle's seats and seat belt systems, and is easy to use (American Academy of Pediatrics, 2002).

**COMMON PROBLEMS DURING NURSERY STAY****Hyperthermia and Hypothermia**

Elevated temperature in newborns can be the result of maternal fever present prior to delivery, excessive swaddling, environmental, hypermetabolic states such as drug withdrawal, dehydration, or true fever associated with infection. In an otherwise healthy infant, less than 3 days old, the first three of the previously mentioned causes are much more common than infection. Therefore, if the newborn is without other abnormal signs and symptoms, causes other than sepsis should be ruled out first.

Mild to moderate hypothermia is not uncommon during the first day or two after birth. Infants experiencing excessive heat loss feed poorly, act somewhat sluggish and may become hypoglycemic and develop metabolic acidosis. Causes of hypothermia include environmental, as well as sepsis or hypovolemia. The infant's internal response to cold stress depletes lipid substrates necessary to generate heat. Lack of feeding secondary to hypothermia then becomes a secondary cause of continuing hypothermia creating a cyclical pattern of cause and effect. The approach to hypothermia starts by determining the underlying cause, addressing the identified cause(s), followed by measures to rewarm the infant. Rewarming the otherwise healthy newborn can be effectively and easily accomplished by placing the infant skin-to-skin next to the mother and covering both

with warm blankets. This method has the additional advantage of not disrupting mother-infant contact and encouraging feeding. Occasionally, placing the infant in a heated enclosed incubator unit or under a radiant warmer may be temporarily necessary.

Preventive measures aimed at reducing the thermal gradient known to promote heat loss from the infant to the environment are commonly incorporated into general hospital practices. Starting in the delivery room, newborns should be delivered into a dry warm towel and immediately wiped of surface fluids. Special attention should be directed to drying the head and face which together represent a large surface area from which evaporative heat loss can be significant. The initial drying can be followed by skin-to-skin swaddling against the mother or complete swaddling in dry warm blankets. Placing a cap on the head gives additional protection against excessive heat loss. Warming the room a few degrees is helpful, however the mother's comfort needs to be considered as well.

**Maternal Conditions Affecting the Baby**

Maternal conditions such as chorioamnionitis, prenatal infections (HIV, GBS colonization), substance abuse, and diabetes, and other chronic immunologic diseases are examples of conditions that may affect the newborn. Maternal health should be reviewed as part of obtaining the medical history of the newborn. The approach to the infant varies with the specific condition, details of which can be found through this textbook. For the asymptomatic, healthy newborn, a determination should be made as to whether the condition is likely to be transferable to the infant and whether measures can be taken to prevent or lessen the likelihood of transmission as in the case of group B streptococcus or HIV. Some conditions such as maternal substance abuse or diabetes have direct effects that may require treatment during the first few days of life.

**Abnormal Prenatal Ultrasounds**

Prenatal ultrasonography has improved remarkably over the past decade, resulting in the detection of many findings at variance from normal. The dilemma for physicians is sorting out which findings are of clinical significance to the health of the newborn and require intervention. Examples of sonographic findings associated with variable clinical outcomes include isolated abnormal or absent corpus callosum, small intracranial cysts, nonspecific dilation of the renal pelvices, isolated choroid plexus cysts, and echogenic cardiac foci (Maizels et al, 2002). The decision to obtain postnatal re-imaging and other investigative studies depends on the presence of other sonographic abnormalities and/or abnormal postnatal physical examination. Subspecialty consultation may be helpful in determining further work-up.

**Breast-Feeding Problems**

Common early problems are generally associated with the initiation of breast-feeding such as sleepy baby (disinterest), poor latch, sore nipples, pain with latching on, maternal

anxiety regarding breast milk production and supply, and maternal breast engorgement. Much of the time, with proper management of the breast-feeding couple, many of these problems can be minimized or avoided altogether.

Creating a supportive environment is key to the successful establishment of breast-feeding. This would include allowing the mother ready access to her infant in the delivery room and facilitating breast-feeding at that time, should the infant show interest in nursing. Rooming-in should be encouraged so that the mother can readily respond to her infant's feeding cues. Nursing staff from all areas of the perinatal unit—labor and delivery, postpartum, and nursery—should be trained and experienced in the management of breast-feeding. The advice should be consistent and free from personal bias. Physicians as well should be knowledgeable regarding the science of breast-feeding, able to recognize problems, and understand the appropriate intervention approaches.

While a detailed discussion of the management of specific problems is beyond the scope of this chapter, there are important points that should be mentioned. The diagnosis of breast-feeding problems begins with an assessment of risk factors such as previous breast surgery, prolonged or difficult labor, cesarean section delivery, excessive maternal blood loss, or need for newborn resuscitation. Examination of the mother's breasts includes assessing the presence of engorgement, flat, inverted, or cracked nipples. Note mother's position for feeding. Is she sitting or reclining comfortably? Is the infant being held in a comfortable, supportive position with ready access and alignment to the breast? Direct observation of the latch, position of the infant's tongue, and quality of the suck and the pattern of suckling and swallowing are keys to proper diagnosis and intervention decisions. Lactation specialists can be especially helpful in developing a reasonable and appropriate management plan (Lawrence, 1994) While all newborns normally lose weight during the first few days of life, breastfed infants are at risk for excessive weight loss. By 72 hours after birth most breastfed newborns have generally lost about 7%-8% of their birthweight. Any newborn whose weight loss reaches 10% risks becoming dehydrated and should be carefully evaluated and monitored. In these instances short term supplementation may be required while continuing to work on establishing breast-feeding.

### Respiratory Problems

The normal respiratory rate of the fullterm newborn after transition is 35 to 60 breaths per minute. Tachypnea, one of the more common problems encountered in the newborn nursery may occur as an isolated finding or in combination with other signs of respiratory distress including nasal flaring, grunting, retractions, or cyanosis. The possible causes of tachypnea in the newborn range from benign conditions such as transient tachypnea of the newborn (TTNB) to more serious conditions such as primary pulmonary disease, sepsis, cardiac disease, metabolic problems, hypovolemia, anemia, polycythemia, and neurologic abnormalities. Identifying those infants needing aggressive intervention and transfer to a neonatal intensive care unit quickly requires using a reasoned approach

combining assessment of maternal risk factors (e.g., GBS status, substance abuse), the labor and delivery experience (meconium, cesarean section, ashyxia, trauma, excessive blood loss), presence of additional findings on physical exam (e.g., respiratory distress, cardiovascular dysfunction, dysmorphic features), and a few key tests (blood gas, complete blood count, glucose, chest x-ray).

TTNB, thought to result primarily from retained fetal lung fluid, occurs in near-term and fullterm newborns following vaginal and cesarean section deliveries. The disorder, as described in 1966 by Avery and associates, presents typically shortly after birth (Avery et al, 1966). Tachypnea is often the only finding, however some infants may become more symptomatic with retractions, grunting respirations, and mild cyanosis. Chest radiographs characteristically show hyperaeration, pleural fluid, and prominent pulmonary vascular markings. The condition resolves by the third or fourth day. Management for many infants is limited to close observation. These babies generally are able to continue oral feedings. More symptomatic infants respond readily to oxygen supplementation and may require intravenous fluids to avoid hypoglycemia if the tachypnea prevents oral feedings.

### Cardiovascular Issues

Distinguishing the otherwise healthy newborn who is progressing normally through cardiovascular transition with an associated benign, transient murmur from the occasional newborn whose murmur is associated with a serious heart defect presents a common challenge for practitioners in the normal newborn nursery. The situation is further complicated if the mother is ready for discharge after a shortened hospital stay prior to completion of the major components of physiologic transition from fetal to neonatal circulation, which generally occurs over 2-3 days but may take as long as 7 days.

Further cardiac investigation is indicated if a murmur is found in association with other abnormal findings. The evaluation of newborns with murmurs includes taking note of maternal medications or drugs taken just before or during pregnancy. Infants whose family history is positive for first-degree relatives with congenital heart defects have a higher risk of also having congenital heart disease compared with those infants without a positive family history. The physical examination should focus on determining the presence of other anomalies and evidence of cardiac dysfunction such as tachypnea, tachycardia, cyanosis or pallor, absence of peripheral pulses, or poor perfusion. The reader is referred to Chapter 57 for a detailed discussion on the evaluation and management of cardiac disease.

### Voiding and Stooling

Delayed voiding or stooling is a common complaint during, however, the first void or stool is often missed and unrecorded because it may have happened shortly after birth in the delivery room, or a diaper may have been inadvertently discarded without being documented in the chart.

Ninety-five percent of newborns regardless of gestational age will spontaneously void for the first time by 24 hours of

age (Clark, 1997). If a newborn has not voided by 48 hours, diagnostic investigation should be considered. Clues from the physical examination include palpable enlarged kidneys or enlarged bladder. The genitalia and lower back should be inspected for abnormalities as well as a carefully performed neurologic examination of the lower extremities, noting the anal “wink.” Dysfunctional voiding may be a sign of a tethered spinal cord.

The first stool passed by newborns may be later than the first void, however most newborns will pass a meconium stool within the first 48 hours of life and certainly by 72 hours (Clark, 1997). Infants who have not spontaneously stoolled by 72 hours should be assessed for any of the numerous obstructive causes. Retrieval of stool by artificial stimulation methods such as rectal insertion of a thermometer or suppository is discouraged as these maneuvers may delay the diagnosis of a serious condition.

### Jaundice

The important issues are to be aware of risk factors that may increase the likelihood of nonphysiologic hyperbilirubinemia. Those risk factors include siblings who required treatment for hyperbilirubinemia, maternal blood group type O, Rh negative or positive antibody screen, maternal diabetes, male gender, Asian race, pre-term gestation, jaundice presenting in the first 24 hours of life, cephalohematoma or excessive bruising, and breast-feeding infants, especially those with excessive weight loss.

Reports of kernicterus associated with early hospital discharge and delay of recognition of significant jaundice (American Academy of Pediatrics Subcommittee on Neonatal Hyperbilirubinemia, 2001) have led to the development of predictive models based on the timing of an initial bilirubin prior to discharge (Bhutari et al, 1999). These models are intended to help the practitioner determine which infants should have repeated bilirubin determinations made or even a delay in discharge in order to avoid the development of extreme untreated hyperbilirubinemia. If a jaundiced infant has been cleared for discharge, follow-up within 24-48 hours should be arranged for further assessment and a possible redraw of bilirubin levels. Treatment guidelines are suggested by the AAP Task Force on Hyperbilirubinemia published in 1994 (American Academy of Pediatrics Provisional Committee for Quality Improvement and Subcommittee on Hyperbilirubinemia Practice Parameter, 1994).

### Family and Social Issues

Hospital policies should encourage the involvement of family and important support persons. This includes such practices as attendance during labor and delivery by the father or other support person and unrestricted postpartum visiting by family and friends. The provision of a professional support person such as a doula during labor, delivery, and immediately postpartum has been associated

with fewer obstetric complications, greater breast-feeding success, and faster postpartum recovery. Allowances for sibling visitation have also become popular in many institutions. Guidelines addressing visitation by children are institution specific and generally focus on infection control as well as proper supervision of young siblings. Siblings should be free of contagious illnesses. Some guidelines require a brief screening by nursing. Visits should occur in the mother's room, limiting contact with non-sibling neonates. Siblings should be adequately supervised throughout their visits by a responsible adult other than the neonate's mother. The adult should be someone familiar to the visiting child and who can reliably monitor behavior, the child's handling of the neonate, and attend to the child's needs.

While the primary concern of hospital providers is caring for the mother and newborn in a supportive and medically safe hospital environment, the post-discharge environment should not be neglected. Determination of the adequacy of the home should address space, supplies and equipment, availability of support from family or friends, heating, telephone access, and other basic needs. Single, first-time mothers, and teenage mothers living on their own are especially vulnerable to inadequate support following hospital discharge. Lack of a supportive home environment is associated with mothers who are less likely to sustain successful breast-feeding and are at higher risk for postpartum depression and child abuse. The presence or likelihood of domestic violence should also be determined prior to discharge. When social challenges are identified, enlisting the help from the unit's social worker before discharge is recommended.

## Newborn Screening

Simone Albers and Harvey L. Levy

Newborn screening is directed primarily at disorders in which the clinical complications develop postnatally. In metabolic diseases, these complications result from biochemical abnormalities that appear after birth, when the infant is no longer protected by fetal-maternal exchange. The infant with phenylketonuria (PKU), for instance, has a normal blood phenylalanine level at birth but within a few hours demonstrates hyperphenylalaninemia. If this and other biochemical abnormalities of PKU are not corrected or at least controlled by dietary treatment, the infant begins to show signs of developmental delay and, subsequently, becomes mentally retarded. If dietary therapy begins during the first weeks of life and the blood phenylalanine level is controlled, mental retardation is prevented (Levy and Cornier, 1994).

PKU was the first metabolic disorder known to benefit from dietary therapy. This fact was established by the mid-1950s. By the late 1950s, it was evident that the diet could prevent mental retardation if initiated in the neonatal period. Detecting PKU in all affected infants at that early age, before irreversible brain damage occurred, then became the challenge. This meant neonatal screening for a biochemical marker of the disease. In 1962, Guthrie developed a simple bacterial assay for phenylalanine that required only a small amount of whole blood soaked into filter paper (Guthrie and Susi, 1963). Thus, infants in newborn nurseries could be routinely tested for PKU in blood specimens obtained by lancing the heel and blotting the drops of blood onto a filter paper card. This filter paper blood specimen (Guthrie specimen) could be mailed to a central laboratory for PKU testing. An increased concentration of phenylalanine in the specimen indicated PKU in the infant.

By the mid-1960s, many states had established routine newborn screening programs for PKU using the Guthrie method. Infants with PKU were identified in larger numbers than anticipated and were showing normal development while receiving treatment (O'Flynn, 1992). The success of PKU screening led to the addition of tests for other metabolic diseases, including galactosemia, maple syrup disease (MSUD), and homocystinuria. These additional tests could be applied to the same blood specimen obtained for PKU screening. Later, a test for an endocrine disorder, congenital hypothyroidism, was added, followed by screening tests for sickle cell disease, congenital adrenal hyperplasia (CAH), biotinidase deficiency, cystic fibrosis, and others. Furthermore, urine soaked into filter paper was used to screen for neuroblastoma.

In 1990, tandem mass spectrometry (MS/MS) was first applied to the Guthrie specimen, opening a new era in newborn screening (Levy, 1998; Millington et al, 1990). The technology allows for the detection of more than 20 biochemical genetic disorders with a single assay of high specificity and an extremely low rate of false-positive results (Chace and Naylor, 1999) (Table 27-1). By the early 1990s, Naylor in Pittsburgh (Chace and Naylor, 1999) and Rashed and collaborators (1995) in Saudi Arabia were routinely screening neonates with this technology. Today, more and more state programs in the United States and screening programs in Europe and elsewhere have integrated MS/MS into newborn screening, thereby greatly expanding their possibilities for early detection of metabolic diseases in the newborn period (Levy and Albers, 2000). This single method is replacing the multiple procedures traditionally used by programs in screening for metabolic disorders.

Molecular testing (DNA) analysis has been another addition to newborn screening. As secondary or "second-tier" testing for diseases such as cystic fibrosis or medium-chain acyl-coenzyme A (CoA) dehydrogenase deficiency (MCADD), molecular testing substantially improves the positive predictive value of a primary screening result that is based on metabolite testing only (Ranieri et al, 1994; Wilcken et al, 1995; Ziadeh et al, 1995). The use of molecular testing for second-tier testing will most likely further expand with advances in DNA technology.

### SCREENING PROCEDURE

#### Specimen

The blood specimen is obtained from the heel of the infant. This simple sampling method, conceived and introduced by Guthrie, has had an enormous effect on newborn screening. The specimen is not only easily obtained but also easily and inexpensively sent by mail to a central testing facility. There are no complications in obtaining the specimen from the newborn, contrary to early fears that its collection would lead to infection or result in excessive bleeding.

#### Specimen Collection Procedure

The blood specimen should be obtained from the lateral or the medial side of the heel (Fig. 27-1). Blood should be applied to only one side of the filter paper card but should saturate each circle on the card. Contamination of the filter paper specimen with iodine, alcohol, petroleum jelly, stool, urine, milk, or a substance such as oil from the fingers can adversely affect the results of the screening tests. Also, exposure to heat and humidity can inactivate enzymes and produce false results. The specimen should be dried in air at room temperature for at least 3 hours before being placed in an envelope.

Specimens are sometimes collected in capillary tubes, by venipuncture of a dorsal vein or from a central line, and then spotted on filter paper. There is little or no substantial difference in analyte levels between blood collected

TABLE 27-1

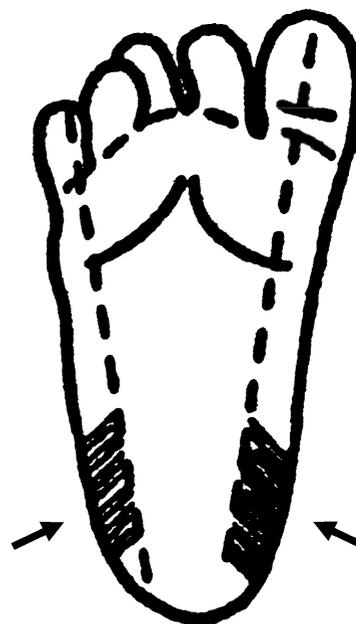

**The Most Likely Disorders Identifiable in Expanded Newborn Screening**

Amino acid disorders	Phenylketonuria (PKU) Homocystinuria and other hypermethioninemias Maple syrup urine disease (MSUD) Tyrosinemia Citruillinemia Argininosuccinic acidemia (ASA) Argininemia (arginase deficiency)
Organic acid disorders	Propionic acidemia (PPA) Methylmalonic acidemia (MMA) Isovaleric acidemia (IVA) Glutaric acidemia type I (GA I) $\beta$ -Keto thiolase deficiency 3-Methylcrotonyl-coenzyme A (CoA) carboxylase (3-MCC) deficiency 3-Hydroxy-3-methylglutaryl (HMG)-CoA lyase deficiency
Fatty acid oxidation disorders	Medium-chain acyl-CoA dehydrogenase deficiency (MCADD) Short-chain acyl-CoA dehydrogenase deficiency (SCADD) Very-long-chain acyl-CoA dehydrogenase deficiency (VLCADD) Long-chain hydroxyacyl-CoA dehydrogenase deficiency (LCHADD) Carnitine deficiency Carnitine palmitoyltransferase II (CPT II) deficiency Glutaric acidemia type II (GA II)

directly from the heel and that collected by any of these other methods (Lorey and Cunningham, 1994). However, there is the danger of introducing amino acids from total parental nutrition (TPN) solutions given through a central line into blood collected from this line, resulting in a false-positive increase in amino acids in the Guthrie specimen. In general, it is preferable that blood for screening be spotted on filter paper directly from the heel.

### Timing of the Collection

The specimen should be obtained from every newborn infant before nursery discharge or by the third day of life (whichever is first). With the practice of early nursery discharge, often during the first day of life, there is concern that some infants with metabolic disorders will not have ingested sufficient protein for an amino acid elevation to occur and, therefore, may not be identified. Lack of amino acid elevation is unlikely for severe forms of PKU but could occur in mild PKU and in disorders such as homocystinuria. In addition, because of maternally transferred thyroxine,

**FIGURE 27-1.** Hatched areas at medial and lateral sides of the heel in this drawing of the sole indicate the proper sites for heel-stick in the newborn.

testing of an early specimen could result in missing an infant with congenital hypothyroidism in programs that use a low thyroxine ( $T_4$ ) level as the indicator of this disorder. Consequently, to be certain that an infant with a disorder is not missed, a second blood specimen should be obtained no later than 7 days of age from infants whose initial specimen was obtained within the first 24 hours of life.

Since the introduction of MS/MS, the reliability of newborn screening has considerably improved, even in very early specimens (Chace and Naylor, 1999). With MS/MS, PKU can be detected within the first 24 hours of life (Chace et al, 1998). Lowering the cutoff level for methionine in screening for homocystinuria, which MS/MS readily accommodates, is likely to enhance the reliability of early detection of this disorder (Peterschmitt et al, 1999).

Special circumstances require specific attention to newborn blood specimen collection. For *premature* or *very low birth weight* infants as well as infants who are sick, especially those in neonatal intensive care units (NICUs), additional specimens should be collected and submitted for rescreening for all disorders at 2 weeks of age or at discharge, whichever is earlier. Moreover, additional thyroid testing should be performed for these infants at 6 and 10 weeks of age or until they reach a 1500-g body weight.

In a newborn who is to receive a *blood transfusion*, a screening specimen should be collected before transfusion and a second specimen collected 2 days after the transfusion. In addition, a third screening specimen should be obtained 2 months after the transfusion, when most of the donor red blood cells (RBCs) have been replaced. This practice ensures reliable testing for analytes present in RBCs, if a pretransfusion specimen has not been obtained.

A blood specimen should be collected before transfer from any infant who is being *transferred* to a different

hospital or to a NICU, regardless of age, and a second specimen collected at the receiving hospital by 4 days of age. This dual collection policy covers the infant from whom a newborn specimen might not have been obtained in the turmoil that frequently accompanies the transfer of neonates.

### Screening Laboratory

Newborn screening tests are usually performed in a centralized state, provincial, or regional laboratory. In a regional program, the specimens may be received by the state program and then delivered to the regional state or private laboratory, or they may be sent directly to the regional laboratory. In either case, the individual state programs serve as the state data and follow-up centers.

### Screening Tests

The testing procedure begins with the punching of small discs (each usually 3 mm in diameter) from the Guthrie specimen. In the bacterial assays for PKU and several other inborn errors of metabolism (galactosemia, homocystinuria, and MSUD), the discs are placed on agar or silica gels that contain bacteria, growth media, and other necessary factors. The constituents of each bacterial plate are specified for response to a particular metabolite, and the amount of bacterial growth around the disc is proportional to the concentration of the metabolite in the blood. In many newborn screening programs, the bacterial assays have been replaced by MS/MS, which allows for coverage of many inborn errors of metabolism (see Table 27-1) and offers many advantages over alternative methods of analysis.

Immunoassays, including radioimmunoassay (RIA), fluoroimmunoassay (FIA), and enzyme-linked immunosorbent assays (ELISA), are used to test for endocrinopathies such as congenital hypothyroidism and CAH, for infectious diseases such as congenital toxoplasmosis and human immunodeficiency virus (HIV) seropositivity, and for cystic fibrosis. Hemoglobin electrophoresis of blood eluted from the filter paper disc is employed for sickle cell disease screening. An enzyme assay is often used to screen for galactosemia and always used to screen for biotinidase deficiency.

### Secondary Tests

An abnormal finding on a newborn screening test is not diagnostic of a disorder. Abnormalities in the newborn specimen can be transient or artifactual. Accordingly, when an abnormality is identified, additional tests may be performed by the screening laboratory to substantiate the original finding. Also, the original specimen is retested for the analyte that was abnormal.

In screening for congenital hypothyroidism, the original newborn blood specimen in which a low T<sub>4</sub> level was found is further tested by immunoassay for an increased level of thyroid-stimulating hormone (TSH), which would indicate congenital hypothyroidism. A normal TSH level would suggest transient low T<sub>4</sub>, a common finding in premature infants, or thyroxine-binding globulin (TBG) deficiency. Confirmation of PKU, galactosemia, or other inborn errors of metabolism requires additional specimens. Consequently, a second blood specimen (filter paper or plasma) and, on occasion, a urine specimen are necessary for specific testing when the newborn blood specimen suggests a disorder. Urine may also be valuable in confirmatory testing (e.g., organic acid and fatty acid oxidation disorders).

DNA analysis is now commonly used for the confirmation of disorders identified by newborn screening. The combination of gene amplification by the polymerase chain reaction (PCR) and either hybridization with specific oligonucleotide probes (“dot blotting”) or analysis using restriction enzymes and band staining allows for the application of DNA analysis to the Guthrie specimen. DNA analysis is the second tier in cystic fibrosis screening (Wilcken et al, 1995). This two-tiered immunoreactive trypsinogen/DNA approach can identify up to 95% of patients with cystic fibrosis with a greatly increased specificity (Wilcken, 1993). Molecular testing for the prevalent A985G mutation in MCADD and the predominant E474Q mutation in long-chain 3-hydroxyacyl-CoA dehydrogenase deficiency (LCHADD), major metabolic causes of sudden infant death (SIDS), is performed as second-tier screening of specimens identified by MS/MS (Dobrowolski et al, 1999). Table 27-2 lists the disorders for which molecular testing is conducted and the corresponding second-tier mutations. It is likely that the use of molecular testing for second-tier screening will expand with advances in DNA technology.

**TABLE 27-2**

#### Molecular Testing Performed as Second-Tier Newborn Screening

Disorder	Primary Analyte	Mutation(s)
Cystic fibrosis	Immunoreactive trypsinogen (IRT)	ΔF508, others
Medium-chain acyl-CoA dehydrogenase deficiency	Fatty acylcarnitine (C8)	A985G
Long-chain hydroxyacyl-CoA dehydrogenase deficiency	Fatty acylcarnitine (C16-OH)	E474Q
Galactosemia	Galactose, galactose-1-phosphate uridylyltransferase (GALT)	Q188R, N314D

## Physician Contact for Abnormal Results

Table 27–3 indicates disorders or other reasons for abnormal screening results and the initial evaluation required when the primary care physician (medical home) is contacted. For instance, a low  $T_4$  level together with an elevated TSH concentration indicates congenital hypothyroidism. A specific markedly elevated level of phenylalanine, galactose, methionine, or leucine indicates, respectively, the probability of PKU, galactosemia, homocystinuria, or MSUD. A marked elevation of 17-hydroxyprogesterone (17-OHP) indicates the likelihood of CAH. An elevation of an acylcarnitine could point to an organic acid or fatty acid oxidation disorder.

Any infant for whom such a screening result is reported should be seen as soon as possible and evaluated with a careful history and physical examination. If the infant is ill or if the likely disorder requires immediate attention (see Table 27–3), a metabolic physician should be contacted; also, the baby should be admitted to a special care nursery, preferably in a center that has a pediatric metabolic unit with experience in the diagnosis and treatment of inborn errors of metabolism, where further evaluation and therapy for the illness can be initiated without delay. If the infant is active and alert with good feeding and shows no abnormal signs on initial evaluation, and the suspected disorder does not require immediate attention, a second filter paper blood specimen can be obtained and sent to the screening laboratory for repeat testing. If the second test confirms a disorder, the infant should be referred to a pediatric metabolic center.

Less striking abnormalities found by newborn screening are followed up with a letter sent to the physician from the screening program requesting another specimen. The physician should be notified of these results as soon as possible.

Most infants with a positive screening result, particularly when this result is only mildly or moderately abnormal, do not have a disorder (see later discussion of false-positive results). Transient or nonspecific abnormalities are quite common. Although all infants with an abnormal screening result must undergo repeat testing, the families should be informed that an initial positive result may have no medical implications. This approach can alleviate excessive anxiety and prevent unnecessary diagnostic procedures and treatment.

The physician should contact the screening laboratory when an infant has symptoms that suggest a metabolic disorder. The screening laboratory can check the results in the infant's newborn specimen. If the testing has been completed and the newborn specimens retained in storage, the laboratory may wish to recover the specimen and repeat the tests. The physician should also contact the screening laboratory for the results of repeat tests and inform the family of the results as soon as possible. If the second result is normal, the duration of family anxiety is thereby shortened.

## DISORDERS MOST COMMONLY SCREENED FOR

Following are brief summaries of the disorders most commonly screened for and detected by newborn screening. There is no attempt to describe any of the disorders in detail nor their very rare variants.

## Phenylketonuria

PKU is the paradigm for the disorders screened in the newborn. The cardinal screening feature is an increased level of phenylalanine. PKU should always be identified by newborn screening. If untreated, patients with PKU experience severe mental retardation and other neurologic abnormalities. The average incidence of the disorder is approximately 1 in 12,000 live births. With screening by MS/MS, PKU can reliably be identified as early as on the first day of life (Chace et al, 1998).

Not all infants with an elevation of phenylalanine have PKU. Mild elevations can indicate benign mild hyperphenylalaninemia. Liver disease, such as that associated with galactosemia or tyrosinemia I, can also produce increased phenylalanine. Therefore, treatment for PKU should never be given on the basis of a positive screening test result alone. The dietary therapy is complicated and can be hazardous to an infant who does not have PKU. If the screening test reveals a marked elevation of phenylalanine ( $\geq 6$  mg/dl), the infant should be referred directly to a metabolic center for confirmatory testing and prompt consideration of dietary treatment. If the screening level of phenylalanine is only slightly increased ( $< 6$  mg/dl), a second specimen should be tested.

## Congenital Hypothyroidism

Congenital hypothyroidism is the most common disorder identified by routine newborn screening. It is found in 1 in 3000 to 5000 screened infants (Dussault, 1993). The major clinical features of untreated congenital hypothyroidism are growth retardation and delayed cognitive development leading to mental deficiency. If treatment with pharmacologic doses of thyroxine is initiated early, growth and mental development are normal.

Two screening approaches are used. One is primary screening for low  $T_4$  with secondary screening for high TSH. The other is primary screening for high TSH. Either procedure reliably identifies congenital hypothyroidism. Nevertheless, in either approach, affected infants can be missed. This situation may be due to lack of the identifying marker. Specifically, the  $T_4$  level during the first 24 hours of life in an affected infant might not yet be sufficiently decreased for identification due to persistence of maternally transmitted  $T_4$ . Moreover, in the premature infant with congenital hypothyroidism, it might take 2 weeks or more for a TSH elevation to develop.

The rate of false-positive results of screening for congenital hypothyroidism is approximately 0.04% to 0.5% (Table 27–4). Infants with false-positive results have transiently low  $T_4$  or elevated TSH. Many of those with low  $T_4$  are premature infants with a normal TSH concentration or infants with perinatal stress and elevated TSH. To avoid missing congenital hypothyroidism, screening programs require a second blood specimen from each of these infants. In addition to false-positive results, a low  $T_4$  level with a normal TSH value can result from benign TBG deficiency (Dussault, 1993; Mandel et al, 1993) or hypothyroidism secondary to pituitary deficiency.

Infants with a positive screening test result should not be labeled as having congenital hypothyroidism or treated

TABLE 27-3

**Abnormal Newborn Screening Results: Possible Implications and Initial Evaluation Required**

Newborn Screening Finding*	Differential Diagnosis	Initial Evaluation Required
<b>Medical emergency; immediate action required (admission to neonatal intensive care unit if infant is critically ill)</b>		
↑ Leucine	Maple syrup urine disease	Clinical evaluation, urinary ketone measurement, acid-base status determination, blood amino acid and urine organic acid measurements
↑ 17-hydroxyprogesterone	Congenital adrenal hyperplasia, prematurity, low birth weight, stress in neonatal period, early specimen	Clinical evaluation including examination of genitals, serum electrolyte determination
↑ Galactose (galactose-1-phosphate)	Galactosemia, liver disease, portosystemic shunt, transferase deficiency variant	Clinical evaluation, analysis of urine for reducing substances
↑ Citrulline	Citrullinemia, argininosuccinic acid lyase deficiency	Clinical evaluation, blood ammonia and amino acid measurements, acid-base status determination
↑ Arginine	Arginase deficiency	Clinical evaluation, blood ammonia and amino acid measurements, acid-base status determination
↑ C3 (propionylcarnitine)	Propionic acidemia, methylmalonic acidemia	Clinical evaluation, urine organic acid and blood amino acid analysis, urinary ketone measurements, acid-base status determination
↑ C5 (isovalerylcarnitine)	Isovaleric acidemia, antibiotic treatment of mother during delivery	Clinical evaluation, urine organic acid and ketone measurements, acid-base status determination
<b>Medical urgency; rapid but not immediate action required</b>		
↑ Phenylalanine	Phenylketonuria (PKU), non-PKU hyperphenylalaninemia, pterin defect	Second blood specimen for screening; if result is positive, send infant to metabolic center for urine pterins and dietary treatment
↓ Thyroxine (T <sub>4</sub> ), ↑ thyroid-stimulating hormone (TSH)	Congenital hypothyroidism, iodine exposure	Second blood specimen for screening; if result is positive, send infant to endocrinologist for thyroxine treatment
↑ C4 (butyrylcarnitine)	Short-chain acyl-CoA dehydrogenase deficiency (SCADD)	Second blood specimen for screening; avoid fasting >4 hr until diagnosis ruled out
↑ C8 (octanoylcarnitine)	Medium-chain acyl-CoA dehydrogenase deficiency (MCADD)	Second blood specimen for screening and DNA analysis; avoid fasting >4 hr until diagnosis ruled out
↑ C14:1 (tetradecanoylcarnitine)	Very-long-chain acyl-CoA dehydrogenase deficiency (VLCADD)	Second blood specimen for screening; avoid fasting >4 hr until diagnosis ruled out
↑ C16OH (hydroxydecanoylcarnitine)	Long-chain hydroxyacyl-CoA dehydrogenase deficiency (LCHADD)	Second blood specimen for screening; avoid fasting >4 hr until diagnosis ruled out DNA analysis
↑ C16 (palmitoylcarnitine), ↑ C18:1 (octadecanoylcarnitine)	Carnitine palmitoyltransferase (CPT) II deficiency	Second blood specimen for screening
↑ C5OH (3-hydroxyisovalerylcarnitine)	Hydroxymethylglutaryl (HMG)-CoA lyase, β-ketothiolase, or 3-methylcrotonyl-CoA carboxylase deficiency	Second blood specimen for screening
↑ Ornithine	Hyperammonemia-hyperornithinemia-homocitrullinemia (HHH) syndrome	Second blood specimen for screening

**TABLE 27-3**

**Abnormal Newborn Screening Results: Possible Implications and Initial Evaluation Required—Cont'd**

Newborn Screening Finding*	Differential Diagnosis	Initial Evaluation Required
Medical necessity; action required without urgency		
↑ Methionine	Homocystinuria, isolated hypermethioninemia, liver dysfunction, tyrosinemia type I	Second blood specimen for screening
↑ Tyrosine	Tyrosinemia type I, II, or III, liver disease	Second blood specimen for screening
↑ Trypsinogen	Cystic fibrosis, intestinal abnormalities, perinatal stress, trisomy 13 or 18, renal failure	Second blood specimen for repeat screening and DNA analysis; sweat test may be needed
↓ Biotinidase	Biotinidase deficiency	Serum biotinidase assay
↑ C5 (glutaryl carnitine)	Glutaric acidemia (GA) type I or II	Second blood specimen for screening
Presence of S-hemoglobin	Sickle cell disease, sickle cell trait	Hemoglobin electrophoresis

\*Every finding could also be transient or a false-positive result, especially if it is mild.

until testing of a second specimen confirms the disorder. This is especially true if the TSH concentration reported by the screening program is normal. If congenital hypothyroidism is confirmed, however, administration of thyroxine should be started without delay to prevent irreversible brain damage.

**Galactosemia**

Galactosemia typically manifests in the neonatal period as failure to thrive, vomiting, and liver disease. Death from bacterial sepsis, usually due to *Escherichia coli*, occurs in a

high percentage of untreated neonates (Levy et al, 1977). The average incidence of the disorder is 1 in 62,000.

Some screening programs use a metabolite assay for total galactose (galactose and galactose-1-phosphate) to detect galactosemia. Other programs screen the newborn specimen with a specific enzyme assay for activity of galactose-1-phosphate uridylyltransferase (GALT), which is undetectable in severe galactosemia. The enzyme assay identifies only galactosemia, however, whereas the metabolite assay also identifies other galactose metabolic disorders, such as deficiencies of galactokinase and epimerase. Severe neonatal liver disease and portosystemic shunting due to anomalies in the portal system can also increase the galactose level.

**TABLE 27-4**

**Approximate Rates of False-Positive Results in Newborn Screening**

Abnormal Analyte or Result	Disorder for Which Screening is Conducted	Rate of False-Positive Results (%)
17-Hydroxyprogesterone	Congenital adrenal hyperplasia	0.2-0.5
Thyroxine/thyroid-stimulating hormone	Congenital hypothyroidism	0.04-0.5
Galactose or galactose-1-phosphate uridylyltransferase	Galactosemia	0.05-0.7
Tyrosine	Tyrosinemia	0.03
Phenylalanine	Phenylketonuria	0.03-0.1
Leucine	Maple syrup urine disease	0.05
Methionine	Homocystinuria	0.01-0.06
Hemoglobins	Hemoglobinopathies	0.03
Biotinidase	Biotinidase deficiency	0.05
Immunoreactive trypsinogen/DNA analysis	Cystic fibrosis	0.09
C8 (octanoyl carnitine)	Medium-chain acyl-CoA dehydrogenase deficiency	0.02

The most rapid confirmatory test for a positive result in galactosemia screening is urine testing for reducing substance. In almost all cases of severe galactosemia, this test produces a strongly positive reaction. Galactosemia with residual GALT activity, however, may be accompanied by a negative or only slightly positive result for urine reducing substance. If the urine contains reducing substance and the infant has clinical signs of galactosemia (e.g., poor feeding, jaundice, hepatomegaly), a blood specimen for confirmatory testing should be collected, and milk feeding (breast or formula) should be discontinued with substitution of a non-lactose formula such as soy or elemental. The infant should then be referred immediately to a pediatric metabolic center, where confirmatory testing should include the measurement of RBC galactose-1-phosphate and an enzyme assay for RBC GALT activity (Levy and Hammersen, 1978). Molecular testing for GALT mutations should also be performed (see Table 27–2). About 70% of the patients with galactosemia carry the Q188R mutation (Elsas and Lai, 1998). Variant galactosemia is produced by mutations such as S135L. The N314D mutation produces the benign Duarte variant.

If the urine test is negative for reducing substance, the newborn screening result is most likely to be false-positive or to indicate a benign GALT enzyme variant (e.g., Duarte variant). Nevertheless, urine reducing substance may be absent in infants with clinically significant variants of galactosemia. Consequently, screening should be repeated for all infants with an initial positive galactosemia screening result.

### Homocystinuria

Individuals with homocystinuria are clinically normal at birth but, if untreated, experience ectopia lentis (dislocation of the lens), thromboembolism, osteoporosis, mental retardation, or a combination of these problems. The worldwide frequency of all forms of homocystinuria has been estimated at about 1 in 344,000.

The newborn blood screening marker for detection of homocystinuria is an increased level of methionine. Infants with homocystinuria are missed, however, if the screening program does not include methionine in its list of measured analytes or because the blood methionine concentration was not elevated at the time the newborn specimen was collected (Whiteman et al, 1979). Reducing the cutoff value for methionine can substantially increase the frequency of identified infants (Peterschmitt et al, 1999). The introduction of MS/MS to newborn screening will most likely further improve the detection rates because it has a greater sensitivity for methionine than the bacterial assay. Moreover, because MS/MS measures methionine along with other amino acids (e.g., phenylalanine) without requiring a separate assay, many programs that formerly have not screened for homocystinuria will include the disorder (Chace et al, 1996).

A high methionine level by itself is not diagnostic of homocystinuria. Liver disease can produce a strikingly high methionine level, as can isolated hypermethioninemia (methionine-S-adenosyltransferase [MAT] I/III deficiency), a metabolic disorder that may be benign. Tyrosinemia type I (hereditary tyrosinemia) is usually associated with a high

methionine level, most likely due to the liver disease. Furthermore, transient hypermethioninemia may occur in newborn infants. The initial action required when a methionine elevation is detected on newborn screening is submission of a second screening blood specimen. If the methionine level is increased in that specimen, the infant should be seen at a pediatric metabolic center, where quantitative amino acid analyses of plasma and urine should be performed. In the infant with homocystinuria, homocystine is usually detectable in plasma and urine, plasma total homocysteine is increased as is methionine, and cystine is reduced. In isolated hypermethioninemia, methionine is markedly increased in plasma, but there is no detectable homocystine in plasma or urine, and the plasma cystine concentration is normal. Hypermethioninemia secondary to liver disease or tyrosinemia type I is usually accompanied by increased tyrosine.

### Maple Syrup Urine Disease

The marker for MSUD is an increase in leucine in the newborn blood specimen. Newborns with classic MSUD almost always have at least a fourfold elevation of leucine. Transient increases in the blood leucine concentration are uncommon and are usually no more than twice the normal concentration. The average incidence of classic MSUD is 1 in 185,000.

MSUD can be a fulminant disease associated with severe ketoacidosis, vomiting, and lethargy and may rapidly progress to coma and death. Consequently, the finding of a substantially increased leucine level in the newborn blood specimen should prompt an immediate phone call from the screening program to the attending physician. If the infant is ill, he or she should be immediately transported to a NICU at a medical center with a metabolic specialist. Confirmatory plasma and urine specimens should be obtained, and emergency therapy initiated. Plasma amino acid analysis in the infant with MSUD will show marked increases in leucine, isoleucine, and valine (the branched-chain amino acids). The urine specimen will test strongly positive for ketones and will contain large quantities of the branched-chain ketoacids and amino acids. The characteristic odor reminiscent of maple syrup, which appears earliest in cerumen and only later in urine, will probably be detected on a cotton-tipped swab inserted in the infant's ear.

Milder variants of MSUD can be missed by newborn screening. The newborn with the *intermediate* variant may not have a blood leucine elevation or the increase may be so mild as to be below the cutoff value. In the *intermittent* variant, the blood leucine concentration is normal in the newborn period, becoming elevated only in later infancy or childhood during acute metabolic episodes precipitated by febrile illness or surgery.

### Congenital Adrenal Hyperplasia

A decidedly increased level of 17-OHP suggests CAH due to 21-hydroxylase deficiency. Infants with the salt-losing form of CAH can rapidly become hyperkalemic and die precipitously, often without a specific diagnosis. The clinical

diagnosis may be suspected in the newborn girl because of ambiguous genitalia. However, the diagnosis is usually unsuspected in boys and in girls with atypical forms of CAH in which ambiguous genitalia may not occur. Even infant girls with ambiguous genitalia may be unrecognized as having CAH if the ambiguity is not obvious, or may be misassigned as boys, if the ambiguity is advanced. Because accurate gender assignment and initiation of hormone therapy as soon as possible are critical to a favorable prognosis in CAH, newborn screening is important in leading to early diagnosis and prompt therapy with pharmacologic doses of hydrocortisone. Consequently, testing for CAH has been incorporated into routine newborn screening in a number of programs in North America, Europe, and Asia (Pang and Clark, 1993).

Unfortunately, false-positive results in newborn screening for CAH are relatively common, the rate often as high as 0.5% (see Table 27-4). The finding may be truly increased 17-OHP such as in perinatal stress and early specimen collection (within the first 24 hours of life), or due to cross-reacting steroids, such as in prematurity and low birth weight (al Saedi et al, 1996). Cross-reacting steroids are produced by residual fetal adrenal cortex or result from decreased metabolic clearance by an immature liver.

A second blood specimen is required from any infant found on screening to have increased 17-OHP. If the infant shows signs of illness or has ambiguous genitalia, serum electrolytes should be measured. If these results indicate hyponatremia and hyperkalemia, the infant should be hospitalized without delay, and the electrolyte imbalance should be corrected immediately. Pediatric endocrinology consultation should also be sought.

### **Biotinidase Deficiency**

Biotin recycling is necessary for the maintenance of sufficient intracellular biotin to activate carboxylase enzymes. Biotinidase is a key enzyme in biotin recycling. Lack of biotinidase activity results in reduced carboxylase activities and an organic acid disorder known as multiple carboxylase deficiency (Wolf and Heard, 1991). The clinical features of the disorder are developmental delay, seizures, hearing loss, alopecia, and dermatitis. The developmental delay and seizures usually manifest at 3 to 4 months of age. Death during infancy has also been reported.

The initiation of biotin therapy in early infancy, when the disorder is presymptomatic, prevents all of the features of biotinidase deficiency. For this reason, a screening test has been developed and added to newborn screening in a number of newborn screening programs throughout the world (Hart et al, 1992). The frequency of identified newborns in these programs has a wide range, from 1 in 30,000 to 235,000. The average frequency is about 1 in 70,000. Almost all identified infants have been asymptomatic and have remained normal with biotin treatment.

### **Sickle Cell Disease**

In most newborn screening programs in the United States, the blood specimen is routinely tested for hemoglobin abnormalities. The major goal of this testing is to

identify infants with sickle cell disease so that they can be given penicillin prophylaxis to prevent pneumococcal septicemia. Additional benefits of early detection are early referral to a comprehensive sickle cell program and early education and genetic counseling for parents (Smith and Kinney, 1993). Unfortunately, the long-term complications are not yet preventable.

Sickle cell screening is usually performed by means of hemoglobin electrophoresis of blood eluted from a disc of the Guthrie specimen. This procedure identifies not only sickle cell disease but also sickle cell trait and several other abnormal hemoglobins. Other than sickle cell disease, most of these abnormalities are benign. The finding of a hemoglobin abnormality on screening must be followed by confirmatory testing. This is especially critical in differentiating the common and benign sickle cell trait from the much rarer sickle cell disease (homozygosity for S hemoglobin). For instance, sickle cell disease affects approximately 1 in 600 African-American persons, whereas sickle cell trait (carrier status for S hemoglobin) is present in 1 in 12. Infants with sickle cell trait do not have complications and should not be stigmatized as having sickle cell disease.

When sickle cell disease is confirmed, penicillin prophylaxis should be initiated as soon as possible, and the infant referred to a sickle cell disease center or hematologist. The combination of screening and careful follow-up has been very effective in preventing pneumococcal sepsis in infants with sickle cell disease.

## **OTHER DISORDERS DETECTED BY NEWBORN SCREENING**

### **Amino Acid Disorders**

In addition to the amino acid disorders traditionally detected in newborn screening (PKU, MSUD, and homocystinuria), three disorders of the urea cycle as well as the tyrosinemias can be identified by expanded screening using MS/MS technology. These disorders are listed in Table 27-1.

The urea cycle disorders manifest as episodes of hyperammonemia, often in the neonatal period, producing poor feeding, tachypnea, lethargy, and vomiting. Respiratory alkalosis is characteristic. The clinical picture of presentation after the newborn period is very like that of Reye syndrome. Severe hyperammonemia in the newborn is a medical emergency and should trigger prompt consultation with a metabolic specialist or referral to a NICU at a metabolic center. Discontinuation of protein and provision of intravenous fluids with very high caloric content are the first steps to take. Administration of L-arginine or L-citrulline, sodium phenylbutyrate, and sodium benzoate, as well as hemodialysis, are required to control the neurotoxic hyperammonemia, which can lead to irreversible brain damage, coma, and death. It is hoped that with early identification through newborn screening, patients with urea cycle disorders will be protected through presymptomatic therapy in the neonatal period.

Tyrosinemia type I is an amino acid disorder that may be diagnosed through an elevation of tyrosine on the MS/MS profile. This disorder leads to liver and renal

tubular disease and can later result in hepatocellular carcinoma. It is treated with administration of NTBC (2-nitro-4-trifluoro-methylbenzoyl-1,3-cyclohexanedione) and a diet low in phenylalanine and tyrosine. Unfortunately, moderate elevations of tyrosine that are transient occur frequently in neonates, especially those who have low birth weights and are sick, necessitating a cutoff value for tyrosine that is higher than the level in many neonates with tyrosinemia type I. Consequently, the newborn detection of tyrosinemia type I by a tyrosine marker is problematic. Tyrosinemia type II, which can result in mental retardation, painful hyperkeratoses, and keratoconjunctivitis, and tyrosinemia type III, which possibly causes cognitive loss, may also be detected by expanded newborn screening.

### Medium-Chain Acyl-CoA Dehydrogenase Deficiency and Other Fatty Acid Oxidation Disorders

The fatty acid oxidation disorders can be identified in programs that have adopted MS/MS technology. These disorders include those in which the long-chain fatty acids cannot traverse the mitochondrial membranes to be oxidized within the mitochondrial matrix and those that constitute defects in fatty acid oxidation per se. In either category, the problem is the inability to fully oxidize fatty acids. Fatty acid oxidation is essential to supply energy as adenosine triphosphate (ATP) via the Krebs cycle and as ketones in the presence of a low supply of glucose. The disorders involving defective *transport* concern carnitine, where those with defective *oxidation* are named according to the enzyme that is deficient (see Table 27–1). The clinical consequence of these disorders is fasting intolerance resulting in hypoketotic hypoglycemia, lethargy, hyperammonemia, metabolic acidosis, hepatomegaly and, not uncommonly, sudden death. Cardiomyopathy and developmental delay are additional features of very-long-chain acyl-CoA dehydrogenase deficiency (VLCADD) and LCHADD. Each fatty acid disorder is associated with a specific or almost specific acylcarnitine pattern on MS/MS analysis.

The most common fatty acid oxidation disorder is MCADD. Tragically, this disorder has often been diagnosed only retrospectively after a sudden unexplained death, usually when postmortem examination disclosed a fatty liver. This devastating outcome and a frequency of 1 in 15,000 to 20,000 (Zytkovicz et al, 2001), comparable with that of PKU, has made MCADD the primary reason for the addition of MS/MS technology to newborn screening. To reduce the rate of false-positive results in screening for MCADD, some programs have added molecular testing of the A985G MCADD mutation as second-tier screening. Because this mutation occurs in as many as 90% of persons with MCADD, this additional analysis of a newborn blood specimen with an elevation of the octanoylcarnitine (C8) marker for MCADD substantially improves the predictive value of the screening abnormality (Zytkovicz et al, 2001).

The most important treatment for fatty acid oxidation disorders in general is avoidance of fasting with frequent high-carbohydrate, low-fat feedings. Some centers also include carnitine supplements. Any infant diagnosed with a fatty acid oxidation disorder should be evaluated at a

metabolic center. Most of these disorders are treatable, but even when early treatment may not be effective, such as in neonatal carnitine palmitoyltransferase II (CPT II) deficiency, screening enables early diagnosis and genetic counseling of the family (Albers et al, 2001a).

### Organic Acid Disorders

Organic acid disorders are a heterogeneous group of disorders with a combined frequency of approximately 1 in 50,000 (Zytkovicz et al, 2001). Many of them can now be identified through MS/MS screening (see Table 27–1). The marker for this disease group, as for the fatty acid oxidation disorders, is an abnormal acylcarnitine pattern (see Table 27–3). If a screening result suggests an organic acidemia, a metabolic specialist should be consulted immediately.

Any of the organic acidemias can manifest in the neonatal period as a life-threatening, sepsis-like picture of feeding difficulties, lethargy, vomiting, and seizures. Metabolic acidosis virtually always accompanies this presentation, and hyperammonemia is common. In this situation, protein administration should be discontinued and replaced by administration of intravenous fluids with very high caloric content and carnitine. The hyperammonemia rarely requires specific treatment.

The effects of early diagnosis and treatment on the clinical and neurologic development of individuals affected by an organic acid disorder are currently under investigation (Albers et al, 2001b).

### Cystic Fibrosis

The frequency (1 in 2000 to 3000) and severity of cystic fibrosis explain its inclusion in routine newborn screening. As with sickle cell disease, therapy that can prevent the ultimate complications of cystic fibrosis is not yet available. However, early and usually presymptomatic diagnosis through screening leads to early nutritional therapy, pancreatic enzyme replacement, and antibiotic prophylaxis for pulmonary infection. Data from newborn screening suggests better growth in children identified by screening (Farrell et al, 2001). Other benefits of newborn screening are identifying the parents' genetic potential for producing additional children with cystic fibrosis and, through presymptomatic identification, allowing the family to avoid months or years of delay in the correct diagnosis of a child with chronic respiratory problems or poor growth (Farrell and Mischler, 1992; Wilcken, 1993).

The analyte marker in newborn screening for cystic fibrosis is increased immunoreactive trypsinogen (IRT). Transient increases in IRT are common in normal newborns as a result of perinatal stress or for unknown reasons. Consequently, the rate of false-positive results in cystic fibrosis screening is relatively high (see Table 27–4). To reduce this rate, screening programs have adopted a second-tier DNA analysis for one or more of the cystic fibrosis mutations when the specimen has increased IRT (Ferec et al, 1995). Despite this expanded approach to screening detection, a substantial number of infants who do not have cystic fibrosis must undergo a sweat test before the diagnosis can be eliminated. The high false-positive rate and the need for this

somewhat complicated follow-up test have inhibited most programs from adopting screening for cystic fibrosis.

Gene therapy for cystic fibrosis has been intensively investigated. If gene therapy becomes available, advocacy for cystic fibrosis screening would greatly increase, because screening would then enable potentially curative treatment before the onset of irreversible pulmonary damage.

### Neuroblastoma

Neuroblastoma is the most common solid tumor of childhood, accounting for a significant number of deaths in preschool children. It is characterized by the excretion of increased vanillylmandelic acid (VMA) and homovanillic acid (HVA). In Japan and in some European programs, screening for neuroblastoma is conducted on filter paper urine specimens collected when infants are 6 months old. VMA and HVA are measured by high-performance liquid chromatography on urine eluted from the paper (Sawada, 1992). In a large, externally controlled study conducted in Quebec, filter paper urine specimens collected at 3 weeks and again at 6 months of age were screened for VMA and HVA by thin-layer chromatography with confirmatory follow-up by gas chromatography–mass spectrometry. The results indicated that screening does not reduce mortality from neuroblastoma. Notably, in almost all of the affected children with poor-prognosis neuroblastoma, screening results were falsely negative, the children being subsequently diagnosed clinically; in contrast, most of the infants identified by screening as having the disease had good-prognosis neuroblastoma, which either spontaneously regresses or can be effectively treated after clinical detection (Woods et al, 2003). Consequently, screening for neuroblastoma seems to be unnecessary and counterproductive, causing inappropriate anxiety and intervention.

## SPECIFIC ISSUES IN NEWBORN SCREENING

### False-Positive Results

The majority of positive results in newborn screening are not due to metabolic or any other disease. Table 27–4 lists the approximate rates of false-positive results for the most important inborn errors of metabolism. The rates are highest when the indicator is an abnormal metabolite level, such as thyroxine in congenital hypothyroidism, 17-OHP in CAH, or galactose in galactosemia. False-positivity rates are also high when the indicator is low activity of an enzyme, such as GALT in galactosemia. When the gene product can be directly examined, as for the hemoglobinopathies, the rate of false-positive results is low.

False-positive results are more common in preterm and low-birth-weight infants than in full-term babies. For example, up to 85% of preterm babies have transiently low thyroxine levels (Paul et al, 1998). Transient increases in 17-OHP are another common abnormality in infants who are preterm or have low birth weights or have experienced perinatal stress (Pang and Shook, 1997). Finally, transient tyrosinemia is commonly observed in preterm and low-birth-weight babies, although it can also occur in full-term infants (Levy et al, 1969).

Artifacts produced in the collection or transport of the Guthrie specimen account for some false-positive results. As mentioned in the discussion of the specimen collection procedure, collection of the specimen from a central line can result in mixing with amino acids in TPN solution and a false increase of amino acids in the specimen. Contamination with milk (or coffee containing milk) can result in a false elevation in the bacterial assay result for galactose and the mistaken suspicion of galactosemia. Prolonged exposure to heat can reduce the activity of GALT in the specimen and also produce a false impression of galactosemia when the Beutler spot enzyme assay is used to screen for this disorder; this error is common during the summer, especially when the specimens remain in a mailbox for a period of time.

With the expansion of molecular testing as second-tier screening, which is now commonly performed for cystic fibrosis and galactosemia, and the substitution of MS/MS for the traditional bacterial or specific assays, such as those for PKU and MSUD, the number of false-positive results will most likely be significantly reduced (Chace and Naylor, 1999). Nevertheless, false-positive results cannot be entirely eliminated, in particular among high-risk infants in NICUs. Therefore, it is important to reassure the parents that not every abnormal result of newborn screening inevitably implies a disorder.

### Missed Cases

Infants with PKU, congenital hypothyroidism, and other screened disorders have been missed in newborn screening. Laboratory or program error is the usual cause of these missed cases (Holtzman et al, 1974). In some instances, a specimen was never collected, particularly for an infant who was transferred to another hospital. In other instances, mistakes occurred because the laboratory was not properly supervised. Thus, physicians must exercise clinical judgment and not fall into the trap of excluding a diagnosis because an infant has presumably been screened. Specific testing for metabolic and endocrine disorders should be performed in any infant or child with symptoms that suggest the presence of such a disorder, regardless of the assumed or actual newborn screening result.

# CARE OF THE HIGH-RISK INFANT

Editor: ROBERTA A. BALLARD

## CHAPTER 28

### Resuscitation in the Delivery Room

Jeffrey D. Merrill and Roberta A. Ballard

#### PHYSIOLOGY OF BIRTH

During normal gestation, labor, and delivery, powerful biochemical and mechanical forces act on the fetus to prepare it to adapt to extrauterine life. However, a myriad of adverse circumstances—genetic, maternal, and fetal—that vary in duration, degree, and implication for outcome can occur during the antepartum and intrapartum periods and impair the infant's ability to make this adaptation successfully. Hence, there is a need for resuscitative efforts to assist in this process. The approach to the resuscitation of any infant depends on a keen appreciation of the historical factors behind the need, an understanding of the physiologic mechanisms of adaptation, and sensitivity to the individual infant's responses as well as skill in resuscitative techniques. Thus, successful resuscitation depends on much more than the “mechanical” application of practiced routines; it requires a clear understanding of basic physiologic principles and excellent assessment skills as well as the essential equipment and practiced teamwork.

#### “Stress” of Birth

As Lagercrantz and Slotkin (1986) point out, “At first thought, being born would seem to be a terrible and dangerous ordeal. The human fetus is squeezed through the birth canal for several hours, during which the head sustains considerable pressure, and the infant is intermittently deprived of oxygen. . . . then delivered from a warm, dark, sheltered environment into a cold, bright hospital room. . . . (In response) the fetus produces unusually high levels of the “stress” hormones, adrenalin and noradrenalin, . . . typically used to prepare the body to fight or flee from a perceived threat to survival.” Surely, the process of labor and delivery is the time of greatest jeopardy that occurs during life, but would avoidance of this stress and the consequent

elevation of catecholamine levels lead to better outcomes? Catecholamines clearly contribute to the regulation of many processes important to the infant's adaptation at birth, including resorption of lung liquid, release of surfactant into the alveoli, mobilization of readily usable fuel for nutrition, defense against cold stress, and modulation of cardiac output to ensure the preferential flow of blood to vital organs, such as the heart and brain. Perhaps, as some researchers have suggested, elevations of catecholamines even promote attachment between mother and child by increasing the appearance of alertness of the infant (Fig. 28–1).

The normal preterm infant has lower catecholamine levels at birth than the normal term infant, a feature that contributes to the disadvantages of preterm infants in establishing ventilation and maintaining temperature. In both term and preterm infants, catecholamine levels are higher with delivery after labor and also higher in girls than in boys. Levels are proportionately very much higher in each of these groups when there is asphyxia (Greenough et al, 1987; Newnham et al, 1984). The endogenous opiate peptides (enkephalins and endorphins) also probably modulate the cardiovascular response to stress and play a role in the infant's adaptation at birth (Martinez et al, 1988). It is hoped that greater understanding of the interaction of these and other agents will eventually allow optimal preparation of the fetus for labor. This understanding may also provide insight as to which interventions should be used during labor and at birth to ensure an optimal outcome.

#### Transition from Fetal to Neonatal Circulation

Before birth, the placenta serves as the gas-exchange organ for the fetus and provides a low-resistance “shunt” compared with the high resistance of the fetus's peripheral circulation. As a result, the fetus normally has two large right-to-left shunts, one from the right atrium to the left atrium through the foramen ovale, and the other from the pulmonary artery to the aorta across the ductus arteriosus (Fig. 28–2). In utero, as a result of constricted pulmonary arterioles that produce high pulmonary vascular resistance, only a small percentage of the fetal cardiac output flows through the lungs. The fetus accommodates well to a normal  $PO_2$  of 20 to 25 mm Hg in its best-oxygenated blood, which comes through the umbilical vein from the placenta. As a result of the right-to-left shunts through the foramen ovale and the ductus arteriosus, the best-oxygenated blood streams from the umbilical vein to the inferior vena cava, through the foramen ovale into the left atrium and ventricle, and then out the aorta, thus

Rights were not granted to include this figure in electronic media.  
Please refer to the printed publication.

**FIGURE 28-1.** Adaptational effects of a catecholamine surge during delivery include promotion of normal breathing, alteration of blood flow to protect the heart and brain against potential asphyxia, immediate mobilization of fuel for energy and, possibly, enhancement of maternal-infant attachment. (From Lagercrantz H, Slotkin TA: *The “stress” of being born*. *Sci Am* 254:100, 1986. Copyright 1986 by Scientific American, Inc. All rights reserved.)

supplying best-oxygenated blood to the brain and myocardium of the fetus (see Fig. 28-2).

At delivery, two major changes occur in this system. First, the umbilical cord is clamped, eliminating the placenta as a gas-exchange organ and low-resistance “shunt.” Second, respiration is initiated by the fetus. Expansion of the lungs results in a marked decrease in pulmonary vascular resistance that is furthered by the higher level of oxygenation that occurs as the infant begins to breathe (Fig. 28-3). With these changes, the flow of blood to the left atrium via the pulmonary veins increases, so that left atrial pressure exceeds right atrial pressure and functionally closes the foramen ovale. When pulmonary vascular resistance decreases to a level lower than the systemic vascular pressure, the ductus arteriosus is functionally closed.

At birth, the lungs normally are partially filled with fluid. Therefore, the initial breaths taken by the infant must inflate the lungs and effect a change in vascular pressures so that lung water is absorbed into the pulmonary arterial system and cleared from the lung. At the same time, inflation is a powerful mechanism for the release of pulmonary surface-active material, which increases compliance of the lung and enables stabilization of functional residual capacity (Massaro and Massaro, 1983; Tausch et al, 1974).

### Fetal Reserve

Because the fetus is normally relatively hypoxemic ( $PO_2$  of 20 to 24 mm Hg) and during labor is subjected to stresses associated with both increased oxygen consumption and interrupted gas exchange, the fetus is at particular risk for asphyxia at the time of birth. However, the fetus has several compensatory mechanisms that help protect it. Fetal hemoglobin has greater oxygen affinity than adult hemoglobin, fetal tissues have an increased ability to

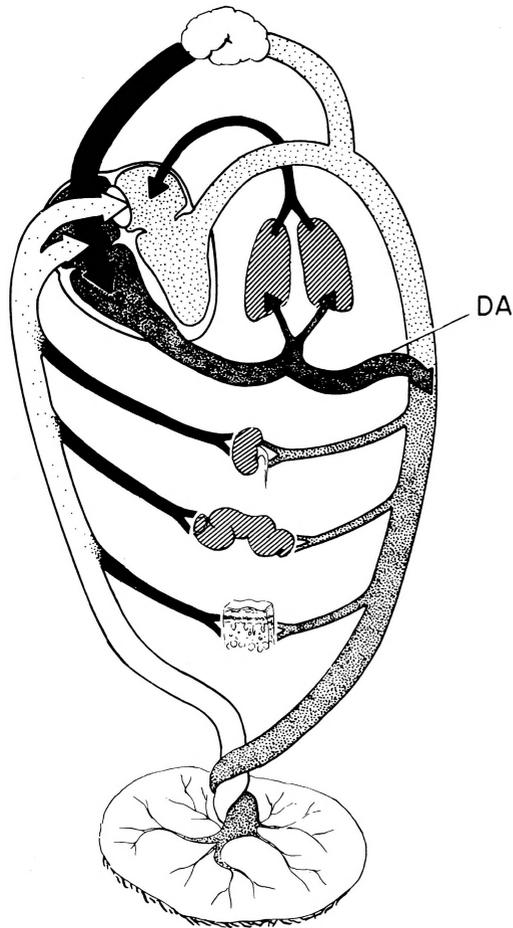

extract oxygen, and the fetus has greater tissue resistance to acidosis than the adult. In addition, the fetus has mechanisms that compensate for asphyxia. These include bradycardia and the “diving reflex” (similar to that found in diving mammals), which allows a preferential distribution of blood flow to the brain, adrenal glands, and heart and away from the lungs, gut, liver, spleen, kidney, and carcass. The fetus is also capable of reducing oxygen consumption and switching to anaerobic glycolysis, as long as liver glycogen stores are adequate.

## ASPHYXIA

### Physiology

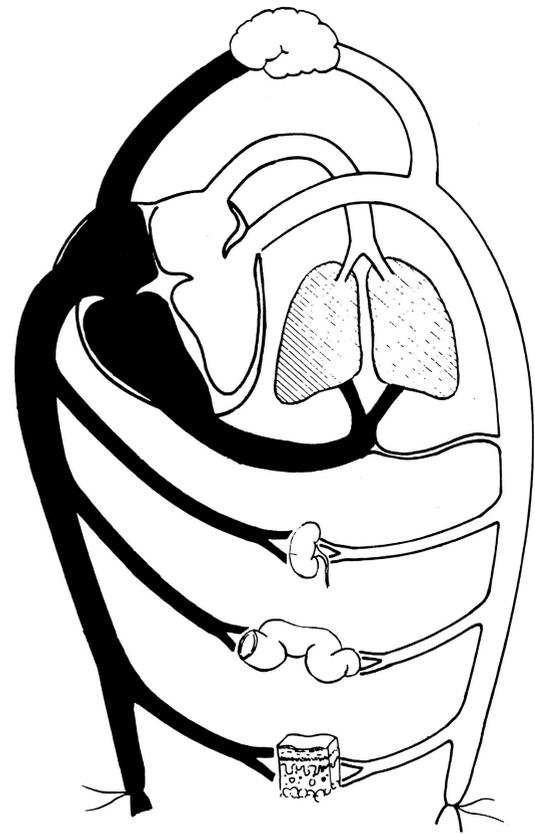

*Asphyxia* is defined as a combination of *hypoxemia*, *hypercapnia*, and *metabolic acidemia* (Strang, 1977). If lung expansion does not occur in the minutes after birth and the infant is unable to establish ventilation and pulmonary perfusion, a progressive cycle of worsening hypoxemia, hypercapnia, and metabolic acidemia evolves. Pulmonary vascular resistance remains high, the ductus arteriosus remains widely patent (Fig. 28-4), and right-to-left shunting through the foramen ovale also persists. Once this process begins, it tends to be self-perpetuating and may result in serious tissue hypoxia, ischemia, and acidosis, which ultimately may lead to irreversible organ damage. Asphyxia may be caused by maternal, placental, or fetal factors that reduce the fetal reserve (Table 28-1). The duration of asphyxia is critical to the outcome of the infant, so it is important to evaluate rapidly all of the factors contributing to the asphyxia and to interrupt the process as soon as possible.

Figure 28-5 demonstrates the classic cardiopulmonary changes seen in the animal model of asphyxia, as described

**FIGURE 28-2.** The fetal circulation. Oxygenated blood leaves the placenta by way of the umbilical vein (vessel without stippling). It flows into the portal sinus in the liver (not shown), and a variable portion of it perfuses the liver. The remainder passes from the portal sinus through the ductus venosus into the inferior vena cava, where it joins blood from the viscera (represented by the kidney, gut, and skin). About half of the inferior vena cava flow passes through the foramen ovale to the left atrium, where it mixes with a small amount of pulmonary venous blood. This relatively well-oxygenated blood (light stippling) supplies the heart and brain by way of the ascending aorta. The other half of the inferior vena cava stream mixes with superior vena cava blood and enters the right ventricle (blood in the right atrium and ventricle has little oxygen, which is denoted by heavy stippling). Because the pulmonary arterioles are constricted, most of the blood in the main pulmonary artery flows through the ductus arteriosus (DA) so that the descending aorta's blood has less oxygen (heavy stippling) than blood in the ascending aorta (light stippling). (From Avery GN: *Neonatology*. Philadelphia, JB Lippincott, 1987.)

by Dawes (1968). The initial phase of asphyxia is marked by increased respiratory effort (*primary hyperpnea*). This is followed by *primary apnea*, which lasts approximately 1 minute. Rhythmic gasping then begins and is maintained at a rate of 8 to 10 gasps per minute for several minutes, after which the gasps become weaker and slower until they cease, which is called *secondary apnea*. Some variation occurs in the period of gasping as a result of prior maternal and fetal medications or conditions that may have affected the infant's level of asphyxia at the moment of birth.

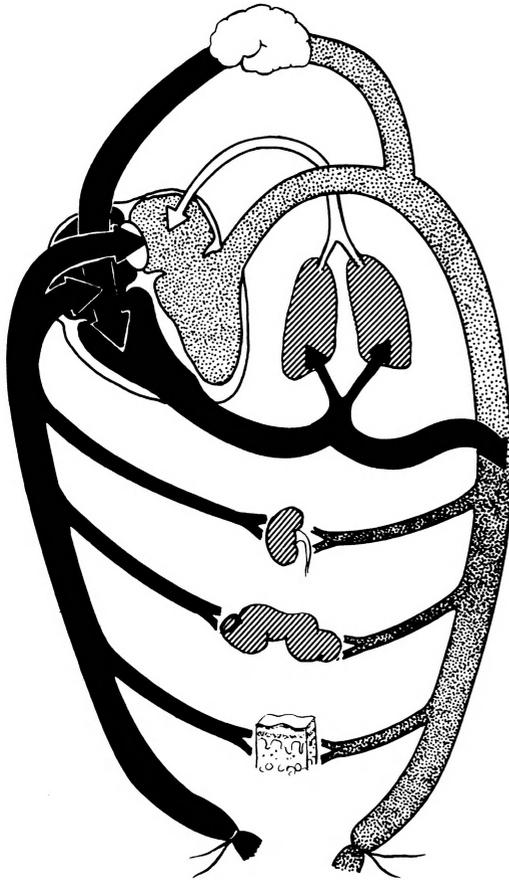

**FIGURE 28-3.** The circulation in the normal newborn. After expansion of the lungs and ligation of the umbilical cord, pulmonary blood flow increases and left atrial and systemic arterial pressures increase while pulmonary arterial and right heart pressures decrease. When the left atrial pressure exceeds right atrial pressure, the foramen ovale closes so that all of the inferior and superior vena cava blood leaves the right atrium, enters the right ventricle, and is pumped through the pulmonary artery toward the lung. With the increase in systemic arterial pressure and decrease in pulmonary arterial pressure, flow through the ductus arteriosus becomes left to right, and the ductus constricts and closes. The course of the circulation is the same as in the adult. (From Avery GN: *Neonatology*. Philadelphia, JB Lippincott, 1987.)

## Universal Prerequisites for Resuscitation

### Skilled Personnel

In the United States, 4 million babies per year are born in 5000 hospitals with delivery services (Martin et al, 2002). Ninety percent of these hospitals are small, level 1 services; 5% are level 2; and another 5% are level 3 (Bloom and Cropley, 1987). Thus, most infants are born in hospitals that do not have sophisticated perinatal programs. Yet 10% of newborns require some assistance at birth, and 1% require a more extensive resuscitation (Wu and Carlo, 2002).

The Neonatal Resuscitation Program (NRP), a combined effort of the American Heart Association (AHA) and the American Academy of Pediatrics (AAP), began in the 1980s as a means to ensure that all personnel in hospital delivery rooms have the knowledge and skills to provide optimal care to newborns immediately after birth. Implementation of the

**FIGURE 28-4.** The circulation in an asphyxiated newborn with incomplete expansion of the lungs. Pulmonary vascular resistance is high, pulmonary blood flow is low (normal number of pulmonary veins), and flow through the ductus arteriosus is high. With little pulmonary arterial flow, left atrial pressure decreases below right atrial pressure, the foramen ovale opens, and vena cava blood flows through the foramen into the left atrium. Partially venous blood goes to the brain via the ascending aorta. The blood of the descending aorta that goes to the viscera has less oxygen than that of the ascending aorta (heavy stippling) because of the reverse flow through the ductus arteriosus. Thus, the circulation is the same as in the fetus except that there is less well-oxygenated blood in the inferior vena cava and umbilical vein. (From Avery GN: *Neonatology*. Philadelphia, JB Lippincott, 1987.)

NRP has been associated with improvement in Apgar scores (Patel et al, 2001). The NRP emphasizes the basic principle that effective resuscitation must begin with the awareness that *well-trained personnel must be immediately available in any setting where an infant is likely to be delivered*. (The American College of Obstetrics and Gynecology [ACOG], the American Society of Anesthesiology, the American Academy of Family Physicians, and the Canadian Pediatric Society have also stated their support for this principle.) Identification and training of staff are, therefore, the first steps in preparation for neonatal resuscitation. The second step is close communication between obstetricians and pediatricians to identify women with high-risk fetuses before labor if possible, to prevent abnormal labors, and to

**TABLE 28-1**

**Conditions Affecting Fetal Reserve**

Determinants	Common Disorders
<b>Maternal</b>	
Infection	Amnionitis
Lungs	Pneumonia, asthma, adult respiratory distress syndrome
Heart	Arrhythmia, structural defect, failure
Blood	Anemia, hemoglobinopathy
Blood vessels	Systemic lupus erythematosus, diabetes, hypertension, hypotension
Uterus	Hypertonus, malformation, rupture
Other	Genetic, drugs, deformities, preterm labor, multiple gestation, abnormal fetal presentation
<b>Placental</b>	
Age	Postmaturity
Size, morphology	Abruptio placentae, placenta previa
<b>Fetal</b>	
Umbilical cord	Knot, entanglement, prolapse, compression, thrombosis
Blood	Anemia
Metabolic	Inborn error, aneuploidy
Other	Infection, hydrops, malformations, multiple gestation

Data from Jacobs M, Phibbs R: Prevention, recognition, and treatment of perinatal asphyxia. *Clin Perinatol* 16:785, 1989.

focus planning for the resuscitation of infants thus identified. Understanding the special needs of different kinds of infants enables caregivers to anticipate and prepare for various types of resuscitation appropriately.

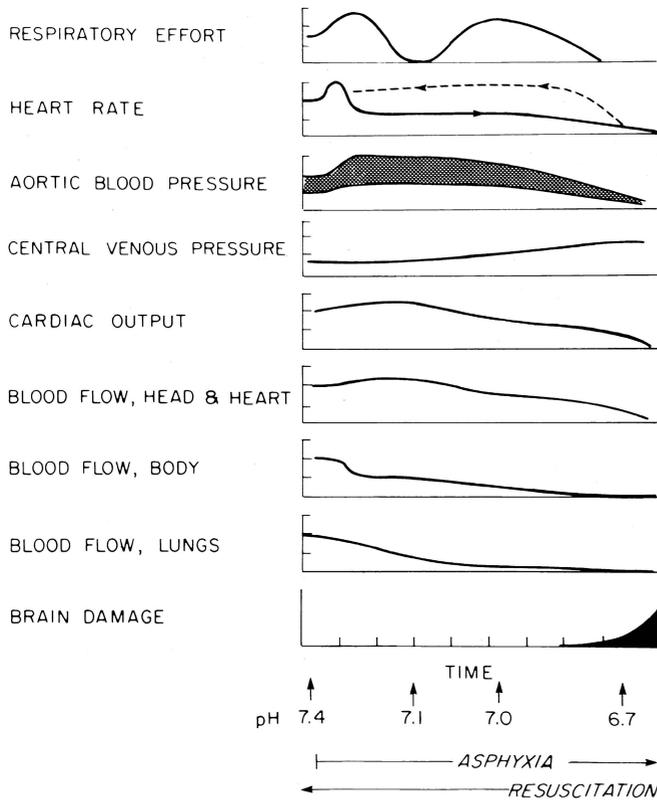

### Equipment

Resuscitation of the newborn is best performed in the delivery room or immediately adjacent to it, to minimize the time lapse between delivery and initiation of resuscitation. The equipment that should be available for neonatal resuscitation is listed in Table 28-2 ; it is divided into (1) items needed in every institution for resuscitation of low-risk term infants with unexpected problems and (2) additional equipment required for resuscitation of high-risk or known preterm infants.

## MANAGEMENT AT DELIVERY

### Initial Assessment

The NRP algorithm for resuscitation in the delivery room begins with an initial evaluation of the newborn (Fig. 28-6). Abnormalities in breathing, tone, and color as well as the presence of meconium or evidence of prematurity are indicative of the need for further resuscitation. One begins by placing the infant under a radiant heater, positioning the infant's head to open the airway, clearing upper

**FIGURE 28-5.** The sequence of cardiopulmonary changes with asphyxia and resuscitation. Time is on the horizontal axis. Asphyxia progresses from left to right; resuscitation proceeds from right to left. Units of time are not given. If there is complete interruption of respiratory gas exchange, the entire process of asphyxia from extreme left to right could occur in about 10 minutes. It could take much longer with an asphyxiating process that only partly interrupts gas exchange or does so completely, but only for repeated brief periods. With resuscitation, the process reverses, beginning at the point to which asphyxia has proceeded. (Adapted from Dawes G: *Foetal and Neonatal Physiology*. Chicago, Year Book, 1968, and Avery GN: *Neonatology*. Philadelphia, JB Lippincott, 1987.)

airway secretions, and drying and stimulating the infant. A brief delivery of oxygen, blown over the face, may be given as necessary for cyanosis. It is important to remember that at birth, the newborn infant's lungs are normally full of fluid which is cleared by resorption into the pulmonary vascular system (Walters, 1978). Excessive suctioning of clear fluid from the nasopharynx is not helpful and may contribute to atelectasis. The infant is next quickly assessed for respiration, heart rate, and color. The presence of apnea or a heart rate of less than 100 beats/min indicates the need for positive-pressure ventilation.

### Assisted Ventilation

*Effective ventilation* of the lung is the single most important step in the resuscitation of the compromised newborn. Previous studies demonstrate that reversal of hypoxia, bradycardia, and acidosis depends on adequate inflation

(Wu and Carlo, 2002). The airway must be cleared before attempts to expand the lung are made. Initial inflation of a gasless fluid-filled lung may require relatively high inflation pressures (sufficient to move the chest, usually 25 to 40 cm H<sub>2</sub>O) using a relatively long inspiratory time (0.5 to 1 second). The objective is to inflate the lung as well as to trap some gas during exhalation, thereby creating a functional residual capacity. This process occurs over a series of breaths. The term infant with a strong chest wall and large terminal airways is better able to generate the necessary forces to achieve lung inflation than the premature infant, who may need to be assisted. Lung inflation also stimulates surfactant secretion in mature lungs, and this response is enhanced by large-volume inflation. Once lung expansion is achieved, subsequent inflation pressure should be reduced to that necessary to sufficiently move the chest.

Concerns have been raised about the value of resuscitation with 100% oxygen versus room air. Traditionally, 100% oxygen has been used for rapid reversal of hypoxia (Rootwelt et al, 1992). Saugstad (1990, 1996) and others (Ramji et al, 1993) have raised concerns about the possibility that oxygen radicals produced in excess during the post-hypoxic reoxygenation period may cause tissue damage, particularly to the brain. One study has shown that asphyxiated infants resuscitated with room air exhibit shorter time to spontaneous respirations and first cry, with no differences in mortality or neurologic morbidity, than those resuscitated with 100% oxygen; in addition, biochemical markers of oxidative stress were reduced in the room air resuscitation group (Vento et al, 2001). Present data, however, are insufficient to change the current recommendation that 100% oxygen be used if assisted ventilation is required. If oxygen is not available, resuscitation should be initiated with room air.

Assisted ventilation should continue until the heart exceeds 100 beats/min and the infant begins spontaneous respiratory effort. For newborns requiring bag-and-mask ventilation for longer than several minutes, an orogastric tube should be inserted and left in place. If the need for positive-pressure ventilation lasts beyond several minutes, one should consider intubation of the trachea to improve efficiency of ventilation. Figure 28-7 shows landmarks of the larynx that should be visualized for successful intubation of the newborn. No attempt at intubation should last longer than 30 to 45 seconds before a return to bag-and-mask ventilation to support the neonate. If severe respiratory decompensation persists despite restoration of normal heart rate and color, and the mother has been given narcotics within 4 hours of delivery, one may consider naloxone administration. Naloxone should not be given to infants of mothers with a history of narcotic abuse during pregnancy. Once naloxone is administered, the infant should be observed for recurrence of respiratory depression, because of the shorter duration of effect of naloxone in comparison with opiates.

### Chest Compressions

Most infants respond to assisted ventilation alone during neonatal resuscitation. In a study by Perlman and Risser (1995), only 0.12% of infants required chest compressions,

**Equipment for Neonatal Resuscitation**

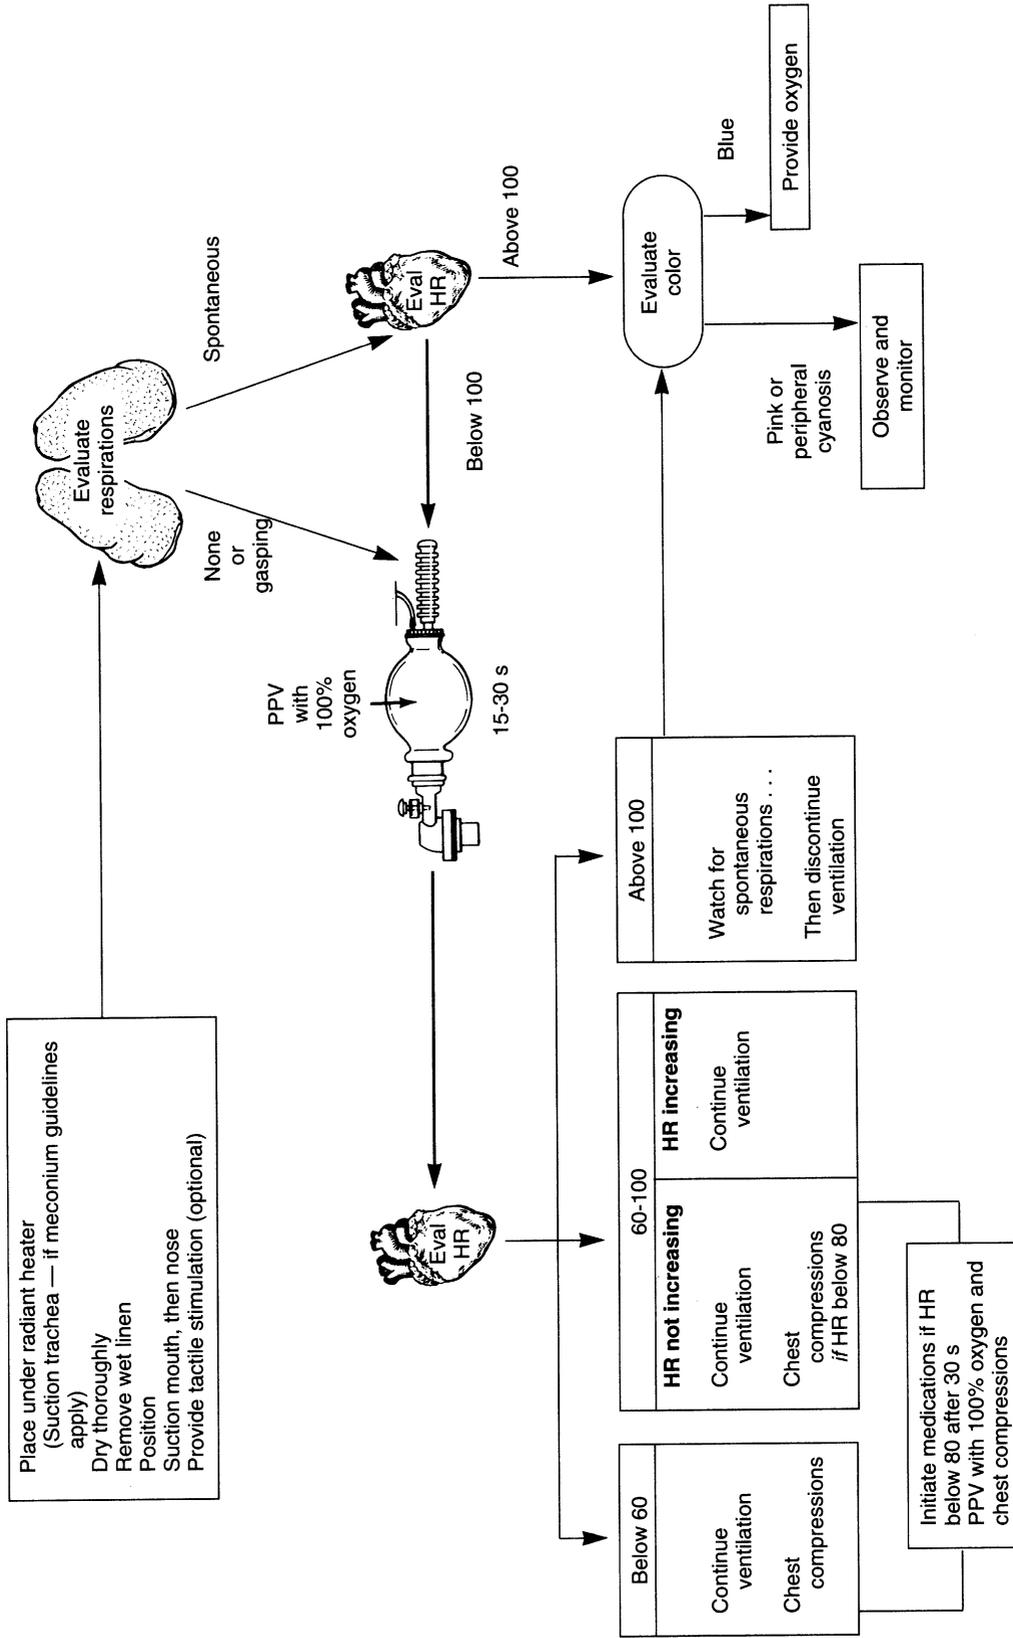

Low-risk and term infants	Radiant warmer to maintain temperature control Stethoscope Source of warm, humidified oxygen with flowmeter Bulb syringe Suction source Suction catheter and meconium aspirator Nasogastric tube and syringe Oral airway Apparatus for bag-and-mask ventilation of infant, either an anesthesia bag, or A bag with masks for different-sized infants Laryngoscope with straight blades Nos. 0 and 1 Endotracheal tubes—sizes 2.5, 3.0, 3.5, 4.0—and stylet Gloves, gowns, masks, hats for sterile procedures Tape Scissors Fluids (10% dextrose in water, normal saline) Medications (naloxone hydrochloride [Narcan], sodium bicarbonate [4.2%], calcium gluconate, epinephrine) Clock or stopwatch Volume expander (normal saline preferred) and/or blood available on emergency basis Tubes for obtaining blood gas or other samples Equipment for placing umbilical catheter Equipment for microtechnique of measuring blood gases Portable radiographic equipment
High-risk and preterm infants	All of the equipment listed for low-risk and term infants, plus: Spotlight Manometer for gauging pressure being used in ventilation Blender for delivering oxygen in concentrations ranging from room air to 100%, with heated nebulizer Oxygen analyzer Electrocardiographic electrodes Heart rate monitoring equipment Blood pressure monitoring equipment Hemoglobin saturation monitor Blood gas syringes, heparinized and ready to use Blood gas laboratory immediately available (10-minute processing time) Umbilical artery and vein catheters set up and ready to insert, with vascular pressure monitor Gowns, masks, hats, for sterile procedures Emergency medications with estimated dosages calculated

epinephrine, or both during resuscitation. In approximately two thirds of these infants, ineffective initial ventilatory support was the presumed mechanism for continued neonatal depression. Because chest compressions interfere with ventilation, they should not be initiated until adequate ventilation is established.

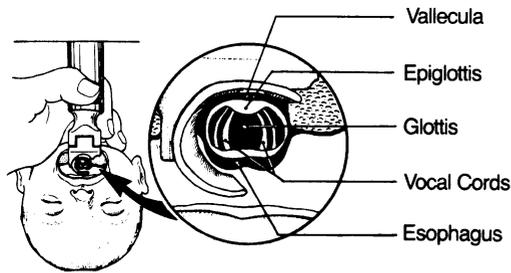

If, after 30 seconds of *effective* ventilation, the heart rate remains less than 60 beats/min, chest compressions should be initiated. The two-thumb technique is preferred over the two-finger technique for chest compressions, because it is more controlled and may offer some advantage in generating higher peak perfusion pressure (Menegazzi et al, 1993). NRP guidelines recommend a compression depth of one third to one half of the anteroposterior diameter of the chest to generate a pulse, at a ratio of three compressions to one breath.

## Epinephrine

If the infant's heart rate remains less than 60 beats/min despite at least 30 seconds of *effective* ventilation and 30 seconds of cardiac compression, epinephrine should be administered either endotracheally or, preferably, intravenously (McCrirrick and Kestin, 1992; Perlman and Risse, 1995). Standard dosage is 0.01 mg/kg of epinephrine using a 1:10,000 standard dilution. Higher doses of epinephrine have been suggested for adults and older children if there is no response to the lower dose, on the base of animal and human studies demonstrating better output and better coronary perfusion (Gonzalez et al, 1989; Paradis et al, 1991). However, such an enhancement of coronary blood flow may not be beneficial in neonates, because the usual terminal rhythm is a bradyarrhythmia from hypoxia, despite

an initial transient rise in cardiac and myocardial ischemia, as seen in adults (Burchfield, 1999). In addition, higher-dose epinephrine administration is associated with significant hypertension after recovery, with a greater risk of intracranial hemorrhage (Pasternak et al, 1983; Reynolds et al, 1979).

Although use of the standard dose via the endotracheal route results in lower serum concentrations than intravenous administration, efficacy of the routine endotracheal dose has been demonstrated (Lindemann, 1984). In addition, use of higher doses of epinephrine via the endotracheal route produces a prolongation of post-resuscitation hypertension that is seen with the intravascular route (Ralston et al, 1985). Therefore, the standard dose is recommended regardless of route of administration.

### Support of the Cardiovascular System

Most infants are not hypovolemic in the delivery room; however, infants are occasionally compromised secondary to acute hemorrhage. It is often a challenge to assess the infant's circulatory status to determine whether hypovolemia is the cause of hypotension or whether the infant is suffering cardiovascular depression because of some other problem. Physiologic variables to be remembered are as follows:

1. Falsely high arterial blood pressure readings have been associated with acidosis (which may respond to administration of sodium bicarbonate).
2. Hypocapnia may be associated with hypotension, so that infants who are being overventilated may have falsely low arterial blood pressure readings.
3. An infant with normal blood pressure who has poor perfusion may be maximally vasoconstricted; therefore, significant hypotension may be masked.
4. An infant who is distressed and in pain may have a falsely elevated blood pressure level.
5. The normal range of blood pressure for very small premature infants may be low. The physician should assume that the blood pressure is normal in an infant with good oxygenation and good peripheral perfusion and no signs of circulatory collapse, particularly if the infant passes urine. In the infant who is not voiding, use of

low-dose dopamine (2 to 5  $\mu\text{g}/\text{kg}/\text{min}$ ) may improve renal perfusion.

6. Monitoring an infant's hematocrit levels over time can be enormously helpful. A decrease in hematocrit value during the first 2 hours after birth may indicate hypovolemia, because infants have the ability to mobilize fluid rapidly.
7. Preterm newborn infants ordinarily do not exhibit tachycardia as a sign of shock; therefore, a rapid heart rate generally is not useful as an indicator of volume status.

Volume expansion may be accomplished with the use of normal saline or lactated Ringer's solution. Albumin infusion is no longer recommended (Wu and Carlo, 2002). It may be appropriate to administer small (10 mL/kg) transfusions of packed red blood cells in cases of hypovolemic shock and severe anemia. It is of the utmost importance that volume replacement be given slowly, because some vascular beds (particularly those of the brain) may already be maximally dilated in response to systemic hypotension, and excessive pressure may be transmitted to the fragile capillaries, leading to intracranial hemorrhage.

In infants who have had prolonged or severe asphyxia, myocardial failure resulting from poor contractility may occur, evidenced by hypotension that persists after initial resuscitation. Such infants may show response to dopamine at a starting dose of 5  $\mu\text{g}/\text{kg}/\text{min}$  which may be increased as needed up to 20  $\mu\text{g}/\text{kg}/\text{min}$  to produce an adequate response. Rarely, dobutamine may be added, at 5  $\mu\text{g}/\text{kg}/\text{min}$  (up to 15  $\mu\text{g}/\text{kg}/\text{min}$ ). It may be useful in these infants to pass a second umbilical catheter through the umbilical vein, via the ductus venosus, and into the right atrium to monitor central venous pressure in addition to arterial pressure.

### Sodium Bicarbonate

If an infant requires substantial resuscitation, samples for infant blood gas determination should be obtained whenever possible. Administration of sodium bicarbonate in neonatal resuscitation is controversial, and routine use of bicarbonate is discouraged. One may consider sodium bicarbonate use in cases of documented severe metabolic acidosis, but only after establishment of adequate ventilation and oxygenation.

The most severely asphyxiated infants are those with an arterial pH of 7.0 or less and a calculated base deficit of 25 mEq/L or greater in the presence of a marked elevation of  $\text{PaCO}_2$ . By means of artificial ventilation alone, this calculated deficit can be reduced by approximately 10 mEq/L if the infant's circulation is normal and oxygenation is achieved. This effect results from a significant bicarbonate shift that occurs when  $\text{PaCO}_2$  exceeds 70 mm Hg and therefore must be taken into consideration in calculations for correcting base deficit. Some additional correction occurs with ventilation at pH levels above 7.0; therefore, the dose of bicarbonate administered should always be no more than one fourth of the initially calculated value. Blood gas studies should be repeated before further increments of bicarbonate are given. The equation for calculation of base replacement is

$$\frac{\text{mEq}}{\text{Base}} = \frac{0.3 \times \text{weight in kg} \times \text{base deficit in mEq/L}}{4}$$

Given the hyperosmolarity and CO<sub>2</sub>-generating properties of sodium bicarbonate, this substance should be diluted to a strength of 4.2% with sterile water and administered slowly. Arterial blood pressure should be measured both before and after bicarbonate is given, because the administration of sodium bicarbonate may unmask hypovolemia that has not been apparent because of peripheral vasoconstriction. Table 28–3 provides the recommended drug dosages for neonatal resuscitation.

If an infant remains compromised despite adequate ventilation, chest compressions, and resuscitative medications, one should consider other causes, including pneumothorax, congenital airway malformations such as congenital diaphragmatic hernia, and complex congenital heart disease.

### Umbilical Vessel Catheterization

In the high-risk or significantly asphyxiated infant, it is important to place an umbilical catheter, preferably in the umbilical artery (although commonly a venous catheter can be placed more rapidly), to obtain samples for arterial blood gas and other determinations as well as to monitor arterial pressure. Changes in arterial pulse pressure and mean pressure can thus be followed up during the resuscitation, providing important indicators of cardiovascular responsiveness. In addition, appropriate medications can be administered easily through the catheter, although one should avoid administration of hypertonic medications, calcium, and blood products through an umbilical venous catheter, the tip of which is below the level of the diaphragm and therefore near the portal circulation.

### Continuation of Support after Resuscitation

The Apgar score was initially introduced to help quantify the initial evaluation of newborn infants (Table 28–4). Apgar scores should be assigned at 1, 5, and 10 minutes, and, if the infant still requires resuscitation, at 15 and 20 minutes as well. The score is an indicator of responsiveness to therapy as well as a way of identifying infants who are at high risk for further difficulty. The score at 5 minutes and later is more predictive of survival and neurologic status than the 1-minute score, because the ability to interrupt and reverse the process of asphyxia indicates not only successful intervention but also that the process was not established for a long period in utero.

One of the factors essential to successful resuscitation is the ability to identify the infant who has continuing difficulties after resuscitation and, thus, to facilitate prevention of a relapse. This applies particularly to the premature infant with respiratory distress syndrome (RDS) who initially responds favorably to treatment with ventilation and sodium bicarbonate but then requires continued cardiorespiratory support to prevent respiratory distress from becoming severe and causing another cycle of hypoxia and acidosis. Another example is in the infant born after undergoing an episode of fetal distress, who may have

reactive pulmonary vasculature. If such an infant is allowed to become hypoxic, pulmonary vasoconstriction may occur (or worsen) and may progress to persistent pulmonary hypertension of the newborn.

### THINGS TO AVOID IN RESUSCITATION

Successful resuscitation of a newborn infant involves not only interrupting the cycle of hypoxia and acidemia and bringing the infant back toward the physiologic norm but also avoiding iatrogenic damage. The following are, therefore, some important “rules” of resuscitation:

1. *Do not panic if an endotracheal tube cannot be placed immediately.* Concentrate on bag-and-mask ventilation and call for help. Do not assume that medication is a substitute for ventilation.
2. *Do not perform excessive suctioning of clear fluid from the infant's nasopharynx.* Fluid is normally absorbed into the lungs.
3. *Do not use excessive oxygen concentrations to resuscitate the premature infant unless the infant clearly requires it.*
4. *Do not use too much ventilatory pressure to expand the infant's lungs.* The required initial pressure for expanding the lung may be briefly higher right after birth than it is within just 15 to 30 minutes after birth. Use good clinical judgment. Watch the infant's chest and listen to breath sounds. Try reducing ventilation with hand ventilation to ensure that the lowest pressure necessary is being used. Excessive pressure on lungs that are normalizing may decrease venous return to the heart and decrease cardiac output and cause injury to lung tissue.
5. *Avoid hypocapnia.* There is evidence that even brief overdistention of the lung may raise the risk of bronchopulmonary dysplasia (BPD) (Garland et al, 1995).
6. *Do not give volume replacement or sodium bicarbonate automatically.* Each of these agents has been associated with production of intracranial hemorrhage in animal models.
7. *Do not focus or rely too heavily on cardiac resuscitation,* because, the most likely problem by far in neonatal resuscitation is the need for ventilatory support.
8. *Maintain normoxia in the term or post-term infant with meconium aspiration or asphyxia,* because such an infant may have reactive pulmonary blood vessels, and pulmonary vasoconstriction may develop if hypoxia persists.

### SPECIAL CONDITIONS REQUIRING ATTENTION DURING RESUSCITATION

#### Extremely Premature Infant (<1000 g)

Resuscitation of very premature infants begins in utero; therefore, whenever possible, such infants should be born in a perinatal center with skilled staff from the obstetric, anesthetic, and neonatal teams in attendance. The fragility of these infants requires gentleness in handling and a high level of skill in the staff performing the resuscitation. Because of the relatively large surface area of extremely premature infants, attention to immediate drying and

TABLE 28-3

## Medications for Neonatal Resuscitation

Medication	Concentration to Administer	Preparation	Dosage and Route	Total Dose/Infant		Rate and Precautions
Epinephrine	1:10,000	1 mL	0.1-0.3 mL/kg IV or ET	Weight (kg)	Total mL	Give rapidly May dilute with normal saline to 1-2 mL if giving ET
				1	0.1-0.3	
				2	0.2-0.6	
				3	0.3-0.9	
Volume expanders	Saline Normal saline		10 mL/kg IV	Weight (kg)	Total mL	Give over 5-10 minutes

TABLE 28-4

**Apgar Scoring System**

Feature Evaluated	0 Points	1 Point	2 Points
Heart rate (beats/min)	0	<100	>100
Respiratory effort	Apnea	Irregular, shallow, or gasping respirations	Vigorous and crying
Color	Pale, blue	Pale or blue extremities	Pink
Muscle tone	Absent	Weak, passive tone	Active movement
Reflex irritability	Absent	Grimace	Active avoidance

temperature control is of even greater importance for them than for the normal newborn. When possible, these infants should be moved to a small warm room adjacent to the delivery room, carefully dried, and placed under a radiant warmer for resuscitation. It is essential that the gas used for very small infants, even for resuscitation, be warmed and humidified.

Many extremely premature infants are at risk for respiratory distress syndrome and may benefit from surfactant therapy. Although clinical trials have demonstrated that both synthetic and natural surfactant preparations are effective, several trials documented the benefit of natural surfactant products over synthetic surfactant, including a reduction in pneumothorax and mortality (Soll and Blanco, 2001). The timing of the first dose of surfactant is controversial. Previous studies of extremely immature human infants demonstrated a benefit of surfactant given prophylactically—that is, within minutes after birth—over rescue surfactant therapy given later as symptoms develop (Soll and Morley, 2001). However, later attention has focused on variations in incidence of bronchopulmonary dysplasia among various neonatal intensive care units, and the association of intubation and prolonged ventilation with the development of this disorder (Van Marter et al, 2000). Therefore, many nurseries have instituted early and aggressive use of continuous distending pressure given via nasal prongs (nasal continuous positive airway pressure [CPAP]) in the delivery room, in an attempt to decrease barotrauma and the subsequent development of bronchopulmonary dysplasia. Because surfactant given prophylactically is more effective than late rescue therapy for respiratory distress syndrome, earlier delivery of surfactant, followed by rapid extubation to nasal CPAP, may benefit those extremely premature infants likely to progress to respiratory failure (Verder et al, 1999).

If an infant is intubated, it is critical to avoid overdistention of the lungs—which may lead to volutrauma, interstitial emphysema, and pneumothorax and may interfere with cardiac output—as well as hyperventilation and hypocarbia. Rapid changes in carbon dioxide, or prolonged hypocarbia, may alter cerebral blood flow and produce hypertension and have been associated with higher risk of periventricular leukomalacia (Wiswell et al, 1996). During resuscitation of very small infants, it is also important to avoid hyperoxia; therefore, the oxygen blender should be set at an  $F_{iO_2}$  of 0.40 when resuscitation is begun, then turned down as rapidly as possible, and thereafter increased only if the infant has clinical signs of cyanosis.

Most of these tiny infants also benefit from placement of an umbilical artery catheter so that the initial monitoring of their blood gas values does not require painful procedures for obtaining blood or for the administration of fluid, drugs, or volume replacement. At many centers, umbilical venous lines are also placed. Arterial blood pressure monitoring is important in this group of infants as an adjunct to assessing adequacy of circulating blood volume. The range of mean blood pressure for the tiny infant is wide and initially may be as low as 24 to 30 mm Hg. In an infant who is well oxygenated at low inspired oxygen concentrations and who has good peripheral perfusion, low blood pressure alone should never be used as the basis for volume administration. One may consider initial blood pressure support with low-dose dopamine (2 to 5  $\mu\text{g}/\text{kg}$  per minute) to augment diminished urinary output (Seri, 1995). Careful administration and monitoring of blood glucose concentrations are also critical.

Finally, it is important to move these infants from the resuscitation area to the nursery with as little disruption of their support systems as possible. Therefore, a resuscitation bed that is fully equipped to be moved from the delivery area to the nursery is essential to maintain stabilization. Such a bed also enables continuous observation of these fragile infants, whose courses may change rapidly during the first few hours after birth.

### Meconium Aspiration

Approximately 11% of all pregnancies are complicated by passage of meconium, and 2% of infants have some degree of aspiration syndrome, ranging from some minor initial tachypnea to very severe meconium aspiration pneumonia with pulmonary hypertension. Skilled personnel must be present at the delivery of an infant born through meconium. All infants born through meconium should undergo immediate suctioning of the oropharynx, preferably while still at the perineum and before initiation of respiration (Gregory et al, 1974).

If the infant is born through meconium and has depression of respiratory drive, decreased tone, and a heart rate of less than 100 beats/min, direct suctioning of the trachea soon after delivery is indicated. Vigorous infants may not benefit from tracheal suctioning. One study found no differences in respiratory outcomes of vigorous infants randomly assigned either to immediate tracheal suctioning or to expectant management alone (Wiswell et al, 2000). The

passage of meconium indicates that an infant has been in trouble at some point during gestation. Such infants are more susceptible to having reactive pulmonary vessels, which may reconstrict with hypoxia. They need careful initial evaluation and close observation to ensure that oxygenation is adequate and to prevent the gradual development of hypoxia and consequent pulmonary vasoconstriction, which would set off the cycle that ultimately may result in persistent pulmonary hypertension of the newborn.

### Hydrops

The evaluation and resuscitation of the infant with hydrops, as of the very small premature infant, begins with interdisciplinary management by the perinatal team to assess the fetus and to arrive at decisions as to the optimal time of delivery. Ultrasonographic evaluation is recommended to determine whether the infant would benefit from removal of excessive fluid from either the abdominal or the thoracic cavity before delivery. In preparing for resuscitation of a hydropic infant, it is critical that equipment be set up and a member of the team assigned to perform paracentesis, thoracentesis, or both immediately after the birth, if the amount of fluid interferes with the ability to ventilate the infant. In addition, packed red cells must be available at the resuscitation site if the cause of the hydrops is related to anemia.

The hydropic infant has extremely stiff lungs and may require high ventilatory pressures, including high end-expiratory pressure, for initial stabilization until the infant begins to mobilize and clear fluid. It is always appropriate to catheterize both the umbilical vein and the umbilical artery so that central venous pressure, as well as systemic pressures, can be measured for evaluation of volume status. In addition, for severely anemic infants, the hematocrit value can be augmented by immediate, isovolemic exchange transfusion through the two catheters. Staff should be aware that skin electrodes and saturation monitors commonly do not function accurately when used for infants with hydrops.

### Infants with Severe Malformations

Sometimes the resuscitation team is faced with an infant who has severe malformations. Resuscitation should proceed in a normal fashion unless (1) the staff present at the delivery has enough experience and skill to recognize that the malformations are associated with conditions incompatible with life and (2) there has been some foreknowledge of the possibility of malformations and the family has requested that there be no resuscitation of a severely malformed infant. Otherwise, it is appropriate to proceed with the resuscitation and stabilize the infant so that an accurate diagnosis can be made and the family can see the baby and participate in further decision-making about the child.

### Resuscitation of the Previa Infant

Survival remains extremely low for infants born at less than 23 weeks of postmenstrual age or with birth weights of less than 400 g (El-Metwally et al, 2000). If dating

appears accurate, one should discuss the poor survival and the option of comfort care without resuscitation with the parents before the delivery.

### Duration of Resuscitation

Resuscitation should rarely be pursued beyond 15 minutes in an infant who continues to have no pulse and who does not respond rapidly to adequate ventilation, appropriate cardiac compression, and resuscitative medications. In infants showing response after 15 minutes of resuscitation, the incidence of death or very severe, irreversible neurologic damage is unacceptably high (Casalaz et al, 1998; Davis, 1993; Jain et al, 1991).

### LONG-TERM OUTCOME

The two central questions to be considered in thinking about the outcome of an infant after perinatal asphyxia are as follows:

- What is the contribution of perinatal asphyxia to mental retardation and cerebral palsy in the population?
- How often does documented perinatal asphyxia result in cerebral palsy and mental retardation?

The etiology of severe mental retardation without cerebral palsy is usually not related to perinatal events; rather, it is primarily of genetic, infectious, or developmental origin (Blair and Stanley, 1988; Nelson, 1988; Perlman, 1997). Studies suggest that at least 70% of cases of cerebral palsy are antepartum in origin. Therefore, the number of cases of cerebral palsy related to perinatal asphyxia are few, approximately 20%. Only cases of cerebral palsy associated with severe mental retardation may have a peripartum cause (ACOG/AAP statement, 2003).

The attempt to delineate which cases of perinatal asphyxia lead to cerebral palsy began in 1862, when Little noted the association of suboptimal perinatal events with subsequent poor neurologic outcome. A number of studies since that time have attempted to relate outcome to Apgar score, to the interval between birth and spontaneous respiration, and to various biochemical and biophysical markers of oxygen deprivation. The Collaborative Perinatal Project, conducted from 1959 to 1966, reported on the outcomes of 49,000 infants as correlated with Apgar scores (Nelson and Ellenberg, 1981; Niswander et al, 1975) (Table 28–5). The conclusions of this study were that low Apgar scores are risk factors for cerebral palsy; other findings, however, are as follows:

- 55% of children with cerebral palsy had Apgar scores of 7 to 10 at 1 minute.
- 73% of children with cerebral palsy had Apgar scores of 7 to 10 at 5 minutes.
- Of 99 children who had Apgar scores of 0 to 3 at 10, 15, or 20 minutes, only 12 (12%) had cerebral palsy; however, the mortality rate in the last group was more than 50% in infants weighing more than 2500 g and more than 90% in infants weighing less than 2500 g.
- 11 of the 12 infants with cerebral palsy were mentally retarded.

TABLE 28-5

## Prevalence Rates of Cerebral Palsy by Apgar Score and Birth Weight

Apgar Score	Infants < 2500 g			Infants > 2500 g		
	Mortality in 1st Year (%)	Survivors with Cerebral Palsy (%)	No. of Cases of Cerebral Palsy	Mortality in 1st Year (%)	Survivors with Cerebral Palsy (%)	No. of Cases of Cerebral Palsy
7-10 @ 1 minute	3.8	0.6	13	<1	0.2	53
0-3 @ 1 minute	50	2.9	9	6	1.5	22
0-3 @ 5 minutes	75	6.7	5	15	4.7	13
0-3 @ 10 minutes	85	3.7	1	34	16.7	11
0-3 @ 15 minutes	92	0	0	52	36.0	9
0-3 @ 20 minutes	96	0	0	59	36.0	8

### Hypoxic-Ischemic Encephalopathy

Sarnat and Sarnat (1975) developed a clinical staging system for evaluating hypoxic-ischemic encephalopathy (HIE) (Table 28-6), and Robertson and Finer (1985) reported on the follow-up of infants after HIE (Table 28-7). The latter investigators found that 100% of infants with severe HIE either died or had significant handicaps. Among those with moderate HIE, 26% died or were handicapped; among those with mild HIE, none died subsequently or were handicapped (Robertson and Finer, 1985). Robertson and associates (1989) also noted no differences in school performance (at 8 years of age) between neurologically unim-

paired children who suffered mild or moderate HIE and a matched peer group.

Holden and colleagues (1982) noted that the incidence of seizures was associated with a 17-fold increase in the likelihood of cerebral palsy over that in the absence of seizures. Some investigators have attempted to use injuries to other organs as indicators to help predict eventual outcome. Perlman and Tack (1988) found that oliguria in the perinatal period was significantly associated with signs of HIE, including seizures, death, and long-term neurologic deficits. In general, it can be assumed that an infant who has experienced an asphyxial event severe enough to produce permanent brain damage will show evidence of

TABLE 28-6

## Clinical Staging of Posthypoxia Encephalopathy

Factor	Stage I	Stage II	Stage III
Level of consciousness	Alert	Lethargic	Comatose
Muscle tone	Normal	Hypotonic	Flaccid

§Percentage of the 173 survivors for whom information was available.

Classification data from Sarnat HB, Sarnat MS: Neonatal encephalopathy following fetal distress. *Arch Neurol* 33: 696, 1975; data from Robertson C, Finer H: Term infants with hypoxic-ischemic encephalopathy: Outcome at 3-5 years. *Dev Med Child Neurol* 27:473, 1985.

significant damage to other organs within hours to days after birth.

Sunshine (1989) concluded that infants with perinatal asphyxia should be evaluated for structural abnormalities with current imaging techniques and that if such abnormalities are identified, an attempt should be made to determine whether the abnormalities can be explained by intrapartum asphyxia or are developmental aberrations or abnormalities that occurred before labor. In addition, Sunshine pointed out that infants who are small for gestational age compose a significant percentage of the total number of patients who experience neonatal asphyxia, HIE, and seizures as well as cerebral palsy. Therefore, attempts to improve outcome should focus on recognition of infants who are small for gestational age and on possible types of intervention in pregnancies complicated by intrauterine growth restriction. Other investigations have been directed at the prevention of intracellular calcium accumulation, free radical formation, or excitatory amino acid release—all of which are associated with hypoxic ischemic injury (Perlman, 1997).

The most accurate prediction of neurologic outcome comes from a full knowledge of perinatal and neonatal events, combined with biochemical and imaging studies and careful clinical evaluations performed throughout the first years of life.

# Temperature Regulation of the Premature Infant

Sudhish Chandra and Stephen Baumgart

The human neonate is a homeothermic mammal. Even the smallest premature infants respond adaptively to changes in their environment. Response, however, may be insufficient to maintain core body temperature and render preterm babies functionally poikilothermic, even in moderately temperate environments. Morbidity (e.g., poor brain and somatic growth) and mortality rates increase when core body temperature is permitted to decline much below 36° C (96.8° F).

## THE PROBLEM OF COLD STRESS

Evaporative heat loss is widely regarded as the most stressful cooling event on any infant's delivery at birth. Severe nonevaporative heat loss is also problematic, however, for several reasons. First, the baby's exposed surface area is much larger than the adult's relative to metabolically active body mass (Table 29-1). Especially for the extremely low-birth-weight (ELBW) infant, the heat-dissipating area is proportionately five to six times greater than that of the adult. Second, the tiny baby's small size presents a much smaller heat sink to store thermal reserve. Finally, the radius of curvature of the body is less in the infant than in the adult, resulting in a thinner protective boundary layer of warm, still air.

Aside from these geometric considerations, characteristics of the premature infant's skin contribute to the problem of excessive heat loss. The skin and subcutaneous fascia provide little insulation against the flow of heat from the core to the surface. Moreover, the lack of a keratinized epidermal barrier exposes infants to vastly greater evaporative heat loss.

Finally, premature infants may not induce effective thermogenesis in response to cold stress. They lack shivering, and nonshivering thermogenesis may be compromised by low stores of brown fat. Furthermore, the presence of hypoxia (common with preterm birth) seriously reduces nonshivering thermogenesis by reducing mitochondrial oxidative capacity.

## PHYSICAL ROUTES OF HEAT LOSS

### Convection

Convective heat loss in newborns occurs when ambient air temperature is less than the infant's skin temperature. Convective heat loss occurs through (1) natural convection,

or passage of heat from the skin to the ambient still air, and (2) forced convection, in which mass movement of air over the infant conveys heat away from the skin. The quantity of heat lost is proportional to the difference between air and skin temperatures and to air speed. The effect of forced convection in disrupting the microenvironment of warm, humid air layered near an infant's skin is usually not appreciated in the nursery, where drafts, air turbulence, and, consequently, heat loss may occur even within the relatively protective environment of an incubator (Okken, 1982).

### Evaporation

Passive transcutaneous evaporation of water from a newborn's skin (insensible water loss) results in the dissipation of 0.58 kcal/mL latent heat. As shown in Figure 29-1, transcutaneous water loss increases exponentially with decreasing body size and gestation. The tiniest premature baby, least able to tolerate cold stress, may incur evaporative heat loss in excess of 4 kcal/kg/hour ( $\approx 7$  mL water/kg/hour). Evaporation is enhanced by low vapor pressure (high temperature and low relative humidity) and air turbulence. The highest evaporative losses occur on the first day of life. During the first week of life in infants of 25 to 27 weeks of gestation, evaporative heat losses may be higher than radiant losses (Hammarlund et al, 1986).

### Radiation

Radiant heat loss constitutes the transfer of heat from an infant's warm skin via infrared electromagnetic waves to the cooler surrounding walls that absorb this heat. Radiant heat loss is proportional to the temperature gradient between the skin and surrounding walls. An infant's posture may affect radiant heat loss by increasing or reducing the exposed radiating surface area. In a humid environment (relative humidity  $\approx 50\%$ ), babies experience an ambient temperature (termed *operant temperature*) determined 60% by wall temperature and 40% by air temperature.

### Conduction

Conductive heat loss to cooler surfaces in contact with an infant's skin depends on the conductivity of the surface material as well as its temperature. Usually, babies are nursed on insulating mattresses and blankets that minimize conductive heat loss.

## PHYSIOLOGY OF COLD RESPONSE

### Afferents

Homeothermic response to a cold environment begins with the sensation of temperature. Traditional physiology identifies two temperature-sensitive sites, the hypothalamus and the skin. Sensing of cold by the neonatal skin triggers a cold-adaptive response long before core sensors in the hypothalamus become chilled. Some investigators conjecture that neonatal cold reception resides primarily

TABLE 29-1

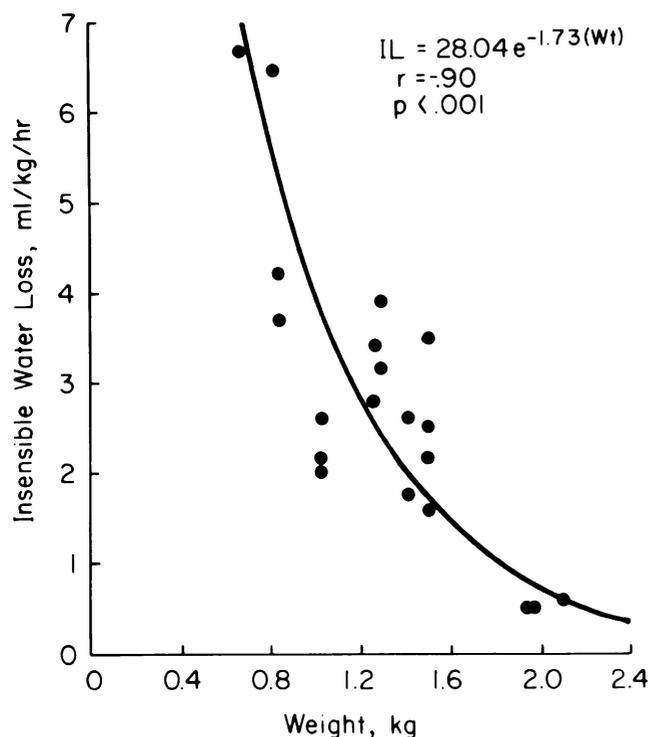

**Body Surface Area to Body Mass Ratio**

	Body Weight (kg)	Surface Area (m <sup>2</sup> )	Ratio (cm <sup>2</sup> /kg)
Adult	70	1.73	250
Very premature infant	1.5	0.13	870
Extremely premature infant	0.5	0.07	1400

in the skin, whereas warm reception resides in the hypothalamus. Both sensors are probably integrated, however, because cold sensory response is inhibited by core sensor hyperthermia, and vice versa. Peripheral skin cold sensation is teleologically important, because early detection of heat loss from the skin aids in the infant's timely response for maintaining core temperature.

**Central Regulation**

Integration of multiple skin temperature inputs probably occurs in the hypothalamus. No single control temperature seems to exist, however. Under different environmental conditions, temperature of the skin may fluctuate by 8° C to 10° C, and temperature of the hypothalamus may vary

**FIGURE 29-1.** Exponential rise in evaporative water loss from the skin of very low-birth-weight infants nurtured under radiant warmers. (Adapted with permission from Baumgart S, Langman CB, Sosulski R, et al: Fluid, electrolyte and glucose maintenance in the very low birth weight infant. *Clin Pediatr* 21:199-206, 1982.)

by 0.5° C. There are also diurnal temperature fluctuations, variations with general sympathetic tone, and blunted regulation with asphyxia, hypoxemia, and other central nervous system defects. Because important thermoregulatory processes are triggered by changes as little as 0.5° C, deviation at any temperature-sensitive site is important (Mayfield, 1984).

**Efferents**

The effector limb of the neonatal thermal response is mediated primarily by the sympathetic nervous system, although infant behavior may also be involved. The earliest maturing response is vasoconstriction in deep dermal arterioles, resulting in reduced flow of warm blood from the infant's core into the exposed periphery. Additionally, reduction of blood flow effectively places a layer of insulating fat between the core and the exposed skin in the term infant. Reduced fat content in LBW babies, however, diminishes this effective insulating property. Vasoconstriction nevertheless remains the newborn's first line of defense, and the response is present even in the most premature infant.

Brown fat constitutes a second sympathetic effector organ that provides a metabolic source of nonshivering thermogenesis (babies do not shiver like adults do to generate heat). Brown fat located in axillary, mediastinal, perinephric, and other regions of the newborn is especially innervated and equipped with an abundance of mitochondria to hydrolyze and re-esterify triglycerides and to oxidize free fatty acids. In the term infant, these reactions are exothermic and may increase metabolic rate twofold or more. Preterm babies, however, have little brown fat and may not be capable of more than a 25% increase in metabolic rate despite the most severe cold stress (Hull, 1966).

Finally, evidence suggests that control of voluntary muscle tone, posture, and increased motor activity with agitation may serve to augment heat production in skeletal muscle via glycogenolysis and glucose oxidation. Clinical observations of infant posture, behavior, and skin perfusion, and measurements of skin and core temperature gradients may ultimately provide the most useful guidelines for assessing infant comfort during incubation.

**MODERN INCUBATION: INCUBATORS AND RADIANT WARMERS**

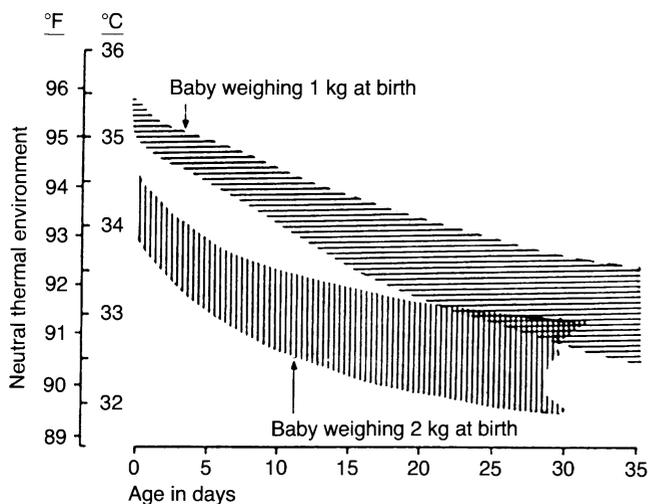

The lifesaving requirement of an appropriate thermal environment was demonstrated conclusively by Day and colleagues (1964) and further defined by Silverman and associates (1966). Minor changes in heat balance exact oxygen and energy costs, inducing an increase in metabolic rate that can be met only by an increase in ventilation or inspired oxygen and appropriate cardiovascular response.

**Thermal Neutral Zone**

The thermal neutral zone is a narrow range of environmental temperatures within which an infant's metabolic rate is at a minimum and normal body temperature is

maintained. When thermally neutral, infants regulate temperature through vasomotor tone alone without regulatory changes in metabolic heat production. A range of “critical” environmental temperatures relevant to modern incubators was clearly articulated by Hey and Katz (1970) (Fig. 29–2; Table 29–2). Below this range, these researchers observed an increase in the infant’s minimal metabolic rate. The thermal neutral temperature range, therefore, was defined as the optimal incubator operating (operant) temperature. Several important considerations in regulating incubator temperature were included in these studies; (1) incubator wall temperature was maintained identical to air temperature, (2) relative humidity was controlled near 50%, and (3) the environment was kept in a steady state, uninterrupted by turbulence or invasion of the incubator’s enclosed perimeter.

Rigid application of older air temperature recommendations should be modified. Many modern incubators now incorporate a double-walled design that results in lower radiant heat loss to cold incubator walls than is encountered in single-walled designs. Therefore, slightly cooler air temperature may be required (Bell and Rios, 1983a; Marks, 1981). Also, many nurseries do not humidify incubators artificially, fearing the occurrence of condensation (“rain-out”) resulting in bacterial colonization, particularly around door openings. Finally, it is important to recognize that the incubator’s steady-state temperature control is frequently interrupted for nursing and medical procedures that require opening doors to care for the

**FIGURE 29–2.** The range of temperature needed to provide neutral environmental conditions for a baby lying naked on a warm mattress in draft-free surroundings of moderate humidity (50% saturation) when mean radiant temperature is the same as air temperature. The *hatched areas* indicate the average neutral temperature range for a healthy baby weighing 1 kg or 2 kg at birth. Optimum temperature probably approximates the lower limit of neutral range as defined here. Approximately 1° C should be added to these operative temperatures to derive the appropriate neutral air temperature for a single-walled incubator when room temperature is less than 27° C (80° F), and more should be added if room temperature is very much less. (From Hey EN, Katz G: *The optimum thermal environment for naked babies*. *Arch Dis Child* 45:328,1970, with permission BMJ Publishing Group.)

**TABLE 29–2**

**Mean Temperature Needed to Provide Thermal Neutrality for a Healthy Baby Nursed Naked in Draft-Free Surroundings of Uniform Temperature and Moderate Humidity after Birth**

Birth Weight (kg)	Operative Environmental Temperature*			
	35° C	34° C	33° C	32° C
1.0	For 10 days	After 10 days	After 3 weeks	After 5 weeks
1.5	—	For 10 days	After 10 days	After 4 weeks
2.0	—	For 2 days	After 2 days	After 3 weeks
>2.5	—	—	For 2 days	After 2 days

\*To estimate operative temperature in a single-walled incubator, subtract 1° C from incubator air temperature for every 7° C by which this temperature exceeds room temperature.

Data from Hey E: Thermal neutrality. *Br Med Bull* 31:69-74, 1975.

infant. More than an hour may be required to recover previous steady-state conditions after such procedures. Therefore, the thermal neutral zone must be redefined in practical terms.

Silverman and colleagues (1966) used a modified concept of the thermal neutral zone to simplify clinical application. Reasoning that infants sense environmental temperature first on the skin, electronic negative-feedback (servo-controlled) regulation of the incubator heater in response to skin temperature was used. These investigators demonstrated minimal metabolic expenditure near 36.5° C (97.7° F) abdominal skin temperature measured by a shielded thermistor in a less rigidly defined incubator environment. The importance of frequently checking core temperatures (axillary or rectal) must be emphasized, however, before the infant’s environment can be delegated to such thermostatic control (Bell and Rios, 1983b). In addition, Chessex and associates (1988) have demonstrated that incubator temperature may vary by more than 2° C when skin temperature is servo-controlled rather than air temperature control is used.

Finally, with the modern use of open radiant warmer beds (improving access to the critically ill premature infant without interrupting heat delivery), skin temperature servo-control is the only practical method for approximating the thermal neutral zone (Malin and Baumgart, 1987). These variations in incubator design and technique, and the extension of infant warming to include extremely LBW (ELBW), critically ill premature babies, have generated new problems for determining a universally accepted optimal environment.

### Partitioning Infant Heat Losses and Heat Gains

Wheldon and Rutter (1982) demonstrated the special problems encountered in incubating very LBW (VLBW) infants in a convection-warmed, closed-hood incubator

environment. The top graph of Figure 29–3A, reproduced from their study, demonstrates the thermal balance achieved by a series of 12 infants (mean weight 1.58 kg). Heat losses to radiation (R), convection (C), and evaporation (E) are modest, and their sum ( $\Sigma$ ) is balanced by the infant's metabolic heat production (M). Used in this fashion, the incubator reduces physical heat losses such that the infant's minimal metabolism (larger than any single avenue of heat loss) delicately balances minimal physical heat losses within the controlled thermal environment.

In contrast, a VLBW subject (1.08 kg) is evaluated in Figure 29–3B. As the incubator servo-control increases warming power (to accommodate massive evaporative heat loss), convective "loss" becomes a net "gain" (negative histogram bar). Radiant loss is diminished by warm walls inside the incubator. These conditions differ strikingly from those discussed previously in the following ways: (1) the incubator truly warms the infant rather than modestly attenuating

convective heat loss and (2) evaporative heat loss vastly exceeds the infant's metabolism. The very small infant's body temperature is balanced, therefore, between opposing physical parameters of evaporative and convective heat transfer, and metabolism plays a secondary role.

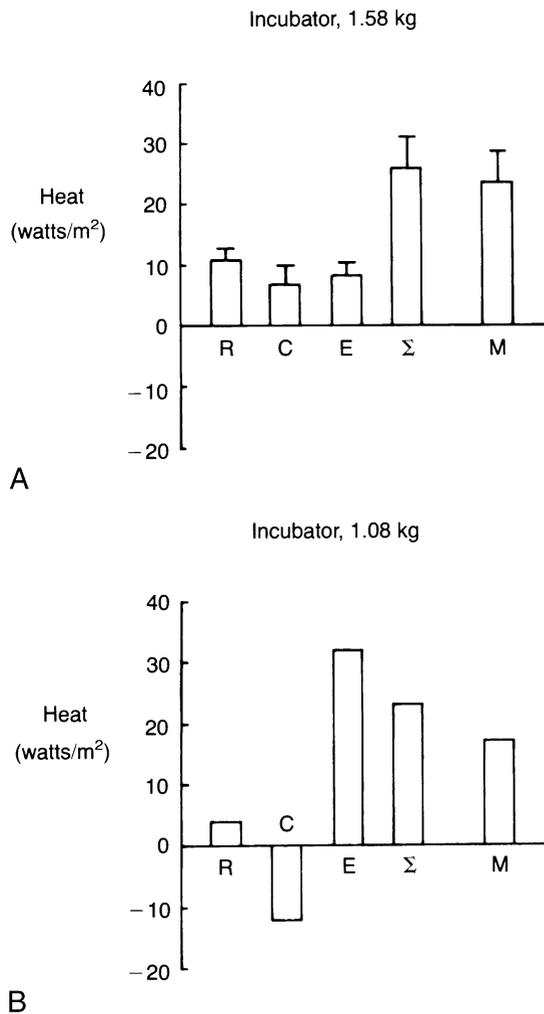

The modern use of radiant warmers that are servo-controlled to maintain infant abdominal skin temperature between 36.5° C and 37° C (97.7° F to 98.6° F) also demonstrates the opposition of physical forces described earlier. Figure 29–4 demonstrates the heat balance partition for 10 critically ill premature infants (mean weight 1.39 kg) nursed on open radiant warmer beds (Baumgart, 1985, 1990). Because ambient room air temperature is 5° C to 10° C cooler than air inside an incubator, convective heat loss is nearly double the infant's metabolic heat production. Evaporation adds to the net physical heat loss. Also, small amounts of heat are lost to conduction and radiation (to cooler room walls). The infant's metabolism provides only one third of the energy required to maintain body temperature, with the majority of heat supplied by the servo-controlled radiant heat source. In this instance, radiant warming (not convection, as in the incubator discussed earlier) delicately balances the infant's physical temperature environment. Wheldon and Rutter (1982) demonstrated similar results in their studies.

## LESS CONVENTIONAL TECHNIQUES

### Plastic Hoods

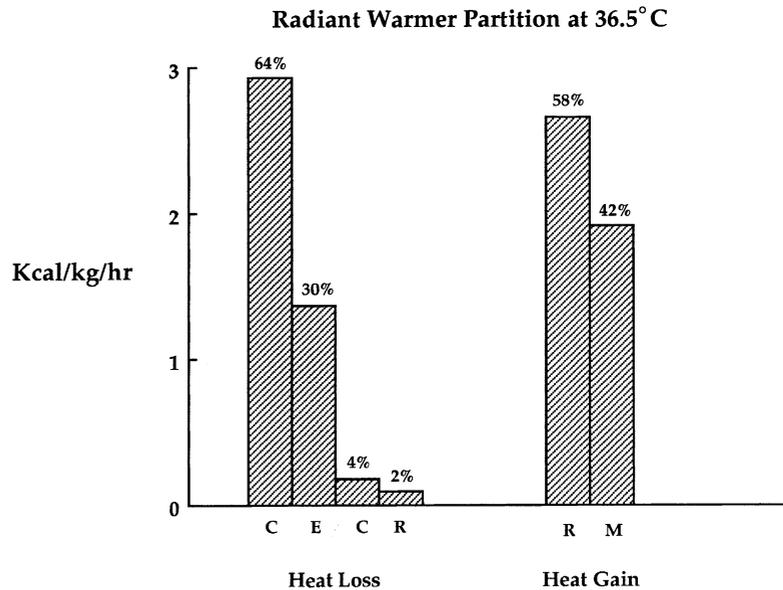

Plastic hoods are rigid body shields sometimes used as miniature incubator hoods placed over infants on open radiant beds. Hoods are usually made of 1- to 3-mm thick plastic and, when placed between an infant and the radiant warming element, may obstruct the delivery of radiant heat to the baby's skin. The plastic may form a heat sink, warming to 42° C to 44° C, but disrupts the radiant warmer's servo-control mechanism; in our opinion, use of such hoods is a poor strategy. In addition, such devices may not diminish insensible water loss, especially when used without humidity (Bell and Weinstein et al, 1980). Their use with humidity (a technique never validated) encourages bacterial colonization with waterborne pathogens.

A new development in commercial convection-warmed incubator and radiant warming technology is a hybrid design, combining the two separate warming modes into one device. In the incubator mode, movable plastic walls enclose the tiny premature infant, providing servo-controlled air warming, and the overhead radiant warmer is turned off. In the radiant warmer mode, the plastic walls are retracted to the sides, and the radiant warmer rapidly heats up to maintain servo-controlled skin temperature during procedures. The infant is not moved during the transition, and no plastic barrier is interposed between the infant and the radiant heater when it is on. The servo-control algorithms and the integrity of the plastic enclosure in incubator mode are critical to the performance of such devices, and the utility of these products is yet to be proven.

**FIGURE 29–3.** **A**, Partition of heat losses and gains in 12 premature infants nursed in incubators. **B**, Partition in a 1.08 kg low birth weight newborn. See text for detailed discussion. (From Wheldon AE, Rutter N: *The heat balance of small babies nursed in incubators and under radiant warmers*. *Early Hum Dev* 6:131–143, 1982.)

**FIGURE 29-4.** Partitional calorimetry in ten critically ill, low-birth-weight, premature newborns nursed under open radiant warmers. (From Baumgart S: *Radiant heat loss vs. radiant heat gain in premature neonates under radiant warmers.* *Biol Neonate* 57:10-20, 1990; reproduced with permission of S. Karger AG, Basel.)

### Plastic Blankets

As an alternative, a thin, flexible saran or polyethylene plastic “blanket” was introduced for covering premature infants under radiant warmers (Baumgart, 1984; Baumgart et al, 1982a, 1982b). This blanket prevents convective heat loss and is thin enough to transmit radiant heat from the warmer almost completely. The flexible plastic molds closely around the infant’s body (with care taken to avoid skin adhesion), conserves evaporation, and forms a microenvironment near the baby’s body. The plastic is enough of a mechanical barrier to prevent convective turbulence from disrupting this microenvironment. A two-thirds reduction in insensible water (and evaporative heat) loss under radiant warmers is achieved, so that less servo-controlled radiant heat delivery is required to maintain body temperature in even the smallest infants. Through moderation of heat losses, oxygen consumption is reduced by about 10%. Risks of plastic blankets include sticking to immature skin (causing skin breakdown) and accidental airway obstruction in non-intubated patients. In rare cases, partial detachment of the skin thermistor may result in life-threatening hyperthermia. Diligence is required to avoid these complications. The risk of abnormal bacterial colonization with the use of plastic blankets has not been evaluated.

Vohra and colleagues (1999) evaluated the capacity of a polyethylene plastic bag to promote temperature maintenance during resuscitation performed at delivery (under radiant warmers) and the transport of infants to the neonatal intensive care unit (NICU). Significantly higher admission rectal temperatures and subsequent survival rates were reported for infants younger than 28 weeks of gestation with use of the bag. A larger, randomized trial of this technique is underway.

### Semipermeable Polyurethane “Skin”

A semipermeable, semi-occlusive polyurethane dressing (Tegaderm or Op-Site) can be applied like an artificial skin to shield VLBW premature infants. These “breathing”

polyurethane plastics do not cause skin breakdown and are often used to dress central venous catheter sites. Because such dressings adhere to the skin, the temperature probe is less likely to become detached. These dressings can be tailored to avoid airway obstruction. Insensible water loss may be reduced more than 30% with these dressings, and after their careful removal, the skin’s naturally developing keratin moisture barrier may be preserved (Knauth et al, 1988). Porot and associates (1993) demonstrated that an adherent polyurethane layer over the torso and extremities of VLBW infants not only improved fluid and electrolyte balance but also reduced the occurrences of PDA and IVH and improved survival rates. Further studies are required to demonstrate the safety of this technique.

### Petroleum Ointments

Another occlusive dressing for the skin of LBW preterm infants during the first week of life is the application of Aquaphor™. Early results were encouraging for preservation of skin integrity and perhaps control of excessive dehydration in incubators (Nopper et al, 1996). However, the findings of a multicenter randomized trial have not yet been published, and some anecdotal reports suggest that bacterial infections may actually be more common with the use of this technique (Edwards, 2001; Oski, 2001). Until the results of the multicenter trial are conclusive, clinicians should exercise critical judgment about adopting this practice.

### Kangaroo Care

*Kangaroo care* is the warming of the infant through skin-to-skin contact with the mother or father; the parent holds the naked premature infant against her or his skin between the axilla or the breasts, mimicking a kangaroo’s pouch. First implemented in Bogota, Columbia, this method was popularized for non-intubated premature infants in Scandinavian and European countries in the 1980s. Early studies suggested

a significant reduction in early mortality and morbidity in premature infants weighing less than 1.5 kg who were nursed by kangaroo care. Furthermore, randomized clinical trials demonstrated enhanced mother-infant attachment, greater maternal self-esteem, prolonged and enhanced lactation, increased infant alertness, and better weight gain with earlier hospital discharge. Behavioral studies found more stable sleep patterns, less irritability at 6 months of age, and more eye contact with caregivers in infants nursed with kangaroo care. Kangaroo care has been shown to promote a thermal neutral metabolic response and temperature stability in stable growing premature babies. Moreover, during kangaroo nursing, infants with bronchopulmonary dysplasia have better oxygenation, and other infants show less periodic breathing and reduced apnea. In the modern nursery, kangaroo care may be initiated even during mechanical ventilation for patients without other complications. The infant should be put between the breasts with maximum skin contact and then should be covered with a blanket to avoid outward convective and evaporative heat losses. After initial sessions of 30 minutes to 1 hour with careful intermittent temperature monitoring, kangaroo care can be practiced for up to 4 hours. Kangaroo care integrates the family into the neonatal intensive care team. To our knowledge, no adverse reports about the approach have been published, and its use in many nurseries is on the rise.

## SPECIAL CASE MANAGEMENT

### CASE STUDY 1

A 510-g baby boy was born at 23 weeks and 4 days of gestation; he was limp and cyanotic, with no respiratory effort and a heart rate higher than 100 beats/min. The baby was resuscitated under a radiant warmer and dried, and a stocking cap was placed over his head. The warmer's temperature probe was recording a low skin temperature because it did not attach well to the skin. The radiant warmer was on full power to compensate for this low probe reading. After resuscitation, the baby was transported to the NICU in an incubator preheated to a temperature of 35° C.

On arrival in the NICU, the baby was weighed quickly and put onto a preheated radiant warmer bed. Skin probe (servo-control) temperature registered as 33° C, rectal temperature as 35° C, and axillary temperature as 34° C. The radiant warmer set point was targeted at 37° C, and temperatures were monitored every 15 minutes. A saran blanket was used to minimize heat loss. Heated and 100%-humidified air from a respiratory pack was run underneath the saran blanket. Then the baby's skin was prepared with iodine solution and he was draped completely for umbilical catheterization (a 30-minute procedure). Over the first 2 hours of life, rectal temperature increased to only 34.5° C. The baby was transferred into a preheated and humidified incubator regulated by a skin probe set at 37° C. Two 250-watt light bulbs were positioned over the incubator hood for supplemental heat and for warming during any procedure that required opening of the incubator (e.g., serial weight determinations). Over the next 12 hours, the baby had difficulty maintaining his temperature even though the incubator air temperature was running near the set temperature of 37° C and sometimes above at 38.5° C.

Temperature maintenance of an extremely premature infant should be part of resuscitation from the time of delivery. Despite radiant warming in the delivery room and convective incubation during transport, this baby was nevertheless hypothermic on

admission to the NICU. Low admission temperature correlates with increased mortality rates in these infants. They are born wet and prone to excessive transepidermal evaporative and convective heat losses. In addition, suboptimal radiant heating, blowing noncontrolled warm, humidified air under plastic blankets (probably not as effective as the still air envelope conserved by the blanket), and the pressure for performing procedures with surgical drapes blocking radiant heat delivery may worsen heat loss.

Quickly drying such babies, properly placing them directly under a radiant heater at birth, and covering the head are small but important steps in temperature resuscitation. Other techniques described in this chapter might be considered from birth, such as the use of a plastic bag described by (Vohra and colleagues, 1999) or of a saran blanket or polyurethane drape during umbilical catheterization. Finally, transferring such an infant into an incubator before adequately rewarming him or her under a radiant warmer may prolong thermal recovery in a hypoxic subject incapable of generating enough metabolic heat to do so. The use of light bulbs to provide supplemental radiant heat in incubators attests to the incubator's intrinsic operating power deficiency (seeking to reduce heat loss rather than to rewarm a cold baby). Moreover, such supplemental radiant heat sources are not controlled, produce more radiation in the visible light range, and are inefficient if not potentially dangerous, as they promote burns if placed too close to the infant.

There are no data describing the best rate of rewarming. Cold-stressed babies should probably be nursed under a servo-controlled radiant heat source, and heat losses minimized. During rewarming, they should be closely monitored and the heat delivery should be servo-controlled. A rate of about +1° C to +2° C per hour seems reasonable but may not be achievable. Alternatively, a preheated and humidified incubator may also be used for rewarming infants, although the rate may be slower. The incubator air or skin servo-control temperature can be set 1° C higher than the baby's temperature and gradually increased until a normal core temperature is achieved. Hybrid incubators that can also be used as radiant warmer beds are now available and may be helpful in rewarming scenarios.

## NEONATAL FEVER—A PROBLEM OF TEMPERATURE ELEVATION

There is no universally accepted definition of neonatal fever. Craig (1963) defined *neonatal pyrexia* as a rectal (core body) temperature higher than 37.4° C; however, other investigators accept normal temperatures up to 37.8° C. Between 1% and 2.5% of all newborns admitted to the normal nursery have fever as judged from rectal or axillary temperatures and depending on the limits chosen. Fever is an inconsistent and uncommon sign of sepsis (fewer than 10% of febrile neonates have culture-proven sepsis), and temperature elevation may be seen with several other clinical entities.

### Mechanisms Producing Neonatal Fever

The mechanisms producing neonatal fever are incompletely understood. They result from disturbances in the complex interactions between heat conservation and heat dissipation mechanisms. Fever may occur when immunogenic pyrogens (commonly, prostaglandin E<sub>2</sub>) lead to upward displacement of the normal thermal set point in the hypothalamus, leading to activation of heat conservation and heat generation physiologic responses. Generally,

heat conservation starts with peripheral vasoconstriction and is followed by thermogenesis (usually the nonshivering type in neonates) while the new set point is achieved. It is important to note that newborn infants of different animal species react in peculiar ways to different known pyrogens. Thus, human newborns may suffer severe documented bacterial infections without increased body temperature.

Phenomena besides pyrogenic mechanisms of febrile response in newborns may lead to the elevation of body temperature. In fact, newborn infants have poor heat dissipation mechanisms (absence of sweating), so exposure to excess heat or insulation (too much swaddling) can quickly raise the core temperature. Such overheating commonly occurs when term babies are nursed in uncontrolled incubators or under radiant warmers. Temperature elevation may also occur with increased infant metabolic rate, such as that seen with skeletal muscle rigidity and status epilepticus.

Temperature elevation is occasionally observed in well, breast-feeding newborn infants on the third to fourth day of life; it is believed to result from dehydration due to insufficient milk production. Finally, a higher incidence of neonatal fever has been reported in infants of mothers receiving epidural analgesia. The mechanisms for temperature elevation in these latter two cases (see later) are unknown.

### Determining the Cause of Fever

Sepsis is an uncommon cause of fever; paradoxically, septic neonates more commonly present with hypothermia. However, sepsis is probably the most treatable life-threatening illness occurring in febrile newborn infants, especially those with temperature elevations exceeding 38° C to 39° C, who are more likely to have bacteremia, purulent meningitis, and pneumonia. Most neonatal febrile episodes are noted in the first day of life (54% in one series); however, any fever occurring on the third day of life and fever above 39° C have both been correlated with a significantly higher chance of bacterial disease. Severe temperature elevation is also associated with viral disease, particularly herpes simplex encephalitis, so septic evaluations in these infants should include a lumbar puncture.

Hyperthermia has been reported in tiny premature infants as a complication of the improper use of shielding devices either in convection-warmed incubators or under radiant warmers. When incubated, babies should always have a strictly monitored and controlled source of heat. Fever secondary to overheating (particularly in association with incubators) is more common in equatorial and tropical countries.

Dehydration is an uncommonly recognized cause of fever in the newborn period. Dehydration occurring in healthy term infants between the third and fourth days of life as noted previously, is probably due to an inadequate intake of milk. Dehydration fever is commonly seen in large breast-fed babies whose milk intake is poor and who may be exposed to high environmental temperatures in the summer or in the tropics. Temperature may be anywhere between 37.8° C and 40° C. Rehydration leads to resolution of fever and is key to the diagnosis of this entity.

Two studies have found fever is much more common in neonates whose mothers received epidural analgesia during labor than in those whose mothers did not (7.5% vs 2.5% and 14.5% vs 1%) (Lieberman et al, 1997; Pleasure and Stahl, 1990). One of these reports observed more common sepsis evaluations and use of antibiotics in the offspring of women receiving epidural analgesia. With the growing use of epidural analgesia during labor, the recognition of epidural neonatal fever is an important consideration in the evaluation of the febrile neonate.

Unusual and uncommon causes of neonatal fever include neonatal typhoid fever and congenital malaria, which should be considered in immigrant populations or in third world countries. An increase in unexplained neonatal fevers was associated with the introduction of routine hepatitis B vaccination (compared with historical controls). In addition, temperature elevations may be seen with hypothalamic or other central nervous system malformations or masses. Subarachnoid or other intracranial hemorrhages may also be associated with temperature elevation. On rare occasions, neonatal spinal neurenteric cysts can manifest as long-lasting neonatal fever and should be considered in the differential diagnosis of acute myelopathy with persistent fever in infancy (>3 weeks in duration). The presence of myelopathy helps establish this diagnosis.

### Management

The clinical problem is that fever may be the only indication of severe bacterial disease. The relevant perinatal history should be evaluated for risk factors so as to mitigate a laboratory evaluation or presumptive treatment for infection. Furthermore, signs suggestive of sepsis (diminished activity, irritability, seizures) should be considered. All neonates with fever should be evaluated for hydration, weight loss, and foci of infection (cellulitis, septic arthritis or osteomyelitis, omphalitis, and presence of colonized foreign bodies; e.g., in a central venous line).

However, febrile neonates without clinical histories or any signs of infection present a challenge, and there are insufficient data in our literature about appropriate management. An infant's environment should be examined for overheating, and in breast-feeding infants with fever at 3 to 4 days of life and excessive weight loss, dehydration fever should be considered and treated to establish this diagnosis. Mothers receiving epidural analgesia often manifest shivering with their temperature rise, and they experience a rapid defervescence after discontinuation of the epidural infusion; recognition of this pattern may avoid unnecessary sepsis evaluations in neonates with early fever.

### CONCLUSION

The LBW premature newborn is extremely vulnerable to harsh fluctuations in physical environment. These infants require frequent assessments of skin, core, and air temperatures and relative humidity so that an optimal strategy may be designed for thermal regulation. In the care of smaller babies, heat replacement is often required, and refinement of techniques to accomplish heat replacement without inducing hyperthermia is needed.

# Acid-Base, Fluid, and Electrolyte Management

Istvan Seri, Rangasamy Ramanathan, and Jacquelyn R. Evans

## FLUID AND ELECTROLYTE BALANCE

Maintenance of fluid and electrolyte balance is essential for normal cell and organ function both during intrauterine development and throughout extrauterine life. Pathologic conditions in the newborn often lead to disruption of the complex regulatory mechanisms of fluid and electrolyte homeostasis and may result in irreversible cell damage. Thus, a thorough understanding of the physiologic changes in neonatal fluid and electrolyte homeostasis and the provision of appropriate fluid and electrolyte therapy based on the principles of developmental fluid and electrolyte physiology are among the cornerstones of modern neonatal intensive care.

### **Developmental Changes in Body Composition, Fluid Compartments, and Organ Function Affecting Prenatal, Perinatal, and Postnatal Fluid and Electrolyte Balance**

Protection of the intracellular milieu implies that the organism must be able to monitor and correct changes in the composition and volume of the extracellular (ECF) compartment resulting from its interaction with the ever-changing environment. Recognition of this basic physiologic requirement along with the advances in our understanding of the developmental changes in body composition, fluid compartments, and organ functions regulating fluid and electrolyte balance have resulted in the emergence of the modern principles of neonatal fluid and electrolyte therapy.

#### **Developmental Changes in Body Composition and Fluid Compartments**

Dynamic changes occur in body composition and fluid distribution during intrauterine life, labor and delivery, and the early postnatal period. Thereafter, the rate of change in body composition and fluid distribution gradually decreases, with more subtle changes taking place especially after the first year of life (Friis-Hansen, 1961).

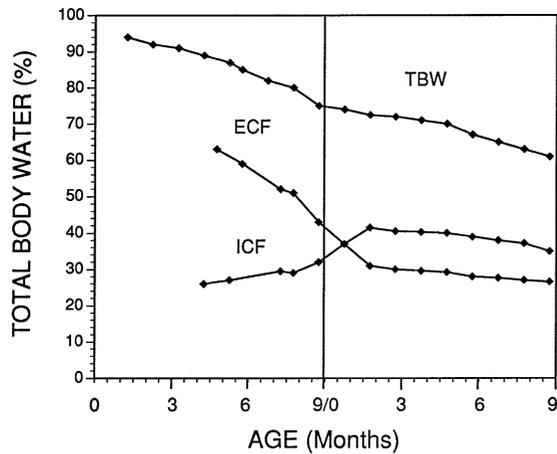

#### ***Changes During Intrauterine Development***

In early gestation, body composition is characterized by a high proportion of TBW (TBW) and a large extracellular compartment (Brans, 1986; Friis-Hansen, 1983). There also appears to be a prolactin-mediated increase in the water-binding capacity of fetal cells and perhaps the interstitium, contributing to the maintenance of increased total fetal body water content (Coulter, 1983). As gestation advances, however, the rapid cellular growth, accretion of body solids, and fat deposition result in gradual reductions in TBW content and extracellular water volume while the intracellular fluid compartment increases (Friis-Hansen, 1983). In the 16-week fetus, TBW represents approximately 94% of total body weight, and roughly two thirds of the TBW are distributed in the extracellular and one third in the intracellular compartment. In the term neonate, TBW are only about 75% of body weight, and almost half is located in the intracellular space (Fig. 30-1). Thus, infants born prematurely are in a state of TBW excess and extracellular volume expansion compared with their term counterparts, with the majority of the expanded extracellular volume being distributed in the interstitium (Brace, 1992).

During intrauterine development, the placenta provides an ample supply of nutrients and electrolytes for the fetus. To maintain normal weight gain, especially during the third trimester when an acceleration of fetal mass accumulation occurs, the fetus must be in a positive electrolyte balance.

#### ***Changes During Labor and Delivery***

Additional and more acute changes in TBW and its distribution take place during labor and delivery. Arterial blood pressure rises a few days before delivery in response to increases in catecholamine, vasopressin, and cortisol plasma concentrations and translocation of blood from the placenta into the fetus. The rise in arterial blood pressure and the changes in the fetal hormonal milieu, along with the borderline intrapartum hypoxia-induced increase in capillary permeability, result in a shift of fluid from the intravascular to the interstitial compartment. This fluid shift results in an approximately 25% reduction in circulating plasma volume in the human fetus during labor and delivery (Brace, 1992). Because the expanded interstitial fluid is not immediately accessible for filtration and excretion by the kidneys, it may serve as a source of volume supply until maternal milk production becomes adequate. Thus, the translocation of fluid from the intravascular to the interstitial compartment during labor and delivery is a part of the physiologic adaptation for the transition to extrauterine life. The postnatal increase in oxygenation and changes in vasoactive hormone production then restore capillary membrane integrity and favor absorption of interstitial fluid into the intravascular compartment. The ensuing gradual movement of fluid from the expanded interstitial space into the vessels aids in maintaining intravascular volume during the first 24 to 48 hours, when oral fluid intake may be limited. However, prematurity, pathologic conditions, or both may disrupt this delicate process and interfere with the physiologic contraction of the ECF compartment in the immediate period.

**FIGURE 30-1.** Total body water (TBW) content and its distribution between the extracellular fluid (ECF) and intracellular fluid (ICF) compartments in the human fetus, newborn, and infant from conception until 9 months of age. The data represent average values from Friis-Hansen (1961).

In the fetus, body composition and fluid balance depend on the electrolyte and water exchange among mother, fetus, and amniotic space (Brace, 1986). Therefore, several antenatal events influencing this exchange may have significant effects on the postnatal fluid balance. Maternal indomethacin treatment or excessive administration of intravenous fluids during labor may result in neonatal hyponatremia with expanded extracellular water content (Heijden et al, 1988; Rojas et al, 1984). Hydrops fetalis is the ultimate example of extreme fetal extracellular volume expansion. On the other hand, placental insufficiency or maternal diuretic therapy may impair fetal hydration, leading to decreases in extracellular volume, urine output, and amniotic fluid volume (Van Otterlo et al, 1977). Infants born under such conditions have an attenuated postnatal diuresis and weight loss and initially require greater fluid intake to correct the state of prenatal dehydration. Finally, there is no evidence that the mode of delivery influences neonatal extracellular water content (Cheek et al, 1982).

The timing of cord clamping after delivery is another important factor significantly affecting total circulating blood volume and extracellular volume in the neonate. Immediate clamping of the cord results in an average hematocrit of 48% to 51%, and there is little change in the neonate's hematocrit value over the next days (Linderkamp, 1982; Yao and Lind, 1974). However, if the cord is clamped only 3 to 4 minutes after delivery with the newborn positioned at or below the level of the placenta, up to 25 to 50 mL/kg of blood is transfused into the neonate, representing an approximately 25% to 50% increase in the total blood volume (Linderkamp, 1982; Yao and Lind, 1974). Because in these cases the higher transcapillary hydrostatic pressure forces an additional 25 to 30 mL/kg of intravascular fluid into the interstitium, the hematocrit may gradually increase to 60% to 65% or higher over the first 3 to 4 hours of life (Brace, 1992; Linderkamp, 1982; Yao and Lind, 1974). Thus, if the neonate is suspected to have received a prolonged placental transfusion and the initial hematocrit value is between 60% and 65%, the hematocrit should be checked again 4 to 6 hours later. The effects of the timing

of cord clamping on intravascular and extracellular volumes are modified by the presence of asphyxia and neonatal breathing.

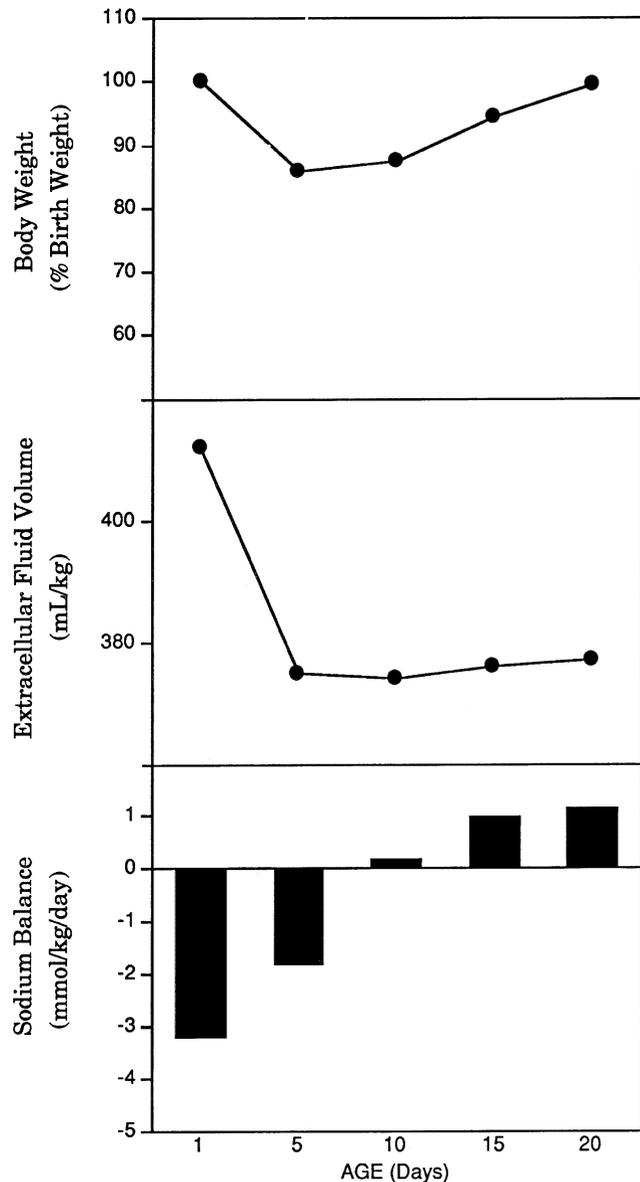

### **Changes in the Postnatal Period**

In the first few days and weeks after birth, the most important effects on the pace of further changes in body composition, TBW content, and its distribution are exerted by gestational and postnatal ages, the presence or absence of pathologic conditions, the immediate environment, and the type of nutrition.

During the early transitional period, the healthy newborn loses weight. It is generally accepted that this postnatal weight loss is primarily due to the contraction of the expanded ECF compartment (Cheek et al, 1961) and that it approximates the total body fluid loss (Shaffer et al, 1986). However, water loss from the intracellular space may also contribute to the physiologic weight loss (Coulter, 1983; MacLaurin, 1966), especially if there are rapid changes in serum osmolality. Such changes in serum osmolality may be seen in extremely low-birth-weight (LBW) infants with increased transepidermal water losses (Costarino and Baumgart, 1991; Sedin, 1995).

Although the exact mechanisms of the ECF contraction are unknown, several studies have suggested that atrial natriuretic peptide plays a role in this process (Kojima et al, 1987; Ronconi et al, 1995; Rozycki and Baumgart, 1991; Tulassay et al, 1987). The postnatal increase in capillary membrane integrity favors absorption of the interstitial fluid into the intravascular compartment. The ensuing rise in circulating blood volume stimulates release of atrial natriuretic peptide from the heart, which in turn enhances renal sodium and water excretion (Sagnella and MacGregor, 1984). The concomitant diminution in the release of vasoconstrictive and antidiuretic hormones further enhances the diuretic action of atrial natriuretic peptide.

The TBW excess and extracellular volume expansion of the preterm infants imply that their negative water and sodium balance during the first 5 to 10 postnatal days (Fig. 30-2) (Shaffer and Meade, 1989) represent an appropriate adaptation to extrauterine life and should not be compensated for by increased fluid administration and sodium supplementation. If this principle is not followed and a positive fluid balance (i.e., weight gain) is achieved during the transitional period, preterm infants are at higher risk of a more severe course of respiratory distress syndrome (Shaffer and Weismann, 1992) as well as a higher incidence of patent ductus arteriosus (Bell et al, 1980), congestive heart failure (Bell et al, 1980), pulmonary edema (Shaffer and Weismann, 1992), necrotizing enterocolitis (Bell et al, 1979), and bronchopulmonary dysplasia (Van Marter et al, 1990). Only the thorough understanding of the principles of developmental fluid and electrolyte physiology will enable the clinician to adjust fluid and caloric requirements appropriately during the transitional period in the sick term and preterm neonate and, thus, minimize the impact of abnormalities in postnatal fluid and electrolyte homeostasis on different short- and long-term outcome measures (see section on fluid and electrolyte management).

**FIGURE 30-2.** Postnatal changes in body weight (expressed in percent of birth weight), extracellular fluid volume (estimated by the bromide dilution method), and sodium balance (defined as the difference between sodium intake and urinary sodium excretion). (From Shaffer SG, Weismann DN: *Fluid requirements in the preterm infant*. *Clin Perinatol* 19:233-250, 1992).

Healthy term newborns lose an average of 5% to 10% of their body weight during the first 4 to 7 days of life (Brace, 1992). Thereafter they establish a pattern of steady weight gain. Because preterm infants have an increased TBW content and extracellular volume, they lose on average 15% of their body weight during transition (Shaffer et al, 1987) and, depending on the degree of prematurity and associated pathologic conditions, these neonates regain their birth weight only at 10 to 20 days after birth. However, because TBW content at birth is also influenced by factors other than maturity, as discussed earlier, weight loss may differ significantly among patients of the same gestational age, and there is no established optimal rate or extent of

weight loss in infants born prematurely (Lorenz et al, 1982).

The healthy term infant is born after having developed adequate macromineral stores. After the extracellular volume contraction, these infants maintain an appropriate positive macromineral balance and steadily gain weight. On the other hand, preterm infants, especially those born before the third trimester, have missed the period of intrauterine life when the highest rate of macromineral retention takes place. To achieve and maintain normal growth, these neonates must be in a positive macromineral balance after their transitional period. However, certain pathologic conditions and the long-term administration of diuretics may hinder their ability to achieve a positive macromineral balance and, thus, appropriate growth rate.

### Physiology of the Regulation of Body Composition and Fluid Compartments

Although human cells have the ability to adjust their intracellular composition, ultimate regulation of the intracellular volume and osmolality relies on the control of the extracellular compartment. Therefore, the human body must be able to monitor the volume and osmolality of the extracellular compartment and to correct the changes resulting from its interaction with the environment.

### Regulation of the Intracellular Solute and Water Compartment

The major intracellular solutes are the cellular proteins necessary for cell function, the organic phosphates associated with cellular energy production and storage, and the equivalent cations balancing the phosphate and protein anions (MacKnight and Leaf, 1977). As a result of the activity of the cell membrane-bound sodium-potassium adenosine triphosphatase, potassium is the major intracellular cation and sodium is the major extracellular cation. The energy derived from the concentration differences for sodium and potassium between the intracellular and extracellular compartments is used for cellular work.

Because changes in osmolality of the extracellular compartment are reflected as net movements of water in or out of the cell, regulation of ECF concentration ultimately controls the osmolality and size of the intracellular compartment (MacKnight and Leaf, 1977). This physiologic principle must be kept in mind by the neonatologist managing sick term and preterm neonates with disturbances of sodium homeostasis. Rapid changes in serum sodium concentration and thus in extracellular osmolality directly affect the osmolality and size of the intracellular compartment and may lead to irreversible cell damage, especially in the central nervous system (see later).

### Regulation of the Intracellular-Extracellular Interface: The Interstitial Compartment

There are small but important differences in the composition of the interstitial and intravascular fluid compartments that allow the movement of water, solute, and nutrients from the blood into the interstitium and the

transport of cellular waste products into the circulation for final elimination. The tightly regulated differences in the composition of the interstitium and the intravascular fluid space result from the interaction of the intravascular and interstitial hydrostatic and oncotic pressures (Starling, 1896). According to this principle, water movement across the capillary wall can be described by the equation

$$J_V = K_F [(P_C - P_T) - \delta (\pi_P - \pi_T)]$$

where  $J_V$  = the net flow across the capillary,  $K_F$  = filtration coefficient,  $P_C$  = capillary hydrostatic pressure,  $P_T$  = interstitial hydrostatic pressure,  $\delta$  = protein reflection coefficient,  $\pi_P$  = plasma oncotic pressure, and  $\pi_T$  = interstitial oncotic pressure. Thus, the movement of fluid out of the capillary is determined by the product of the water permeability characteristics of the capillary wall ( $K_F$ ) and the net driving pressure  $[(P_C - P_T) - \delta (\pi_P - \pi_T)]$  that forces fluid out from the capillary. The net driving pressure is the difference between the hydrostatic ( $P_C - P_T$ ) and oncotic ( $\pi_P - \pi_T$ ) pressures on either side of the capillary wall (Fig. 30-3).

Under physiologic conditions, a small amount of fluid leaves the plasma at the arterial end of the capillary circulation as a result of the balance of these forces. As capillary hydrostatic pressure falls and plasma oncotic pressure increases along the capillary bed, filtration ceases and much of the filtered fluid reenters at the venous end of the capillary circulation. The difference between the filtered fluid and the reabsorbed fluid is cleared from the interstitium by the lymphatic system (Taylor, 1981). The reflection coefficient ( $\delta$ ) describes the protein permeability characteristics of the capillary wall, which is tissue specific. In

tissues with capillaries that are virtually impermeable to proteins (brain, skin:  $\delta = 0.8$ ), the oncotic pressure difference plays an important role in counterbalancing the tendency of the hydrostatic forces to move fluid out from the capillaries. In tissues with high capillary permeability to protein (liver, spleen:  $\delta = 0.2$ ), the lymphatic circulation plays a more important role in regulating the volume of the interstitial fluid compartment.

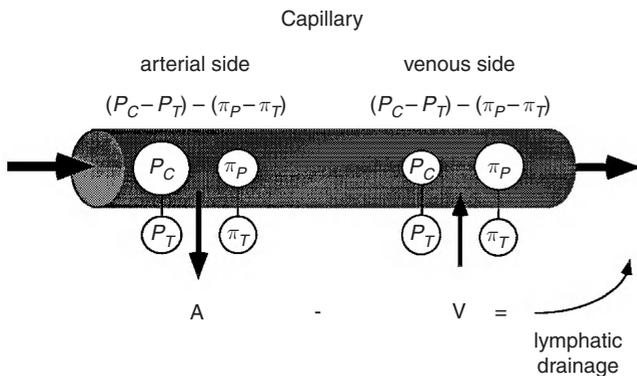

In the healthy term neonate, hydrostatic and oncotic pressures are well balanced, being roughly half of those in the adult (Sola and Gregory, 1981). However, pathologic conditions readily disturb the delicate balance between the hydrostatic and oncotic forces, leading to an expansion of the interstitial compartment at the expense of the intravascular volume. The increased interstitial fluid volume (edema) then further affects tissue perfusion by altering the normal function of the extracellular-intracellular interface. Table 30-1 summarizes the conditions resulting in increased edema formation in the neonate.

There also are some important developmentally regulated differences between the newborn and the adult relating to the pathomechanisms of edema formation. Capillary permeability to proteins is increased during the early stages of development; this increase is reflected by a lower tissue-specific protein reflection coefficient ( $\delta$ ) in the fetus and newborn than in the adult (Brace, 1992; Gold and Brace, 1988). Because, under pathologic conditions, neonatal capillary permeability is further increased (see Table 30-1), protein concentration in the interstitial compartment may approach that of the intravascular space, favoring further intravascular volume depletion and interstitial volume expansion. When neonates with such conditions are treated with frequent albumin boluses, much of the infused albumin leaks into the interstitium, creating a vicious cycle of intravascular volume depletion and edema formation. If the cycle is not interrupted, the result may be the formation of anasarca with an extremely poor prognosis. As mentioned previously, when the permeability of the capillary endothelium to protein is increased, the final balance between fluid filtration and reabsorption is more dependent on an effective lymphatic drainage (Taylor, 1981). However, because lymph flow in the neonate is readily disrupted by even a small elevation in venous pressure (Brace, 1992), pathologic conditions and therapeutic maneuvers that increase venous pressure are commonly associated with decreased lymphatic clearance and thus edema formation in the sick infant.

In summary, the sick neonate has a limited capacity to maintain appropriate intravascular volume and to regulate the volume and composition of the interstitium. The ensuing intravascular hypovolemia and edema formation result in vasoconstriction and disturbances in tissue perfusion and cellular function with further impairments in the regulation of extracellular volume distribution.

### Regulation of the Extracellular Solute and Water Compartment

The regulation of the volume and osmolality of the extracellular compartment ensures the integrity of the circulation and maintains the osmolality of the extracellular compartment within 2% of the osmolar set point between 275 and

**FIGURE 30-3.** Filtration and reabsorption of fluid along the capillary under physiologic conditions. Movement of fluid across the capillary is determined by the direction of the net driving pressure  $[(P_C - P_T) - (\pi_P - \pi_T)]$  and the water and protein permeability characteristics of the capillary wall. At the arterial end of the capillary, intracapillary hydrostatic pressure ( $P_C$ ) is high, and plasma oncotic pressure ( $\pi_P$ ) is relatively low, resulting in a net movement of fluid out of the capillary. As filtration of relatively protein-poor fluid continues along the capillary, plasma oncotic pressure rises and intracapillary hydrostatic pressure drops. Therefore, on the venous side, fluid moves from the interstitium into the capillary, so that much of the filtered fluid is reabsorbed at the end of the capillary bed. The fluid remaining in the interstitium (arterial-venous side of the capillary) is drained by the lymphatic system. Interstitial hydrostatic ( $P_T$ ) and oncotic ( $\pi_T$ ) pressures remain virtually unchanged along the capillary bed. See text for details.

290 mOsm (Robertson and Berl, 1986). Blood pressure and serum sodium concentration (i.e., osmolality) are monitored by baroreceptors and osmoreceptors, respectively. The effector limb of the regulatory system consists of the heart, the vascular bed, the kidneys, and the gastrointestinal intake of fluid in response to thirst. The latter part of the effector system is inactive in the critically ill term and preterm neonates whose fluid intake is completely controlled by the caregivers. By regulating the function of the effector organs, several hormones play a role in the control of the extracellular compartment, including the renin-angiotensin-aldosterone system, vasopressin, atrial natriuretic peptide, bradykinin, prostaglandins, and catecholamines.

Because volume changes in the extracellular compartment must be reflected by similar changes in the intravascular volume for effective operation of the regulatory mechanisms, regulation of the extracellular compartment relies on intact cardiovascular function as well as on the integrity of the capillary endothelium (Robertson and Berl, 1986). For instance, under physiologic conditions, an increase in the extracellular volume is reflected by an increase in the circulating plasma volume, leading to rises

in blood pressure and renal blood flow. The ensuing increase in glomerular filtration and urine output returns the extracellular volume to normal.

In critically ill neonates, however, the capillary leak and reduced myocardial responsiveness resulting from immaturity and the underlying pathologic condition limit the increase in the circulating blood volume when extracellular volume expands. Thus, especially in sick preterm infants, blood pressure may rise only transiently, and renal blood flow and glomerular filtration rate remain low after volume boluses as fluid rapidly leaks out into the interstitium. By causing peripheral vasodilation, inappropriate central regulation of vascular tone further decreases effective circulating blood volume. With the concomitant release of catecholamines, vasopressin, and renin-angiotensin-aldosterone, renal tubular sodium and water reabsorption continue to be favored in order to increase diminished intravascular volume. However, this compensatory mechanism fails as the retained fluid continues to leak from the intravascular space into the interstitium, further compromising tissue perfusion. This leads to impaired gas exchange in the lungs, resulting in hypoxia with further increases in

capillary leak. Thus, unless interrupted by appropriate therapeutic measures (see later), a vicious cycle with further deterioration rather than an effective extracellular volume regulation occurs in the sick preterm and term neonate.

### **Maturation of Organs Regulating Body Composition and Fluid Compartments**

The heart, the kidneys, the skin, and the endocrine system play the most important roles in the regulation of extracellular (and thus intracellular) fluid and electrolyte balance in the neonate. Immaturity of these organ systems, especially in very LBW infants, results in a compromised regulatory capacity, which one must remember when estimating daily fluid and electrolyte requirements in these patients. Other organs, including the gastrointestinal tract, are also involved in the physiologic regulation of fluid and electrolyte homeostasis. However, the impact of the maturational state of these organs is less significant for the fluid and electrolyte management in the critically ill newborn.

#### ***Maturation of the Cardiovascular System***

There is a direct relationship between gestational maturity and the ability of the neonatal heart to respond to acute volume loading (Baylen et al, 1986). The blunted Starling response of the immature myocardium results from its lower content of contractile elements and incomplete sympathetic innervation (Mahony, 1995). Because central vasoregulation and endothelial integrity are also developmentally regulated (Brace, 1992; Gold and Brace, 1988), an appropriate effective intravascular volume is seldom maintained in a critically ill preterm infant. Since regulation of the extracellular volume requires the maintenance of an adequate effective circulating blood volume, the immaturity of the cardiovascular system contributes to the limited capacity of sick preterm infants to effectively regulate the total volume of their extracellular compartment.

#### ***Maturation of Renal Function***

The kidney plays a crucial role in the physiologic control of fluid and electrolyte balance. It regulates extracellular volume and osmolality through the selective reabsorption of sodium and water, respectively. In the fetus, nephrogenesis is incomplete until 34 to 36 weeks of gestation (Robillard et al, 1990; see also Chapter 80). Thus, in addition to immaturity of tubular functions, preterm infants have a decreased number of glomeruli and the postnatal increase in their renal blood flow and glomerular filtration rate is attenuated compared with that of the term neonate (Arant, 1978). Tubular immaturity in preterm infants is reflected by their increased sodium, bicarbonate, and free water excretion and decreased renal concentrating capacity (Jones and Chesney, 1992; see also Chapter 80).

Some aspects of developmental renal physiology significantly influence the clinical management of the sick neonate. Because prenatal steroid administration acceler-

ates maturation of renal function (van den Anker et al, 1994), preterm infants treated with steroids in utero have a better capacity to regulate their postnatal ECF contractions, which may facilitate their pulmonary recovery. Immaturity of their renal function renders preterm infants susceptible to both excessive sodium losses and sodium as well as volume overloading (El-Dahr and Chevalier, 1990). Sodium losses occur in spite of the low glomerular filtration rate and are mainly due to the immaturity of the tubular membrane transport processes and their hormonal regulation (Spitzer, 1982, Sulyok et al, 1985, Tulassay et al, 1986). The high urinary sodium excretion may be of clinical benefit during the period of transition because it promotes contraction of the expanded extracellular volume. Sodium retention is necessary for normal growth, however, so a negative sodium balance beyond the first 1 to 2 weeks of postnatal life may hinder appropriate weight gain (Sulyok et al, 1985). The inability of the preterm infant to respond promptly to a sodium or volume load results in a tendency of extracellular volume expansion with edema formation. This is a consequence primarily of the limited glomerular filtration rate, and it occurs despite the preterm infant's ability to produce a dilute urine (El-Dahr and Chevalier, 1990).

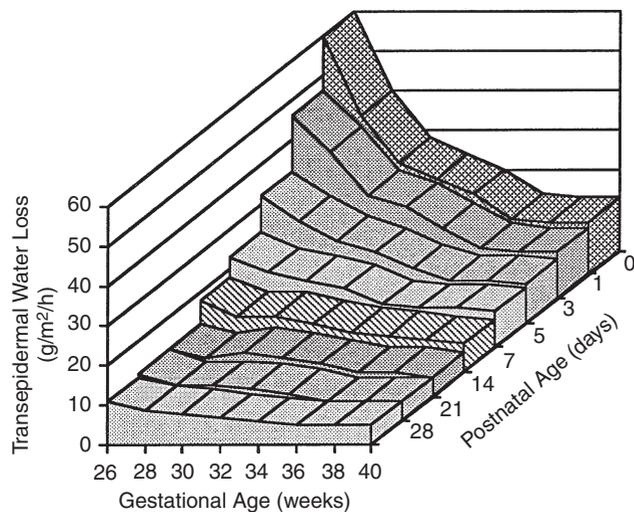

#### ***Maturation of the Skin***

Although term infants have a well-developed cornified layer of the epidermis, extremely immature neonates have only two to three cell layers in the epidermis (Cartledge-Patrick and Rutter, 1992). Because of the lack of an effective barrier to diffusion of water through the immature skin, transepidermal free water losses in the immature infant may be extremely high during the first few days of life. Gestational age, postnatal age, the pattern of intrauterine growth, and environmental factors play crucial roles in the magnitude of transepidermal free water losses (Fig. 30-4). Although skin cornification rapidly increases even in the extremely immature (23 to 26 weeks of gestational age) infant during the first few days of life, full maturation of the epidermis does not occur for more than 28 days after birth (Sedin, 1995). Chronic intrauterine stress (Hammarlund et al, 1983) and prenatal steroid treatment (Aszterbaum et al, 1993) also enhance maturation of the skin.

Because regulation of ECF volume and osmolality ultimately controls the intracellular compartment, increases in free water losses through the immature skin in the very LBW infant may result in early postnatal hypertonic dehydration with rapid changes in intracellular volume and osmolality. In many organs, especially the brain, the abrupt changes in intracellular volume and osmolality may lead to cellular dysfunction and ultimately to cell death (see later).

#### ***Maturation of End-Organ Responsiveness To Hormones Involved in the Regulation of Fluid and Electrolyte Balance***

Several hormones, including but not limited to the renin-angiotensin-aldosterone system, vasopressin, atrial natriuretic peptide, dopamine and noradrenaline, directly

**FIGURE 30-4.** Transepidermal water loss in relation to gestational age during the first 28 postnatal days in appropriate-for-gestational-age infants. There is an exponential relationship between transepidermal water loss and gestational age, the water loss being higher in preterm infants than in term infants. Transepidermal water loss is also significantly affected by postnatal age, especially in the immature preterm infant. The measurements were performed at an ambient air humidity of 50% and with the infants calm and quiet. (From Hammarlund K, Sedin G, Stromberg B: *Transepidermal water loss in newborn infants. VIII: Relation to gestational age and postnatal age in appropriate and small for gestational age infants. Acta Paediatr Scand* 72:721-728, 1983.)

regulate the volume or composition of the extracellular compartment. These hormones exert their effects mainly by altering renal sodium and water excretion and by inducing changes in systemic vascular resistance and myocardial contractility. Other hormones, including the prostaglandins, bradykinin, and prolactin, modulate the actions of many of the regulatory hormones.

**Renin-Angiotensin-Aldosterone System.** Decreases in renal capillary blood flow and tubular sodium delivery to the juxtaglomerular apparatus stimulate renin secretion, which in turn initiates the production of angiotensin. Angiotensin induces vasoconstriction, increases in tubular sodium and water reabsorption, and release of aldosterone (Riordan, 1995). Aldosterone increases potassium secretion and further enhances sodium reabsorption in the distal tubule. Thus, the primary function of this system is to protect the volume of the extracellular compartment and maintain adequate tissue perfusion (Baillie, 1992). However, its effectiveness in the neonate is somewhat limited by the decreased responsiveness of the immature kidney to the sodium- and water-retaining effects of these hormones (Sulyok et al, 1985). This is also one of the reasons why this system remains activated for several weeks to months after birth especially in the more immature or critically ill neonate (Godard et al, 1979; Sulyok et al, 1979).

Vasodilatory and natriuretic prostaglandins generated in the kidney (Gleason, 1987) are the main counter-regulatory hormones balancing the renal actions of the renin-angiotensin-aldosterone system. Therefore, when prosta-

glandin production is inhibited by indomethacin, the unopposed vasoconstrictive and sodium-retentive actions of the activated renin-angiotensin-aldosterone system contribute to the development of the drug-induced renal failure in the preterm infant (Gleason, 1987; Seri, 1995; Seri et al, 2002).

**Vasopressin (Antidiuretic Hormone).** The rise in serum osmolality is a much more potent stimulus for vasopressin secretion than the decrease in systemic blood pressure (Dunn et al, 1973). This indicates that vasopressin is more important for maintaining the osmolality of the extracellular compartment than it is for regulating total extracellular volume and effective circulating blood volume. By midgestation, the fetus is able to respond to both osmotic and baroreceptor stimulation as well as to hypoxia with increased vasopressin release (Kelly et al, 1983, Leake, 1992; Weitzman et al, 1978). The primary renal action of vasopressin is to selectively raise free water reabsorption via the insertion of water channels into the luminal membrane of the distal tubular and collecting duct epithelium (Elliott et al, 1996). This free water retention is counterbalanced by locally generated prostaglandins (Bonvalet et al, 1987). Administration of indomethacin abolishes this regulatory effect, and the unopposed vasopressin-induced free water reabsorption contributes to the development of the drug-induced renal side effects (Gleason, 1987; Seri, 1995; Seri et al, 2002).

The primary cardiovascular action of vasopressin is peripheral vasoconstriction resulting in blood pressure elevation and redistribution of blood flow (Leake, 1992). Plasma levels of vasopressin are markedly elevated in the neonate, especially after vaginal delivery, and its cardiovascular actions facilitate neonatal adaptation (Pohjavouri and Raivio, 1985). The high vasopressin levels are in part also responsible for the diminished urine output of the healthy term neonate during the first day of life.

Under certain pathologic conditions, the dysregulated release of, or the end-organ unresponsiveness to, vasopressin significantly affects renal and cardiovascular functions in the sick preterm and term infant. In the syndrome of inappropriate secretion of antidiuretic hormone (SIADH), an uncontrolled release of vasopressin occurs in sick preterm and term infants. SIADH may be associated with birth asphyxia, intracerebral hemorrhage, respiratory distress syndrome, pneumothorax, and the use of continuous positive-pressure ventilation (El-Dahr and Chevalier, 1990; Leake, 1992). The syndrome is characterized by renal-free water retention, with decreased serum sodium values and serum osmolality, as well as by oliguria, increased urine concentration, and weight gain with edema formation. However, because the urinary concentrating capacity of the newborn is limited, a less than maximally diluted urine satisfies the diagnosis of SIADH in the presence of the other symptoms. The treatment is based on fluid and sodium restriction despite the oliguria and hyponatremia as well as on appropriate circulatory and ventilatory support. The clinician must remember that total body sodium is normal but TBW is elevated in such an infant, and that it is particularly dangerous to treat the hyponatremia caused by free water retention with large amounts of sodium. Owing to their more immature renal functions, extremely LBW infants during the first few weeks of life usually do not present with the full-blown syndrome in spite of their

sometimes excessively high plasma vasopressin levels (Aperia et al, 1983).

Diminished vasopressin secretion or complete unresponsiveness of the renal tubules results in polyuria, diluted urine production, and increased serum osmolality (Leake, 1992). The treatment of these neonates consists of allowing for adequate free water intake. During the first few weeks of life, hemodynamically stable but extremely immature infants produce a dilute urine and may become polyuric despite appropriate vasopressin production, because of their renal tubular immaturity. As tubular functions mature, their concentrating capacity gradually improves from the second to fourth week of life. However, it takes years for the developing kidney to reach the concentrating capacity of the adult kidney. Finally, diminished vasopressin release may contribute to the development of vasopressor-resistant vasodilatory shock in critically ill preterm and term neonates (see Chapter 31).

**Atrial Natriuretic Peptide.** Via its direct vasodilatory and renal natriuretic actions, atrial natriuretic peptide regulates the volume of the extracellular compartment in the fetus and neonate in a fashion opposite to that of the renin-angiotensin-aldosterone system (Iwamoto, 1992; Needleman and Greenwald, 1986; Seymour, 1985.). This opposing action is further reflected by its direct inhibitory effect on renin production and aldosterone release (Christensen, 1993). The stretch of the atrial wall caused by an increase in the circulating blood volume is the most potent stimulus for the release of this hormone. During early development, atrial natriuretic peptide is produced by all the chambers of the heart, and plasma levels of the hormone are high in the fetus (Claycomb, 1988).

There are a few specific conditions in which the actions of atrial natriuretic peptide are directly relevant for the neonatologist. For instance, the hormone is involved in the regulation of both the fluid shifts during labor (Brace, 1992) and the extracellular volume contraction during postnatal transition (Kojima et al, 1987; Ronconi et al, 1995; Rozycki and Baumgart, 1991; Tulassay et al, 1987). Furthermore, the oliguric effects of positive end-expiratory pressure ventilation are due in part to a decrease in atrial natriuretic peptide secretion (Christensen, 1993) along with the enhanced release of vasopressin (El-Dahr and Chevalier, 1990).

**Dopamine, Noradrenaline, and Adrenaline.** Dopamine produced in the renal proximal tubule cells and the dopaminergic nerve endings of the kidneys and mesenterium regulates total ECF volume by enhancing sodium excretion and selectively increasing blood flow to the kidney and the intestine (Seri, 1995). In general, adrenaline and locally produced noradrenaline exert opposite renal vascular and tubular effects in the fetus and neonate (Robillard et al, 1990). Both the dopaminergic and  $\alpha$ -adrenergic systems appear to be functionally mature even in the preterm neonate, as evidenced by the cardiovascular and renal response to dopamine treatment (Seri, 1995; Seri et al, 1998a, 2002).

**Prostaglandins.** Prostaglandins play a well-documented counter-regulatory role for the renal vascular and tubular effects of renin-angiotensin-aldosterone and vasopressin (Bonvalet et al, 1987). The inhibition of these actions of prostaglandins by indomethacin results in clinically impor-

tant and sometimes detrimental renal vascular and tubular effects in the preterm infant (see later). The actions of prostaglandins modulating the effects of the other regulatory hormones of the neonatal fluid and electrolyte homeostasis are less well studied.

**Kallikrein-Kinin System.** The renal cortical enzyme kallikrein catalyzes the formation of the vasodilator and natriuretic hormone bradykinin. The kallikrein-kinin system is activated at birth and stimulates renal prostaglandin production. Bradykinin also antagonizes the renal actions of vasopressin, renin, and angiotensin (Siegel, 1982).

**Prolactin.** Prolactin plays a permissive role in the regulation of fetal and neonatal water homeostasis (Coulter, 1983; Pullano et al, 1989). High fetal plasma prolactin levels contribute to the increased tissue water content of the fetus. Interestingly, postnatal prolactin levels remain high in the preterm neonate until around the 40th postconceptional week (Perlman et al, 1978). Dopamine inhibits prolactin secretion in the preterm and term neonate (de Zegher et al, 1993; Seri et al, 1985), potentially resulting in a decrease in water-binding capacity of the tissues (Coulter, 1983). However, the clinical significance of this hypolactotropic effect in the dopamine-treated edematous preterm infant remains to be demonstrated. Finally, it is important to note that prolactin also modulates certain immune and inflammatory responses and T-cell proliferation (Yu-Lee, 2002). Whether the hypolactotropic effects of dopamine would negatively affect neonatal immune function is unknown.

## Fluid And Electrolyte Management in Preterm and Term Neonates

### Patient Evaluation

Maternal conditions during pregnancy, drugs and fluids administered to the mother during labor and delivery, and specific fetal and neonatal conditions all affect the fluid and electrolyte balance of the newborn and should be taken into consideration by the clinician prescribing the infant's initial daily fluid intake.

Clinical evaluation of the newborn's fluid and electrolyte status should be based on clinical signs of dehydration or edema formation and on accurate serial measurements of body weight. Laboratory studies aiding in daily fluid and electrolyte management are serial measurements of serum electrolytes, blood urea nitrogen, serum creatinine, serum albumin, and serum osmolality. The frequency of monitoring depends on the extent of immaturity as well as the severity of the fluid and electrolyte disturbance and of the underlying pathologic condition.

### General Principles of Fluid and Electrolyte Management

The most important principle of fluid and electrolyte management of the sick preterm or term infant is to prevent, or at least to decrease the likelihood of, significant pulmonary and extrapulmonary edema formation. The measures to achieve this goal are (1) provision of a negative fluid and electrolyte balance during the first few postnatal days

through restriction of fluid and salt administration, (2) avoidance of excessive fluid intake during the rest of the first months of life, (3) early closure of the ductus arteriosus, (4) the use of blood transfusions rather than that of colloid or crystalloid boluses for volume support if appropriate, and (5) the provision of sufficient nutrition. Because peripheral vasodilation due to disturbed regulation of vascular tone almost always contributes to the development of hypotension in the sick neonate, early administration of low to moderate doses of dopamine may further reduce the need for volume boluses, and via its renal and hormonal effects, dopamine may facilitate the process of extracellular volume contraction (Seri, 1995).

Water and electrolyte requirements depend on the daily losses and the state of metabolic activity. Water requirement should be estimated on the basis of the volume status and the sensible and insensible losses in the given infant. Because abrupt alterations in serum sodium concentration are associated with similar changes in serum osmolality, they may have severe central nervous system sequelae and should be avoided.

## Abnormalities of Sodium Homeostasis

### Hyponatremia

Hyponatremia (serum sodium  $<130$  mEq/L) represents a deficit of sodium in relation to body water content and may be due to either total body sodium deficit or free water excess. When hyponatremia is caused by total body sodium deficit, free water may be decreased (hyponatremia with volume contraction), normal, or increased (hyponatremia with volume expansion). Similarly, when hyponatremia is caused by free water excess, total body sodium may be low, normal, or high. Depending on the osmolality of the serum, hyponatremia may be hypotonic, isotonic, or hypertonic. The most common manifestation of hyponatremia in the neonate is hypotonic hyponatremia due to excessive administration or retention of free water.

**Hypotonic Hyponatremia.** Serum osmolality is reduced in hypotonic hyponatremia ( $<280$  mOsm/L). In cases of *hypotonic hyponatremia with volume contraction*, there is a disproportionately greater loss of sodium than of water. In the preterm or term neonate, volume contraction with hypotonic hyponatremia may occur secondary to excessive renal losses of sodium due to renal immaturity, use of diuretics, and adrenal insufficiency as well as in cerebral salt wasting and during recovery from an acute renal insult (asphyxia, shock). Although cerebral salt wasting is uncommon in newborn infants (Ganong and Kappy, 1993), this condition must be differentiated from SIADH. In contrast to patients with SIADH, patients with cerebral salt wasting have decreases in plasma volume as well as plasma aldosterone and vasopressin levels and a normal plasma uric acid concentration. Treatment of hypotonic hyponatremia with volume contraction consists of replacement of both the free water and the sodium deficit.

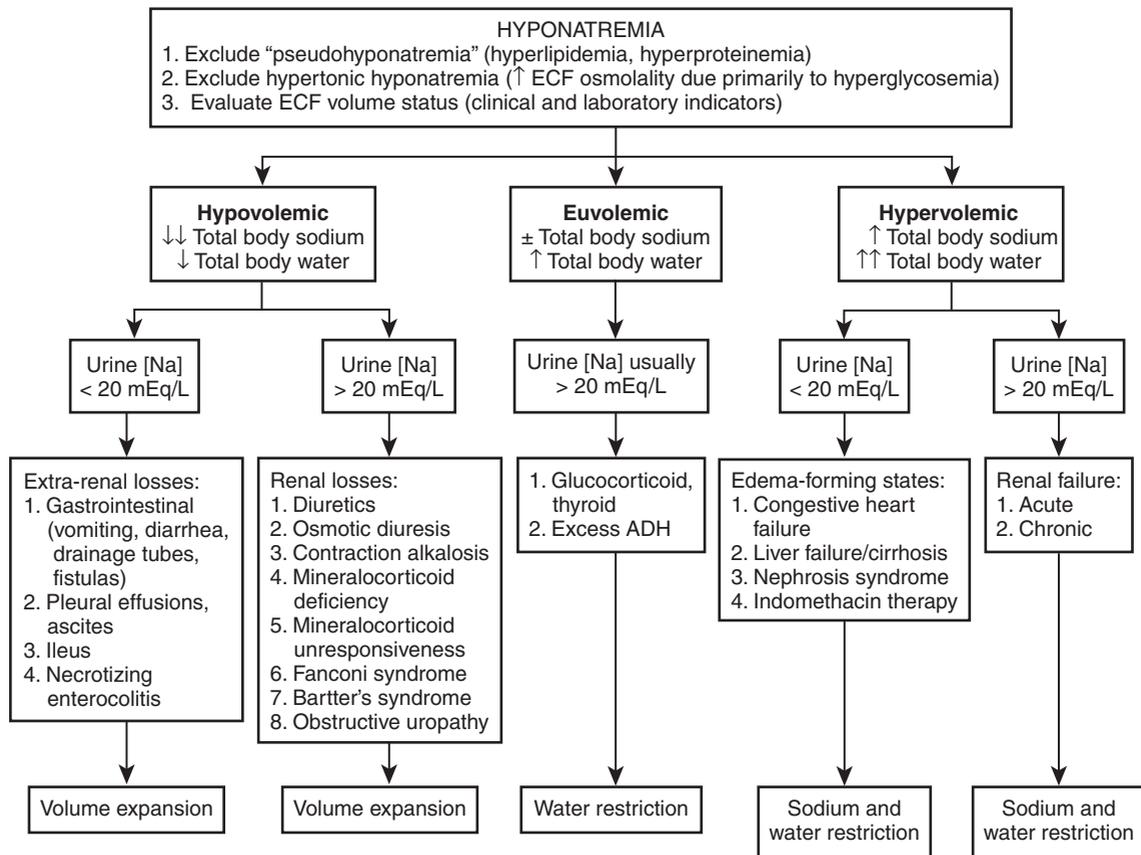

*Hypotonic hyponatremia with volume expansion* results from positive water balance, and the diagnosis is based on the clinical signs of edema and weight gain as well as the history of increased free water administration or medical

conditions associated with enhanced vasopressin production (central nervous system injury, congestive heart failure). Total body sodium is usually normal or somewhat elevated. Thus, appropriate restriction of free water intake, not administration of sodium, is the treatment of choice for this disorder.

**Isotonic Pseudohyponatremia.** Hyponatremia in the presence of normal serum osmolality (285 to 295 mOsm/L) is referred to as *pseudohyponatremia*. Under physiologic conditions, 93% of the total plasma volume is an aqueous phase that contains the electrolytes, and the remaining 7% is a solid phase composed primarily of lipids and proteins. In hyperlipidemia or hyperproteinemia, the solid phase increases at the expense of the aqueous phase, and serum sodium concentration measured in the total plasma compartment decreases. Thus, in patients with pseudohyponatremia, total body sodium, TBW content, and sodium concentration in the aqueous phase are all within normal limits, but sodium concentration measured in the total plasma compartment is reduced. In these patients, the laboratory test results indicate hyponatremia, but serum osmolality is normal, and additional tests reveal the presence of hyperproteinemia or hyperlipidemia.

**Hypertonic Hyponatremia.** In patients with hypertonic hyponatremia, the hyponatremia is associated with increased serum osmolality ( $>295$  mOsm/L). This condition occurs because of the presence of an osmotically active substance in the plasma, such as glucose, which results in hypertonicity. Hypertonicity, in turn, causes water to shift from the intracellular space into the interstitium and the intravascular compartment, leading to a decrease in the plasma sodium concentration. With a serum glucose concentration in excess of 100 mg/dL, every 100-mg/dL rise in plasma glucose results in a 1.6-mEq/L decrease in the serum sodium concentration. This diagnosis should be suspected if hyponatremia is detected along with a serum osmolality of greater than 295 mOsm/L or if the measured serum osmolality is 20 mOsm/L higher than the calculated serum osmolality.

**Treatment of Hyponatremia.** If serum sodium concentration is less than 120 mEq/L, correction of hyponatremia is recommended with 3% saline solution (513 mEq of sodium per liter) up to 120 mEq/L of serum sodium concentration over 4 to 6 hours depending on the severity of hyponatremia (Avner, 1995). Although rapid intravenous bolus administration of 4 to 6 mL/kg of 3% saline solution has been effective in children with seizures or coma (Sarnaik et al, 1991), one must keep in mind that rapid and complete correction of low serum sodium concentration in adults with chronic hyponatremia has been shown to be associated with pontine and extrapontine myelinolysis. Therefore, once the risk of central nervous system symptoms has been minimized and serum sodium concentration has reached 120 mEq/L, complete correction of hyponatremia should be performed more slowly, over 24 to 48 hours. In patients with asymptomatic hyponatremia whose serum sodium concentration exceeds 120 mEq/L, hypertonic infusions are not indicated. The use of 5% dextrose in water with 0.45% to 0.9% saline is reasonable. Figure 30–5 summarizes the clinical evaluation and therapy of neonates with hyponatremia.

**FIGURE 30-5.** Flow diagram for the clinical evaluation and therapy of neonates with hyponatremia. ECF, extracellular fluid. (Modified from Avner ED: *Clinical disorders of water metabolism: Hyponatremia and hypernatremia*. *Pediatr Ann* 24:23-30, 1995).

### Hypernatremia

Hypernatremia (serum sodium  $>150$  mEq/L) reflects the deficiency of water relative to total body sodium and is most often a disorder of water rather than sodium homeostasis. Hypernatremia does not indicate total body sodium content, which can be high, normal, or low depending on the etiology of the condition. If the primary cause is a disorder of water homeostasis, hypernatremia can result from pure water loss, from water loss coupled with a lesser degree of sodium deficit, or from sodium gain, and it can be associated with hypovolemia, normovolemia, or hypervolemia (Table 30-2). If hypernatremia is primarily due to changes in sodium balance, it can result from pure sodium gain or, more commonly, sodium gain coupled with a lesser degree of water accumulation or, rarely, sodium gain coupled with water loss. The hypernatremia-induced hypertonicity causes water to shift from the intracellular to the extracellular compartment, resulting in intracellular dehydration and the relative preservation of the extracellular compartment. This is the main reason that neonates with chronic and severe hypernatremic dehydration do not demonstrate overt clinical signs of dehydration until late in the course of the condition.

Compared with the other organs, the central nervous system has a unique adaptive capacity to respond to the

**TABLE 30-2**

#### Conditions Causing Hypernatremia

##### Hypovolemic hypernatremia:

- Inadequate breast milk intake
- Diarrhea
- Radiant warmers
- Excessive sweating
- Renal dysplasia
- Osmotic diuresis

##### Euvolemic hypernatremia:

###### Decreased production of antidiuretic hormone:

- Central diabetes insipidus, head trauma, central nervous system tumors (craniopharyngioma), meningitis, or encephalitis

###### Decrease or absence of renal responsiveness:

- Nephrogenic diabetes insipidus, extreme immaturity, renal insult and medications such as amphotericin, hydantoin, aminoglycosides

##### Hypervolemic hypernatremia:

- Improperly mixed formula
- $\text{NaHCO}_3$  administration
- $\text{NaCl}$  administration
- Primary hyperaldosteronism

hypernatremia-induced hypertonicity, leading to a relative preservation of neuronal cell volume. The shrinkage of the brain stimulates the uptake of electrolytes such as sodium, potassium, and chloride (immediate effect) as well as the synthesis of osmoprotective amino acids and organic solutes (more delayed response). Osmoprotective amino acids include glutamate, glutamine, phosphocreatine and taurine; organic solutes, known as idiogenic osmols, include myo-inositol, glycerophosphoryl-choline, and betaine. The idiogenic osmols aid in maintaining normal brain-cell volume and protect intracellular proteins during longer periods of hyperosmolar stress (Trachtman, 1991). As long as hypernatremia develops rapidly (within hours), as in accidental sodium loading, a relatively rapid correction of the condition improves the prognosis without raising the risk of edema formation. This occurs because the accumulated electrolytes (sodium, potassium, and chloride) are rapidly extruded from the brain cells and effective idiogenic osmol synthesis has not yet taken place. In these cases, reducing serum sodium concentration by 1 mEq/L per hour (24 mEq/L per day) is appropriate (Adrogué and Madias, 2000).

However, because of the slow dissipation of idiogenic osmols over a period of several days (Adrogué and Madias, 2000), in cases of chronic hypernatremia, such as that in the breast-fed neonate with hypernatremic dehydration, the hypernatremia should be corrected more slowly, at a maximal rate of 0.5 mEq/L per hour (12 mEq/L per day). If correction is performed more rapidly in cases of chronic hypernatremia, the abrupt fall in the extracellular tonicity results in the movement of water into the brain cells, which have a relatively fixed hypertonicity because of the presence of the osmoprotective molecules. The result is the development of brain edema with deleterious consequences (Adrogué and Madias, 2000; Molteni, 1994).

In the *exclusively breast-fed neonate*, hypernatremia is usually due to high sodium levels in maternal breast milk as well as poor overall intake and dehydration. Reduction in breast-feeding frequency has been shown to be associated with a marked rise in the sodium concentration of breast milk (Neville et al, 1991). A vicious cycle can ensue in which the infant sucks poorly, breast milk production drops and sodium concentration rises, and the infant becomes increasingly dehydrated, hypernatremic, and lethargic. Hypernatremia associated with breast-feeding usually manifests at the end of the first to the third week after birth and may be delayed because these infants may appear quiet and content early on. The combination of inadequate fluid intake and hyperosmolarity can be devastating, with complications such as seizures, diffuse intravascular coagulation, and permanent neurologic and vascular injury.

In the *extremely immature neonate*, hypernatremia most commonly occurs from excessive transepidermal free water losses. The condition usually develops rapidly, within 24 to 48 hours after birth; it has become less common probably because of the more frequent use of antenatal steroids and humidified incubators. The diagnosis is based on the attendant decrease in body weight and clinical signs of extracellular volume contraction. Prevention of this condition by frequent monitoring of serum electrolyte levels, appropriate adjustments of free water intake, and the

use of humidified incubators has been successful in the majority of immature neonates.

In the *breast-fed term neonate*, hypernatremia most commonly develops because of dehydration due to inadequate breast milk intake (Molteni, 1994). Because this is a more chronic process, usually occurring over 7 to 14 days, signs of extracellular volume contraction are less prominent until the development of the full clinical presentation consisting of lethargy, irritability, abnormal muscle tone with or without seizures, and cardiovascular collapse with renal failure. This presentation can be associated with especially significant central nervous system morbidity from both the hypertonicity (sagittal or other venous sinus thrombosis, subdural capillary hemorrhage, white matter injury) and inappropriately rapid rehydration therapy (brain edema, myelinolysis).

The *central and nephrogenic forms of diabetes insipidus* are much less commonly encountered and result in hypernatremia due to the lack of production of and renal responsiveness to ADH, respectively. Because ADH is the primary neuroendocrine mechanism protecting against the rapid development of hypernatremia, central nervous system and renal immaturity make the sick preterm infant especially vulnerable to the rapid development of hypernatremia due to excessive free water losses. Finally, hypernatremia may also develop in response to excessive sodium supplementation, mainly in the sick neonate receiving repeated volume boluses for cardiovascular support. In these cases, clinical signs of edema, increased body weight, and the history of volume boluses help establish the diagnosis.

In the critically ill infant, the etiology of the serum sodium abnormality may be multifactorial, and the treatment less straightforward. However, thorough analysis of the medical history and the changes in clinical signs, laboratory findings, and body weight usually aid in determining the major etiologic factor and thus the treatment of the more complex cases of serum sodium abnormalities. Because sodium does not freely cross the cell membrane, serum sodium concentration is the major determinant of serum tonicity and, as mentioned previously, correction of its abnormalities should be carried out in a stepwise manner.

The following calculations may be used to govern the fluid and electrolyte replacement therapy in neonates with abnormal fluid and electrolyte status. Sodium deficit (or excess) may be calculated using the formula

$$\text{Na}^+ \text{ deficit (or excess)} = (0.75 \times \text{BW}) \times ([\text{Na}^+]_{\text{desired}} - [\text{Na}^+]_{\text{actual}}).$$

In this formula, sodium deficit (or excess) and body weight (BW) are expressed in mEq/L and kg, respectively, and  $(0.75 \times \text{BW})$  is the estimation of TBW.

Similarly, free water deficit (or excess) may be calculated as

$$\text{H}_2\text{O deficit (or excess)} = (0.75 \times \text{BW}) \times \frac{[\text{Na}^+]_{\text{desired}}}{[\text{Na}^+]_{\text{actual}} - 1}$$

In this formula,  $\text{H}_2\text{O}$  deficit (or excess) and body weight are given in L and kg, respectively, and  $(0.75 \times \text{BW})$  is the estimation of TBW.

Serum osmolality may be calculated by the formula

$$\text{serum osmolality} = 2[\text{Na}^+_{\text{plasma}}] + \frac{\text{BUN}}{2.8} + \frac{\text{blood glucose}}{18}$$

Serum osmolality,  $[\text{Na}^+_{\text{plasma}}]$ , BUN (blood urea nitrogen), and blood glucose should be expressed in mOsm/L, mEq/L, mg/dL, and mg/dL, respectively.

Total free water deficit is calculated as follows

$$\text{free water deficit} = 0.75 \times \text{BW} \times \frac{1 - (\text{current Na concentration})}{145}$$

In this formula, free water deficit, body weight (BW), and sodium concentrations are given in L, kg, and mEq/L, respectively. The amount of free water required to decrease serum sodium by 12 mEq/L over a 24-hour period if serum sodium is  $\geq 195$  mEq/L is calculated as

$$\begin{aligned} \text{free water required} &= \text{current weight (kg)} \times 3 \text{ mL/kg} \\ &\quad \times 12 \text{ mEq/L} \\ \text{or current weight (kg)} &\times 36 \text{ mL/kg/day} \end{aligned}$$

3 mL/kg is used here because it is approximately the amount of free water required to decrease serum sodium concentration by 1 mEq/L when the serum sodium concentration is 195 mEq/L (Molteni, 1994).

**Treatment Guidelines for Cases of Severe, Chronic Hyponatremia.** The patient with severe, chronic hyponatremia is usually an exclusively breast-fed neonate with inadequate milk supply. The amount of free water required to decrease serum sodium concentration by 1 mEq/L is 4 mL/kg under physiologic circumstances. However, as described previously, when the serum sodium concentration is 195 mEq/L,  $\leq 3$  mL/kg of free water is needed to achieve the same effect. Therefore, the maximum total amount of free water for *deficit replacement* over a 24-hour period should be around 36 mL/kg. *Maintenance fluid* calculations must take into consideration the usually significantly decreased urine output. Therefore, free water

maintenance fluid administration should be based only on calculated insensible losses (30 to 40 mL/kg/day), and urine output should initially be replaced volume for volume every 4 to 6 hours with a solution tailored to the urinary sodium and free water losses (usually 0.45% sodium chloride saline and 50 to 75 mEq of sodium bicarbonate per L). To calculate the replacement and maintenance free water requirements, one must also know the free water content of the intravenous fluids used (Table 30–3).

The major goals of fluid therapy in the treatment of severe and chronic hypernatremic dehydration are (1) establishment and maintenance of appropriate intravascular volume, (2) replacement of water and electrolyte deficits, (3) replacement of ongoing urine and stool water and electrolyte losses as well as insensible water losses, and (4) establishment of a rate of decline in serum sodium concentration that does not exceed 12 mEq/L/day. Boluses used for stabilization of the intravascular volume should be given through the use of intravenous fluids with a sodium concentration *either equal to the serum sodium concentration or at most 10 mEq/L less than that concentration*. This practice limits free water delivery and avoids sudden drops in serum sodium concentration and thus in tonicity. One should then calculate the amount of free water required to decrease the serum sodium concentration by 12 mEq/L during the first 24 hours (see preceding calculation), subtract the free water content (if any) of the initial fluid boluses, add the insensible losses and remaining free water deficit-replacement volumes, and provide the resulting volume as 0.2% saline in 5% or 10% dextrose in water. Finally, ongoing urine losses should be replaced volume for volume with the use of a solution adjusted to the urinary electrolyte losses.

Serum electrolyte, blood urea nitrogen, and serum creatinine values should be monitored every 2 to 4 hours until an appropriate rate of decline in serum sodium concentration has been established. At this point, the frequency of the laboratory measurements can be relaxed to every 4 to 6 hours (and later to 8 to 12 hours), until the serum sodium concentration is less than 145 mEq/L. This approach provides

**TABLE 30–3**

**Free Water Content as Volume % of Common Intravenous Solutions at Normal and High Serum Sodium Concentrations\***

Intravenous Fluid	Serum Sodium Concentration			
	145 mEq/L		195 mEq/L	
	Isotonic (%)	Water (%)	Isotonic (%)	Water (%)
D5W	0	100	0	100
0.2% saline	22	78	17	83
0.45% saline	50	50	39	61
0.9% saline	100	0	79	21
Lactated Ringer's solution	86	14	68	32

\*Note that isotonic saline provides 21% free water when given to a patient with a serum sodium concentration of 195 mEq/L and therefore will induce undesirable decreases in serum sodium concentration when used for volume resuscitation in the severely dehydrated hypernatremic neonate. See text for details.

Modified from Molteni KH: Initial management of hypernatremic dehydration in the breastfed infant. Clin Pediatr 33:731-740, 1994.

a reasonable chance to gradually decrease serum sodium concentration to the normal range over 5 to 7 days depending on the initial sodium values.

Once serum sodium concentration, urine output, and renal function are normal, the patient should receive standard maintenance fluids, either intravenously or orally, depending on his or her condition. At this time, electrolyte status must still be monitored for an additional 24 hours to ensure that complete recovery has occurred. Hyperglycemia and hypocalcemia commonly accompany hypernatremia. Treatment of hyperglycemia with insulin is not recommended because it may increase brain idiogenic osmol content. Hypocalcemia should be corrected with appropriate calcium supplementation.

Although magnetic resonance imaging of the brain before discharge provides information on potential insults associated with the condition and its treatment, long-term neurodevelopmental follow-up should be arranged for every neonate who has experienced severe hypernatremic dehydration.

### **Water Requirements**

To appropriately estimate the daily free water requirements of the sick neonate, all sources of water losses must be taken into account—the insensible, sensible, and surgical water losses. Free water losses occurring through the skin and the respiratory tract are considered insensible losses, whereas the sensible water losses are composed of the amounts lost through urine and feces.

### **Insensible Losses**

As described in the earlier discussion of the maturation of the skin, gestational age, postnatal age and environmental factors determine the amount of daily insensible water losses through the skin (see Fig. 30–4). During the first few postnatal days, transepidermal water losses may be 15 times higher in extremely premature infants born at 24 to 26 weeks of gestation than in term neonates (Sedin, 1995). Although the skin rapidly matures shortly after birth even in extremely immature infants, the insensible water losses in such patients are still somewhat higher at the end of the first months than those of their term counterparts.

Among the environmental factors, ambient humidity has the greatest impact on transepidermal water loss. In extremely immature neonates, a rise in the ambient humidity of the incubator from 20% to 80% decreases the transepidermal water loss by approximately 75% (Sedin, 1995). The difference in daily free water losses between 20% and 80% ambient humidity values is around 150 mL/kg. On the other hand, the use of an open radiant warmer more than doubles transepidermal water losses. However, if a plastic heat shield is applied while the infant is under the warmer, transepidermal water loss may be decreased by 30% to 50% (Costarino and Baumgart, 1991). At low ambient humidity, phototherapy increases transepidermal water losses by approximately 30%. However, in infants older than 28 weeks gestation, phototherapy does not increase the transepidermal water loss if the ambient humidity is
