in growth factor activity may account for rapid proliferation in some masses and later regression in others. In addition to an increased proliferative index, there also may be decreased apoptosis in these lesions (Cass et al, 1998).

### Prenatal Diagnosis

In prenatal diagnosis with the ultrasound scan, there may be confusion with bronchopulmonary sequestration, in which case color flow Doppler studies should be used to distinguish the systemic blood supply of the bronchopulmonary sequestration (Morin et al, 1994). The MRI scan is very useful for distinguishing cystic adenomatoid malformation of the lung from diaphragmatic hernia (Hubbard et al, 1999). Chromosome analysis and fetal echocardiography should be performed, and the fetus should be followed for increasing mass size, mediastinal shift, and signs of hydrops fetalis.

### Prenatal Management

Those fetal patients at 32 weeks or more should have betamethasone prophylaxis against respiratory distress syndrome if necessary and then delivery as soon as possible. Those fetal patients at less than 32 weeks should be considered for fetal surgery if there are signs of hydrops fetalis. In the case of large cysts, it is possible to perform fetal thoracentesis, perhaps on a repeated basis, to drain the fluid from the mass, allowing the remaining lung to develop normally (Obwegeser et al, 1993). In another approach, a catheter may be placed from the cystic mass to the amniotic cavity, to provide a more prolonged decompression of the mass (Bernaschek et al, 1994). Adzick and colleagues (1993) reported three cases managed by placement of a thoracoamniotic shunt; two infants survived, but they had pulmonary hypoplasia and needed high-frequency oscillatory ventilation and ECMO. Dommergues and colleagues (1997) advocated thoracoamniotic shunting for cases with hydrops fetalis or severe polyhydramnios and expectant management for the other fetuses without hydrops.

As an alternative to shunting, surgeons have performed lobectomy in fetuses with large cystic adenomatoid malformations, particularly microcystic lesions, producing mass effects with mediastinal shift, lung hypoplasia, vena caval compression, and hydrops fetalis. Harrison and coworkers (1990) reported one fetus with early hydrops successfully operated on at 23 weeks of gestation. Adzick and colleagues (1993) reported a series of six cases with microcystic disease and hydrops; the first fetus died of premature delivery and pulmonary hypoplasia soon after operation, four fetuses survived with resolution of hydrops and good lung development, and the last was a fetal death occurring for unknown reasons in the postoperative phase. There are no established criteria for use of the radical lobectomy operation versus the more conservative thoracoamniotic shunt procedure.

Various authors have claimed that many cases improve spontaneously during the last trimester (Bagolan et al, 1999; Revillon et al, 1993; Roggin et al, 2000); however, in a large series the chance of this occurring was considered by the authors to be low (MacGillivray et al, 1993). Hydrops fetalis, the usual indication for surgery, is not known to

resolve spontaneously and always signifies a poor outcome without surgery (Miller et al, 1996); however, if the lesion decreases in size with time, the outcome is usually good. Winters and colleagues (1997) reported a series of seven cases in which there was improvement or disappearance of the fetal lesion with time; on the postnatal radiograph, there were normal findings in one, subtle findings in four, and clearly abnormal findings in only two cases. Findings on the chest CT scan were abnormal in all seven infants, mostly air-filled cysts. It would appear that regression of these lesions is an important factor that must be considered in determinations about prenatal surgery, especially in the absence of hydrops fetalis.

### Postnatal Management

Prenatal diagnosis may also allow plans to be made for resection of the tumor immediately after delivery (Adzick et al, 1985). If severe gas trapping is present, selective bronchial intubation and either needle or tube thoracotomy may give temporary relief, but the treatment of choice is lobectomy as soon as possible after delivery (Morin et al, 1994). In infants subjected to early lobectomy, pulmonary hypertension secondary to lung hypoplasia has been successfully managed with the use of ECMO (Njinimbam et al, 1999; Rescoria et al, 1990). Lobectomy is recommended for all lesions, even when there are no signs of illness.

### Bronchopulmonary Sequestration

More than 300 cases of bronchopulmonary sequestration (BPS) have been reported in the literature; these were reviewed by Carter in 1969 and by Landing in 1979. BPS has only rarely produced symptoms in newborn infants and usually has been detected on chest radiographs taken for other reasons; more commonly, a sequestered lobe manifests itself in children or young adults by repeated infections in a fluid-filled lung cyst. The lesion should be suspected in infants with cystic lesions, especially in the lower lobes. The malformation is slightly more common in males and is distinctly more likely on the left side; approximately two thirds of the cases involve the left lower lobe.

*Sequestration* is characterized by the presence of non-functioning lung tissue that does not communicate with the tracheobronchial tree and that derives its blood supply from the aorta. A single large anomalous vessel may be present, but sometimes multiple small anomalous arteries from above or below the diaphragm supply the sequestered lobe. The venous drainage may be pulmonary or systemic. In the latter case, drainage may be into the inferior vena cava, the azygous vein, or the portal vein; in the case of pulmonary venous return, there may be a large left-to-right shunt and possible congestive heart failure. In greater than 80% of the cases, a communication with the foregut can be demonstrated by contrast studies (Heithoff et al, 1976); the usual location is the lower esophagus or gastric fundus. The affected lung is highly abnormal, consisting of atelectatic areas interspersed with fluid-filled cysts. The incidence of associated malformations (e.g., diaphragmatic hernia, congenital heart disease, eventration of the diaphragm, duplication cysts, vertebral or rib anomalies) is increased.

Bronchopulmonary sequestration is thought to be caused by an accessory lung bud originating lower down in the primitive foregut. The lesion may be associated with abnormal expression of the homeobox gene product Hoxb-5, which is necessary for normal airway branching (Volpe et al, 2000). If the bud originates early, the normal and sequestered lungs have a common pleural covering, in which case the sequestration is considered to be intralobar; whereas if the supernumerary bud originates later, the sequestered lung has its own pleura and is considered to be extralobar; in some cases, an extralobar sequestration may be subdiaphragmatic in location. About 75% of cases are intralobar sequestrations, but in cases presenting in the newborn period, extralobar sequestrations are far more common. If the sequestered lobe is found to obtain its blood supply from the pulmonary system, rather than from the systemic system, it may be called an accessory lung lobe. Other malformations occur in 60% of extralobar sequestrations and in 10% of intralobar sequestrations.

### Prenatal Diagnosis

The diagnosis of BPS may be made in the fetus, but in some cases solid chest masses have been known to resolve by the time of delivery (MacGillivray et al, 1993). A sequestration is a solid, highly echogenic chest mass, seen on the fetal ultrasound scan, and the systemic blood supply may be demonstrated by color-coded Doppler ultrasonography (Dolkart et al, 1992). The MRI scan is superior for confirming the diagnosis. In some cases, the lesions have been associated with mediastinal shift, polyhydramnios, and hydrops fetalis, in which case the prognosis is poor and stillbirth or early neonatal death is common. Unilateral or bilateral pleural effusions may be present; the pathomechanism is thought to be torsion of the lesion around a pedicle with obstruction of the venous or lymphatic drainage, leading to pleural effusion. According to Lopoo and colleagues (1999), the only reason for hydrops fetalis in BPS is the presence of a tension hydrothorax.

### Postnatal Diagnosis

Most infants with BPS are not symptomatic in the neonatal period, but if the sequestration is sufficiently large, there may be persistent cyanosis and respiratory distress (Pearl, 1972), with or without lung hypoplasia. Some cases may manifest with a large unilateral hydrothorax, possibly secondary to lymphatic obstruction in the sequestration (Boyer et al, 1996; Hernanz-Schulman et al, 1991). Brus and colleagues (1993) described an infant with nonimmune hydrops fetalis, bilateral hydrothoraces, and severe pulmonary hypoplasia secondary to an extralobar pulmonary sequestration. Chan and associates (1996) reported a case in which a fetus with a pleural effusion was treated with a pleuroamniotic shunt; this infant did well after excision of the sequestration. Evans (1996) reported on three infants who did well after hydrops fetalis, mechanical ventilation, and surgical excision. Infants with a large left-to-right shunt through the sequestration may present with congestive heart failure in the newborn period, especially if born prematurely so that the pulmonary vascular resistance is low (Kolls et al, 1992; Spinella et al, 1998). Later in infancy, frequent bouts of pneumonia may occur. On the chest

radiograph, the classic appearance consists of a triangular or oval-shaped basal lung mass on one side of the chest, usually the left side. Ultrasound examination confirms the presence of a thoracic mass (Schlesinger et al, 1994); the chest CT scan also is helpful (Boyer et al, 1996). The definitive diagnosis is made with angiography, which delineates the feeding vessels to the sequestration; the usual study is contrast aortography (Kravitz, 1994), but other less invasive techniques, such as magnetic resonance angiography (Doyle, 1992) and color-coded Doppler ultrasonography (Eisenberg et al, 1992; Smart and Hendry, 1991), have been used successfully. The barium swallow examination frequently demonstrates contrast material entering the sequestered lung from a communication originating in the foregut, either the esophagus or the gastric fundus.

### Management

If a large hydrothorax is discovered before birth, this may be drained by insertion of a thoracoamniotic shunt to allow further lung development (Hernanz-Schulman et al, 1991). Depending on the degree of associated lung hypoplasia, the newborn infant may need no mechanical ventilation, only conventional ventilation, or high-frequency oscillatory ventilation and ECMO (Morin et al, 1994). Large pleural effusions present at birth should be treated with immediate tube thoracostomy drainage.

Further treatment consists of surgical resection of the involved lobe in all cases; resection is indicated even if there are no signs of respiratory distress, because repeated lung infections in the future are the rule. Resection of an extralobar lesion in the newborn infant causes no loss of functional lung tissue, unlike in the case of intralobar lesions in older infants who need a lobectomy. A preoperative angiographic study is helpful to alert the surgeon to the position of the anomalous vessels from the aorta and to the position of the venous drainage system. The arterial vessels may bleed postoperatively if not found and ligated, and the venous drainage may represent the sole venous drainage of the ipsilateral lung. There may be problems with management of pulmonary hypertension in the postoperative period.

If the lesion disappears before birth, the residual lesion should be sought with chest CT scans or chest MRI scans (Blau et al, 2002); if found, these lesions should be resected because of the risks for infection, hemorrhage, and malignant transformation. Although lung resection is recommended, resection of an intralobar sequestration may make the management of pulmonary hypoplasia more difficult; fortunately, most newborns have extralobar masses.

### Congenital Lobar Emphysema

Congenital lobar emphysema describes a pathologic condition characterized by respiratory distress caused by overinflation of one lobe of the lung, usually the left upper, right upper, or right middle lobe. There is no emphysematous destruction of lung tissue, as the name might imply. The onset may be at any time in the first 6 months of life, but 50% of cases manifest in the newborn period. The respiratory distress may be severe, but in many cases it is mild, without cyanosis in room air. The chest radi-

ograph shows overdistention of one lobe, compression of the adjacent lung, herniation across the mediastinum, and diaphragmatic depression. The chest CT scan shows decreased vessels due to compression in the involved lung and increased vessels due to overperfusion on the opposite side. About 15% of the cases are associated with congenital heart disease, usually patent ductus arteriosus or ventricular septal defect, and other cases may be associated with rib anomalies and cystic renal lesions (Kravitz, 1994). Before this diagnosis is made, a mucous plug obstruction should be excluded by vigorous physical therapy or suction applied at rigid bronchoscopy in the operating room.

Some authors contend that most cases are caused by local bronchial cartilage deficiency, with airway collapse and gas trapping with exhalation (Campbell, 1969). Other causes have been suggested (e.g., redundant bronchial mucosal fold, stenosis of the bronchial wall, external compression by an anomalous pulmonary artery or a mediastinal mass). It is possible for a lobe to be rotated on its pedicle, with resultant obstruction (Hislop and Reid, 1971).

Sometimes the condition represents a polyalveolar lobe, in which, despite a normal number of airways, there is a fivefold increase in the number of alveoli in each acinus (Hislop and Reid, 1970). Infants with this condition tend to have prolonged retention of fetal lung liquid in the affected lobe after birth and to have early signs of respiratory distress on the first day of life (Cleveland and Weber, 1993).

Most cases can be evaluated with the chest radiograph, especially if films are taken on both inspiration and expiration. The chest CT scan is useful for defining a mediastinal mass or a vascular ring and in the evaluation of possible bronchial stenosis (Stigers et al, 1992). The ventilation-perfusion study is useful in assessing lung function, which may be surprisingly good in many cases. Some cases have been detected by increased echogenicity on the fetal ultrasound scan; continued observation suggests that the abnormalities tend to diminish with time; but postnatal assessment has confirmed the presence of congenital lobar emphysema (Olutoye et al, 2000).

In infants with congenital lobar emphysema and severe respiratory distress, the treatment is surgical lobectomy, the results of which have been excellent. In infants with mild tachypnea and no significant oxygen requirement, the treatment may be expectant (Shannon et al, 1977). The mild symptoms frequently subside by the age of 1 year. Stigers and coworkers (1992) managed five of their eight cases without surgery. Whether treated medically or surgically, at age 10 most such children have evidence of mild airway obstruction, suggesting a more generalized abnormality of the airways (McBride et al, 1980).

### Unilateral Pulmonary Agenesis

Unilateral pulmonary agenesis may be a unilateral lung agenesis without main bronchus development on one side, and therefore without a carina, or it may be a unilateral lung aplasia, with a carina and a rudimentary main bronchial pouch as evidence of arrested bronchial development. Left-

sided lung agenesis is slightly more common and sometimes is associated with severe congenital heart disease, such as tetralogy of Fallot; however, cases have been described in asymptomatic adults. Right-sided lung agenesis may cause more problems from mediastinal shift, with obstruction of major vessels and airways, and is more frequently associated with congenital heart disease, such as obstructed anomalous pulmonary venous drainage (Finci et al, 1999), ventricular septal defect, and coarctation of the aorta. The contralateral lung may be enlarged and hypertrophied, it may be overdistended and overperfused with congestion, and it may herniate into the opposite hemithorax, usually through the anterior mediastinum. Thus, there may be no obvious evidence for asymmetry of the chest in the newborn, and asymmetry may develop only with further growth during later infancy. For this reason, breath sounds may be heard on the involved side, but not posteriorly.

Some patients with this condition may die in the delivery room. Others may have severe respiratory distress that does not respond to mechanical ventilation; the appearance may be that of total main bronchus obstruction from a mucous or meconium plug, which may lead to consideration for ECMO. Some patients may have only modest and transient respiratory distress at birth, or signs of illness may be absent in the newborn. The clinical presentation may be that of congenital heart disease, frequently with cyanosis. Signs of pulmonary hypertension may be present because the entire cardiac output must traverse only one lung; this may be the case especially if the ductus arteriosus closes early. In lung agenesis, the ipsilateral pulmonary artery is absent, so cyanosis cannot be attributed to perfusion of airless lung mesenchyme. There may be other anomalies, such as esophageal atresia and polycystic kidneys, and hemivertebrae are particularly common.

The chest radiograph shows homogeneous density in place of the lung in one hemithorax, the ribs may appear closer together on the involved side, and there is mediastinal shift with tracheal deviation. A chest CT scan may be necessary to confirm the absence of lung tissue on one side (Kravitz, 1994). Bronchoscopy shows the absence of the ipsilateral main bronchus, which may be confirmed by bronchography. The echocardiogram demonstrates the absence of the ipsilateral pulmonary artery, the contralateral pulmonary artery appears dilated, and there may be other signs associated with congenital heart disease. If there is confusion with dextrocardia, as in right lung agenesis, an electrocardiogram may be useful.

If affected infants survive beyond the neonatal period, recurrent pneumonia and reactive airways disease may develop, but the pathomechanism is not clear. One suggestion is that in the case of lung aplasia, the remnant bronchial pouch allows the accumulation of stagnant secretions and therefore predisposes to infection in the normal lung (Borja et al, 1970).

### **Pulmonary Hypoplasia**

Pulmonary hypoplasia is a pathologic condition in which the combined lung weight is less than 1.2% of body weight, the standardized autopsy lung volume is less than

60% of predicted lung volume, the lung DNA is less than 100 mg/kg of body weight, or the radial alveolar count is less than 4 (Langston and Thurlbeck, 1986). The incidence at autopsy is approximately 10% of newborns, and the overall incidence is thought to be approximately 2 per 1000 live births (Knox and Barson, 1986).

Infants with pulmonary hypoplasia present usually with respiratory distress and cyanosis in room air. On the chest radiograph, the lungs appear small, and they are clear unless another condition such as pneumonia is superimposed; the hemidiaphragms are elevated, and the thorax may appear bell-shaped. These infants have significant hypercarbia, which responds poorly to mechanical ventilation, and the risk of pneumothorax is high. They often have persistent pulmonary hypertension, as a result of a reduced vascular bed and secondary arterial muscle hypertrophy (Hislop et al, 1979). Conventional therapy may fail in these infants, who then become candidates for ECMO, in which case it will be necessary to make a clinical judgment concerning the permanent size of the lungs. In addition, the hypoplastic lung also may have an immature surfactant profile, so a significant number of infants also have respiratory distress syndrome (Nakamura et al, 1988; Wigglesworth et al, 1981), and require surfactant replacement therapy.

Normal lung growth depends on lung distention with stretch (Wigglesworth and Desai, 1982), which in turn depends on (1) lung expansion caused by lung liquid secretion and fetal breathing and (2) available space within the thorax. The fetal lung actively secretes lung liquid at a rate equivalent to about 10% of body weight per day (Kitterman, 1996). Escape of liquid from the lungs is resisted at the larynx. The resultant distending pressure maintains the fetal lung volume at levels very similar to those after birth. Experiments in which lung liquid is drained from the fetal lung showed that this causes severe lung hypoplasia (Alcorn et al, 1977). If fetal breathing is abolished by cervical spinal cord section above the phrenic nerve, the position of the diaphragm and therefore the lung volume are not changed; such experiments have shown the development of severe lung hypoplasia and indicate that fetal breathing also is necessary for lung development (Wigglesworth and Desai, 1979).

Conditions causing oligohydramnios and fetal thoracic compression are associated with pulmonary hypoplasia, due to increased loss of lung fluid into the amniotic cavity and reduced fetal lung volume. It is possible that in oligohydramnios the amniotic fluid pressure is low, so that when the larynx is opened periodically, excess lung fluid is expelled and fetal lung volume is reduced (Kitterman, 1984). It is also likely that increased anterior spinal flexion produced by oligohydramnios may elevate the fetal diaphragm, with resultant application of pressure to the lungs and consequent reduction in thoracic volume (Harding and Liggins, 1991). Clinical conditions associated with oligohydramnios include renal agenesis, renal dysplasia, obstructive uropathy (Thomas and Smith, 1974), and chronic amnion rupture (Thibeault et al, 1985).

Increased lung compression may be due to lesions within the thorax or outside the thorax; such problems include congenital diaphragmatic hernia, cystic lung disease,

eventration of the diaphragm, ascites, and pleural effusion, all of which may cause reduced fetal lung volume and thus pulmonary hypoplasia. Patients with a giant omphalocele may have pulmonary hypoplasia because the lower chest cage is not adequately supported by abdominal contents and thoracic volume is reduced (Hershenson et al, 1985).

Effective fetal breathing may be impaired by brainstem malformations such as iniencephaly, by neuromuscular problems such as spinal muscular atrophy or congenital myotonic dystrophy, by skeletal chest cage insufficiency as in congenital thoracic dystrophy or short rib–polydactyly syndrome; these conditions would also result in reduced fetal lung volume and lung hypoplasia. In the fetal akinesia sequence there may be nemaline myopathy, multiple joint contractures, and pulmonary hypoplasia. Finally, in a significant number of infants, no cause for primary pulmonary hypoplasia can be found (Swischuk et al, 1979), although suppression of fetal breathing caused by maternal use of tobacco, barbiturates, or ethanol may be implicated (Collins et al, 1985; Inselman et al, 1985).

In many cases of lung hypoplasia, the number of bronchial generations is reduced, suggesting an insult occurring between 10 and 14 weeks of gestation during the glandular phase of lung development; this is a finding in diaphragmatic hernia or renal dysplasia. Although the total number of acini is reduced, along with the number of bronchi, the number of alveoli per acinus is relatively well preserved in these cases (Hislop et al, 1979). There may be a maturation arrest, especially in cases associated with oligohydramnios, with a wide blood-gas septal interface, immature epithelial cells, a lack of elastic tissue, and low surfactant phospholipid concentrations (Porter, 1999).

### **Lung Hypoplasia Associated with Chronic Amnion Rupture**

In chronic amnion rupture, Nimrod and colleagues (1984) concluded that serious lung hypoplasia was unlikely to occur if the membranes ruptured after 26 weeks of gestation, apparently because a sufficient number of acinar units with respiratory bronchioles and saccules may have developed by then. This is in agreement with the data of Moessinger and associates (1986), who found in a guinea pig model that hypoplasia was most likely if amnion rupture occurred in the canalicular (acinar) stage of lung development and was not significant if amnion rupture occurred in the saccular stage of lung development, with primitive alveoli (subsacculles) already present. McIntosh and Harrison (1994) found that the minimal duration of rupture for the development of lung hypoplasia was 2 weeks for survivors and 3 weeks for those who died. In addition, the median length of rupture for infants with compression deformities of the face and limbs was 28 days, and for those with pulmonary hypoplasia it was 31 days, indicating the close relationship of pulmonary hypoplasia with the fetal compression syndrome. In patients with membrane rupture before 25 weeks of gestation and with oligohydramnios lasting 14 days or more, the risk of death is more than 75% (Geary and Whitsett, 2002).

Although fetal breathing movements may disappear in oligohydramnios, thoracic compression and loss of lung liquid are the main causes of lung hypoplasia in chronic amnion rupture (Adzick et al, 1984). Blott and associates (1987), however, found that the presence of sustained fetal breathing movements may protect against the development of pulmonary hypoplasia.

In many cases of chronic amnion rupture, the onset is quite late, so the major effects are on elements that develop later, and the resultant lung hypoplasia is therefore less severe. The bronchial number is normal, the acinar number may be near normal, and only the number of alveoli per acinus is reduced, because the amnion rupture occurred during the saccular phase of lung development with primitive alveoli (subsacculles) already present.

In the Netherlands, Laudy and colleagues (2002) have assessed the obstetric prediction of lethal pulmonary hypoplasia before delivery; they were especially interested in cases in which the gestational age was less than 24 weeks, so that pregnancy termination might be an option for the mother. They found that amnion rupture before 20 weeks of gestation, associated with amniotic pockets less than 1 cm and presence of rupture for more than 8 weeks before delivery, was associated reliably with lethal lung hypoplasia, but this was not a common clinical finding. A reduced ratio of thoracic to abdominal circumference was helpful, as was a reduced Doppler flow velocity in the pulmonary artery, but neither of these alone or in combination could reliably predict lethal pulmonary hypoplasia.

The possibilities for treatment of lung hypoplasia are limited; the clinician can only manage the associated complications. A major objective of fetal surgery is the relief of fetal lung compression, such as that caused by diaphragmatic hernia, pleural effusion, lung cysts, and other problems. As these infants may have congenital pneumonia or respiratory distress syndrome, they usually are treated with antibiotics and surfactant replacement. They also may have persistent pulmonary hypertension and respond to inhaled nitric oxide therapy (Geary and Whitsett, 2002; Peliowski et al, 1995). Mechanical ventilation should be designed to avoid lung rupture and its complications. When all else fails, lobar lung transplantation for severe pulmonary hypoplasia may become possible in the future.

Kitterman (1993) has warned that many infants with severe respiratory distress syndrome, and born in clinical circumstances suggestive of pulmonary hypoplasia, in fact do not have any pulmonary hypoplasia and make a good recovery; he suggests that clinicians be skeptical of this diagnosis in infants who survive. McIntosh (1988) described three infants with prolonged amnion rupture, small lungs, and compression deformities who required high pressures with mechanical ventilation on the first day of life, but who markedly improved on the second day of life and recovered in room air.

### **Pulmonary Hemangiomas**

Pulmonary hemangiomas is a proliferation of small blood vessels that may be peribronchovascular, septal, or pleural in location. If the lesions also involve the airways, hemoptysis may occur.

### Natural History

Pulmonary hemangiomatosis may be a part of a disseminated hemangiomatosis that can involve the liver, gastrointestinal tract, central nervous system, and skin. Cutaneous lesions may be present at birth or develop within the first few weeks of life. In some instances, the hemangiomas may be confined to the lung and remain asymptomatic until childhood. Because the flow through the hemangiomas in the lung is right to left, venous admixture is significant, with associated clubbing of all digits. In some instances, clubbing may take place even in the absence of arterial desaturation. The major symptom is dyspnea, which is progressive. The most likely cause of death is bleeding or, in adults, pulmonary hypertension.

### Diagnosis

The diagnosis is suggested by appearance on the chest radiograph, which may resemble that of an interstitial infiltrate or thickened fissures. Pulmonary angiography and MRI are useful in diagnosis.

### Treatment

In at least one instance, a 12-year-old boy had a good response to treatment with interferon alfa-2a administered subcutaneously. He received daily interferon therapy for 14 months, during which his dyspnea remitted, his digital clubbing resolved, and results on pulmonary function tests were restored to normal. Abnormal vessels were still evident in the angiogram, but their density had been substantially reduced (White, 1990). This therapy seems to be less toxic than long-term corticosteroid and cyclophosphamide regimens, which have been used in the past.

### Prognosis

Experience with interferon is too recent to determine whether all visceral hemangiomas respond.

### Pulmonary Arteriovenous Malformations

A rare lesion, pulmonary arteriovenous fistula or angioma is characterized by persistent cyanosis in the newborn, but unless the fistula is large and compresses the surrounding lung, it does not cause respiratory distress (Hodgson et al, 1959). Lesions may be single or multiple and aneurysmal or microscopic in size. About 50% of the cases are associated with hereditary hemorrhagic telangiectasia (Rendu-Osler-Weber syndrome). The chest radiograph most commonly shows a small mass lesion, usually in the lower lobes; the electrocardiogram may suggest unusual left ventricular dominance. The diagnosis can be made at cardiac catheterization, in which a selective cine angiogram of the pulmonary artery shows the lesion in the lung (Mitchell and Austin, 1993). Alternatively, the diagnosis may be made with a radionuclide perfusion study or digital subtraction angiography. The best treatment is conservative surgical excision, with lobectomy or segmentectomy as necessary. For large lesions, embolotherapy may be useful. Multiple hemangiomas may respond to glucocorticoid therapy or newer inhibitors of angiogenesis. Mortality and morbidity rates in untreated cases are considerable

(Dines et al, 1983). Most cases are diagnosed in adults; less than 10% are diagnosed in infancy.

## Disorders of the Chest Wall, Pleural Cavity, and Diaphragm

Thomas N. Hansen, Anthony Corbet, and Roberta A. Ballard

### DISORDERS OF THE CHEST WALL

Abnormalities of the bone and muscle of the chest wall may be a mechanical hindrance to ventilation.

#### Skeletal Disorders

Although abnormalities involving bone are rare, they may be recognized immediately and are sometimes amenable to operative correction.

#### Defects of Sternal Fusion

Defects in fusion of the sternum are uncommon. Complete separation of the two halves of the sternum allows protrusion of cardiovascular structures, a condition known as *ectopia cordis* (Maier and Bortone, 1949). Lethal malformations of the heart are commonly associated with this condition. Upper sternal clefts are more common. Early operation is advised to shield the underlying structures from injury, and because of the greater ease of approximating the separated parts in the first days of life compared with later (Sabiston, 1958). A lower sternal cleft and *ectopia cordis* with a congenital heart defect may be associated with congenital apertures in the upper abdominal wall, in the pericardium, and in the anterior diaphragm, with a Morgagni-type diaphragmatic hernia, the so-called pentalogy of Cantrell (Cantrell et al, 1958).

#### Pectus Excavatum

The most common of the sternal defects is pectus excavatum, sometimes associated with Pierre Robin syndrome or Marfan syndrome. Rarely is it a fixed or severe deformity until several months of postnatal age. A family history of some type of anterior thoracic deformity was found in 37% of patients, according to Welch (1980). The heart may be compressed between the sternum and the vertebral column and displaced to the left, impinging on the space of the left lung. There is usually no respiratory or cardiac distress. Only later in childhood may there be cosmetic and psychological distress sufficient to warrant intervention. The indications

for operative correction are debatable. In our opinion, correction should not be undertaken until the child is several years of age and then only in those few children in whom the deformity appears to be progressing. Serial photographs are the best way to document changes in pectus excavatum. Periodic evaluation of cardiovascular status with ultrasonography and electrocardiography and assessment of pulmonary function are appropriate in the presence of progressive deformity. Results of operative correction are excellent in more than 80% of patients; surgery is almost always associated with functional improvement. Recurrences are possible during later active growth.

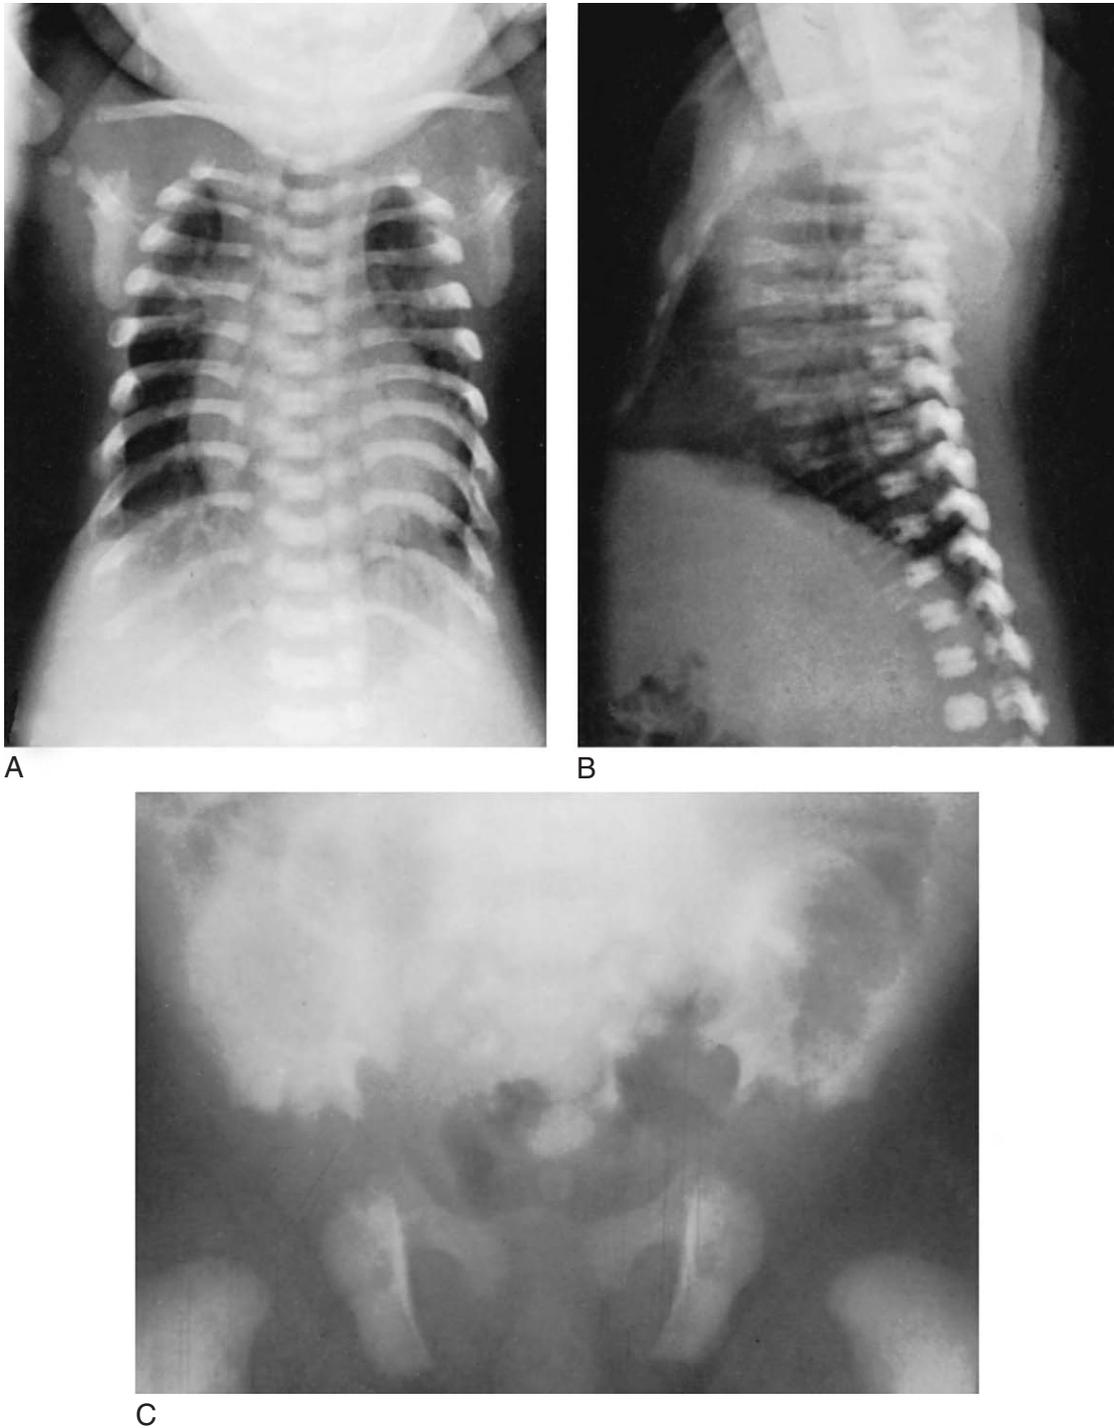

#### Poland Syndrome

Deficiency of pectoral muscles on one side, so-called Poland syndrome, may be associated with a deficiency of the second through the fifth ribs on the same side—the ribs of attachment for the pectoralis major muscle. There may be associated syndactyly, hemivertebrae and scoliosis, and later hypoplasia of breast development. Breathing may be paradoxical and the cardiac impulse easily observed through the soft tissues, but there usually is no distress. Later in childhood, and uncommonly, there may be increasing respiratory distress with scoliosis lung disease and heart failure. No operative intervention is required in infancy, although mammaplasty may be desirable later on in affected girls after puberty.

#### Thoracic Dystrophies

##### *Asphyxiating Thoracic Dystrophy*

A rare deformity of the thoracic cage, asphyxiating thoracic dystrophy is part of a serious generalized chondrodystrophy, with short-limbed dwarfism and often polydactyly (Fig. 51-1). It was first described by Jeune and coworkers (1954). The ribs are horizontal, hypoplastic, and short, with flared costochondral junctions. The thorax is small, bell-shaped, and rigid; this results in displacement of the liver and spleen well into the abdominal cavity. Some degree of lung hypoplasia may be present, often severe and lethal. The pelvis shows flaring of the iliac wings and acetabular abnormalities (Kohler et al, 1970). Prenatal diagnosis with ultrasonography is possible. Renal cystic dysplasia may be present, resulting in hypertension and renal failure. In the past, most patients with this condition did not survive the first month. Oberkaid and coworkers (1977) studied 10 cases and noted that only two patients were alive at the time of the report. One of the two was in excellent health at 15 years of age. The more severely affected infants had respiratory distress from birth. Three patients have been described in one family; as it is an autosomal recessive trait, the expectation would be for an occurrence in one of four siblings, so mutations must be common. No parent-child occurrence has been described. Recently, Davis and coworkers (2001) reported an operative technique for lateral thoracic expansion in 10 patients with chest wall deformities limiting thoracic capacity—including 8 patients

**FIGURE 51-1.** Radiographs from an infant with asphyxiating thoracic dystrophy. **A** and **B**, On anteroposterior and lateral views of the chest, the thoracic dimension is seen to be reduced in comparison with the abdominal dimension. **C**, Radiograph of the pelvis shows flaring of the iliac crests and bony protrusions of the acetabulae. with classic Jeune syndrome. Three were younger than 1 year of age at the time of surgery, and 6 were ventilator dependent. All of the infants older than 1 year of age at the time of surgery improved, with measured lung volumes increasing in 2 of 3 studied, and thoracic volumes

by computed tomography increasing in 4 of 5 studied. The only deaths were in 2 infants younger than 1 year of age at the time of surgery. These results suggest that lateral thoracic expansion is a safe and effective procedure for patients beyond the first year of age.

### **Other Thoracic Dystrophies**

Severe underdevelopment of the thoracic rib cage, accompanied usually by lethal pulmonary hypoplasia, may be seen in other conditions, such as the thanatophoric dwarfism syndrome, the short rib–polydactyly syndrome, and the camptomelic dwarfism syndrome. Affected infants do not survive for long after birth.

### **Neuromuscular Disorders**

Other causes of thoracic dysfunction are diseases of the nerves and muscles, including congenital myasthenia gravis, congenital spinal muscular atrophy (Werdnig-Hoffmann disease), congenital myotonic dystrophy, glycogen storage disease, and congenital spinal injury. Such conditions are usually recognized in the context of the associated systemic muscular weakness. Newborns with myasthenia gravis have episodes of muscle weakness, poor feeding, weak cry, hypoventilation, and apnea with a positive response to an anticholinesterase medication. In congenital spinal muscular atrophy, there is lung hypoplasia associated with absent fetal breathing, and as a result the thorax is small. Other features include severe hypotonia, muscle fasciculation, respiratory failure, and early death; the inheritance is autosomal recessive. In congenital myotonic dystrophy, there is lung hypoplasia from absent fetal breathing; affected infants have respiratory distress at birth, rapidly need mechanical ventilation, and are soon ventilator dependent. Mothers of these infants have myotonia, difficulty in relaxing muscle contractions; the inheritance is autosomal dominant.

## **DISORDERS OF THE PLEURAL CAVITY**

The pleural space exists between the parietal pleura of the chest wall and the visceral pleura of the lung. Each pleural surface is composed of a mesothelial layer that covers a layer of connective tissue containing lymphatics, blood vessels, and nerves. In the parietal pleura, lymphatic channels communicate with the pleural space to provide a direct pathway for fluid and protein reabsorption. It was initially believed that the blood supply to the parietal pleura emanated from the systemic circulation and that the blood supply to the visceral pleura emanated from the pulmonary circulation. The capillary hydrostatic pressure in the visceral pleura was believed to be correspondingly low, leading to the assumption that fluid was filtered out of the parietal pleura and reabsorbed by the visceral pleura. Data now show, however, that the blood supply to the visceral pleura emanates from the bronchial circulation. Both pleural surfaces filter fluid into the pleural space, and the lymphatics are responsible for most of the fluid reabsorption (Wiener-Kronish et al, 1985).

### **Pathomechanisms of Pleural Effusion**

Fluid accumulates in the pleural space only if the rate of filtration increases or if the rate of lymphatic clearance decreases or if both of these processes occur.

### **Increased Fluid Filtration**

The rate of fluid filtration can be increased by increasing the filtration pressure. The parietal pleura is drained by the systemic veins, and the visceral pleura is drained by the pulmonary veins. Therefore, filtration pressure is increased with increases in either systemic or pulmonary venous pressure (Mellins et al, 1970). Raised venous pressure is the most likely cause for pleural effusions that complicate heart failure, as well as for the effusions that occur with hydrops fetalis. It is not believed that hypoproteinemia plays a primary role in the accumulation of fluid (Moise et al, 1991), because low protein would be reflected in both the vascular and the interstitial spaces, with little change in the transvascular oncotic pressure. The rate of fluid filtration into the pleural space also is increased if the permeability of the pleura to water and protein is increased, as in the case of infections.

### **Decreased Fluid Clearance**

The rate of fluid clearance from the pleural space may be decreased by any impairment of lymphatic function caused by direct mechanical obstruction (Mellins et al, 1970). As the main lymphatic channels drain into the systemic venous system, elevated systemic venous pressure will also impair lymphatic clearance. The main thoracic duct on the left side drains into the angle of junction of the left subclavian and internal jugular veins; the right lymphatic duct drains into the angle of junction of the right subclavian and internal jugular veins. Small valves prevent the reflux of venous blood into the lymphatic ducts.

### **Diagnosis of Effusion**

Pleural effusions should be suspected in any infant with respiratory difficulty who is hydropic or who has been receiving intravenous nutrition. Infants who receive central venous alimentation should have the glucose content of the pleural fluid checked immediately to make sure that the catheter has not perforated into the pleural space. Differential breath sounds are valuable in localizing unilateral effusions. The chest radiograph is diagnostic (Fig. 51–2). Thoracentesis is useful to identify effusions secondary to infections and to distinguish chylothorax from other causes of pleural effusions.

### **Congenital Chylothorax**

Accumulations of chyle in the pleural space may be congenital or acquired. Congenital chylothorax occurs more commonly in males than in females (2:1), and it occurs more commonly on the right side. Chernick and Reed (1970) said that 53% of the cases were on the right side, 35% on the left side, and 12% were bilateral. In some classifications this condition may be called primary hydrothorax.

Congenital chylothorax is probably one part of the spectrum of anomalies that results from intrauterine obstruction of the thoracic duct (Chervenak et al, 1983; Smeltzer et al, 1986). It may occur alone or in combination with other lymphatic anomalies as part of the jugular lymphatic obstruction

**FIGURE 51-2.** Chest radiograph from an infant with a right-sided chylothorax.

sequence. Infants may have cystic hygroma malformations or severe webbing of the neck, the residue of a fetal cystic hygroma that has resolved. Presumably, lymph flow obstruction results in the development of fistulas between the thoracic duct and the pleural space or in rupture of the thoracic duct. Dutheil et al (1998) described an infant with generalized lymphangiomatosis with skin lymphangiomas and congenital chylothorax. Njolstad and colleagues (1998) described several siblings with congenital pulmonary lymphangiectasia and nonimmune hydrops with congenital distal lymphedema. Chylothorax has been described as a complication of Down syndrome, in which there is presumably a significant maldevelopment of the lymphatic system (Yamamoto et al, 1996). Other patients may have Turner or Noonan syndrome.

Congenital chylothorax frequently is diagnosed in utero by ultrasonography (Devine and Malone, 2000). If the problem occurs early and is severe enough, the fetus may have significant pulmonary hypoplasia, and after

birth the infant may have severe respiratory distress. If the chylothorax is large enough or bilateral, intrathoracic pressure may be sufficiently increased to cause esophageal dysfunction with polyhydramnios, and compression of central veins also may be sufficient to cause ascites or general hydrops, in which case the clinical picture may be very confusing. In some cases the chylothorax may resolve before birth, but this is unlikely if hydrops is present. Some fetuses have been treated by placement of a drainage tube from the pleural cavity into the amniotic fluid, a pleuroamniotic shunt (Rodeck et al, 1988; Schmidt et al, 1985). If the problem is present just before birth, it is better to drain the effusion after delivery, because drainage may cause hypovolemia, necessitating further treatment. Others have described ex utero treatment with intact placental circulation, by catheter aspiration of the effusions before cord clamping and tracheal intubation for mechanical ventilation (Prontera et al, 2002).

Bilateral chylothoraces should be considered in the differential diagnosis for any infant who cannot be ventilated in the delivery room. An emergency thoracentesis may be required and life-saving. In less severe cases, thoracentesis is still required for a definitive diagnosis. Chyle can be distinguished from a transudate by its high protein and lipid content; it can be distinguished from an exudate by its high lipid content, the characteristic preponderance of lymphocytes, and its slightly alkaline pH (Table 51-1). Differential count of the white cells reveals more than 80% lymphocytes. It should be remembered that the lipid characteristics depend on the infant's having been fed with a formula. Before feeding, it can be quite difficult to distinguish chylothorax from hydrothorax (Eddleman et al, 1991).

Treatment of chylothorax may require repeated thoracenteses or even thoracostomy tube drainage to prevent respiratory failure (Brodman, 1975). The clinician should be careful to replace plasma proteins lost in the pleural fluid. Once drainage is accomplished, these infants are placed on formulas containing medium-chain triglycerides (MCTs), rather than long-chain fatty acids, to reduce thoracic duct lymph flow. Oral intake of protein and water also stimulates thoracic duct lymph flow, so in resistant cases the infant is managed with nothing by mouth, with nutritional support provided through an indwelling intravenous catheter. Some researchers have claimed that total

**TABLE 51-1**

**Composition of Chyle**

Measurement	Units	Mean	Range
Total protein	g/dL	3.56	1.89-6.17
Albumin	g/dL	2.24	1.26-3.0
Total lipids	mg/dL	1180	56-3500
Cholesterol	mg/dL	81	48-200
Triglycerides	mg/dL	197	123-234
White blood cells	/mm <sup>3</sup>	15,200	0-29,000
Lymphocytes	%	90	70-100

Specific gravity	—	1.013	1.008-1.027

Data from Brodman RF: Congenital chylothorax: Recommendation for treatment. NY State J Med 75:553, 1975.

parenteral nutrition (TPN) results in significantly earlier resolution of chylothorax than treatment with enteral MCT formula (Fernandez Alvarez et al, 1999).

A variety of approaches have been used with some success to treat the infant with persistent chylothorax, including direct attempts at repair, patching with fibrin glue (Stenzl et al, 1983), and obliteration of the pleural space with sclerosing agents. Congenital chylothorax also has been managed successfully using a pleuroperitoneal shunt (Azizkhan et al, 1983). Finally, some reports suggest that ligation of the thoracic duct below the area of leakage is highly effective (Stringel et al, 1984); this procedure appears to be surprisingly well tolerated without accumulations of fluid in the peripheral tissues or in the peritoneum.

The prognosis for infants with congenital chylothorax is good. In a review of 34 cases, two thirds of the infants with chylothorax responded to thoracentesis alone, without the need for indwelling drainage tubes, and only 5 infants died. The complications reported in this review included weight loss from malnutrition, hypoproteinemia, and lymphopenia (Brodman, 1975).

### **Acquired Chylothorax**

Acquired chylothorax results from damage to the thoracic duct. It has been reported as a surgical complication in the repair of diaphragmatic hernia, tracheoesophageal fistula, and a variety of congenital heart disorders. This complication may also occur following the use of extracorporeal membrane oxygenation (ECMO) catheters, following patent ductus arteriosus (PDA) ligation, and with insertion of chest tubes too far when such tubes are used for the treatment of pneumothorax. Acquired chylothorax usually is diagnosed by a chest radiograph obtained because of a change in respiratory status. The management is the same as for congenital chylothorax. It has been reported that a continuous infusion of somatostatin may be efficacious (Buettiker et al, 2001), presumably by reducing splanchnic blood flow and lymph production.

### **Congenital Hydrothorax**

Congenital hydrothorax may be unilateral or bilateral. It may be isolated but is more often associated with ascites or hydrops fetalis. Hydrothorax may manifest with difficulties in the delivery room and require immediate treatment by pleural drainage tube.

The following conditions should be considered in the differential diagnosis: (1) immune hydrops with fetal anemia and heart failure, usually due to Rh isoimmunization or a similar disorder; (2) nonimmune hydrops with fetal anemia and heart failure (e.g., with twin-to-twin transfusion syndrome, chronic fetal maternal transfusion syndrome, fetal parvoviral infection); (3) nonimmune hydrops without fetal anemia but with fetal heart failure (e.g., with fetal tachyarrhythmia, fetal bradyarrhythmia, arteriovenous malformations at various locations including the placenta and causing large systemic-to-venous shunts, cardiac malformations with ventricular hypoplasia and premature closure of the foramen ovale, fetal viral infections such as cytomegalovirus infection, probably with associated myo-

carditis); (4) large space-occupying lesions within the thorax that obstruct venous return to the heart (e.g., congenital cystic adenomatoid malformation, congenital mediastinal teratoma, congenital diaphragmatic hernia, large pleural effusions, enlarged fetal lungs associated with laryngeal atresia, large fetal chylothorax); and (5) chromosome abnormalities such as Turner syndrome and Down syndrome and other trisomies, which may be associated with more subtle lymphatic drainage malformations and hydrothoraces or chylothoraces. In some cases, but not all, once the underlying abnormality is corrected, the effusions may resolve without further need for drainage.

Thibeault and colleagues (1995) described two infants who had congenital hydrothoraces due to lymphatic hypoplasia, so that normal filtered fluid could not be drained from the pleural spaces. Small pleural effusions may be associated with “wet lung syndrome” or group B streptococcal pneumonia in the newborn. Pleural effusions also may be associated with bronchopulmonary sequestrations and with right-sided diaphragmatic hernias; in such cases the hydrothorax may be quite large.

### **Acquired Hydrothorax**

#### **Central Catheters**

Infants with central venous catheters for infusion of total parenteral nutrition solutions are at risk for the development of pleural effusions, sometimes associated with pericardial effusion and pericardial tamponade. The catheter tip may burrow directly through the pleura, or there may be localized damage from hypertonic solutions with diffusion of fluid into the pleural space. In an infant with severe clinical difficulties and a central catheter, this diagnosis must be considered immediately, especially if there is pericardial tamponade. The fluid aspirated from the pleural space or from the pericardial sac may look like TPN or lipid solution, but if there is doubt it should be checked for its high glucose or lipid content.

#### **Superior Vena Cava Syndrome**

In cases of superior vena cava obstruction with venous thrombosis, significant hydrothoraces may develop because of elevated central venous pressure (Dhande et al, 1983). Such hydrothoraces may be extremely troublesome and require repeated tube drainage or even a surgical shunt procedure. In some infants with superior vena cava thrombosis, chylothoraces rather than hydrothoraces may develop, presumably because lymphatic drainage into the venous system is impaired. Treatment of caval thrombosis may consist of long-acting heparin, tissue plasminogen activator, or a surgical procedure.

## **DISORDERS OF THE DIAPHRAGM**

### **Congenital Diaphragmatic Hernia**

Most infants with congenital diaphragmatic hernia (CDH) are male, two thirds are male, and in 90% the hernia is left-sided. The incidence has been reported at between 1 in

2000 and 1 in 10,000 live births (Langham et al, 1996), with an overall estimate of 1 per 3500 live births. The incidence may be higher because some affected infants are not born alive; Morin and colleagues (1994) suggested an incidence of 1 per 2200 when all cases of fetal demise are included. In the newborn, nearly all hernias pass through the posterolateral foramen of Bochdalek. The pathophysiology of CDH has been reviewed by Glick and colleagues (1996).

### Pathogenesis

#### *Lung Hypoplasia and Arterial Muscle Hyperplasia*

The diaphragm develops anteriorly as a septum between the heart and liver and progresses backward to close last at the left Bochdalek foramen around 8 to 10 weeks of gestation. The bowel migrates from the yolk sac at about 10 weeks, and if it arrives in the abdominal cavity before the foramen has closed, a hernia into the left hemithorax may result. Lung compression from an early age is associated with pulmonary hypoplasia, most severe on the ipsilateral side but also present on the contralateral side if there is mediastinal shift to the right. There is a marked reduction in the number of bronchial generations, with a less marked reduction in the number of alveoli per acinus. In autopsy specimens from infants with CDH, expression of the mitogen insulin growth factor in macrophages and granular pneumocytes is increased, as demonstrated by *in situ* hybridization studies (Miyazaki et al, 1998), which may reflect a failure of the normal decrease with maturation of the lung. Expression of vascular endothelial growth factor is increased in infants with pulmonary hypertension (Shehata et al, 1999). In the rat nitrofen CDH model there is a marked reduction in mitogen-activated protein kinase activity levels associated with lung growth (Kling et al, 2001). In this same model, there may be alterations of fibroblast growth factors, which are important in branching morphogenesis of the airways (Jesudason et al, 2000).

The number of arterial generations is reduced proportionately to the reduction in airway numbers (Bohn et al, 1987), and there is a modest increase in the medial muscle of pulmonary arterioles, together with abnormal peripheral extension of muscle into arterioles at the acinar level (Geggel et al, 1985). In many cases, herniation occurs comparatively late in gestation, or the hernia is small, in which case the lung hypoplasia and developmental changes in the lung vessels are less marked (Adzick et al, 1985).

After birth, when the hernia fills with swallowed air, compression of the lungs is increased, thus superimposing atelectasis on pulmonary hypoplasia. The prognosis depends on the degree of pulmonary hypoplasia (Nguyen et al, 1983), with its associated reduction in alveolar and vascular surface area. There may be severe hypercarbia and hypoxemia with persistent pulmonary hypertension and large right-to-left shunts at the atrial and ductal levels. The pulmonary hypertension has a fixed element because of the vascular anatomic changes associated with lung hypoplasia, and a reactive vasoconstrictive element induced by mediators, which is more responsive to clinical conditions. Kobayashi and Puri (1994) have shown in this condition that pulmonary

hypertension is accompanied by markedly elevated levels of endothelin in the plasma and markedly increased expression of endothelin immunoreactivity in lung endothelial cells. Pulmonary hypertension is markedly improved with selective endothelin receptor antagonists in the lamb CDH model (Kavanagh et al, 2001). Also, the pulmonary vascular resistance in CDH is very dependent on the concentrations of plasma thromboxane and other prostanoids during episodes of clinical deterioration (O'Toole et al, 1996a). Expression of vascular endothelial growth factor is enhanced, especially in pulmonary arterial smooth muscle cells, as demonstrated by immunohistochemical staining in autopsy specimens from infants with CDH (Shehata et al, 1999).

#### *Lung Immaturity and Surfactant Insufficiency*

The lungs are immature even at full-term gestation, appearing arrested in the saccular phase of development. The terminal saccules have fewer septa, the interstitium is thicker, and there are fewer capillaries. Granular pneumocytes are more numerous, but they contain more glycogen and fewer surfactant lamellar bodies. The saccular lining cells are more cuboidal, and thin membranous pneumocytes are less developed (George et al, 1987). In the lamb model of CDH, surfactant phospholipids and proteins are reduced in the lung lavage fluid and in the lung tissue residues, and the surfactant produced has impaired biophysical properties when compared with that from controls (Wilcox et al, 1996b). Such lungs are very susceptible to ventilator-induced injury. In the rat model it has been shown that CDH lungs have a reduced antioxidant response to oxygen breathing, suggesting they are also more prone to oxygen-induced injury. In the nitrofen rat model it has been shown that vitamin A reverses the effects on lung hypoplasia and surfactant depletion (Thebaud et al, 2001).

### Diagnosis

An increasing percentage of diaphragmatic hernias are now diagnosed antenatally by ultrasonography. Antenatal diagnosis allows evaluation of the fetus for possible additional anomalies, as well as counseling of the family about treatment approaches in a tertiary center and discussing with the family the likely short- and long-term prognoses. It is still unclear, however, what factors are the most accurate for predicting eventual outcome (Wilcox et al, 1996a). Among infants in whom CDH was not diagnosed in utero, the onset of symptoms is usually with respiratory distress in the first few hours or days of life. Patients with the most severe symptoms present in the delivery room with a difficult resuscitation and have a high incidence of pneumothorax in the more common left-sided hernias. Breath sounds are absent on the left side, the chest is barrel-shaped, the abdomen is scaphoid, and the heart beat is displaced to the right. The diagnosis is made easily with a chest radiograph, aided by a feeding tube placed in the stomach. The left hemithorax is filled with a mass, usually incorporating air-filled bowel loops, and the stomach tube enters the chest. The heart is displaced to the right, and the abdomen is remarkably devoid of gas patterns (Fig. 51-3).

**FIGURE 51-3.** Left-sided congenital diaphragmatic hernia on day 2 of life. The chest is overexpanded and barrel-shaped. Translucencies of variable sizes fill the left hemithorax, reflecting herniated bowel. The heart is pushed into the right hemithorax.

#### Associated Anomalies

Fauza and Wilson (1994) reviewed 166 cases of CDH and found that 39% had associated anomalies and 61% were isolated; many of the listed anomalies may not be clinically evident, but many have an adverse effect on the outcome. About two thirds of the anomalies were cardiac, including hypoplastic left heart syndrome, atrial septal defect, ventricular septal defect, coarctation of the aorta, and Ebstein anomaly. Other anomalies in this series included esophageal atresia, trisomy 18, hydronephrosis, hydrocephalus, and omphalocele. In the patients discussed by Langham and coauthors (1996), one third had a chromosomal defect or a multiple malformation syndrome involving the brain, heart, kidneys, bowel, or skeleton. Cases have been reported in association with Fryns syndrome, Beckwith-Wiedemann syndrome, Pierre Robin syndrome, and choanal atresia.

#### The Cardiac Function Problem

In addition, there is evidence that cardiac function in these patients is not normal; it is important to assess these patients with echocardiography, but the study is often technically difficult because of the malposition of the heart (Ryan et al, 1994). This cardiac malposition is not corrected by surgical repair of the CDH (Baumgart et al, 1998). It has been reported that left ventricular mass is reduced in CDH and that this may adversely affect the outcome (Schwartz et al, 1994). The cause of the left side reduction in ventricular mass is not clear, but one suggestion is that during development the hernia presses on the left atrium and increases the vascular pressure; left-to-right shunting has been demonstrated in the fetus with diaphragmatic hernia. This reduces the venous return to the left atrium, resulting in underdevelopment of the left heart (Allan et al, 1996). Because there is increased flow in the right heart, pulmonary artery, and ductus arteriosus, these struc-

tures appear larger. In addition, the decreased lung size further reduces the venous return to the left atrium, contributing to the decreased left heart development. Experimentally, gene expression of growth factors in cardiac muscle of the rat diaphragmatic hernia model is reduced (Teramoto and Puri, 2001).

#### Prediction of Outcome

In an early study, it was found that among infants diagnosed during the first 6 hours of life, the mortality rate was 68%, in those diagnosed at 6 to 24 hours of age the mortality rate was 59%, and in those diagnosed after 24 hours of age the mortality rate was 22% (Raphaely and Downes, 1973). In a more recent study, however, which may reflect improvements in care over time, it was found that in those needing treatment in the first 6 hours of life, the mortality rate was 44%, and in those needing treatment after 6 hours, the mortality rate was close to zero (Marshall and Sumner, 1982). These data imply that if the lungs are good enough to bridge the first 6 hours of life, the results of treatment are likely to be good.

Some investigators believe that the prognosis is best assessed by the arterial  $PCO_2$  and the intensity of conventional mechanical ventilation required, as a reflection of the degree of pulmonary hypoplasia. Bohn and coworkers (1987) assessed the mortality in terms of a critical arterial  $PCO_2$  of 40 mm Hg and a critical ventilation index of 1000 (where ventilation index is the product of mean airway pressure and ventilator rate). Their data were accumulated before the availability of ECMO. More recently they have used the product of peak inflation pressure and ventilator rate in a modified ventilation index; a value under 1250 with a  $PCO_2$  of less than 40 mm Hg indicates only a mild or modest degree of lung hypoplasia (Bohn et al, 1996). Wung and colleagues (1995), however, have reported excellent outcomes in infants who have been managed with gentle ventilation and permissive hypercarbia. This approach makes the predictive value of  $PaCO_2$  much less important.

Wilson and colleagues (1991) and O'Rourke and colleagues (1988) have found that a postductal  $PaO_2$  of greater than 100 mm Hg on at least one occasion during the first 24 hours of life was associated with much better survival (91%) than that in infants who never experienced this so-called honeymoon phenomenon (only 7% survival). Obviously, if this  $PaO_2$  is associated with a normal  $PaCO_2$  without vigorous ventilation, this combination is most promising.

Utilizing the 5-minute Apgar score, birth weight, ventilatory index, and arterial  $PCO_2$ , Keshen and colleagues (1997) devised a complex regression equation for predicting survival.

Hasegawa and coworkers (1994) demonstrated the predictive value of the ratio of the left and right pulmonary artery dimensions, as measured at echocardiography. If the left artery was smaller than the right artery, severe pulmonary hypoplasia and severe pulmonary hypertension were more likely to be present. Suda and colleagues (2000) examined another echocardiographic index, the ratio of the dimensions for the combined left and right pulmonary arteries to the descending aorta, in assessing

the likely outcome of CDH. They found that a value of less than 1.3 predicted death with considerable accuracy. With echocardiography, others have investigated an index of left ventricular mass and function as a tool for predicting survivability and have indicated that the results are promising (Springer et al, 2002).

### Initial Treatment

Mothers with infants known to have CDH should receive betamethasone prophylaxis for surfactant insufficiency, even at term gestation. In infants with a prenatal diagnosis, or as soon as the diagnosis is suspected after birth, a double-lumen orogastric tube should be passed and suctioned continuously to reduce the amount of air in the hernia and decrease compression of the lung. The infant should not be ventilated by bag and mask, but instead should be immediately intubated and ventilated using a low peak pressure (less than 30 cm H<sub>2</sub>O) if possible and ventilator rates of 20 to 80 breaths/minute. Finer and colleagues (1998), in their protocol for the management of CDH, prefer to keep the peak inflation pressure less than 24 cm H<sub>2</sub>O to minimize lung injury. Because the danger of pneumothorax is high, with a substantial increase in risk of death (Hansen et al, 1984), paralysis with pancuronium and sedation with morphine, fentanyl, or sufentanyl are indicated; paralysis provides the additional benefit that swallowing air is abolished, which helps keep the hernia decompressed. Exogenous surfactant should be administered because there is accumulating evidence that the lungs in infants with severe diaphragmatic hernias are immature in addition to being hypoplastic (Bohn et al, 1996; Glick et al, 1992b; Wilcox et al, 1996b). This treatment should be performed very early if possible, because mechanical ventilation of the hypoplastic lung is likely to produce significant barotrauma, lung edema, and surfactant inactivation.

The infant should have an umbilical artery catheter inserted and, if possible, an umbilical vein catheter with its tip at the junction of the inferior vena cava and right atrium. In cases of CDH with the liver in the chest, the catheter does not go through the ductus venosus, and it may be advisable not to leave it in place for long. In the absence of an umbilical vein catheter, venous access can be obtained with a Silastic catheter threaded into a central vein or with a larger Broviac catheter inserted by the surgeon. Right-to-left shunting can be followed by the use of pulse oximeters above and below the ductus. Blood pressure support should be given in the form of colloid or crystalloid and continuous dobutamine or dopamine infusion; the mean arterial blood pressure should be maintained at 50 mm Hg or greater to minimize any right-to-left shunt. It is prudent to restrict the volume of fluid administered because pulmonary edema may cause deterioration. Metabolic acidosis may be corrected by administration of sodium bicarbonate or tris(hydroxymethyl)aminomethane (Tham); Finer and colleagues (1998) suggested that the arterial pH should be maintained above 7.25 with the arterial PCO<sub>2</sub> less than 60 mm Hg. To avoid excessive ventilation, they also suggested that oxygen saturation levels of 75% to 85% could be tolerated in the first 6 hours of life. An echocardiogram should be performed to assess pulmonary hypertension

and left ventricular function. Chromosomal analysis should be undertaken as soon as possible, especially if other malformations are detected. Although the definitive treatment is surgical reduction of the hernia, there is no evidence that the condition constitutes an emergency, and time should be spent in adequately stabilizing the infant with mechanical ventilation (Bohn et al, 1996; Charlton et al, 1992; Goh et al, 1992). If possible, the preductal arterial oxygen saturation should be maintained close to 90%, but high peak pressures over 25 cm H<sub>2</sub>O should be avoided. A trial of high-frequency ventilation is often helpful. Inhaled nitric oxide may not be efficacious early in the course of this condition, but it may improve oxygenation modestly for a short time, assisting in the stabilization process. Finally, if all else fails, the infant should be managed using extracorporeal membrane oxygenation (ECMO).

### Advanced Treatment Approaches

#### *Hyperventilation and Alkalinization Therapy*

Deliberate attempts to increase the arterial blood pH above 7.50 with the use of hyperventilation and alkali therapy may help to improve oxygenation in infants with pulmonary hypertension. In many centers this was once the only available approach. Using a newborn piglet model, Davis and colleagues (1989) showed that hyperventilation similar to that used in the clinical situation caused severe lung edema, marked lung inflammation and obvious cell necrosis by 48 hours. This therapy is now considered unwise, in view of the effects of hypocarbia on reduced cerebral circulation and neurodevelopmental outcome, and in view of the effects of high airway pressures and tidal volumes on hypoplastic lungs causing pulmonary air leaks and later bronchopulmonary dysplasia (Nobuhara et al, 1996).

#### *Surfactant Replacement Therapy*

There have been several isolated reports of low lecithin-sphingomyelin ratios in the amniotic fluid of mothers at term with a fetus having CDH. Lower levels of surfactant protein A and surfactant phospholipid have been demonstrated in amniotic fluid in the presence of a fetus with CDH (Moya et al, 1995). It has been shown that the alveolar lavage fluid of lambs with a surgically induced diaphragmatic hernia is deficient in surfactant phospholipids and that exogenous surfactant produces marked improvement in the blood gases and lung mechanics of these lambs (Wilcox et al, 1994). Also, in the rat model of CDH, insufficiency of surfactant development has been demonstrated, and lung surfactant maturation can be accelerated with antenatal betamethasone treatment or thyrotropin-releasing hormone (Suen et al, 1993, 1994a, 1994b). In this same rat model, immunostaining for surfactant protein A is reduced in the lungs of rats with a CDH (Mysore et al, 1998). Both in humans and in the lamb model, however, there is no systematic evidence that the lecithin-sphingomyelin ratio and phosphatidylglycerol profile in amniotic fluid samples accurately indicate lung surfactant immaturity (Sullivan et al, 1994; Wilcox et al, 1995b). It is possible that only the ipsilateral lung is immature (George et al, 1987), and this is hidden by the contribution of both lungs to the amniotic fluid samples. Administration of surfactant not only may treat surfactant deficiency and improve compliance

but also may lower pulmonary vascular resistance and improve pulmonary blood flow (O'Toole et al, 1996b). Lotze and coworkers (1994) gave repeated doses of bovine surfactant to nine infants on ECMO and compared them with eight air-treated controls; they could find no advantage to surfactant treatment. Surfactant may need to be administered prophylactically to be effective, but not after prolonged periods of mechanical ventilation. Glick and colleagues (1992a) reported the outcomes in three infants, two of them premature, whose CDH was diagnosed prenatally and who were given a bovine surfactant in the delivery room. Although they all were high risk by ultrasound criteria, they all survived without ECMO, and despite there being no controls, the authors considered that exogenous surfactant had played an important part in the outcome. Many clinicians currently administer antenatal betamethasone in addition to prophylactic surfactant at birth.

### *High-Frequency Ventilation*

Tamura and colleagues (1988) reported on two infants with high-risk CDH treated successfully with high-frequency oscillatory ventilation (HFOV); the major advantage was improved control of the arterial PCO<sub>2</sub>. For infants with severe respiratory failure on maximal conventional mechanical ventilation and approaching ECMO inclusion criteria, the success rate for high-frequency jet ventilation (HFJV) in avoiding ECMO has been reported as 33% (Baumgart et al, 1992), and the success rate for HFOV in avoiding ECMO has been reported as 22% (Paranka et al, 1995). A trial of up to 6 hours of high-frequency ventilation is considered worthwhile, but most responsive patients improve within 1 hour, so the trial need not be prolonged and ECMO need not be unduly delayed. High-frequency ventilation also may be used in patients with less severe pulmonary hypoplasia. Although there is no evidence that high-frequency ventilation is superior to conventional ventilation, it may be a good choice if the patient develops a pneumothorax on conventional ventilation. Cacciari and associates (2001) reported greatly improved survival in infants managed with HFOV, but the comparison was made with historical controls.

### *Inhaled Nitric Oxide*

Inhaled nitric oxide has been used successfully in the treatment of persistent pulmonary hypertension of the newborn (see Chapter 48), and several investigators have tried this therapy in infants with persistent pulmonary hypertension of the newborn complicating the course of CDH (Bohn et al, 1996; Dillon et al, 1995; Finer et al, 1992; Henneberg et al, 1995). However, a multicenter randomized controlled trial of nitric oxide in CDH failed to show any reduction in the need for ECMO or any reduction in the number of deaths (Neonatal Inhaled Nitric Oxide Group, 1997). Karamanoukian and associates (1994) treated CDH infants with nitric oxide and found that before ECMO there was little response, but about 1 week later, after ECMO, the same patients responded to nitric oxide treatment with sustained improvements in oxygenation. In the lamb model of CDH, there was a good response to nitric oxide but only after the animals had

received exogenous surfactant treatment (Karamanoukian et al, 1995). It is not yet clear whether this is true for the human infant.

### *Liquid Ventilation*

Observations on the use of perfluorocarbon to distend the lung and provide gas exchange (see Chapter 48) have led to current trials of partial liquid ventilation in infants with CDH, both before and during treatment with ECMO (Pranikoff et al, 1996). Animal studies have been promising (Wilcox et al, 1995a). The results of clinical trials have not been as encouraging as promised, so at this time liquid ventilation has not been approved by the Food and Drug Administration (FDA) for use in humans.

### *Extracorporeal Membrane Oxygenation*

No randomized controlled trials have specifically examined the efficacy of ECMO in the management of CDH. Many centers using ECMO have not seen an improvement in the survival of patients with CDH, but this may be because of a change in the referral pattern to these centers, with more severe cases being sent for treatment. Atkinson and coworkers (1991) analyzed data for infants with an oxygenation index of 40 or more; before the availability of ECMO, the mortality rate was 95%, and after the introduction of ECMO, the mortality rate was 31%. Infants who presented with respiratory distress in the first 6 hours of life were analyzed before and after the introduction of ECMO in the Netherlands (vanden Staak et al, 1995). Patients without exclusion criteria, who were suitable candidates for ECMO, were classified according to whether or not they met ECMO inclusion criteria. Before the availability of ECMO, in those who met ECMO inclusion criteria, the mortality rate was 100%, whereas after the introduction of ECMO, in those who met ECMO inclusion criteria, the mortality rate was 39%, a highly significant improvement.

Although most patients receive venoarterial ECMO, patients receiving venovenous ECMO survive at the same rate (Dimmitt et al, 2001). At present, the standard criteria for ECMO are used in CDH patients, but in general the results with ECMO have not been as good as in other conditions, such as meconium aspiration pneumonia. Attempts have been made to decrease the number of infants subjected to ECMO and to improve the results with ECMO treatment of CDH by changing the inclusion criteria. Some centers require that the patient show evidence of the so-called honeymoon period, in which the postductal arterial PO<sub>2</sub> should be at least 100 mm Hg on at least one occasion (O'Rourke et al, 1988; Stolar et al, 1988); otherwise, the patient is considered to have severe pulmonary hypoplasia and not be a candidate for ECMO. Steimle and associates (1994) considered a honeymoon period to be represented by any arterial PO<sub>2</sub> greater than 50 mm Hg. When they included infants who never had a honeymoon period, the results with ECMO overall were worse; they found that survival of the additional patients without a honeymoon period was only 27%. They considered lack of a honeymoon period, as they defined it, to be a relative contraindication to ECMO. This approach is associated with improved results only for those subjected to ECMO treatment, not for all cases of CDH.

Other investigators have wanted to use ECMO in more cases (Newman et al, 1990). Clinicians have argued that the overall results for survival in CDH patients might be improved if infants with CDH were started on ECMO earlier, at a higher level of arterial  $PO_2$ , to take into account that the arterial  $PCO_2$  often is elevated in CDH (vanden Staak et al, 1993). No confirmation of this idea has appeared. Evidence suggests that in ECMO-treated patients, compared with similar patients not treated with ECMO, a favorable remodeling of the pulmonary arteries, especially a reduction in thickening of the arterial adventitia, occurs (Shehata et al, 1999; Shehata et al, 2000); this would favor the early use of ECMO.

In the final analysis, the degree of lung hypoplasia, along with the severity of pulmonary vascular disease, determines the outcome with ECMO. The aim of ECMO is to have the patient survive long enough for the reactive component of pulmonary hypertension to resolve, which may take up to 2 to 3 weeks. If there is severe lung hypoplasia with fixed pulmonary hypertension, however, death becomes inevitable. Antunes and coworkers (1995) evaluated the prognosis with preoperative measurements of lung volume by the helium dilution method; there were clear differences among those who survived without ECMO (16 mL/kg), those who survived with ECMO (12 mL/kg), and those who died despite ECMO (5 mL/kg). A lung volume of less than 9 mL/kg delineated infants with such severe lung hypoplasia that they were unlikely to survive, even after prolonged ECMO for up to 4 weeks.

Thibeault and Haney (1998) assessed the lung development of infants with CDH at autopsy, comparing these data with clinical and echocardiographic findings. All infants needing ECMO had pulmonary-to-systemic pressure ratios of near 1.0, and in nearly all such infants these values were reduced to less than 0.5 after 7 to 14 days of ECMO. Even with successful reduction of pulmonary-to-systemic pressure ratios, many of the infants still died, because lung hypoplasia was too severe. These authors considered that infants with lung volume, lung weight, and lung DNA values less than 45% of predicted normal values had lung hypoplasia too severe for survival following ECMO. More recently, and from a clinical point of view, it has been suggested that infants who never achieve a preductal oxygen saturation of at least 85% for at least an hour have lethal pulmonary hypoplasia and are not suitable candidates for ECMO (Boloker et al, 2002). Infants in whom the arterial  $PCO_2$  cannot be reduced below 60 mm Hg are also poor candidates for ECMO.

The presence of congenital heart disease is a relative contraindication to ECMO, but only if the lesion is known to be untreatable (Ryan et al, 1994), as in the case in hypoplastic left heart syndrome. Overall, the mortality rate is doubled by the presence of congenital heart disease (Cunniff et al, 1990). When other system anomalies are present, it is important to assess the chromosome status as rapidly as possible to avoid using ECMO in infants with severe genetic problems. This may be difficult in an emergency situation, in which case the clinician may have to start ECMO and withdraw it later.

### **Surgery**

For many years, it was considered imperative to reduce the hernia surgically as soon as possible after birth (Langer et al, 1988). Carlidge and associates (1986) reported a markedly improved survival when surgery, instead of being done immediately, was delayed for a period of 4 to 16 hours of stabilization; they recommended that surgery not be performed until the pH was at least 7.20. To explore why early surgery may be harmful, Sakai and colleagues (1987) measured the static respiratory system compliance before and after surgery in infants who presented with CDH in the first 6 hours of life and were operated on immediately. The surgical technique included, when considered necessary, the use of abdominal muscle flaps for diaphragm repair and nonclosure of abdominal muscle to avoid overfilling the abdominal cavity. These clinicians found no improvement in compliance after surgery, and most patients had major reductions in compliance, suggesting that surgery had made matters worse. The reduced compliance was thought to be due mostly to tension in the chest wall generated by the repaired diaphragm, and to tension generated by the abdominal wall after closure of the muscle layers, rather than to changes in the lung itself.

In a prospective controlled trial, Nakayama and coworkers (1991) compared a group of infants who had early emergency repair at about 11 hours of age with a group who had delayed repair, many of them after a period of ECMO, at about 5 to 6 days of age. These investigators confirmed that respiratory system compliance was not improved after surgery and was usually decreased, and this was true whether or not the infants had early or delayed surgery. Before surgery, the delayed surgery group demonstrated a significant improvement in respiratory system compliance, which may ultimately have been helpful. The mortality rate in the early surgery group was 54%, whereas in the delayed surgery group it was only 11%. Although the delayed surgery group was thought to have more severe disease initially, the results for delayed surgery looked better; however, results of this study, similar to others before it, may have been misleading because it was not properly randomized.

Nio and colleagues (1994) have reported the results of a randomized, controlled trial of early versus delayed surgical repair of CDH in 32 infants who presented with respiratory distress within 12 hours of birth. All patients were treated with ECMO according to standard criteria. The early surgery group had surgery at about 10 hours of age, and the delayed surgery group had surgery at about the age of 1 week. There was no difference in the need for ECMO or in the mortality rate between the two groups. The authors concluded that if the patient could be adequately stabilized with mechanical ventilation, early surgery was suitable, but if the patient could not be stabilized, preoperative ECMO with delayed surgery was a more reasonable course. The delay in surgery also helps to select patients with a higher likelihood of survival.

### **SURGICAL MANAGEMENT**

Some surgeons recommend placement of a thoracostomy tube to protect against the catastrophic development of tension pneumothorax, but the underwater seal should be

at atmospheric pressure and not placed to suction. The latter may increase the transpulmonary pressure and overdistend the ipsilateral lung. Others believe that no chest tube should be placed and that air in the pleural cavity should not be removed, to prevent mediastinal displacement and discourage overdistention of the contralateral lung (Cloutier et al, 1983). They believe that overdistention may be sufficient to compress pulmonary capillaries and reduce pulmonary blood flow; Ramenofsky (1979) used a dog model of CDH to show that suction to the ipsilateral pleural space caused overdistention and deterioration of gas exchange, which could be reversed by instillation of air back into the ipsilateral pleural space. No matter what is done concerning the chest tube, every attempt should be made to keep the mediastinum in the midline and not to overdistend the contralateral lung. Such volutrauma may cause high-permeability pulmonary edema with surfactant inactivation. Wung and colleagues (1995) have reported excellent results emphasizing delayed surgery, avoidance of lung overdistention, and no chest tube.

The diaphragmatic defect may be repaired with sutures alone, but because increased tension may compromise total thoracic compliance, a synthetic patch or an abdominal muscle flap procedure may be used (Michalewicz and Chaimoff, 1989). Because abdominal cavity development may be reduced, closure of the abdominal wall may increase tension and cause problems. Surgeons have closed abdominal skin only, with a later repair of the ventral hernia, or they have used patch or silo procedures (Newman et al, 1985; Schnitzer et al, 1995).

#### POSTOPERATIVE CARE

Postoperatively, patients often require quite large volumes of colloid to overcome the effects of third-space fluid losses on systemic perfusion. All too commonly, the course is complicated by the development of pulmonary hypertension. If the systemic arterial pressure is not well maintained with inotropics, there may be increased right-to-left shunting at the ductus arteriosus and foramen ovale. There is no evidence that hyperventilation is helpful in these infants; moreover, Wung and colleagues (1995) have been successful using permissive hypercarbia. Attempts to increase pulmonary blood flow with tolazoline, nitroprusside, magnesium sulfate, and other drugs have only occasionally been successful, and if they reduce systemic arterial pressure they may instead be harmful.

The left lung may take only a few days to expand and fully occupy the hemithorax, which means that atelectasis predominated over hypoplasia preoperatively. Otherwise the space initially filled with air becomes filled with fluid. The lung may slowly increase in size over the next few weeks, but in the most severe cases, growth may take several months. Histologically, growth in the number of alveoli and a reduction in the muscle mass of pulmonary arteries are seen, but these improvements are more marked on the contralateral side (Beals et al, 1992), and the time course is such that it is at least a week before improvement occurs.

#### SURGERY ON OR OFF EXTRACORPOREAL MEMBRANE OXYGENATION

Although delayed surgery has become common, some centers have performed surgery while the patient is still on ECMO (Breux et al, 1991), and some centers wait until the patient can be taken off ECMO (Adolph et al, 1995). The technique of surgery on ECMO calls for the use of topical thrombin powder or fibrin glue, the use of less heparin with acceptance of shorter activated clotting times (180 to 200 seconds, instead of 200 to 220 seconds), and the use of antifibrinolytic agents (Wilson et al, 1994a). In the experience of many, the incidence of hemorrhagic complications is greater; surgical site hemorrhage requiring transfusion occurred in 38%, 18%, and 6% of cases of CDH repaired on, before, and after ECMO, respectively (Vasquez and Cheu, 1994). It is possible that these complications may contribute to a worse outcome (Lally et al, 1992).

The major reason for performing surgical repair on ECMO is the fear of rebound pulmonary hypertension after decannulation. In a large Canadian experience, however, Sigalet and colleagues (1995) have not found rebound pulmonary hypertension to be a problem in following their strategy of initial stabilization, ECMO if necessary, and delayed surgical repair after decannulation. Although it seems reasonable to temporarily maintain the catheters with concentrated heparin infusions, this approach has not proved practical while maintaining coagulation during surgery, and has been associated with an unacceptable incidence of thrombosis. Some centers find it useful to monitor the patient with serial echocardiography and to decannulate only after the pulmonary artery pressure reaches 30 to 50 mm Hg or a left-to-right shunt appears (Haugen et al, 1991). Some centers may decannulate for surgery and then offer a second course of ECMO if necessary; this approach may be quite useful in the case of CDH (Lally and Breux, 1995). Surgical reinsertion of the catheters usually has been possible.

#### LOBAR LUNG TRANSPLANTATION

In infants who come off ECMO, perhaps after a second course, and then have respiratory failure on the ventilator, a few centers now consider lobar lung transplantation as a last resort (Adzick et al, 1985; Adzick, 1992; Van Meurs et al, 1994), but at the present time there are too many difficulties with this approach for it to be widely considered.

#### Mortality

In the review by Langham and colleagues (1996), which involved 2024 patients with CDH, the overall mortality rate was 40%, lower in those with isolated lesions and much higher in those with significant other malformations. Nobuhara and associates (1996) reported that the mortality rate among infants without associated malformations was only 16%.

For those presenting in the first 6 hours of life, Adzick and colleagues (1985) found no difference in mortality rate for left-sided versus right-sided hernias, but all infants with bilateral hernias died. The mortality rate for infants with associated polyhydramnios was 89%, compared with 45% for those without associated polyhydramnios; presumably,

the polyhydramnios reflects a larger hernia. Prematurity was associated with a higher mortality rate, as expected. The mode of delivery, whether vaginal or abdominal, and immediate surgery after birth made no difference to the outcome. Infants with a prenatal diagnosis and planned delivery have better resuscitation at birth, as reflected in the 5-minute Apgar score, but there is no evidence that this has improved the survival rate.

### Complications Following Treatment of Congenital Diaphragmatic Hernia

Failure to thrive is a common problem following treatment of CDH, even with optimization of caloric intake, possibly due to chronic respiratory distress and increased work of breathing (Nobuhara et al, 1996). Many patients remain below the 25th percentile for weight and have severe oral aversion (Muratore et al, 2001). It is common for infants with CDH to have evidence of esophageal dilation, esophageal dysfunction, and gastroesophageal reflux (Stolar et al, 1990), and some of these infants require a Nissen fundoplication and gastrostomy tube placement in the pre-discharge phase (Kieffer et al, 1995; Koot et al, 1993; Nagaya et al, 1994; Sigalet et al, 1994). Esophageal dilation and dysfunction are more common in infants who had polyhydramnios before birth, suggesting that the problem is caused by increased mediastinal pressure. There is often a minimal or absent left diaphragmatic crus, with insufficiency of the gastroesophageal junction, and it may be necessary to refashion this at the time of the hernia repair (Sigalet et al, 1994). It is also possible that a tight primary repair of the diaphragm may apply excessive tension at the gastroesophageal junction and that a synthetic patch should be used more often (Kieffer et al, 1995).

Some infants may develop intestinal obstruction related to volvulus and adhesions and require a laparotomy and "adhesionolysis." In a few instances of CDH repaired with a synthetic patch, a recurrent diaphragmatic hernia has developed, sometimes within a few months but often at about the age of 18 months, and the diaphragmatic patch may need to be repaired (Atkinson and Poon, 1992). Other infants have complications associated with chronic bronchitis (with cough), chronic aspiration pneumonia, and the development of bronchopulmonary dysplasia. Of course, these infants may have the usual complications related to the use of ECMO, other invasive procedures, and indwelling venous catheters; the most notable have been extra-axial fluid collections in the brain, pleural effusions due to chylothorax, and superior vena cava syndrome with acquired hydrothorax.

### Outcome in Survivors

Van Meurs and colleagues (1993) found that neurodevelopmental outcome was the same in ECMO-treated infants with CDH and in ECMO-treated infants with other conditions. This finding may suggest that the outcome is determined by the treatment, not the condition of CDH itself.

D'Agostino and coworkers (1995) provided data for the first year of life in 16 surviving patients who were treated with ECMO during the years 1990 to 1992. Before discharge from the hospital, 13 infants had gastroesophageal

reflux; 11 infants were poor oral feeders and needed tube feedings; and 10 infants had bronchopulmonary dysplasia, some of mild severity. At the age of 1 year, 11 infants had symmetrical hypotonia. In addition, three infants still needed ventilatory support for bronchopulmonary dysplasia. On the Bayley Scales of Infant Development, the mean mental score was 87, which was considered to be average, and the mean psychomotor score was 75, indicating a significant level of motor impairment in some infants. The scores were worse in infants who needed a synthetic patch for repair of the diaphragm and were better in those who did not need a patch (an indicator of severity). The authors considered that seven infants had normal cognitive and motor function. Only one out of 14 infants had a significant hearing loss.

Lund and colleagues (1994) followed 33 patients with CDH for a period of 2 to 3 years; 20 of these patients were treated with ECMO. They found deafness needing amplification in seven infants, seizure disorder that resolved by 12 months of age in four infants, developmental delays without evidence of cerebral palsy in 15 infants, and evidence of growth failure in many infants. Findings on head computed tomography scans were abnormal in 10 infants, usually including bifrontal brain atrophy or ventriculomegaly, both of uncertain significance. Six infants needed surgery for bowel obstruction, and six infants needed fundoplication for gastroesophageal reflux. Chest wall deformities were seen in one third of infants, usually pectus excavatum, presumably the result of chronic respiratory distress, and scoliosis developed in four infants, possibly the result of tight diaphragmatic repairs with more tension on one side than the other side. In other series of older children, although the chest radiograph may appear normal, lung volumes are slightly reduced, and there is persistent evidence of a reduced vascular bed in the left lung (Reid and Hutcherson, 1976; Wohl et al, 1977).

### Approaches to Congenital Diaphragmatic Hernia Before Birth

#### *Prenatal Diagnosis*

The pregnant woman whose fetus has CDH may have a low serum alpha-fetoprotein level on the routine screen, or she may present with polyhydramnios. With routine fetal ultrasound examination, most cases of CDH can be found. Findings commonly include polyhydramnios, absence of the abdominal stomach bubble, presence of a thoracic stomach bubble, mediastinal shift to the right, and fetal hydrops caused by obstructed venous return. Associated malformations should be sought. Amniocentesis for cell culture and chromosomal analysis may be helpful. The most likely abnormalities are trisomies 13 and 18, 3p microdeletion, and 12p tetrasomy. Associated problems greatly reduce the likelihood of a good outcome. With adequate prenatal diagnosis, the mother may be delivered in a tertiary care center and adequate preparation made for delivery of the infant.

#### *Assessment of the Risk before Birth*

It is important to know the mortality with conventional therapy when assessing the suitability of other therapies such as fetal surgery. There has been controversy over how to assess

the results of therapy for CDH, especially whether the denominator should be all fetuses with the condition or all those infants referred for surgical treatment.

Harrison (1994) and Adzick (1985, 1989) and their colleagues at the University of California, San Francisco, have produced evidence that CDH is associated with large hidden mortality that is not reflected in the results reported from ECMO referral centers. A significant number of infants have associated lethal malformations, some are stillborn, some either are electively not resuscitated in the delivery room or cannot be resuscitated despite the best efforts of clinicians, and some are not transported to an appropriate center for surgery and ECMO. These authors concluded that when the diagnosis is made before birth, the true mortality rate is about 60% for those without lethal malformations and about 80% for the total population; this contrasts with the results from ECMO referral centers, which report mortality rates of 20% to 40%, depending on the patients included.

Two other groups of investigators, however, have failed to find relevant differences in mortality rates for those diagnosed before birth versus those diagnosed after birth (Sharland et al, 1992; Wilson et al, 1994b). Most of the difference was explained by a higher incidence of lethal malformations in those with a prenatal diagnosis. It is doubtful that prenatal diagnosis alone indicates an increased risk of death, but it may be that prenatal diagnosis is precipitated by an event such as polyhydramnios that may be associated with a poor prognosis.

It is a logically appealing notion that the earlier in gestation the hernia occurs and the larger the hernia, the more severe the degree of pulmonary hypoplasia and the worse the outcome. To improve the results, Harrison and coworkers (1993a, 1993b) suggested surgical reduction of the hernia before 30 weeks of gestation, and for this to be a viable alternative form of therapy, they needed to identify the fetus at greatest risk. In a group of infants who all had antenatal diagnosis, Adzick and colleagues (1989) found evidence that diagnosis before 24 weeks of gestation and the development of polyhydramnios, usually after 24 weeks, were poor prognostic signs. This finding has not been absolutely confirmed. After exclusion of malformations, Sharland and associates (1992) reported a 72% mortality rate for those diagnosed before 25 weeks of gestation and a 52% mortality rate for those diagnosed later in gestation. Wilson and colleagues (1994b) indicated a similar trend in their subpopulation of infants with prenatal diagnosis.

Harrison and coworkers (1994) found in a homogeneous group of infants, all of whom had prenatal diagnosis before 24 weeks of gestation, that the true mortality rate, after excluding malformations, was 58%, compared with a 37% mortality rate if only infants reaching an ECMO center were considered. Thus, in those with a prenatal diagnosis and without associated malformations, the evidence suggests that diagnosis before 24 weeks of gestation may be associated with a worse outcome; this may justify consideration for fetal surgery. Other data have suggested that the presence of polyhydramnios (Adzick et al, 1985), the presence of the liver in the left hemithorax (Albanese et al, 1998), the presence of stomach in the thoracic hernia (Burge et al, 1989; Hatch et al, 1992), a reduced lung-thorax area ratio (Kamata et al, 1992), a reduced right

lung-to-head ratio (Lipschutz et al, 1997; Mychaliska et al, 1996), or a reduced left ventricular mass (Crawford et al, 1989; Sharland et al, 1992), all possibly reflections of a large hernia, also may predict a bad outcome and may be useful in selecting suitable candidates for fetal surgery. Recently, it has been shown that the prenatal magnetic resonance image also may be used to assess the fetal lung volume; in CDH, the median value for the observed-to-expected lung volume is markedly reduced and is much lower in patients who die than in those who survive (Mahieu-Caputo et al, 2001).

### *Fetal Surgical Repair of the Hernia*

The group at the University of California, San Francisco, performed fetal surgical repair of CDH before 30 weeks of gestation in highly selected cases (Harrison et al, 1990). One of the many difficulties of fetal surgery is in removal of the liver from the chest without kinking the umbilical vein and compromising the umbilical circulation (Harrison et al, 1993b). In their first summary, Harrison and colleagues reported that they operated on six infants chosen from a total of 45; three died intraoperatively, one died at birth, and two died in the late neonatal period. In their second summary, these investigators (1993a) reported that they operated on 14 new infants chosen from a total of 61 additional infants; five died during operation, three died within 48 hours after operation (these were considered fetal deaths), two died of prematurity, and four were survivors, none of whom needed ECMO. In a situation in which the investigators expected 40% survival, they obtained only a 30% survival. Furthermore, not all clinicians agree with the criteria used for selection; the prenatal identification of patients with the most severe lung hypoplasia, those most likely to fail after ECMO, remains a significant problem (Weinstein and Stolar, 1993). In addition, postsurgical premature labor with premature birth is a constant threat to the success of fetal surgery (Longaker et al, 1991). The National Institutes of Health sponsored a randomized trial of fetal surgical repair of CDH, excluding those cases with the liver included in the hernia (Harrison et al, 1997). It was concluded that there was no improvement in survival with fetal surgery over that obtained with the conventional approach, and there was no reduction in the requirement for ventilator or ECMO support. This approach has now been abandoned.

### *Tracheal Plug Operations on the Fetus with Congenital Diaphragmatic Hernia*

Several other approaches to fetal surgery have been suggested. DiFiore and coworkers (1994) and Hedrick and colleagues (1994) found that tracheal ligation in the lamb CDH model caused the lungs to enlarge with lung fluid, resulting in reduction of the hernia and excellent lung growth. As lung distention with saline does not have the same effect, it is clear that growth factors are important. Bealer and colleagues (1995) have used translaryngeal insertion of a hydrophilic plug to obstruct the trachea of fetal lambs; the plug can be removed at birth. On tissue examination, there is increased DNA content with a normal DNA-protein ratio, indicating substantial cell proliferation. The morphology appears more mature, with thin alveolar

septal walls. The vascular development is greatly improved with abnormal muscular hypertrophy reduced (Bratu et al, 2001; Kanai et al, 2001; Sylvester et al, 1998); the resistance to blood flow is improved, and a more normal response to oxygen is restored in the pulmonary circulation. Despite these promising results, tracheal ligation had an adverse effect on the surfactant system, and granular pneumocytes were severely injured (O'Toole et al, 1997; Piedboeuf et al, 1997). Ongoing clinical trials of this technique have not produced definitive results (Mychaliska et al, 1996). Initially, a foam plug was inserted in the fetal trachea using an endoscopic technique, but tracheal injury resulted; a tracheal clip or a small balloon has since been used. Harrison and colleagues (1996) reported a series of eight human fetuses operated on at late second trimester, and there was only one survivor. They (1998) reported a further series of 34 cases, but the total survival in fetuses treated with tracheal occlusion was the same as in infants treated after birth. Several other single cases have been reported, but the results are not encouraging. Porter (1999) indicated after review that fetal tracheal occlusion offers no improvement over the standard clinical approach to CDH. Some centers continue to offer this approach in the most severe cases of isolated CDH: those with gestation of less than 26 weeks, with liver herniation present and a small lung-to-head ratio (Kitano et al, 1999). The use of lung growth factors in the future may offer a better approach to this problem.

### Unilateral Agenesis of the Diaphragm

Among 31 newborns with CDH presenting in the first 6 hours of life, Muraskas and coworkers (1993) reported eight cases of unilateral diaphragmatic agenesis, in which no remnant of skeletal muscle could be found at the subcostal margin. A prenatal diagnosis was more common in agenesis of the diaphragm. Other investigators have found lower Apgar scores and a longer period of preoperative stabilization in this condition (Tsang et al, 1995). The affected infants have more severe gas exchange problems and more severe bilateral pulmonary hypoplasia than even in fatal cases of CDH. Despite repair with a synthetic patch and despite the use of ECMO, the outcome is frequently fatal, and the long-term survival rate is reported as less than 30%. Various muscle flap procedures have been described for the surgical construction of the hemidiaphragm (Samarakkody et al, 2001). Diaphragmatic agenesis has been observed more often in recent years, presumably because of antenatal diagnosis and the improved ability to resuscitate infants and transport them to referral centers. This group of infants should be considered separately in assessing the results for CDH.

### Right-Sided Diaphragmatic Hernia of Delayed Onset

This condition should not be confused with a right-sided hernia that is present at birth, as discussed earlier. Because the liver is a large organ, herniation into the thorax may be a slow process and may occur after birth only with the onset of breathing. The lung problem reflects compression atelectasis rather than hypoplasia, and the right basal mass

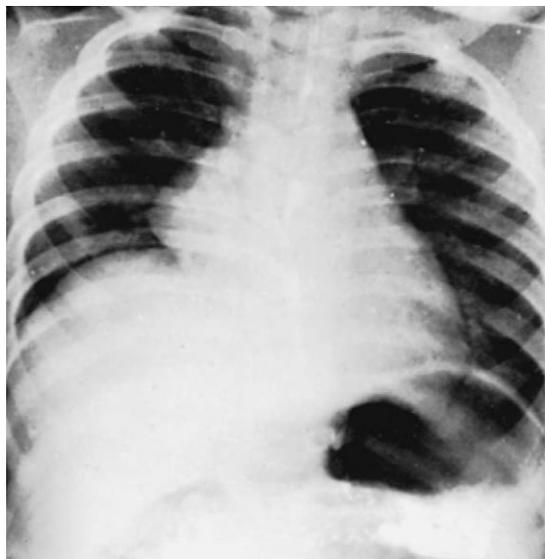

**FIGURE 51-4.** Right-sided congenital diaphragmatic hernia with herniated bowel in the right hemithorax and heart displaced further into the left hemithorax.

may present a confusing appearance on the chest radiograph of the newborn infant (Fig. 51-4). The right leaf of the diaphragm may appear elevated, as in eventration or paralysis of the diaphragm. Alternatively, the clinician may think that the patient has a right basal pneumonia or a pleural effusion; some patients have had a chest tube placed, which may injure the liver. The abdominal gas pattern on the right side may appear higher than usual and the lower edge of the liver more horizontal. Ultrasonography or a radionuclide liver scan usually indicates that the liver location is excessively high. There has been an unexplained association of this condition with group B streptococcal sepsis (Handa et al, 1992); it may be that increased negative pleural pressures and increased positive abdominal pressures encourage herniation into the chest.

### Eventration of the Diaphragm

Eventration of the diaphragm results from insufficient muscle development or the absence of phrenic nerves, so that the diaphragm is replaced by a fibrous sheet. An eventration may be localized or diffuse, and most cases of the latter type are unilateral, frequently on the left side. Many cases, especially those that are localized, produce no clinical signs. When eventration is severe, however, newborns have significant respiratory distress. There may be lung hypoplasia on the affected side and, if the mediastinum is shifted, even hypoplasia on the contralateral side. In addition, basal lung compression may cause atelectasis, poor drainage, and complicating bronchopneumonia. The diagnosis is suspected from undue elevation of the diaphragm

**FIGURE 51-5.** Eventration of the diaphragm in a 3-month-old asymptomatic infant; the right hemidiaphragm is moderately elevated.

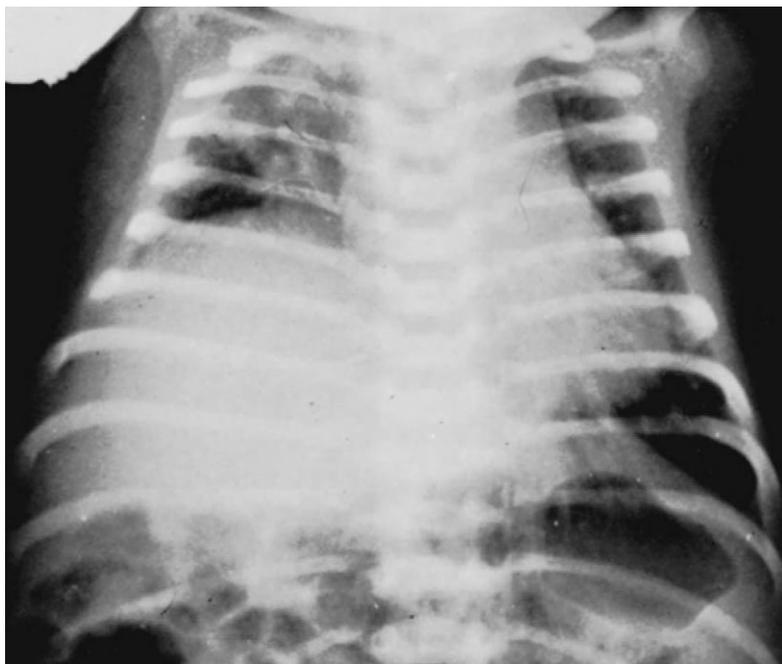

seen on frontal and lateral chest radiographs and may be confirmed by fluoroscopy or ultrasound examination (Fig. 51-5). The major cause of confusion is a paralyzed diaphragm, but evidence for birth trauma or thoracotomy is absent in eventration. The diaphragm may show minimal motion during breathing, or the motion may be paradoxical, rising with inspiration and falling with expiration. In those cases in which signs are persistent, the treatment of choice is surgical plication (Goldstein and Reid, 1980; Wayne et al, 1974). Follow-up evaluation of patients with plicated diaphragms suggests that the functional outcomes are good in nearly all cases (Kizilcan et al, 1993).

### Paralysis of the Diaphragm

Diaphragmatic paralysis may occur in either of two clinical situations: after birth trauma or after thoracotomy.

#### *Birth Trauma*

Although diaphragmatic paralysis sometimes is bilateral, most cases are unilateral, on the right side. The usual presentation is with respiratory distress, produced largely by overactivity of the normal hemidiaphragm. In cases of bilateral paralysis, however, there is cyanosis and a poor breathing effort that necessitates mechanical ventilation. The infants are usually large and have other signs of birth trauma. There is excessive stretching of the C3 to C5 nerve roots in the neck. The diaphragm is an especially important respiratory muscle in the newborn. Furthermore, during active sleep, the intercostals are inhibited, the supine position of the newborn pushes the paralyzed diaphragm upward, and the newborn is especially prone to muscle fatigue. The diagnosis is suggested on the chest radiograph if the right hemidiaphragm is two intercostal spaces higher than the left or if the left hemidiaphragm is one intercostal space higher than the right (Fig. 51-6). On fluoroscopy or ultrasound examination, the involved diaphragm shows either limited or paradoxical motion (Ambler et al, 1985). There may be associated basal atelectasis, which explains why some infants are markedly improved by nasal continuous positive airway pressure. When both hemidiaphragms are paralyzed, these infants require prolonged mechanical ventilation (Aldrich et al, 1980). Although many improve over 2 weeks, further improvement is possible over a period of 2 months. Once it is believed no further improvement will occur, and the patient cannot be weaned from ventilatory support, surgical plication of the diaphragm should be performed.

**FIGURE 51-6.** Right-sided diaphragmatic paralysis associated with a difficult delivery and a right-sided Erbs palsy; the right diaphragm is moderately elevated. The infant had tachypnea.

### Post-Thoracotomy

Diaphragmatic paralysis from phrenic nerve trauma is a known reason for failure to wean from mechanical ventilation after a thoracic operation, such as ligation of patent ductus arteriosus, creation of a systemic pulmonary shunt, or repair of a tracheoesophageal fistula. Management is similar to that for paralysis after birth trauma.

# CARDIOVASCULAR SYSTEM

Editors: ROBERTA A. BALLARD and GIL WERNOVSKY

## CHAPTER 52

### Nomenclature and the Segmental Approach to Congenital Heart Disease

Tal Geva

The spectrum of congenital anomalies of the cardiovascular system is infinite, ranging from benign anatomic variations without clinical implications to complex and lethal anomalies. A comprehensive scheme for classification of congenital heart disease (CHD) based on clear and consistent nomenclature is therefore essential for diagnosis, management, and research. Since the publication of Maude Abbott's seminal *Atlas of Congenital Cardiac Disease* in 1936, many classification schemes have been proposed, each adding a building block to the knowledge and understanding of CHD. The goals of any classification system for CHD are (1) to provide a consistent nomenclature based on anatomic-morphologic features of the cardiac chambers; (2) to devise a systematic analytic approach that produces a specific and unique set of diagnoses for each congenital cardiac malformation; (3) to be applicable to all forms of CHD, including predictable cardiac malformations that have not yet been described; and (4) to promote understanding and exchange of data among clinicians and researchers.

This chapter describes a segment-by-segment approach to the classification and nomenclature of congenital anomalies of the heart and great vessels. This classification system, known as the *segmental approach to congenital heart disease*, was originally proposed by Van Praagh and his colleagues in the 1960s and early 1970s (Van Praagh, 1964, 1966, 1967). It has since been refined by its originators as well as by many other investigators in the fields of developmental biology and embryology, cardiology, cardiovascular surgery, pathology, radiology, and others (Anderson et al, 1984a, 1984b; de la Cruz and Nadal-Ginard, 1972; Freedom, 1984; Lev, 1966; Lev et al, 1971; Rao, 1981; Shinebourne et al, 1976; Stanger et al, 1977; Tynan et al, 1979; Van Praagh, 1984a, 1984b, 1985; Weinberg, 1986).

#### SEGMENTAL ANALYSIS OF CONGENITAL HEART DISEASE

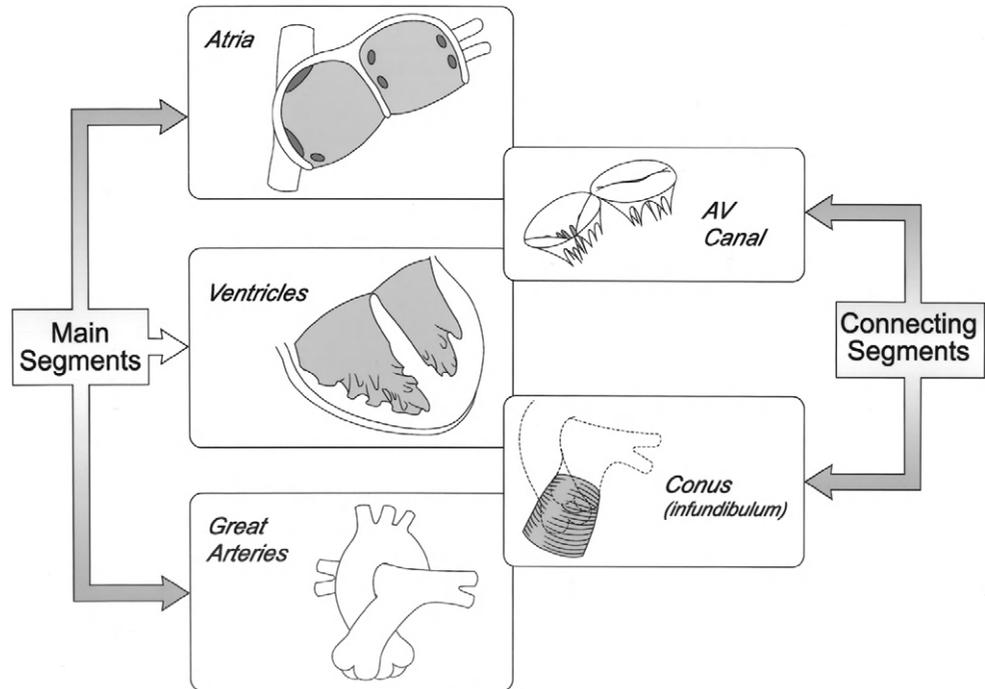

Segmental analysis of CHD is based on an understanding of the development, morphology, and segmental anatomy of the heart and great vessels. The cardiac segments are the anatomic and embryologic building blocks that form the mammalian heart (Fig. 52-1). The three *main segments* are (1) the atria, (2) the ventricles, and (3) the great arteries. There are two *connecting segments* between the main segments: (1) the atrioventricular (AV) canal and (2) the conus, or infundibulum. The AV canal consists of the AV valves (the mitral and tricuspid valves in normally formed hearts) and the atrioventricular septum. The infundibulum, or conus, is the connecting segment between the ventricles and the great arteries. In normally formed hearts, the infundibulum consists of a circumferential subpulmonary myocardium with muscular separation between the pulmonary and tricuspid valves and partial absence of the subaortic infundibular myocardium that results in fibrous continuity between the aortic and mitral valves.

The fundamental principle of the segmental approach to CHD is to analyze each component of the heart in a sequential, step-by-step fashion. First, the anatomic pattern (i.e., *situs*) of the abdominal and thoracic organs is defined and the position of the heart is described. Then, each of the main cardiac segments is examined, described, and assigned a designation based on its unique morphologic features, independent of neighboring segments (Fig. 52-2). For example, each ventricle is defined according to its intrinsic morphology and not by the entering AV valve or the exiting great artery.

Analysis of the main cardiac chambers—atria, ventricles, and great arteries—involves two steps. First, the *identity* of the chamber or great vessel is defined according to its morphology and intrinsic myocardial architecture. For example, the right and left atria are so designated according to their morphology, not according to their spatial location. Second, the *situs* of the cardiac segment is determined. In the case of the atria, there are three possible configurations: *situs solitus* (normal), *situs inversus*, and *situs ambiguus* (indeterminate).

Once the three main cardiac chambers are characterized according to their unique morphologic features, the connecting segments are analyzed and defined. Finally, a complete set of diagnostic categories is formulated by combining the five cardiac segments and all associated cardiovascular anomalies, as described in the following section.

**FIGURE 52-1.** Anatomic segments of the heart. The three main cardiac segments are the atria, ventricles, and great arteries. There are two connecting segments: the atrioventricular (AV) canal (including the AV valves and the interatrial and interventricular components of the AV canal septum) and the conus (or infundibulum). The connecting segments may be viewed as multidirectional joints between the main cardiac segments, allowing infinite possibilities of AV and ventriculoarterial alignments. Essential to the segmental approach to congenital heart disease is that each cardiac segment must be analyzed separately and independent of adjacent segments.

### STEP-BY-STEP SEGMENTAL ANALYSIS

The segmental approach to CHD comprises ten steps, each focusing on a specific anatomic-morphologic component, as follows.

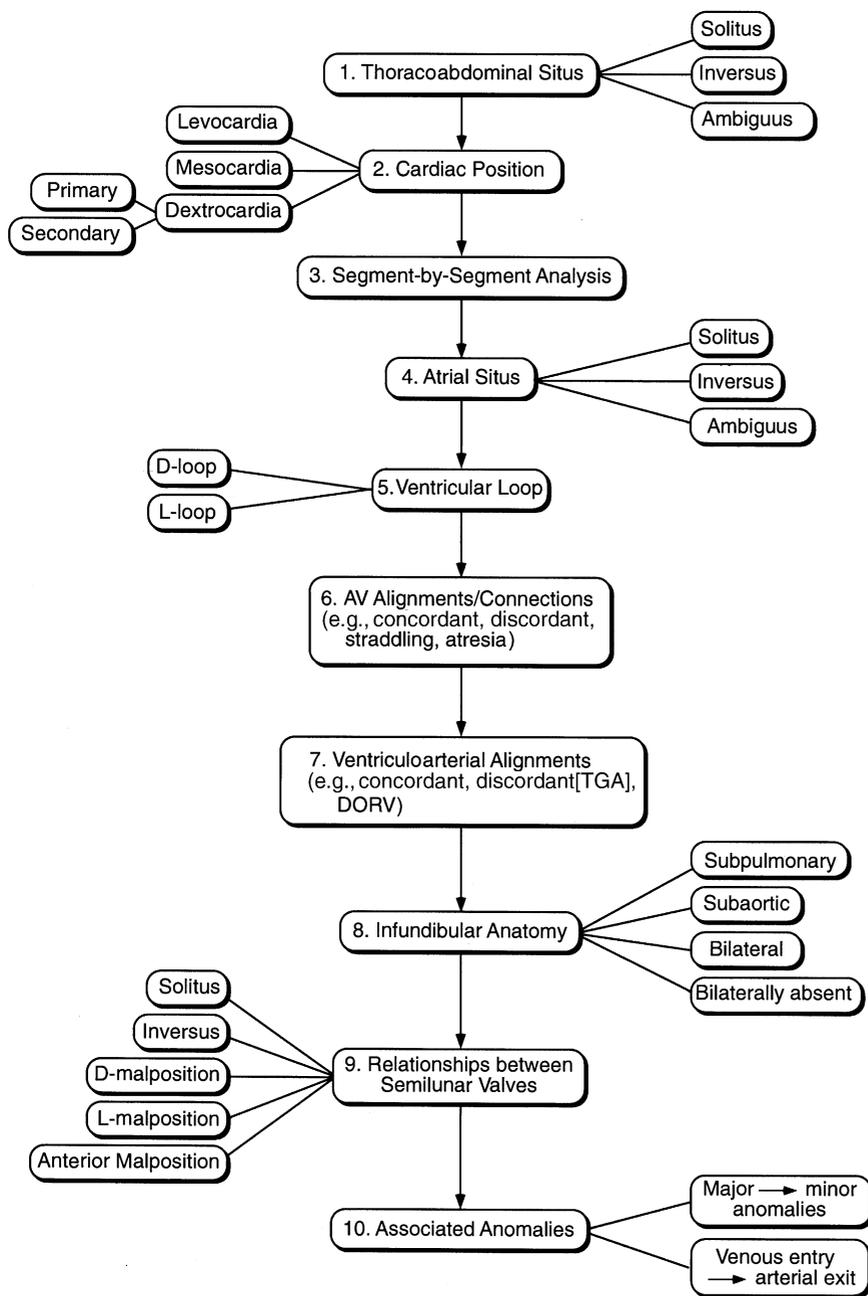

#### 1. Thoracoabdominal Situs (Fig. 52-3)

Before the intracardiac anatomy is considered, the situs of the thoracic and abdominal organs is determined to provide an anatomic framework for further analysis. Normally, the visceral organs are “lateralized.” In other words, the pattern of anatomic organization of the abdominal organs, tracheobronchial tree, and lungs is asymmetrical. In *situs solitus*, the spleen, pancreas, stomach, and sigmoid colon are left-sided; the liver, cecum, and appendix are right-sided; the left lung is bilobed; the left main bronchus is longer and more horizontal compared with the right main bronchus, and the right lung is trilobed. In visceral *situs inversus*, the spatial organization of the abdominal and thoracic organs is mirror-imaged. In other words, there is complete left-right reversal of the position and orientation of the organs. It is worth noting that in visceral *situs inversus*, the pattern of anatomic organization is asymmetrical as it is in *situs solitus*. In *situs ambiguus*, the spatial position and orientation of the abdominal and thoracic organs are abnormally symmetrical and inconsistent. For example, the spleen may be absent, the liver may be midline, both lungs may be bilobed or trilobed, and the bronchi may be similar to each other in length and orientation. Situs ambiguus is typically associated with heterotaxy syndrome, a condition characterized by partial or complete lack of lateral-

ization of the visceral organs, splenic anomalies, congenital heart disease, and extracardiac anomalies. In many patients with heterotaxy syndrome, visceral situs cannot be clearly designated as solitus or inversus—hence the term *situs ambiguus* is used. However, the anatomic organization of the visceral organs in these patients is often partially lateralized, allowing for determination of a “predominant situs.” For example, when the stomach is right-sided and the inferior vena cava is left-sided, the predominant abdominal situs is *situs inversus*, even though the liver may be midline. In such circumstances it is possible to assign a designation of “*situs ambiguus*, predominantly *inversus*” (or “*predominantly solitus*”) for the visceral situs.

#### 2. Cardiac Position (Fig. 52-4)

In levocardia, the heart is predominantly in the left hemithorax with a leftward apex. In dextrocardia, the heart is predominantly in the right hemithorax. Primary dextrocardia is defined as a condition in which the heart is in the right hemithorax due to a structural congenital heart defect. In primary dextrocardia the apex usually points to the right. Secondary dextrocardia is a condition in which the heart is either “pushed” or “pulled” toward the right hemithorax as a result of extracardiac abnormalities. Examples of conditions in which the heart is pushed toward the right hemithorax include left-sided tension pneumothorax, left congenital lobar emphysema, and left-sided diaphragmatic hernia. Conditions in which the heart is pulled toward the right hemithorax include hypoplasia and agenesis of the right lung. In secondary

**FIGURE 52-2.** The ten steps of the segmental approach to diagnosis of congenital heart disease. Before analysis of intracardiac anatomy, the situs of the thoracic and abdominal organs and cardiac position within the thorax must be determined to provide an anatomic framework for further analysis (steps 1 and 2). In describing cardiac anatomy, the following three principles apply: (1) Each cardiac segment must be described in terms of its own unique anatomic features and not according to those of adjacent segments (steps 3–9). For example, the left ventricle is identified according to its internal morphology, particularly its smooth superior septal surface, and not according to the AV valve that connects it with the atria (this usually is the mitral valve but may be both the mitral and tricuspid valves, as in double-inlet left ventricle; it may be a common AV valve or even a tricuspid valve). (2) For each cardiac segment, both its situs and connections must be described specifically and not inferred from each other. (3) Associated malformations (step 10) may be described in order of their hemodynamic importance or in an anatomic order (progressing from the venous entry to the arterial exit of the heart).

dextrocardia, the cardiac apex may point to the left or anteriorly. In mesocardia, the heart is midline and the apex typically points anteriorly or inferiorly.

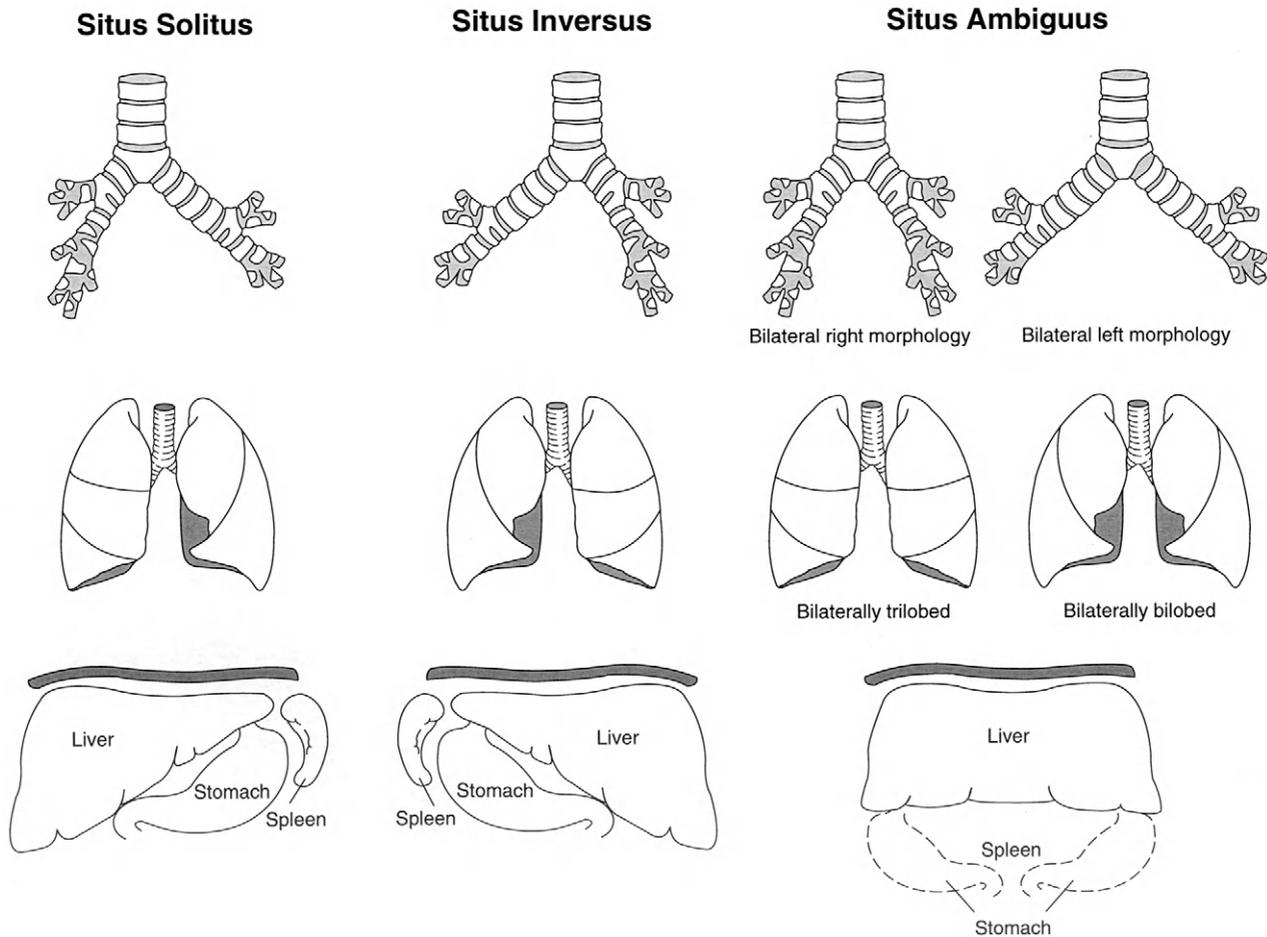

### 3. Segment-by-Segment Analysis of Cardiac Anatomy (see Fig. 52-2)

At this stage, the three main segments and the two connecting segments are analyzed individually (steps 4 through 9 following).

#### 4. Atrial Situs (Fig. 52-5)

The first step in determining atrial situs is to identify the atria according to their morphologic characteristics

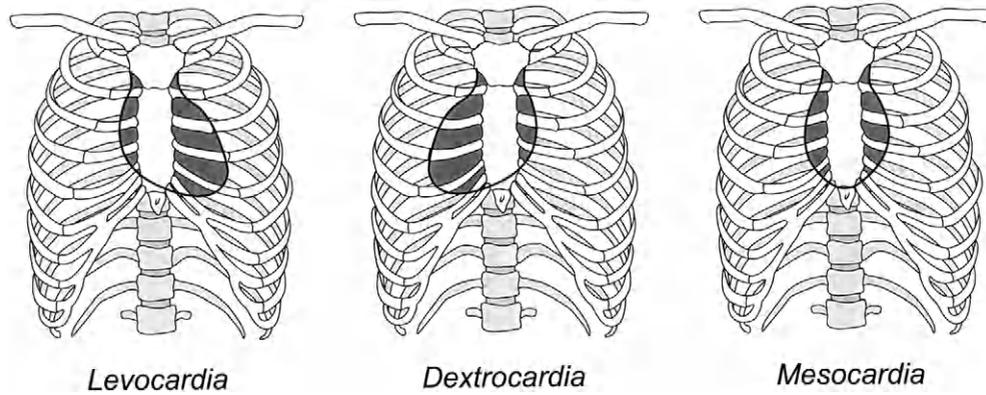

(Table 52-1; see also Fig. 52-5A and B). The right atrium receives the major horn of the sinus venosus, including the superior vena cava, inferior vena cava, and the orifice of the coronary sinus (the cardiac termination of the left horn of the sinus venosus). The right atrial musculature includes the crista terminalis and tinea sagittalis (see Fig. 52-5A). The septal surface of the right atrium features the superior and inferior limbic bands of the fossa ovale. The right atrial appendage is typically broad-based, triangular, and anterior relative to the left atrial appendage (see Fig. 52-5B). In atrial situs solitus (see Fig. 52-5C), the right atrium is right-sided, and in atrial situs inversus, it is left-sided. The left atrium normally receives the pulmonary veins; its septum features septum

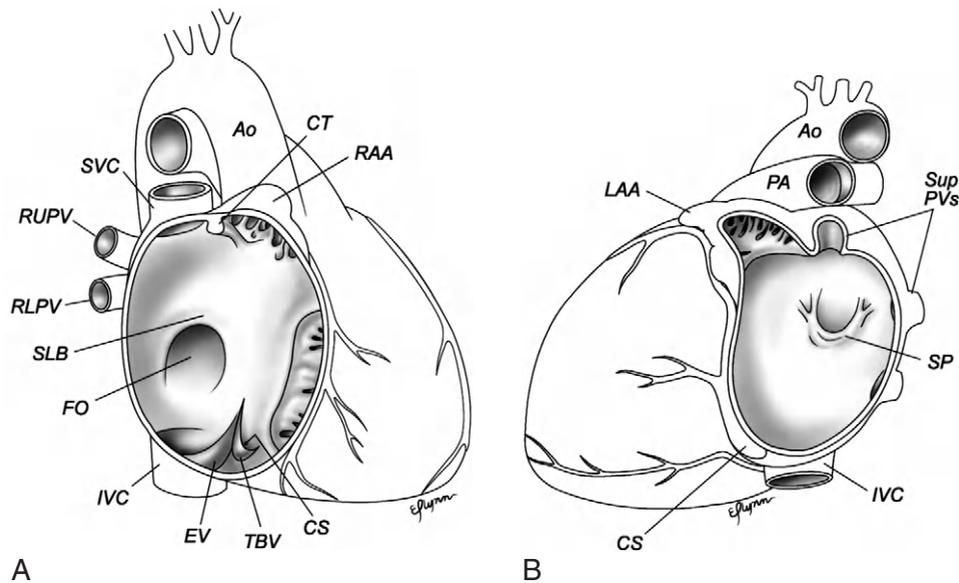

**FIGURE 52-3.** Thoracoabdominal situs. **Top panel,** The morphology of the tracheobronchial tree can be helpful in predicting atrial situs. In situs solitus, the right main bronchus is short and eparterial (its branch for the right upper lobe is over the second branch of the right pulmonary artery) and the left main bronchus is longer and hyparterial (it courses underneath the left pulmonary artery). In situs inversus, the anatomy is a mirror image of that seen in situs solitus. In situs ambiguus, the bronchi can have a bilaterally right or bilaterally left morphology. Bilaterally hyparterial left bronchial morphology can be seen in patients with heterotaxy syndrome and polysplenia, whereas bilaterally eparterial right bronchial morphology is seen in patients with heterotaxy syndrome and asplenia. **Middle panel,** Lung lobation also correlates with atrial situs. A bilobed left lung and a trilobed right lung are typical in situs solitus. In situs inversus, the right lung is bilobed and the left lung is trilobed. As with the tracheobronchial tree, in situs ambiguus the lungs may be bilaterally bilobed or bilaterally trilobed. **Lower panel,** In visceral situs solitus, the liver is right-sided and the stomach and spleen are left-sided. Incomplete lateralization of the abdominal organs with a midline liver and stomach may be seen in patients with heterotaxy syndrome. Splenic anomalies (asplenia, polysplenia, hyposplenia, and a single right-sided spleen) and complex cardiac anomalies are frequent. In patients with heterotaxy syndrome and visceral situs ambiguus, the disposition of the abdominal situs predicts atrial situs less reliably than does the bronchial anatomy.

primum (the flap valve of the foramen ovale) and a narrow-based, elongated posterior appendage. In atrial situs ambiguus, typically seen in patients with heterotaxy syndrome, the anatomic landmarks characteristic of the right and left atria are not sufficient to determine situs (either situs solitus or situs inversus). Often in this situation, the atria are in common, with absence (or presence of only remnants) of the atrial septum, the inferior vena

cava is interrupted between the renal and hepatic segments, there are bilateral superior venae cavae, and the coronary sinus is unroofed. The atrial appendages may be quite similar to each other. Although the distribution of the pectinate muscle has been proposed as a useful marker of atrial identity (Uemura et al, 1995), imaging of the pectinate muscle in living patients has not been consistently achieved.

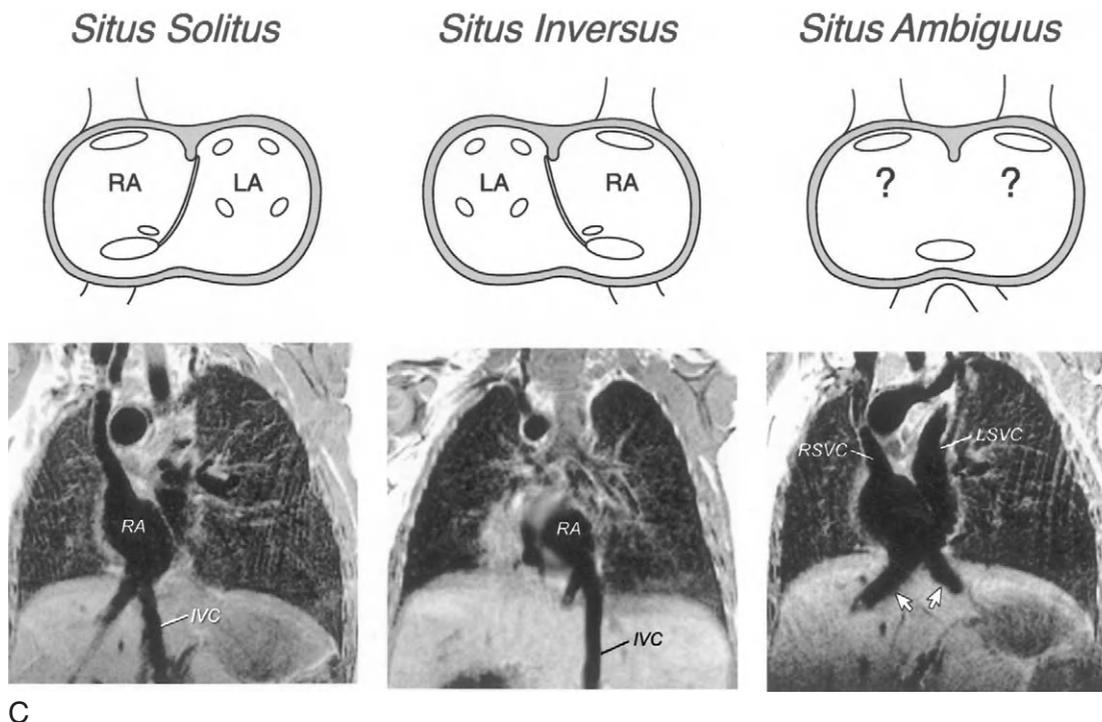

**FIGURE 52-4.** Cardiac position within the thorax. In levocardia, the heart is predominantly in the left hemithorax. In dextrocardia, the heart is predominantly in the right hemithorax. In mesocardia, the heart is midline and the apex typically points anteriorly or inferiorly.

**FIGURE 52-5.** Atrial morphology and situs. **A**, Right atrial morphology: The right atrium (RA) can be divided into three components: 1. The *sinus venosus*, including the orifices of the inferior vena cava (IVC), superior vena cava (SVC), and coronary sinus (CS), which is characterized by its smooth surface (absence of muscular trabeculations). The sinus venosus is separated from the other components of the right atrium by remnants of the embryonic right venous valve system, which includes the thebesian valve (TBV) and the eustachian valve (EV). 2. The *right atrial appendage* (RAA), characterized by a broad-based triangular shape and coarse trabeculations (pectinate muscle). The crista terminalis (CT) is a prominent muscle bar that separates the sinus venosus component of the RA from the trabeculated right atrial appendage and is the site of the sinoatrial node. 3. The *interatrial portion of the AV canal*, which includes the base of the atrial septum and the tricuspid valve annulus. The fossa ovalis (FO) forms the interatrial septum and is characterized by an oval-shaped muscular boundary termed *septum secundum*, or *limbus of the fossa ovalis*, whereas the floor of the fossa is covered by *septum primum*. **B**, Left atrial morphology. Similar to the right atrium, the left atrium can also be divided into three components: 1. Pulmonary venous component. 2. Left atrial appendage (LAA), which is narrow-based and elongated. 3. AV canal region, which is bordered distally by the mitral valve annulus. Note the attachments of *septum primum* (SP) on the left atrial septal surface.

*Continued*

C

**FIGURE 52-5. Cont'd C, Diagram of atrial situs. Upper panel,** In *atrial situs solitus*, the right-sided right atrium receives the major horn of the sinus venosus, including the superior vena cava, inferior vena cava, and the orifice of the coronary sinus. The left-sided left atrium normally receives the pulmonary veins, its septum features septum primum (the flap valve of the foramen ovale) and a narrow-based, elongated posterior appendage (see Table 52-1). In *atrial situs inversus*, the right atrium is left-sided and the left atrium is right-sided. In *atrial situs ambiguus*, typically seen in patients with heterotaxy syndrome, the anatomic landmarks characteristic of the right and left atria are not sufficient to determine situs (either situs solitus or situs inversus). Often in this situation, the atria are in common, with absence (or presence of only remnants) of the atrial septum, the inferior vena cava may be interrupted between the renal and hepatic segments, there may be bilateral superior venae cavae and the coronary sinus may be unroofed. The atrial appendages may be quite similar to each other. **Lower panel,** Coronal plane spin echo MR images in patients with heterotaxy syndrome and atrial situs solitus (*left*), atrial situs inversus (*middle*), and atrial situs ambiguus (*right*). Ao, aorta; LSVC, left superior vena cava; PA, pulmonary artery; RA, right atrium; RLPV, right lower pulmonary vein; RSVC, right superior vena cava; RUPV, right upper pulmonary vein; SLB, superior limbic band of fossa ovale; Sup PVs, superior pulmonary veins.

TABLE 52-1

## Morphologic Criteria for Identification of the Right Atrium and the Left Atrium

Anatomic Feature	Right Atrium	Left Atrium
Veins	Receives the major horn of the sinus venosus: IVC, <sup>°</sup> SVC, <sup>†</sup> CS	Normally receives all pulmonary veins <sup>‡</sup>
Appendage	Broad-based, triangular, anterior	Narrow, finger-like, posterior
Septum	Septum secundum (limbus of the fossa ovale)	Septum primum (valve of the foramen ovale)
Musculature	Crista terminalis, tinea sagittalis	Thin, few trabeculations <sup>§</sup>

<sup>°</sup>In cases with interrupted IVC, the right atrium receives all hepatic veins and CS.

<sup>†</sup>The SVC is not a reliable marker of the right atrium because a persistent left superior vena cava may drain directly into the left atrium when the CS is unroofed. When the CS is unroofed and the IVC is interrupted, the shape, size, and location of the atrial appendages may be used for identification of atrial situs.

<sup>‡</sup>The pulmonary veins are not a reliable marker of the left atrium because of their potential for variable connections.

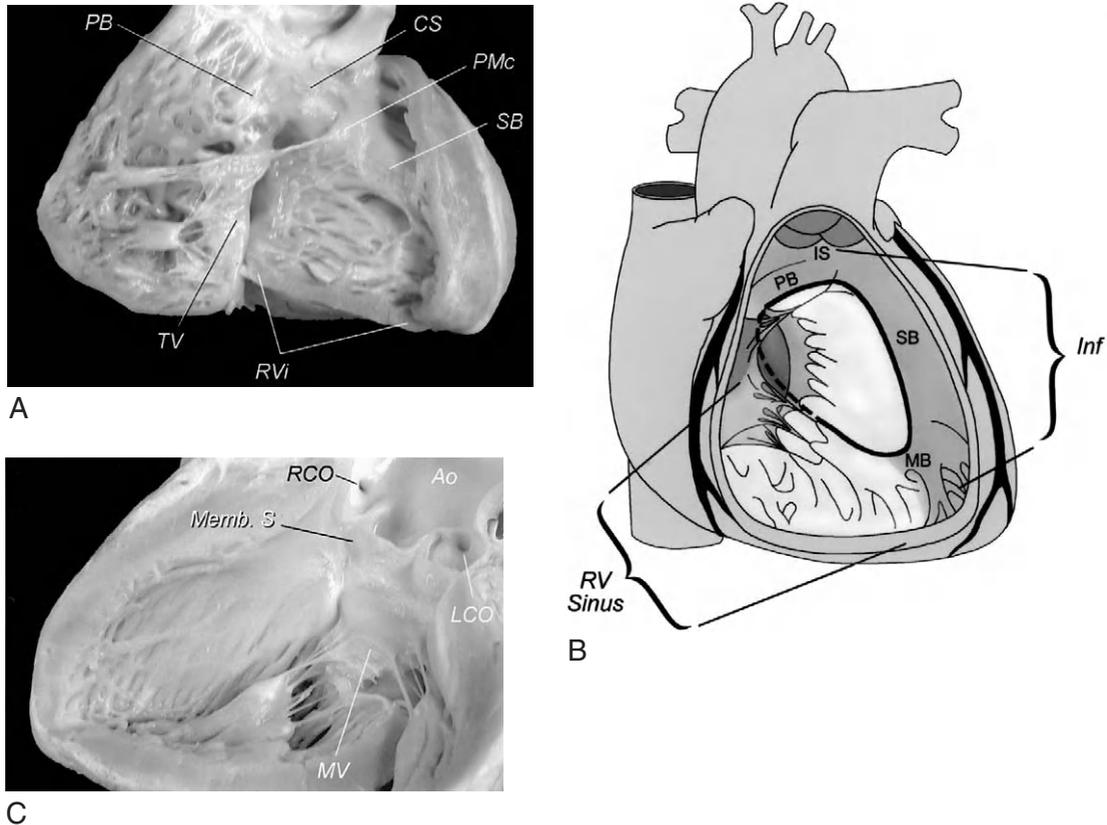

<sup>§</sup>When a persistent left SVC drains directly into the left atrium, a muscle bar similar to a crista terminalis may be present in the left SVC–left atrium junction.

CS, coronary sinus; IVC, inferior vena cava; SVC, superior vena cava.

### 5. Ventricular Loop (Fig. 52–6)

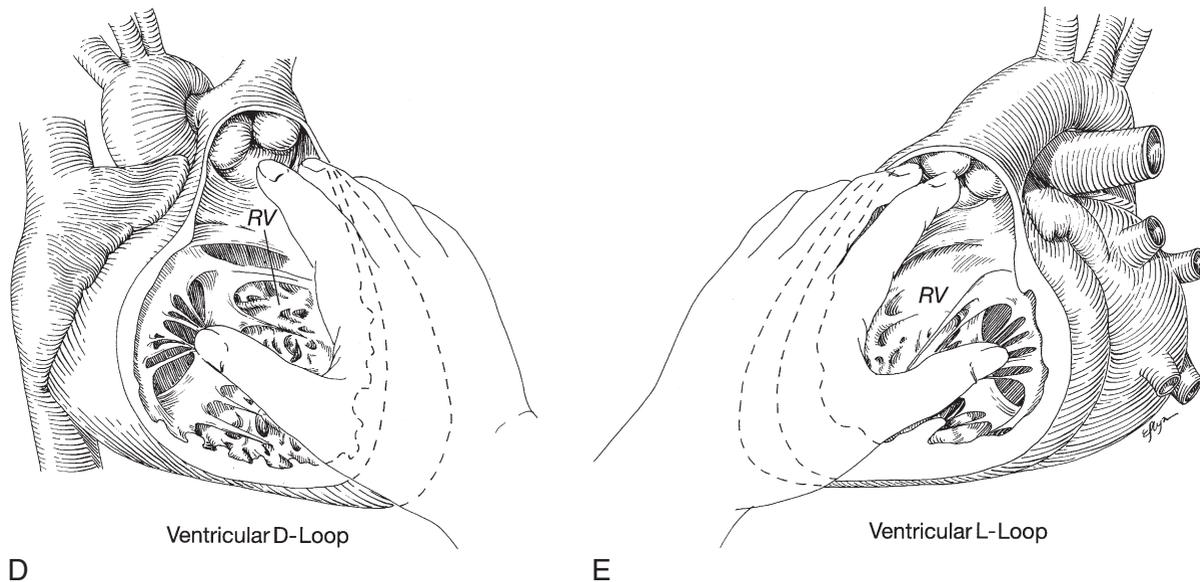

The first step in determining the ventricular loop (situs) is to identify the left and right ventricles. It is important to recognize that between the AV and the semilunar valves (what is generally considered the ventricular mass of the heart), there are three distinct chambers: the left ventricle, the right ventricular sinus, and the infundibulum

(or conus) (Geva et al, 1998; Van Praagh and Van Praagh, 1966, 1967; Van Praagh et al, 1964). The infundibulum is normally well incorporated with the right ventricular sinus, so that their separate identities may be obscured (see Fig. 52–6A and B). However, these chambers have different embryologic and developmental origins. Moreover, in several congenital cardiac anomalies, the infundibulum

**FIGURE 52–6.** Ventricular morphology and situs. **A**, Right ventricular (RV) morphology. Note the coarse trabeculations and the chordal attachments of the tricuspid valve (TV) to the trabeculated septal surface. PB, parietal band; PMc, papillary muscle of the conus; RVi, right ventricular inflow (sinus). **B**, The normal right ventricle comprises two distinct chambers that are well incorporated into each other: the right ventricular (RV) sinus and the infundibulum (Inf). The boundary between the RV sinus and the infundibulum is termed the *proximal os infundibulum* (shown as a dark ring) and is composed of the parietal band (PB), infundibular septum (IS), septal band (SB), moderator band (MB), and the anterior papillary muscle of the tricuspid valve. The RV sinus may be subdivided into an AV canal portion (underneath the septal leaflet of the tricuspid valve) and the trabecular portion, which extends to the RV apex. The infundibulum may be subdivided into a distal (subpulmonary) portion, which includes the distal portion of septal band (SB), infundibular septum (IS), and parietal band (PB), and the proximal infundibulum, which is typically trabeculated and has its own apex adjacent to the RV sinus apex. **C**, Left ventricular morphology. The most reliable morphologic feature of the left ventricle is its smooth superior septal surface. In the normal left ventricle, the finely trabeculated apex (trabeculae carneae) are quite characteristic. However, in a markedly hypertrophied left ventricle, or in a double-inlet or common-inlet left ventricle, the apical trabeculations may be prominently hypertrophied (similar to the trabeculations seen in the right ventricle). In the normal left ventricle, the mitral valve (MV) attaches to two large groups of papillary muscles that attach to the left ventricular free wall. The aortic valve is in fibrous continuity with the mitral valve due to the absence of an intervening conal musculature in this region. More anteriorly, under the right coronary cusp of the aortic valve, conal musculature comprises the infundibular septum. Ao, aorta; LCO, left coronary orifice; Memb. S, membranous septum; RCO, right coronary orifice.

Continued

**FIGURE 52-6. Cont'd D, Ventricular situs.** In ventricular D-loop, the palmar aspect of the right hand is placed over the right ventricular septal surface with the thumb in the tricuspid valve, the fingers in the right ventricular outflow tract, and the dorsum of the right hand facing the right ventricular free wall. **E**, In ventricular L-loop, the palmar aspect of the left hand faces the right ventricular septal surface with the thumb in the tricuspid valve (or inflow), the fingers in the right ventricular outflow tract, and the dorsum of the left hand facing the right ventricular free wall. Using this principle, ventricular situs can be determined regardless of ventricular position in the chest. The same principle also applies to the left ventricle: A right-handed left ventricle will be L-looped and a left-handed left ventricle will be D-looped.

either is poorly incorporated with the right ventricular sinus (e.g., with double-chambered right ventricle [Wong et al, 1991]) or is completely dissociated from the right ventricular sinus and completely associated with the left ventricle (e.g., with anatomically corrected malposition of the great arteries and transposition of the great arteries with posterior aorta [Van Praagh and Van Praagh, 1967; Van Praagh et al, 1971]). The anatomic features of the left ventricle are illustrated in Figure 52-6C.

Once ventricular identity has been established on the basis of morphologic criteria, the type of ventricular loop can be determined (see Fig. 52-6D and E). The clinical relevance of the type of ventricular loop is that it determines the pattern of coronary artery distribution, the disposition of the conduction system, and the internal organization of the ventricular myocardium. Furthermore, ventricular L-loop is associated with increased risks of AV block (either congenital or acquired), Ebstein-like malformation of the left-sided tricuspid valve, and hypoplasia of the left-sided right ventricular sinus. Because the spatial position of the ventricles vary widely, a right-left location relative to each other cannot reliably be used to determine the ventricular loop. Instead, the principle of chirality is used. This method can be applied regardless of the spatial position of the ventricles and requires only the identification of the inflow and outflow tracts, and septal surface of one of the ventricles

(Fig. 52-6D and E). The only circumstance in which the type of ventricular loop cannot be reliably determined is in an anatomically single right ventricle without a recognizable left ventricle or interventricular septum.

#### 6. Atrioventricular Alignments and Connections (Fig. 52-7)

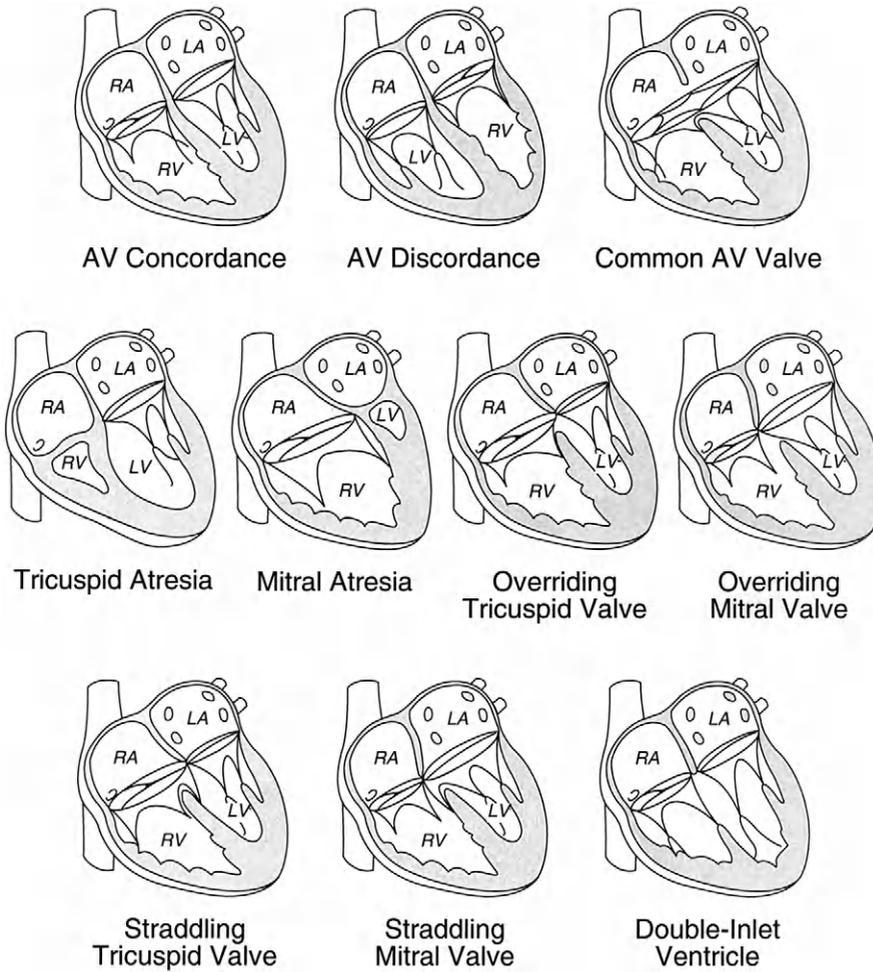

Once the identity and situs of the atria and the ventricles have been established, attention is then focused on the first connecting segment, the AV canal. Figure 52-7 illustrates several representative types of AV alignments and connections. However, it is important to recognize that these patterns are only examples of an anatomic continuum.

#### 7. Ventriculoarterial Alignments (Fig. 52-8)

Next, the outflow of the heart is examined to determine from which cardiac chamber each great artery originates. Figure 52-8 illustrates several representative types of ventriculoarterial (VA) alignments. However, as is the case with AV alignments, it is important to recognize that these patterns are merely examples from a continuous anatomic spectrum.

#### 8. Type of Infundibulum (Conus) (Fig. 52-9)

The infundibulum is the connecting segment between the ventricles and the great arteries. In normal anatomy, there

**FIGURE 52-7.** Diagram illustrating some of the possible atrioventricular (AV) alignments and connections. This step in the segmental approach to congenital heart disease follows identification of atrial and ventricular morphology and situs. LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

is a complete subpulmonary conus with muscular separation between the pulmonary and the AV valves (see Fig. 52-6A and B), whereas the subaortic conus is incomplete, allowing fibrous continuity between the left and noncoronary cusps of the aortic valve and the anterior leaflet of the mitral valve (see Fig. 52-6C). Part of the subaortic conus is normally present in the form of a conal septum represented by the myocardium that separates the anterolateral aspect of the left ventricular outflow tract (the myocardium under the right coronary cusp of the aortic valve) and the right ventricular outflow tract. In some patients, there is an increased distance between the left coronary cusp and the anterior mitral leaflet owing to elongation of the intervalvular fibrosa. In this circumstance, the aortic and mitral valves are said to have *fibrous contiguity*, as opposed to *fibrous continuity*.

Normal-type conus is termed *subpulmonary conus*, indicating the presence of a complete subpulmonary infundibular myocardium and partial absence of the subaortic infundibular free wall.

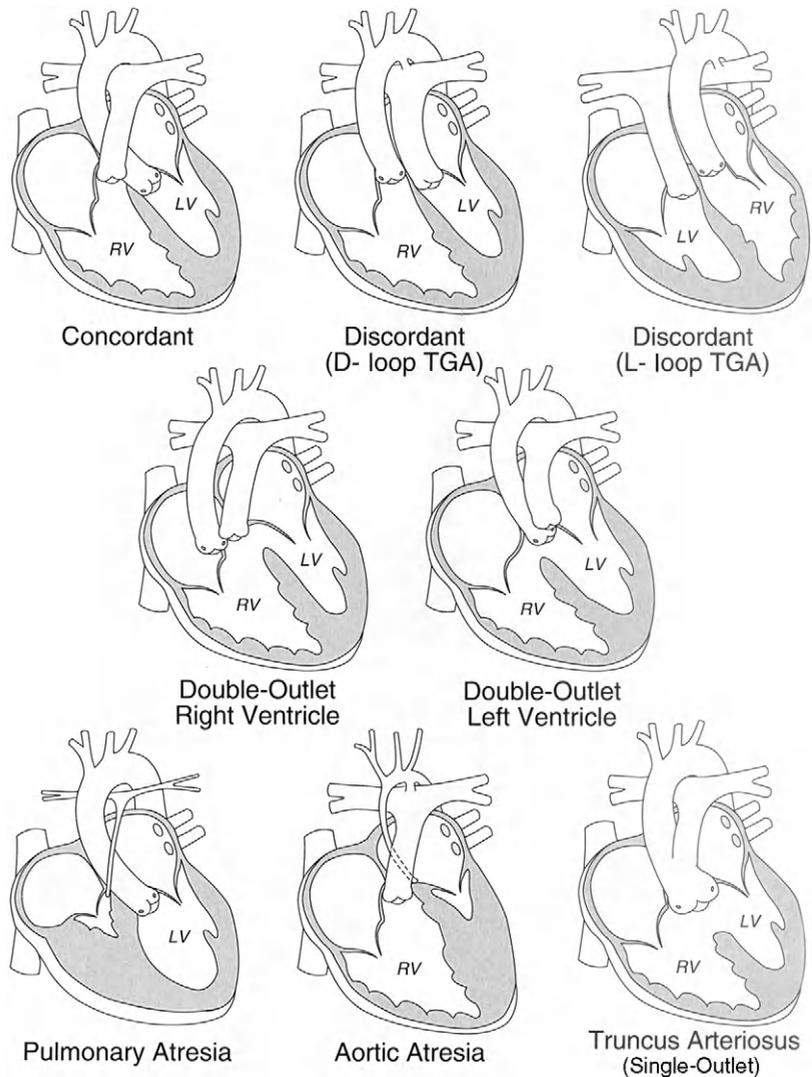

A *subaortic conus* is present when the aortic valve is supported by infundibular myocardium that completely separates it from the AV valve(s). The subpulmonary conus is incomplete with absence of infundibular myocardium between the pulmonary and AV valve(s). A subaortic

conus is often found in transposition of the great arteries. However, it is important to recognize that (1) transposition of the great arteries is a specific type of VA alignment (which great artery originates from which ventricle) and is not defined by the type of conus, and that (2) any type of conus may be present in transposition of the great arteries and any other type of VA alignment (Pasquini et al, 1993).

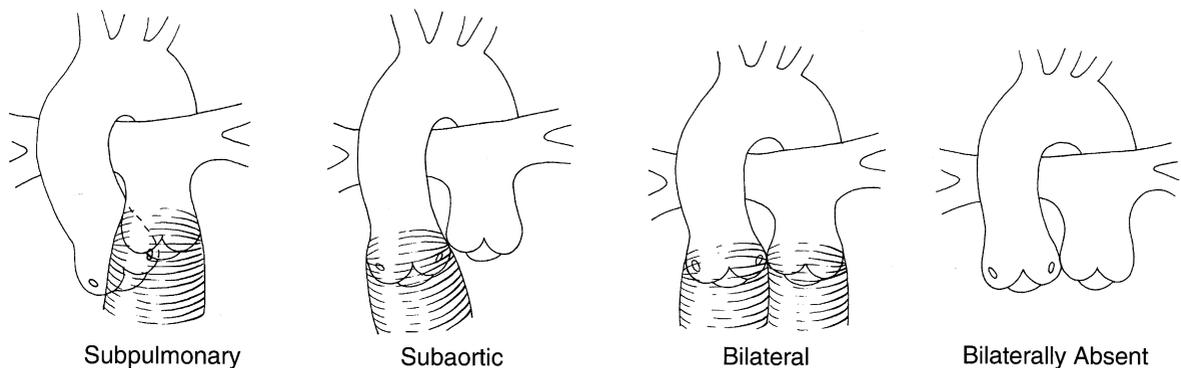

*Bilateral conus* is present when both semilunar valves are completely separated from the AV valve(s) by infundibular myocardium. Although a bilateral conus is commonly associated with a double outlet right ventricle, it is important to recognize that (1) a double outlet right ventricle is a specific type of VA alignment (which great artery originates from which ventricle) and is not defined by the type of conus; and (2) any type of conus may be present in a double outlet right ventricle and any other type of VA alignment.

*Bilaterally absent conus* is the least common type of infundibulum. It is present when both semilunar valves are in direct fibrous continuity with the AV valve(s) as a result of absence of infundibular myocardium.

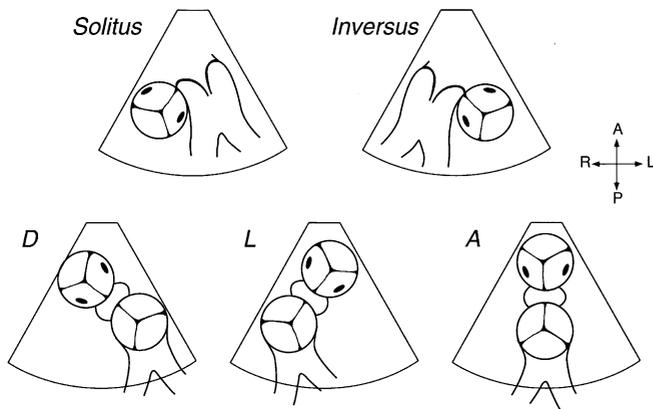

**9. Relationship between Semilunar Valves (Fig. 52-10)**  
This step in the segmental approach to congenital heart disease describes the spatial relationship between the

**FIGURE 52-8.** Diagram illustrating some of the possible ventriculoarterial (VA) alignments and connections. Note that the type of VA alignment is determined by which great artery arises entirely or predominantly from which ventricle. It is clinically impractical to accurately and reproducibly determine great arterial origin from either ventricle in terms of percent origin. Specifically, the so-called “50% rule” is not applicable in vivo. This is due to complex three-dimensional relations between the ventricles and the great arteries and the complex geometric nature of the ventricular septum and cardiac motion in systole and diastole and with respiration. LV, left ventricle; RV, right ventricle; TGA, transposition of great arteries.

**FIGURE 52-9.** Type of infundibulum (conus). In general, there are four types of conus: 1. *subpulmonary*, with absence of subaortic infundibular free wall (found in the normal heart); 2. *subaortic*, with absence of subpulmonary infundibular free wall (often found in transposition of the great arteries); 3. *bilateral conus* (commonly found in patients with a double-outlet right ventricle, but can be rarely found in patients with TGA and even in patients with normally related great arteries); and 4. *bilaterally absent* (found in some patients with a double-outlet left ventricle).

**FIGURE 52-10.** Relationship between semilunar valves. The diagram illustrates several common patterns as seen on a transthoracic echocardiographic parasternal short-axis view. It must be recognized, however, that the relationship depicted constitute samples from an anatomic continuum. A, anterior; R, right; L, left; P, posterior.

aortic and pulmonary valves. Although the spatial relationships between the semilunar valves are often associated with predictable patterns of VA alignments, there are many exceptions to these rules.

### 10. Associated Anomalies

Once the three main cardiac segments and the two connecting segments have been analyzed, all associated cardiovascular anomalies are systematically examined and described. To provide a logical and consistent description of all associated anomalies, they can be described either in order of their hemodynamic importance (from major to minor anomalies) or in an anatomic order (progressing from the venous entry to the arterial exit of the heart).

## CONCLUSIONS

The segmental approach to anatomic analysis of CHD allows an accurate description of all known forms of cardiac anomalies and can be applied to patients of all ages using diagnostic imaging modalities such as angiography, echocardiography, computed tomography, and magnetic resonance imaging. In rare circumstances when the morphology does not conform to a clearly defined diagnostic category, it is essential to provide an accurate detailed description of the anatomy using tools provided by the segmental approach to CHD.

# Embryology and Development of the Cardiovascular System

Kathryn L. Maschhoff and H. Scott Baldwin

The heart is the first organ to form in vertebrates, arising through a complex series of morphogenetic interactions involving cells from several embryonic origins. Long before it has obtained its final four-chambered adult form, the heart must function to support the rapidly growing embryo. The combination of the complex morphogenetic events necessary for cardiogenesis and the superimposed hemodynamic influences may contribute to the exquisite sensitivity of the developing heart to perturbations. This phenomenon is reflected in the estimated 10% incidence of severe cardiac malformations observed in spontaneously aborted fetuses and in the observation that approximately 1 in 100 children is born with congenital heart disease (CHD), which remains the leading cause of noninfectious death in the first year of life.

## MYOCYTE SPECIFICATION AND FORMATION OF THE PRIMITIVE HEART TUBE

Beginning soon after gastrulation (about embryonic day 20 in humans), progenitor cells within the anterior lateral plate mesoderm become committed to a cardiogenic fate in response to an inducing signal thought to emanate from the adjacent endoderm (Schultheiss et al, 1995). This heart-forming region of the developing embryo is primarily restricted to a crescent-shaped region of splanchnic mesoderm lateral and rostral to the forming foregut invagination. The specific signaling molecule(s) responsible for cardiogenic commitment remains to be identified, although bone morphogenetic proteins (BMPs) and fibroblast growth factor 8 (FGF-8) appear to be crucial for this step (Alsan and Schultheiss, 2002; Schultheiss et al, 1995). Cardiac precursors form a bilaterally symmetrical cardiogenic “field,” or cardiogenic crest (Redkar et al, 2001).

In *Drosophila*, formation of the dorsal vessel, which functions as a heart, is dependent on tinman, a member of the homeodomain family of proteins that were initially described to play a role in establishing regional identity of cells and organs during embryogenesis. The expression pattern of *NKX2.5*, a member of the *NKX2* homeodomain family (the vertebrate homologues of tinman), overlaps (but does not entirely coincide with) the crescent-shaped heart-forming region. Unlike tinman, *NKX2.5* is not required for cardioblast specification. However, *NKX2.5* does have a role in cardiac development. In humans, several families

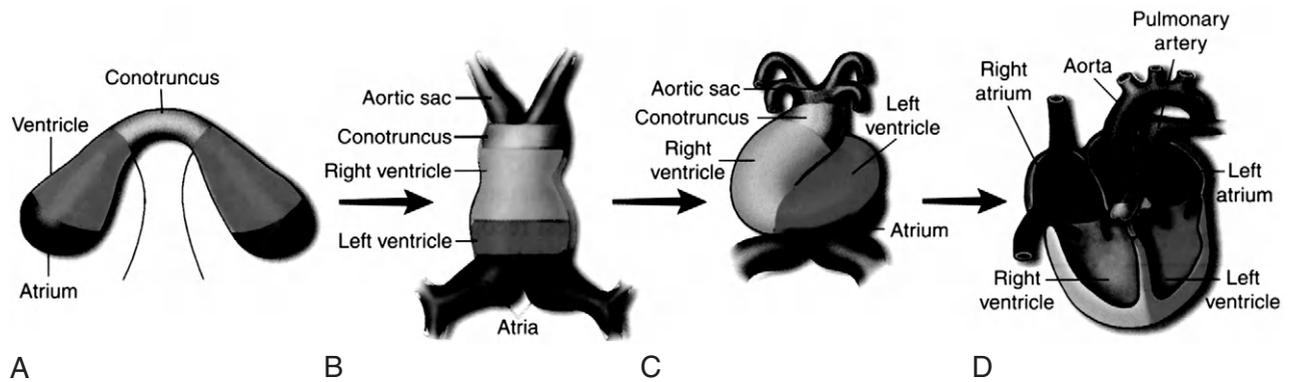

with atrial septal defects, and conduction abnormalities have heterozygous mutations in *NKX2.5* (Schott et al, 1998), and sporadic cases of a wide variety of congenital heart defects also are associated with heterozygous mutations in *NKX2.5* (Benson et al, 1999; Goldmuntz et al, 2001; Kasahara et al, 2000; Tanaka et al, 1999). A recently identified transcription factor called myocardin activates the transcription of a variety of cardiac genes, including *NKX2.5*, and appears to play a crucial role in early differentiation of cardiomyocytes (Wang et al, 2001).

Simultaneously with myocardial differentiation, endocardial differentiation begins in the adjacent splanchnopleuric mesoderm. The endocardium arises almost exclusively by a process known as *vasculogenesis*, the de novo organization of blood vessels by in situ differentiation of endothelial cells from mesoderm. Late in the third week, as the embryo folds, the parallel cardiac primordia fuse at the midline to form the primitive cardiac tube (DeHaan, 1965; Rosenquist and DeHaan, 1966). It has generally been stated that two separate endothelial tubes develop in the lateral body folds and then “fuse” in the midline to form the single heart (O’Rahilly and Muller, 1987). However, a close analysis of mouse heart tube formation suggests that endothelial cells of the precardiac mesoderm organize into an extensive vascular plexus, which then undergoes extensive remodeling during approximation of the lateral body folds to form a single endothelial channel (DeRuiter et al, 1992). The result is a straight heart tube with an outer myocardium and an inner endocardium separated by an extracellular matrix (ECM) known as the *cardiac jelly*.

## CARDIAC CHAMBER FORMATION

The primitive heart begins to beat by 4 weeks. The flow of blood is initially an ebb and flow but soon becomes unidirectional. As the straight heart tube takes shape, four distinct tubular segments form in a temporal sequence along the anteroposterior (AP) axis (Fig. 53–1). The primitive right and left ventricles are the first to be distinguished, followed by the atrioventricular canal segment. The sinoatrial segment forms most caudally and has distinct left-right asymmetry, with the right and left limbs of this segment later contributing to the right and left atria, respectively. The conotruncus is the last segment to form and lies in the most anterior portion of the heart tube. This patterning of the heart along the AP axis to form the conotruncus, ventricles, and atria is set up in the bilaterally symmetrical cardiac primordia before formation of the primitive heart tube (Yutzey and Bader, 1995).

Atrial and ventricular cardiac myocytes express distinct subsets of cardiac muscle genes that confer the contractile, electrophysiologic, and pharmacologic properties unique to each chamber (Lyons, 1994). For example, two related transcription factors, *dHAND* (Srivastava et al, 1995) and *eHAND* (Cserjesi et al, 1995), exhibit a complementary expression pattern in the primitive right and left ventricle segments, respectively (Srivastava et al, 1997; Thomas et al, 1998). Deletion of the *dHAND* gene in mice results in hypoplasia of the right ventricle segment, suggesting

**FIGURE 53-1.** (See also Color Plate 53-1.) Schematic diagram of cardiogenesis. Bilaterally symmetrical cardiac progenitor cells (A) are prepatterned to form distinct regions of the heart, as shown in color-coded fashion. The precardiac mesodermal cells give rise to a linear heart tube (B), which forms a rightward loop (C) and begins to establish the spatial orientation of the four-chambered mature heart (D). (Adapted from Srivastava D, and Olson EN: *Knowing in your heart what's right*. *Trends Cell Biol.* 7:447, 1997.)

that a single gene defect can result in specific ablation of an entire chamber of the heart (Srivastava et al, 1997).

Development of the ventricles is affected by hemodynamic influences in the developing embryo. In chick embryos, reduction of left ventricular preload by ligation of the left atrium results in marked hypoplasia of the left ventricle (Sedmera et al, 1999, 2002). The hypoplasia was accompanied (and probably caused) by a decrease in cardiomyocyte proliferation in the trabeculae and compact myocardium of the left ventricle. Thus, adequate loading is crucial for normal ventricular morphogenesis as well as proper formation of the atrioventricular and semilunar valves (Hove et al, 2003). It is not yet known how the mechanical stimulus is translated into changes in cell division, but the finding that FGF-2 is decreased after left atrial ligation implicates changes in the levels of key growth factors in normal cardiac chamber growth as well as in the pathogenesis of hypoplastic left heart syndrome (HLHS).

After the initial morphogenetic cues have resulted in a four-chambered heart, the individual chambers continue to grow and develop. The myocardium of the ventricles becomes trabeculated, a feature that enables the myocardium to increase its mass before the establishment of the coronary circulation. As development progresses, the outer layer of the myocardium becomes compacted and the trabecular portion becomes more solid. Genes involved in the regulation of both of these processes, trabeculation and compaction, have been identified. Mice homozygous for a null mutation in the retinoid X receptor- $\alpha$  gene (*RXR $\alpha$* ) display ventricular chamber hypoplasia and have a defect in compaction of the myocardium (Chen et al, 2002; Sucof et al, 1994), similar to what has been referred to as “spongy” myocardium in children with noncompaction of the ventricular wall (Angelini et al, 1999). A similar phenotype is seen in mice carrying mutations in the *N-myc*, *VCAM1*, *TEF1*, and neurofibromatosis (*NF1*) genes. Mice deficient for the peptide growth factor neuregulin-1 (expressed in the endocardium) or for its receptors, the *ErbB2/ErbB4* complex (expressed in the myocardium), fail to undergo ventricular trabeculation (Gassmann et al,

1995; Kramer et al, 1996; Lee et al, 1995; Meyer and Birchmeier, 1995). Thus, the neuregulin-signaling pathway between the endocardium and myocardium is a very specific and essential step in ventricular morphogenesis.

### CARDIAC LOOPING AND ESTABLISHMENT OF LEFT-RIGHT CARDIAC ASYMMETRY

Cardiac looping is central to proper alignment of the heart and begins with rightward looping of the heart tube, with the caudal portion of the tube moving to a more anterior and dorsal position. The cellular mechanisms that drive cardiac looping remain poorly understood, but it has been postulated that differential rates of proliferation of cardioblasts, regional differences in intracardiac actin bundles, or altered cell adhesion across the heart tube may be involved. Abnormalities in the process of cardiac looping probably underlie a number of congenital heart defects. Folding of the heart tube positions the inflow cushions adjacent to the outflow cushions and involves extensive remodeling of the inner curvature of the looped heart tube. In the primitive looped heart, the segments of the heart are still in a linear pattern and must be repositioned considerably for alignment of the atrial chambers with the appropriate ventricles, and of the ventricles with the aorta and pulmonary arteries. Looping begins to convert the “in series” heart to an “in parallel” arrangement. Blood streams from the right and left horns of the sinus venosus spiral around each other as they pass through the ventricles and outflow tract. As a result of this spiral streaming, blood from the left ventricle passes to the left fourth aortic arch, whereas the right ventricular output passes to the left sixth aortic arch. As the developing venous system remodels, the systemic venous return comes to flow exclusively into the right atrium. The atrioventricular canal, which originally connects the left atrium and left ventricle, comes to open, by a mechanism that is not yet clear, into both atria. The atrioventricular septum (AVS) begins to divide the common atrioventricular canal (AVC) into a right and a left AVC, and subsequently shifts to the right to position

the AVS over the muscular ventricular septum. This allows the right AVC and the left AVC to be aligned with the right and the left ventricles, respectively. Simultaneously, the conotruncal region becomes divided into the aorta and pulmonary trunks as the conotruncus moves toward the left side of the heart such that the conotruncal septum is positioned over the AVS. The rightward shift of the AVS and the leftward shift of the conotruncus convert the single-inlet, single-outlet heart into a four-chambered heart that has separate atrial inlets and ventricular outlets (Mjaatvedt et al, 1999).

Arrest or incomplete movement of the AVS or conotruncus might result in malalignment of the inflow and outflow tracts. Failure of the AVS to shift to the right would result in communication of the right and left AVCs with the left ventricle, a condition known as double-inlet left ventricle (DILV). Incomplete shifting may be the basis for “unbalanced” AVC defects in which the right AVC only partly communicates with the right ventricle. Similarly, if the conotruncal septum fails to shift to the left, both the aorta and pulmonary artery would arise from the right ventricle, causing a double-outlet right ventricle (DORV). From this embryologic perspective, it is not surprising that DOLVs and DILVs are rarely, if ever, seen clinically, whereas any abnormality in cardiac looping can be associated with DILV or DORV.

Although the molecular basis for the process of cardiac looping is unknown, the pathways that control the direction of cardiac looping along the left-right axis have recently been elucidated. The heart is the first organ to break the bilateral symmetry present in the early embryo, and the direction of its looping reflects a more global establishment of left-right asymmetry throughout the embryo that affects the visceral organs, including the lungs, liver, spleen, and gut. Initial clues to the origin of left-right asymmetry came from clinical studies describing a condition known as Kartagener syndrome in which affected persons have situs inversus totalis, with mirror-image reversal of all organs. Men with Kartagener syndrome also are infertile secondary to immotility of sperm and subsequently both men and women were found to have immotile cilia (Ajzelius, 1976). Recently, a mechanism for a link between ciliary beating and left-right asymmetry has become clear. A region of the early symmetrical embryo known as the *node* contains ciliary processes that beat in a vortical fashion in a counterclockwise direction. The ciliary beating generates a leftward flow of fluid that moves morphogens to the left side of the embryo (Essner et al, 2002; Nonaka et al, 1998, 2002; Okada et al, 1999; Wagner and Yost, 2000). The resultant asymmetrical distribution of morphogens sets up an asymmetrical cascade of signaling molecules, resulting in left- and right-sided programs of gene expression that ultimately control asymmetrical development of the visceral organs (reviewed in Mercola, 1999; Mercola and Levin, 2001). Not all components of the cascade are evolutionarily conserved; however, in all species observed to date, the cascade culminates in left-sided expression of nodal, a transcription factor that induces rightward looping of the midline heart tube, the first overt sign of embryonic left-right asymmetry. Ultimately, the nodal-dependent pathway results in expression of a homeodomain protein, Ptx2, on the left side of

the visceral organs and repression of Ptx2 on the right. Asymmetrical expression of Ptx2 appears to be sufficient for establishing the left-right asymmetry of the heart, lungs, and gut.

Disorders of asymmetry have significant clinical implications. Patients with situs inversus totalis have a well-coordinated reversal of asymmetry and thus have a low incidence of defects in visceral organogenesis. However, the majority of patients with defects have viscerotaxial heterotaxy and thus have randomization of cardiac, pulmonary, and gastrointestinal situs. Heterotaxy almost always results in complex congenital heart defects. Often either the right or the left side predominates, with patients having either bilateral right-sidedness (asplenia syndrome) or bilateral left-sidedness (polysplenia syndrome). Mutations in pathway members are found in some patients with heterotaxy (Kosaki and Casey, 1998; Kosaki et al, 1999; Maeyama et al, 2001). Familial cases of heterotaxy also have led to identification of mutations in a zinc-finger transcription factor, *ZIC3*, that result in axis abnormalities (Gebbia et al, 1997).

## SEPTATION AND VALVULOGENESIS

### Formation of the Endocardial Cushions

The initial event in cardiac septation is the formation of the endocardial cushions (EDCs), regional swellings of extracellular matrix that provide valvelike function in the primitive heart, and are the primordia of the atrioventricular, conotruncal, and interventricular septa, as well as the atrioventricular and semilunar valves. Formation of the endocardial cushions begins with expansion of the extracellular matrix, known as the cardiac jelly, in the atrioventricular junction and outflow tract regions of the heart tube. Components of the cardiac jelly, which separates the endocardium and the myocardium, are synthesized primarily by the myocardium, with some contribution from the endocardium. In response to signals from the myocardium, including proteins in the transforming growth factor- $\beta$  (TGF- $\beta$ ) signaling pathway (Nakajima et al, 2000), some endocardial cells in the atrioventricular junction and outflow regions undergo a transition to a mesenchymal phenotype—a process termed epithelial-mesenchymal transformation (EMT). They then delaminate from the endocardial surface and migrate into the extracellular matrix. The ability to induce EMT in endocardial cells is restricted to myocardium in the regions of the developing endocardial cushions. Similarly, endocardial cells in the regions of the cushions are unique in their ability to respond to signals produced by the atrioventricular and outflow tract (OFT) myocardium (Eisenberg and Markwald, 1995; Mjaatvedt et al, 1999).

Following EMT, the cushion mesenchyme expands as the endocardium-derived mesenchymal cells proliferate. As they leave the zone of proliferation and migrate toward the myocardium, mesenchymal cells down-regulate genes associated with proliferation and begin to differentiate. Finally, as the cushions remodel to form the septa and valves, some cushion cells undergo apoptosis. Thus, morphogenesis of the endocardial cushions appears to be the

result of a carefully orchestrated sequence of cell proliferation, differentiation, and cell death (Zhao and Rivkees, 2000).

### **Atrioventricular Canal Septation and Atrioventricular Valve Formation**

Septation of the atria begins at the end of the fourth week of gestation, when the septum primum begins to grow down from the roof of the atrium, extending into the atrium from the superioposterior wall (Fig. 53–2A). During the fifth week, the free edge of the septum primum grows caudally toward the atrioventricular canal, diminishing the size of the foramen connecting the atria, the ostium primum. By the end of the sixth week, the septum primum has fused with the superior and inferior endocardial cushions, which fuse to form the atrioventricular septum, to divide the atrioventricular canal into the right (tricuspid) and left (mitral) inlets. Fusion of the septum primum with the atrioventricular cushions results in obliteration of the ostium primum. Prior to closure of the ostium primum, apoptosis near the superior edge of the septum primum results in small perforations that coalesce to form the ostium secundum, which allows continued right-to-left shunting of blood. While the septum primum is forming, the septum secundum begins to grow from the ceiling of the right atrium, just adjacent to the septum primum (see Fig. 53–2B). In contrast with the septum primum, the septum secundum is thick and muscular. Growth of the septum secundum stops short of the floor of the right atrium, resulting in the foramen ovale. For the remainder of fetal life, blood flows from the right atrium to the left atrium through two staggered openings, the foramen ovale, near the floor of the right atrium, and the foramen secundum, near the roof of the left atrium (see Fig. 53–2C).

Septation of the atria and the atrioventricular canal occurs simultaneously with the shift of the atrioventricular canal to the right, so that at the time of septation, the resulting atrioventricular channels are aligned with their respective atria and ventricles (Fig. 53–3). The mechanism by which the atrioventricular canal, which originally connects the left atrium and left ventricle, comes to open into both atria is not yet clear. Analysis of the developing human heart suggests that the inlet portion of the right ventricle is derived from the embryonic right (outlet) ventricle (Lamers et al, 1992). The atrioventricular valves themselves are derived in equal proportions from endocardial cushion tissue and ventricular myocardium (Lamers et al, 1995).

Defects in atrioventricular septation—atrioventricular septal defect (AVSD)—occur in 7.3% of human congenital heart malformations. The most common association with AVSD is trisomy 21. Because of synteny between human chromosome 21 and the distal region of mouse chromosome 16, the trisomy 16 mouse has been used as an animal model of the heart defects seen in trisomy 21. The atrioventricular canal defects (AVCDs) in these mice appear to result from inadequate remodeling of the inner curvature of the heart, which results in failure of the atrioventricular junction to expand to the right (Webb et al, 1999). In addition, these embryos exhibit variability in the connection of the primary atrial cardiac segment to the body (known

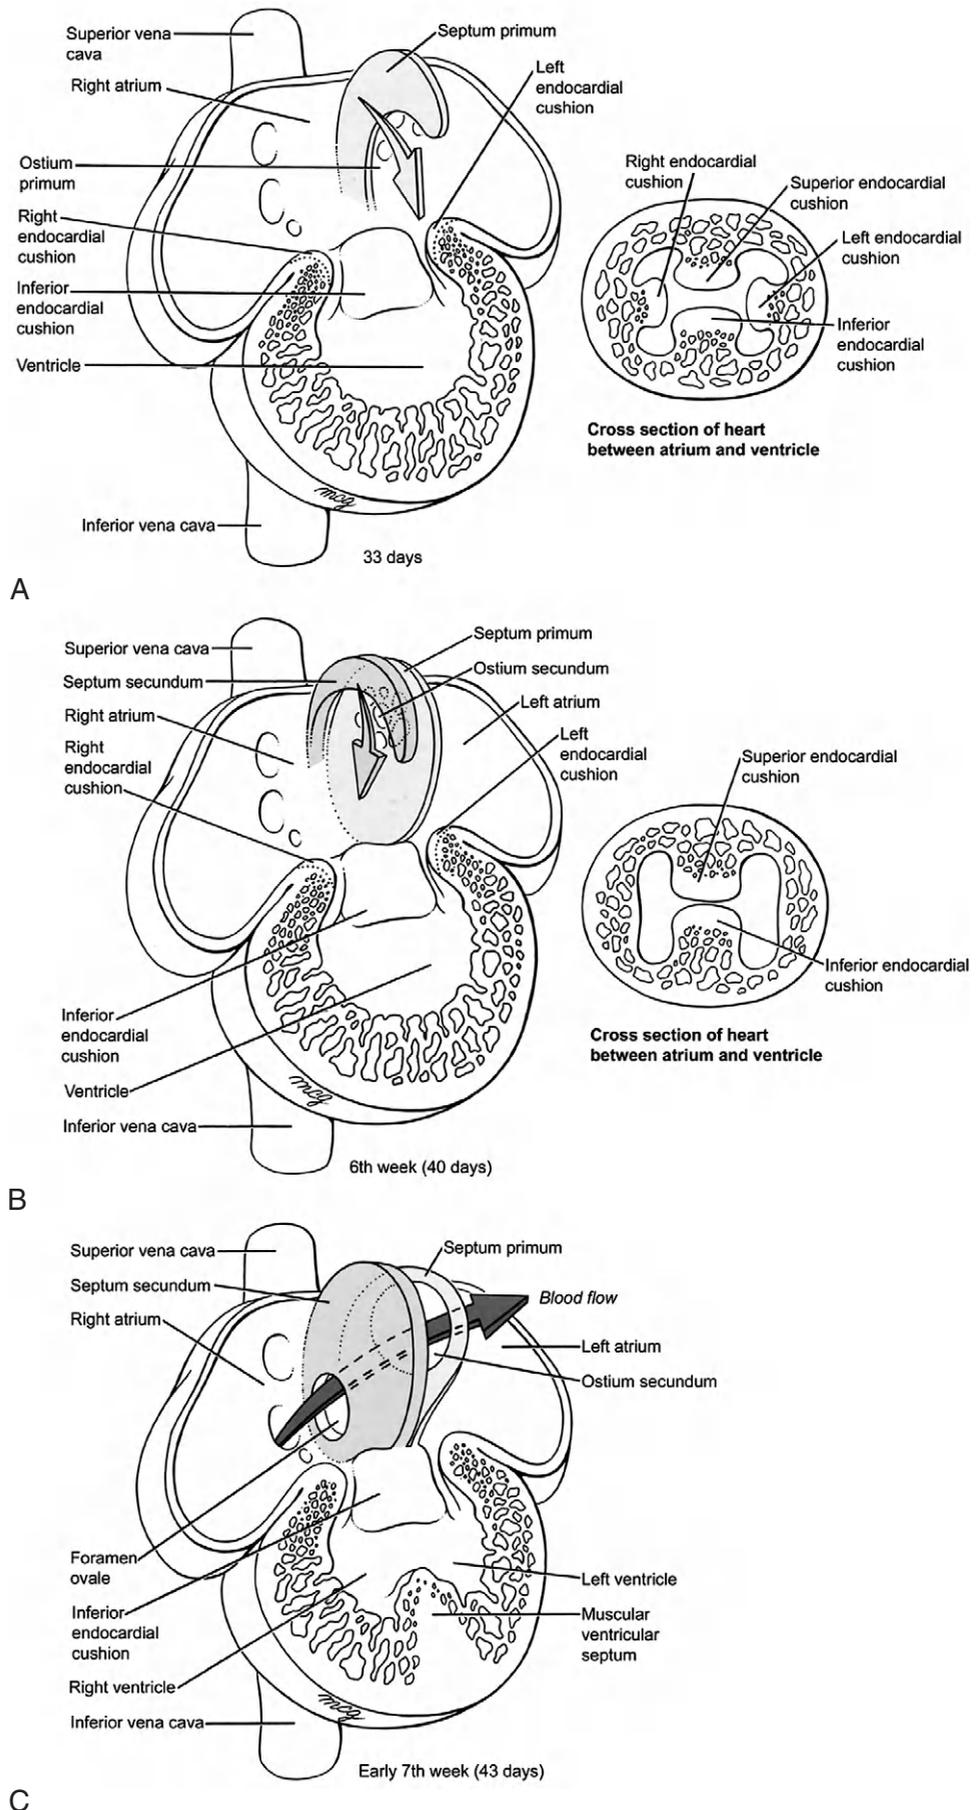

as the dorsal mesocardium). A derivative of the dorsal mesocardium, the spina vestibuli, fails to undergo the forward growth required for proper division of the atrioventricular canal.

Atrial septal defects (ASDs), ventricular septal defects (VSDs), and AVCDs have been seen as components of several disorders with mendelian inheritance. One such autosomal dominant disorder, Holt-Oram syndrome, is characterized by congenital heart defects, most often ASDs and VSDs, and characteristic upper limb malformations. Holt-Oram syndrome is caused by mutations in *Tbx5*, a member of the T-box family of transcription factors (Li et al, 1997b). Of interest, overexpression of *Tbx5* in mouse or chick embryos results in cardiac defects similar to those seen with Holt-Oram syndrome, suggesting that normal embryogenesis requires precise regulation of *Tbx5* dosage (Liberatore et al, 2000). As mentioned previously, mutations in *NKX2.5* can result in ostium secundum ASDs (which probably results from incomplete coverage of the ostium secundum by the septum primum) (Schott et al, 1998). AVSDs are commonly seen with heterotaxy syndromes. AVCDs are the most frequent defects seen in the asplenia (Ivemark) syndrome (i.e., right isomerism) and are seen as a component of the complex malformations seen with polysplenia (Pierpont et al, 2000). Clearly, an understanding of development of the atrioventricular region of the heart will provide insight into the etiology of a common class of congenital cardiac malformations.

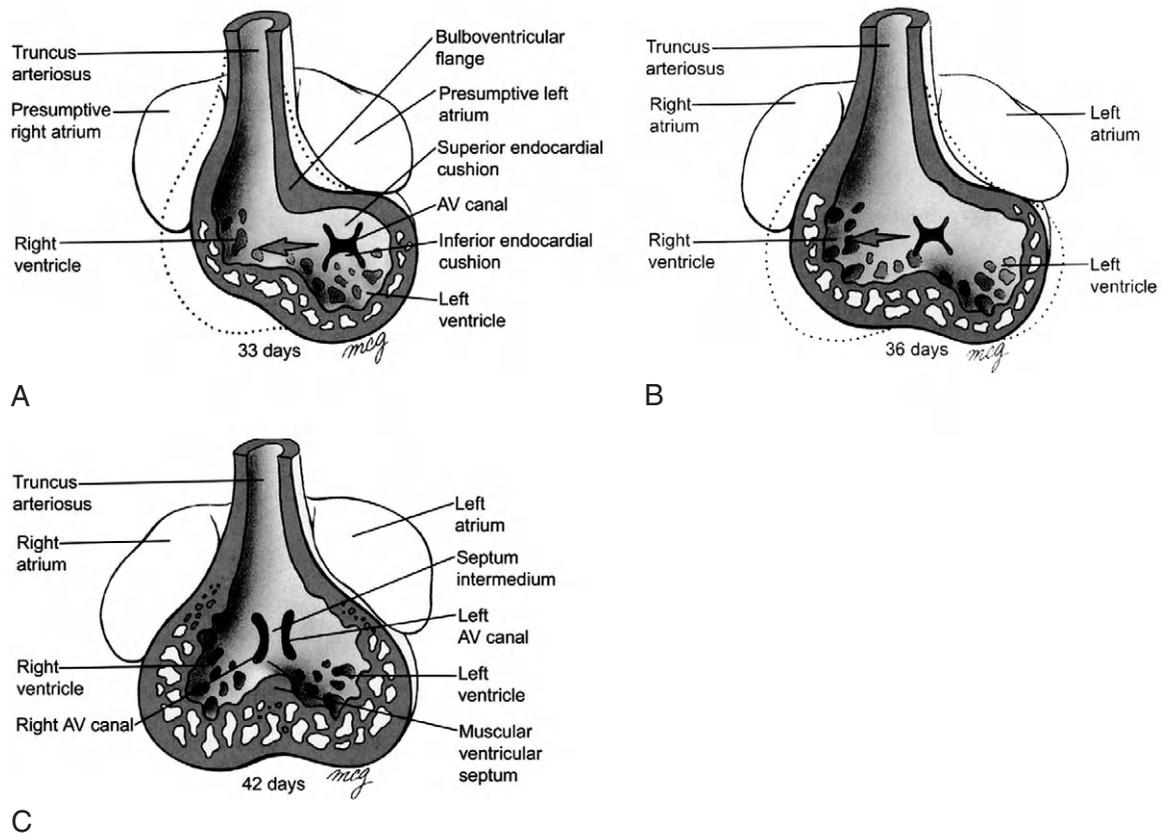

### **Conotruncal and Aortic Arch Development**

Congenital cardiac defects involving the cardiac outflow tract, aortic arch, ductus arteriosus, and proximal pulmonary arteries account for 15% to 20% of all cases of CHD. The cardiac outflow tract, which arises from the primitive right ventricle, can be divided into the muscularized conus and the adjacent truncus arteriosus, collectively termed the conotruncus. The conotruncus shifts to the left to override the forming ventricular septum. As development proceeds, endocardial ridges grow from opposite sides of the conotruncus and meet in the middle to form the conotruncal septum. The endocardial ridges grow in a spiral configuration, placing the aorta in a more dorsal and leftward position and the pulmonary artery in a more ventral and rightward location (Fig. 53–4). The septum splits to divide the truncus arteriosus into the ascending aorta and the pulmonary trunk. Finally, fusion of the endocardial ridges with the inferior endocardial cushion and the muscular interventricular septum results in complete separation of the aortic and pulmonary outflow tracts.

Proper spiraling is crucial for the normal alignment of the aorta and pulmonary artery to the left and right ventricles, respectively. For example, in tetralogy of Fallot (TOF), the conotruncal septum forms, but because of malalignment of the great vessels, the conotruncal septum and aorta are shifted to the right and anterior. This malalignment results in an overriding aorta. Additionally, the failure of the conotruncal septum to connect to the muscular ventricular septum results in a ventricular septal defect that, unlike muscular VSDs, does not close spontaneously after birth.

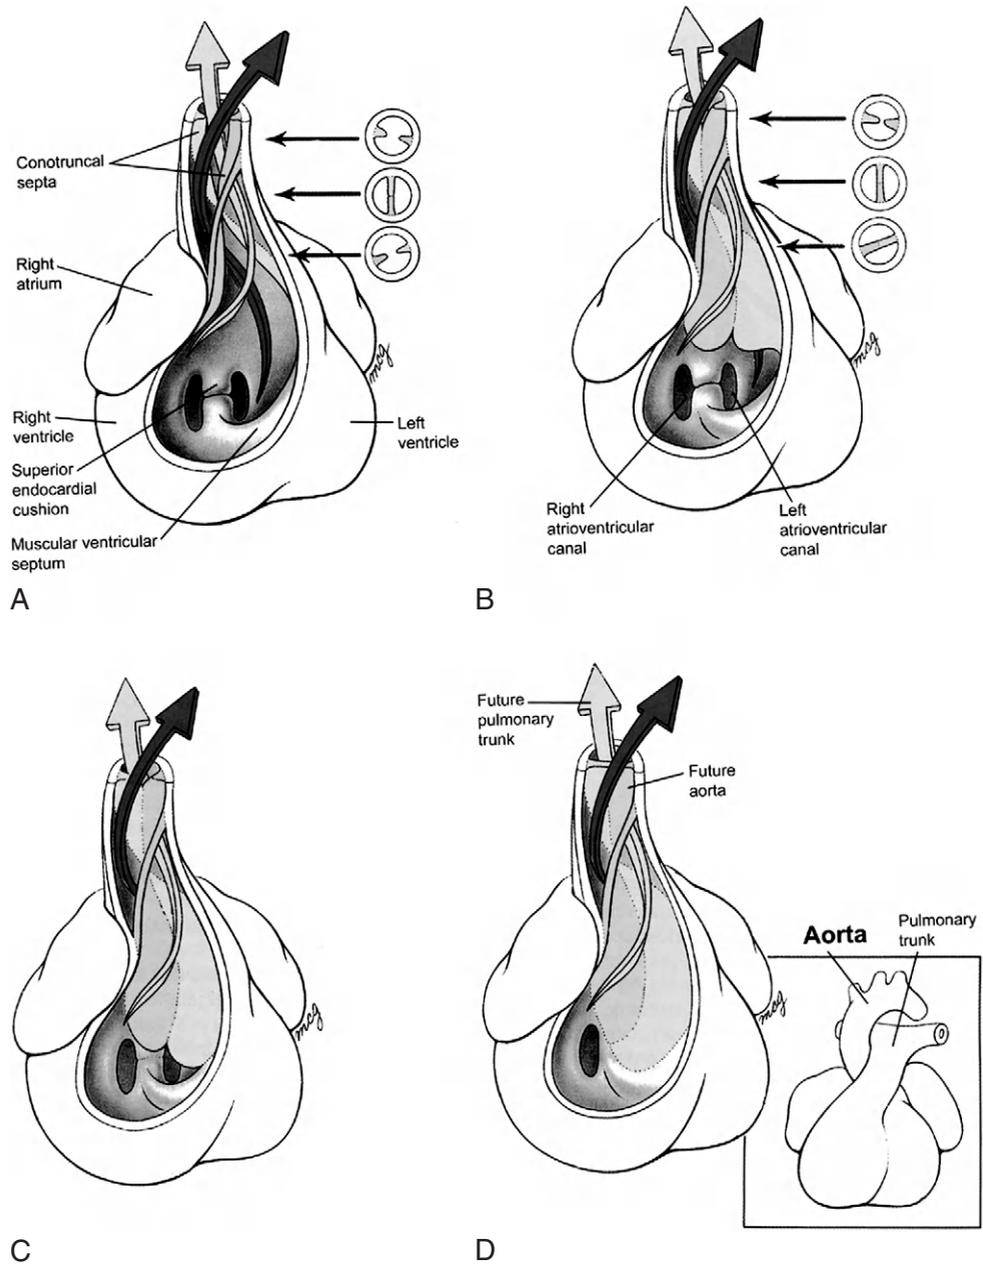

**FIGURE 53-2.** (See also Color Plate 53-2.) Septation of the atria. **A**, Atrial septation begins during the fifth week, when the septum primum forms from the roof of the atrium and grows toward the atrioventricular canal, which is being divided into right and left orifices by the superior and inferior endocardial cushions. **B**, During the sixth week, the septum primum fuses with the superior and inferior endocardial cushions, and the septum secundum grows from the roof of the right ventricle. The ostium secundum forms when small openings in the septum primum coalesce. **C**, Definitive fetal separation of the atria. (From Larsen WJ: *Development of the human heart*. In Larsen WJ [ed]: *Human Embryology*. New York, Churchill Livingstone, 1977, pp 151-188.)

**FIGURE 53-3.** (See also Color Plate 53-3.) Realignment of the heart from 33 days (A) through 36 days (B), and 42 days (C). Remodeling of the heart during the fifth and sixth week, results in progressive alignment of the developing left atrioventricular canal with the left atrium and ventricle and the right atrioventricular canal with the right atrium and ventricle. **A**, The atrioventricular canal initially opens into the presumptive left ventricle. **B**, The atrioventricular canal shifts to the right, so that it will overlie the developing ventricular septum. **C**, The single atrioventricular canal is divided into right and left atrioventricular canals. (From Larsen WJ [ed]: *Human Embryology*. New York, Churchill Livingstone, 1977, pp 151-188.)

The aortic sac lies distal to the conotruncus and gives rise to six bilaterally symmetrical vessels known as aortic arch arteries. The aortic arch arteries arise sequentially along the AP axis, each traversing a pharyngeal arch before joining the paired dorsal aortas. The first and second arch arteries involute, and the fifth arch arteries do not fully form. The third, fourth, and sixth arch arteries undergo extensive remodeling to ultimately form distinct regions of the mature aortic arch and proximal pulmonary arteries. A majority of the right-sided dorsal aorta and aortic arch arteries undergo programmed cell death, leading to a left-sided aortic arch. The third aortic arch artery contributes to the proximal carotid arteries and right subclavian artery. The left fourth aortic arch artery forms the transverse aortic arch between the left common carotid and left subclavian arteries. Finally, the sixth arch artery contributes to the proximal pulmonary artery and the ductus arteriosus (Van Mierop and Kutsche, 1986). Extrapolating from their embryologic origins, it is believed that aberrant right subclavian arteries and other subtle arch anomalies are the results of third aortic arch defects; interrupted aortic arch of fourth arch defects; and patent ductus arteriosus and proximal pulmonary artery hypoplasia/discontinuity of defects in sixth arch artery development.

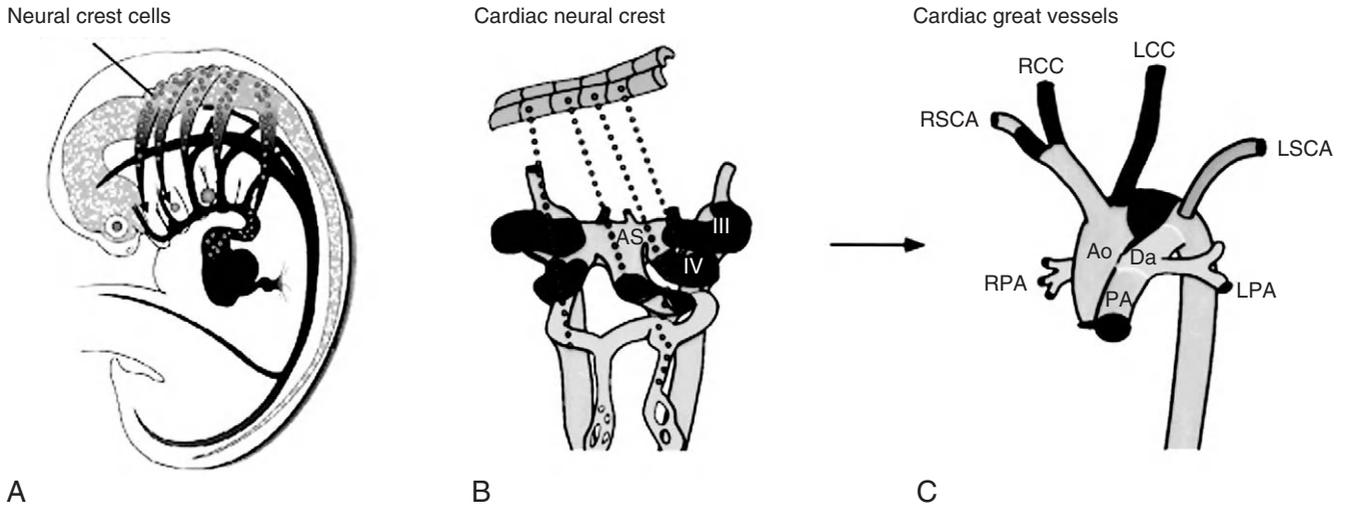

One intriguing feature of cardiac development is the involvement of cells that originate outside the heart and migrate in during cardiogenesis. Two such in-migrating cell populations are the cardiac neural crest cells and cells from the secondary or anterior heart-forming region. Prior to septation of the conotruncus, neural crest cells migrate from a portion of the dorsal neural tube (from the posterior rhombencephalon) into pharyngeal arches 3, 4, and 6, where they are required for proper remodeling of the aortic arch arteries (Fig. 53-5). Some of these cells continue to migrate to the outflow tract of the developing heart, where they become incorporated into the aortocapulmonary septum and the conotruncal cushions (Epstein et al, 2000; Jiang et al, 2000; Phillips et al, 1987; Waldo and Kirby, 1993). Recently, a subpopulation of precursor cells identified in the pharyngeal mesoderm anterior to the heart tube have been shown to give rise to the myocardium of the arterial pole of the heart (Kelly and Buckingham, 2002). The observation that the outflow tract of the heart is derived primarily from the latter addition of these “extracardiac” cell populations provides potential new insights to the potential origin of and accentuated frequency of congenital defects in this region of the heart.

**FIGURE 53-4.** (See also Color Plate 53-4.) Septation of the cardiac outflow tract. During the fifth week, the right and left conotruncal swellings grow out of the wall of the outflow tract in a spiral configuration (**A**), fusing where they meet (**B**). By the ninth week, the inferior portion of the conotruncal swellings has grown onto and fuses with the muscular ventricular septum and the inferior endocardial cushion (**C** and **D**). (From Larsen WJ: *Development of the human heart*. In Larsen WJ [ed]: *Human Embryology*. New York, Churchill Livingstone, 1977, pp 151-188.)

One of the most common chromosomal anomaly syndromes is the 22q11 deletion spectrum (22q11 DS) comprising the DiGeorge, CATCH22, and velocardiofacial (VCFS) syndromes. Because the structures affected—namely, the thymus gland, parathyroid glands, branchial arch arteries, face, and conotruncal region of the heart—are all derived in part from the cranial neural crest, it has been postulated that haploinsufficiency for one or more genes in this region disrupts development of neural crest cells or that of the cells with which they interact in the developing pharyngeal arches (Van Mierop and Kutsche, 1986). The similarity between the phenotype of the 22q11DS and those produced by neural crest ablation in the chicken or by natural or induced mutations of mouse genes important for neural crest development supports this hypothesis. The genes within the 22q11 deletion interval

have been completely mapped and sequenced. Much of the corresponding region on mouse chromosome 16 (the murine DiGeorge chromosomal region, or mudger) has been mapped as well (Botta et al, 1997; Galili et al, 1997; Lund et al, 1999). Recently, haploinsufficiency of one gene in the DiGeorge critical region, *Tbx1*, has been shown to result in many of the features of DiGeorge syndrome in mice (Jerome and Papaioannou, 2001; Lindsay et al, 2001; Merscher et al, 2001; Vitelli et al, 2002). *Tbx1* is not expressed in neural crest cells and is not required for migration of neural crest cells into the pharyngeal arches and conotruncus. Rather, it is expressed in pharyngeal endoderm and mesoderm, where it is involved in signaling pathways that regulate normal differentiation of neural crest cell derivatives (Kochilas et al, 2002). *Tbx1*-mediated neural crest cell differentiation is not required for formation of

**FIGURE 53-5.** (See also Color Plate 53-5.) Contribution of neural crest cells to aortic arch selection and conotruncal development. **A**, Between the fifth and sixth week, neural crest cells migrate from the hindbrain through pharyngeal arches 4 and 6, then invade the truncus arteriosus to form the conotruncal septa. **B**, Neural crest cells are required for normal remodeling of the pharyngeal arch arteries to the adult configuration (**C**). Ao, aorta; Da, ductus arteriosus; LCC, left common carotid artery; LPA, left pulmonary artery; LSCA, left subclavian artery; PA, pulmonary artery; RCC, right common carotid artery; RPA, right pulmonary artery; RSCA, right subclavian artery.

the aortic arch arteries, which initially develop normally in the absence of neural crest cells. Instead, the aortic arch defects seen with *Tbx1* deficiency appear to result from inappropriate regression of aortic arch segments and may be directly related to abnormalities in formation of the early vasculature (Stalmans et al, 2003).

The genetic etiology for conotruncal defects associated with syndromes other than DiGeorge syndrome/VCFS is beginning to be elucidated. The Notch signaling pathway has become a prominent focus in this regard. Initial studies on the genetic etiology of Alagille syndrome, an autosomal dominant disorder involving biliary atresia and conotruncal defects, has revealed an unsuspected role in cardiogenesis for a previously known molecular pathway. Linkage analysis and subsequent DNA sequencing in large kindreds with Alagille syndrome identified mutations in *Jagged 1*, a secreted ligand for the transmembrane receptor Notch (Li et al, 1997a; Oda et al, 1997). Further analyses of nonsyndromic patients with similar cardiac defects have identified previously unsuspected mutations in *Jagged 1* as well (Krantz et al, 1999). In mice, heterozygous mutations in both *Jagged 1* and Notch 2 result in a spectrum of conotruncal defects (McCright et al, 2002). Of interest, other members of the Notch signaling pathway, the HRT family of basic helix-loop-helix (bHLH) transcription factors, have very distinct chamber-specific expression patterns: HRT1 is expressed in the atrial precursors, whereas HRT2 is expressed in the future ventricular cells. HRT proteins are involved in transduction of Notch signals, which are involved in establishing defined regions of gene expression (Greenwald, 1998). HRT2 inactivation in mice results in a phenotype similar to tetralogy of Fallot, one of the most common conotruncal defects (Donovan et al, 2002; Gessler et al, 2002). Finally, *FGF8* has been implicated as a

potential “modifying” factor in the development of DiGeorge syndrome (Abu-Issa et al, 2002; Frank et al, 2002).

### Semilunar Valve Formation

The anlage of the semilunar valve leaflets is provided by three pairs of mesenchymal swellings or endocardial cushions: two from the developing conotruncal ridges and one that grows directly from the wall of the truncus. These endocardial cushions are subsequently “remodeled” to provide true valve leaflets. The mechanisms of this remodeling, however, are not well defined. The critical initial event in the formation of valve cusps appears to be a restricted proliferation of endothelium overlying the conotruncal ridges on the arterial face of the OFT. This proliferation results in a thickened endothelial ridge that protrudes into the lumen of the OFT. Subsequently, there is a gradual expansion of this ridge, combined with excavation in the arterial face, which results in formation of the sinuses of Valsalva and development of a valve cusp. During this process, there appears to be a tightly regulated balance between endothelial proliferation and endothelial cell death in the expanding endothelial ridge, and it is postulated that these processes are regulated by interactions with the underlying mesenchyme (Hurle et al, 1980; Maron and Hutchins, 1974). The balance between endothelial proliferation and cell death does not appear to be a characteristic of mitral or tricuspid valve histogenesis, which involves formation of a leaflet but does not require development of a valve cusp or sinus.

Little is known about the molecular mechanisms directing semilunar valve development. Several genes have been identified that are required for formation of the semilunar

but not atrioventricular valves. NFATc, or NFAT2 (for nuclear factor of activated T cells) (de la Pompa et al, 1998; Ranger et al, 1998), is preferentially expressed by endocardial cells. Null mutations result in complete absence of aortic and pulmonary valve formation. Similarly, a null mutation in the *Sox4* gene (a member of the Sox, or Sry-box, family of transcription factors) results in OFT defects, including truncus arteriosus and abnormal semilunar valve formation (Schilham et al, 1996; Ya et al, 1998), and mutations in the protein tyrosine phosphatase SHP-2 have been associated with abnormalities in pulmonary valve formation associated with Noonan syndrome (Tartaglia et al, 2001, 2002). The downstream targets of these transcription factors and signaling molecules are not yet known; identification of these targets will be an important step in understanding normal and abnormal semilunar valve formation.

### THE EPICARDIUM AND CORONARY VASCULATURE

The origin of coronary vascular endothelium and formation of the coronary vessels has been areas of intense investigation. Several theories ranging from the sprouting of vessels from the aorta into developing myocardium to outgrowth of the endocardial lining of the heart to the epicardial vessels have evolved to explain coronary morphogenesis. Recently, several investigators have demonstrated that the coronary vessels are derived from the epicardium itself. The epicardium originates as a villous projection of mesothelial cells in the area of the sinus venosus. These cells contact the dorsal heart in the region of the atrioventricular junction and subsequently migrate across this bridge to form a cellular monolayer that ultimately covers the surface of the heart. After migration over the surface of the heart, some epicardial cells undergo EMT and invade the extracellular matrix of the underlying subepicardium. Some of these mesenchymal cells become incorporated into the developing coronary endothelial plexus (Dettman et al, 1998; Perez-Pomares et al, 1998; Vrancken Peeters et al, 1999). Epicardially-derived cells (EPDCs) also have been found in the atrioventricular cushions, the myocardial wall, and the fibrous skeleton of the heart. In addition to being the source of coronary blood vessels, the epicardium is probably an important source of growth factors and morphogens, such as retinoic acid, which are required for normal growth and development of the myocardium; disruption of retinoic acid signaling from the epicardium to the myocardium results in thinning of the compact layer of the myocardium (Tran and Sucov, 1998; Xavier-Neto et al, 2000).

Whereas distal coronary development occurs by vasculogenesis, proximal coronary artery morphogenesis appears to result from an angiogenic process. Traditionally, the proximal coronary arteries were described as an outgrowth from the aorta to the epicardial surface of the heart; however, several investigators have recently shown that in fact the angiogenic process is in the reverse direction. Angiogenic sprouts from the subepicardial endothelial plexus form endothelial strands that grow into the aorta and develop multiple communications with all three cusps of the developing aortic valve (Waldo et al, 1990). These observations have obvious implications for determining the factors that direct coronary artery anatomy in CHDs.

### THE CONDUCTION SYSTEM

Although many human congenital heart defects are accompanied by electrophysiologic abnormalities, relatively little is known about development of the cardiac conduction system. Polarity of the vertebrate heart is established early in development, with both the dominant pacemaker activity and the highest beat frequency found at the posterior (atrial) end of the developing cardiac tube. Electrical activity of the primitive heart tube is characterized by slow conduction of the impulse, resulting in a slow peristaltic contraction. As the atrial and ventricular chambers of the heart develop, they begin to contract synchronously and sequentially, resulting in an adult-type electrocardiogram (ECG). Initiation of impulses from a sinoatrial “pacemaker” and delay of conduction through the atrioventricular canal are evident before the appearance of morphologically identifiable sinoatrial and atrioventricular nodes at approximately 5 weeks in the human heart.

Because cells of the conducting system express proteins commonly associated with neural crest cells, such as HNK-1, it had been theorized that the conducting system was derived from in-migrating neural crest cells. However, recent studies have shown that cells of the ventricular conducting system are in fact derived from local recruitment of differentiated ventricular myocytes (Cheng et al, 1999). In avian embryos, only myocytes located adjacent to the developing coronary vasculature are recruited to become conducting cells, suggesting that differentiation occurs in response to signals, from the arterial bed (Gourdie et al, 1995; Hyer et al, 1999). One candidate signal is endothelin-1, which is produced by the developing coronary vasculature in response to blood flow and is able to induce a Purkinje cell phenotype in cardiomyocytes (Takebayashi-Suzuki et al, 2000). A role for the coronary vasculature in mammalian cardiac conduction system development is not as clear. In mammals, in contrast with the chick, the peripheral Purkinje fiber network is largely confined to the subendocardial myocardium, and periarterial fibers have not been clearly documented. In the developing mouse heart, most Purkinje fibers are subendocardial and appear to be derived from the trabeculated myocardium (Rentschler et al, 2001). Indeed, development of the ventricular conduction system appears to require signals from the endocardium. Neuregulin-1, which is required for formation of the trabeculated myocardium, is able to induce at least some features of a conducting phenotype in murine cardiomyocytes (Rentschler et al, 2002). The roles of hemodynamic and endocardial signaling in development of the human conduction system remain to be elucidated. However, these seminal observations pave the way for a more detailed evaluation of the factors that regulate normal and potentially abnormal development of the conduction system.

### FUTURE DIRECTIONS

Development of the cardiovascular system represents a complicated interplay between developing form and function. There has been an explosion in the identification of potential candidate genes regulating these processes, and

the initial translation of basic observations from animal models to clinical relevance is well under way. However, much still needs to be done, particularly in defining the signaling cascades that lead to specific forms of congenital heart diseases. Thus, cardiac morphogenesis provides a fertile field for future investigation by collaborative teams of both basic and clinical scientists.

# Echocardiography in the Neonatal Intensive Care Unit

Jack Rychik and Meryl S. Cohen

*Echocardiography* is the application of ultrasound in evaluation of the cardiovascular system. A variety of diagnostic modalities in echocardiography provide detailed, reliable, and reproducible information on cardiovascular form and function. Fine cardiac structures can be identified, with differentiation of abnormal from normal anatomy, using high-resolution two-dimensional echocardiography. Detailed measures of myocardial thickness and cavity dimensions can be obtained via M-mode echocardiography. Components of hemodynamics, such as blood flow velocity and spatial direction, can be used to derive pressure measurements by the use of Doppler echocardiography.

Echocardiography is a very useful tool in the evaluation of the infant in the neonatal intensive care unit (NICU). The information obtained is real-time, noninvasive, and acquired at the patient's bedside. Physiologic data points can be measured in a serial manner, which can be of great value in managing the sick neonate as conditions are explored and responses to management strategies are gauged. Echocardiography is important not only in the diagnostic evaluation of congenital heart disease but also in the overall assessment of the cardiovascular system in disorders unique to the newborn infant. This chapter reviews the basic principles of echocardiography and their applications in the infant in the NICU setting.

## BASIC PRINCIPLES AND INSTRUMENTATION OF ECHOCARDIOGRAPHY

Ultrasound energy is generated by the stimulation of piezoelectric crystals housed in a unit called a transducer. When ultrasound energy is transmitted into biologic tissue, the majority is absorbed; however, a small amount is reflected back to the transducer. Reflected energy is processed and an image created on a screen. Ultrasound scatter is greatest at the interfaces between biologic tissues of disparate densities. Hence, bone and air, when adjacent to soft tissues such as the heart, create poor acoustic windows for ultrasound transmission. Soft tissue and fluid are excellent media for ultrasound transmission and provide clear windows for cardiac imaging (Weyman, 1994).

The range of frequencies used for diagnostic assessment of biologic tissue is 2 to 10 MHz (1 MHz = 1 million

cycles per second). Low-frequency ultrasound energy penetrates tissue better than high-frequency ultrasound; however, higher frequency ultrasound provides for greater spatial resolution of fine structures. This principle is dictated by a fundamental law of physics that defines the relation between ultrasound frequency and wavelength, in which

velocity of sound in biologic tissue = ultrasound frequency  $\times$  wavelength

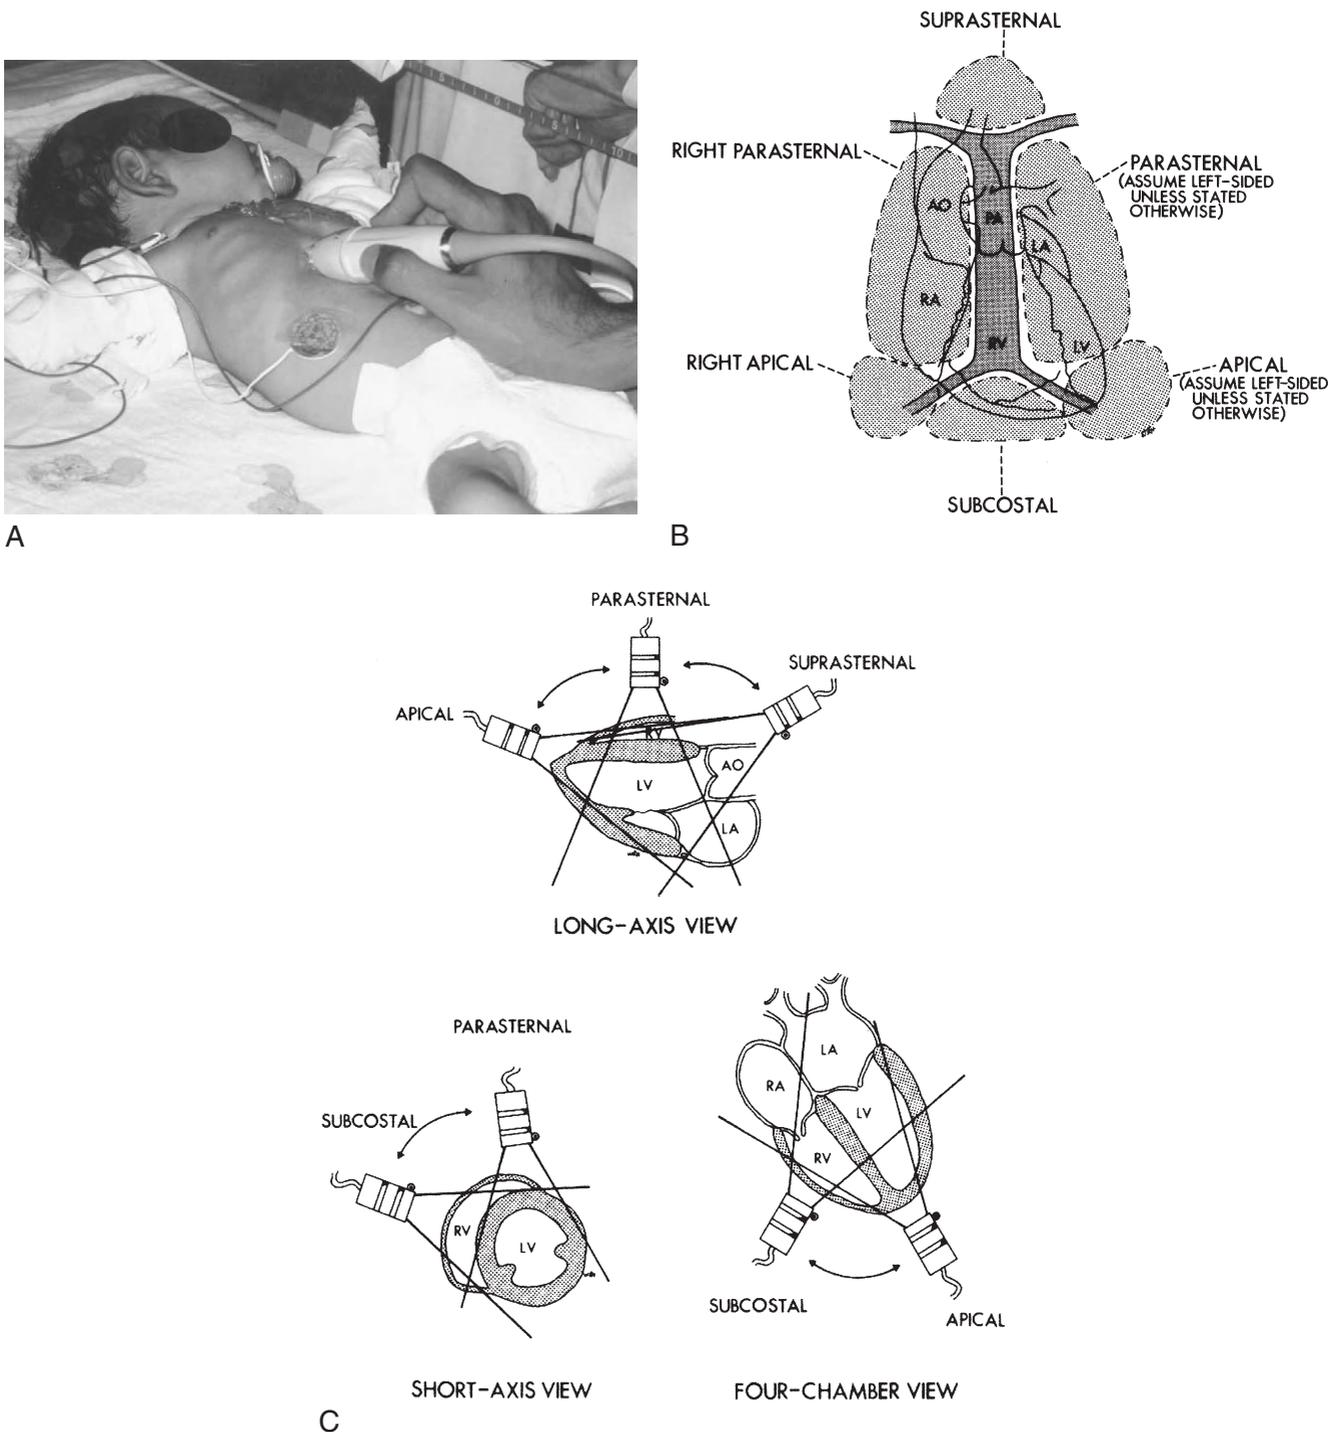

An ultrasound wavelength distance is the physical limit beyond which two structures in space cannot be distinguished. Hence, the smaller the wavelength (i.e., the higher the frequency), the greater the ability to distinguish two points in space that are very close to each other.

Let us look at the following example. Two structures exist in space 0.5 mm apart from each other. The velocity of sound in biologic tissue is a constant at approximately 1540 meters/second. Applying a frequency of 2 MHz of ultrasound energy will result in a wavelength of 0.77 mm, whereas applying a frequency of 8 MHz of ultrasound energy will result in a wavelength of 0.19 mm. Hence, to the operator using the 2-MHz transducer, the two structures will not be distinguishable from each other and will appear as one, whereas the operator using the 8-MHz transducer will be able to differentiate between the structures with ease. Accordingly, higher frequencies, in the range of 5 MHz or greater, are always used in the neonatal setting, because penetration is less important in the small subject and the objective is to maximize fine structure resolution.

Technologic advancements in miniaturization have allowed for the development of tiny transducer housings and small footprints for the performance of surface echocardiography in the neonate. Similar technology has allowed for the development of transesophageal echocardiography (TEE), in which a small transducer can be introduced into the esophagus of an infant weighing as little as 2.5 to 3.0 kg. TEE is helpful in elucidating structures in the posterior mediastinum, such as pulmonary veins, and in overcoming acoustic impediments at the surface such as air and bone (Randolph et al, 2002). Most important, TEE has allowed for imaging to take place during interventional procedures in the operating room or catheterization laboratory by eliminating the need to place a transducer directly on the chest or abdomen, thereby avoiding potential interference in the operative field. Interventional procedures can be guided by TEE imaging with immediate feedback provided and overall outcome improved. Recently, ultrasound transducer technology has been incorporated into the tips of catheters, allowing for intracardiac imaging (Li et al, 2002). These catheter-based ultrasound devices probably herald the development of TEE for tiny premature infants in the future (Bruce et al, 2002).

## How to Perform the Neonatal Echocardiogram

A systematic and standardized approach is important in performing the echocardiogram in the neonate. Follow-up echocardiographic studies may be curtailed and limited

**FIGURE 54-1.** **A**, Demonstration of position of ultrasound transducer utilizing the subcostal approach in a neonate. **B**, By moving the transducer to multiple windows surrounding the heart, echocardiographic two-dimensional tomographic imaging provides for a three-dimensional look at the heart via “mental reconstruction” once each of the corresponding windows has been examined. **C**, Long-axis, short-axis, and four-chamber views of the heart contribute to visualization of the overall detail of complex cardiac anatomy. (*B and C, Courtesy of the American Society of Echocardiography.*)

in scope; however, initial evaluation should be complete and include investigation of all aspects of the heart and great vessels using two-dimensional, Doppler, color Doppler, and M-mode imaging. More than a dozen sweeps and views through numerous windows and from various angles are used to create a complete picture of the heart and great vessels (Fig. 54-1). The technique of subcostal (sub-xiphoid) two-dimensional sweep imaging with tomographic cuts of the heart provides for a three-dimensional (3D) look at cardiac structures via “mental reconstruction” once each of the corresponding windows has been examined. Usefulness of subcostal imaging is unique to neonates and pediatric patients, as the liver acts to enhance acoustic transmission and the heart is only a short distance away in the young subject.

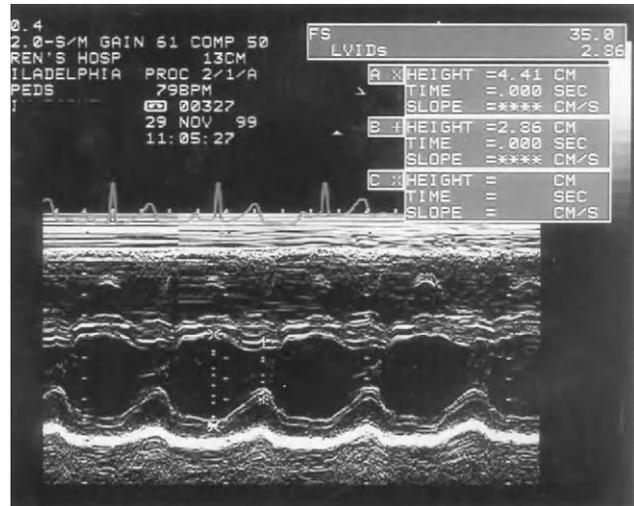

Although echocardiography is considered a noninvasive diagnostic test, care should be taken during the performance of the echocardiogram, particularly in small, premature infants. Often, sedation is necessary to obtain patient compliance, so that continuing assessment during the procedure and monitoring thereafter are essential. Application of cold ultrasound gel and exposure to air may cause temperature instability. Applying pressure on the abdomen during subcostal imaging or extending the neck during suprasternal imaging may cause destabilization of the patient. Either the person performing the echocardiogram or another assigned person should monitor heart rate, blood pressure, and ventilatory parameters during the procedure in unstable, ill infants.

## MODALITIES OF ECHOCARDIOGRAPHY AND THEIR APPLICATIONS

### M-Mode Echocardiography

The earliest form of echocardiographic imaging, M-mode echocardiography, displays fine detail of cardiac structure along a time line. A single thin plane of ultrasound energy is focused onto a targeted region of the heart. All structures within the targeted plane of insonation are then displayed in real time as they change during various portions of the cardiac cycle.

M-mode echocardiography is commonly used for measurement of myocardial wall thickness and cavity dimensions and is useful in estimating ventricular cavity size for calculation of the ventricular *shortening fraction*—an estimate of ventricular function. By angling the plane of insonation through the short axis of the left ventricle at the level of the tips of the papillary muscles, the clinician can obtain an M-mode display of the change in ventricular cavity dimension over time (Fig. 54-2). The ratio of the difference between left ventricle end-diastolic dimension (LVEDD) and left ventricle end-systolic dimension (LVESD) to the left ventricle end-diastolic dimension is the shortening fraction  $[(LVEDD - LVESD)/LVEDD \times 100 = \%SF]$ . The normal range is 28% to 38%, which correlates with a ventricular volumetric ejection fraction ratio of 55% to 65%, suggesting normal ventricular function. Interpretation of the  $\%SF$  must also take into account the over-

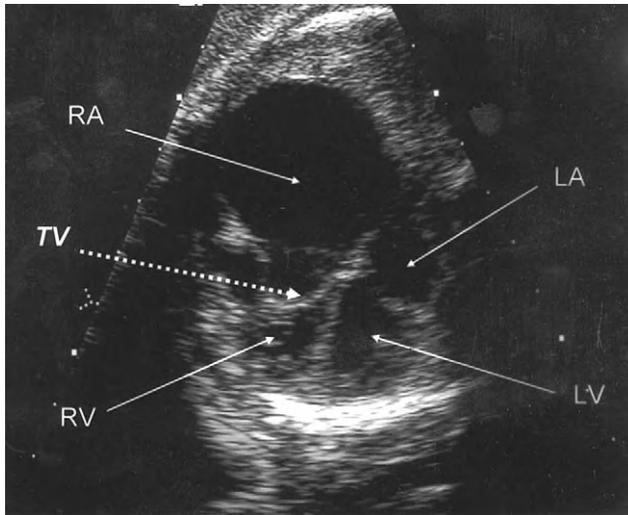

**FIGURE 54-2.** (See also Color Plate 54-2.) M-mode tracing of the left ventricle dimensions over time obtained in the short-axis view. The electrocardiographic tracing helps identify the timing of the cardiac cycle as systolic or diastolic. Measurement A demonstrates the left ventricle end-diastolic dimension, and measurement B, the left ventricle end-systolic measurement. The shortening fraction is calculated at 35%.

all dimensions of the left ventricle. For example, an infant with a volume load due to mitral regurgitation or a large patent ductus arteriosus (PDA) may have a normal  $\%SF$  but may have a dilated, enlarged left ventricle for age. The  $\%SF$  also can be helpful in investigating the cause of hypotension in infants. With hypotension due to myocardial dysfunction, the infant will have a dilated left ventricle and diminished  $\%SF$ . With hypotension due to vasodilatation, such as seen in various conditions of sepsis, the infant may have a normal or hyperdynamic  $\%SF$ , often exceeding 40%. Volume-depleted infants will exhibit a normal  $\%SF$  but a small left ventricular cavity size.

Although it is the most commonly used technique for determination of ventricular function, the M-mode measurement of  $\%SF$  has a number of limitations. It provides for only a single-plane assessment of ventricular contraction and is invalid in conditions in which there is wall motion abnormality. Paradoxical movement of the ventricular septum away from the posterior wall during systole may create a spuriously low  $\%SF$  value. Hence,  $\%SF$  measures may be difficult to interpret in the presence of right bundle branch block, right ventricle dilatation due to atrial septal defect, frequent premature ventricular contractions, or complete heart block.

### Two-Dimensional Echocardiography

Development of phased-array transducers has allowed for sector scanning and the display of two-dimensional images. This is the most commonly applied modality of echocardiography and is used primarily for determination of anatomic structure (Fig. 54-3).

**FIGURE 54-3.** A two-dimensional echocardiographic image from an infant with Ebstein anomaly of the tricuspid valve. This apical view demonstrates the detail of anatomy that is obtainable with two-dimensional imaging. *Arrow* points to the apically displaced tricuspid valve, classically seen in Ebstein anomaly. LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle; TV, tricuspid valve.

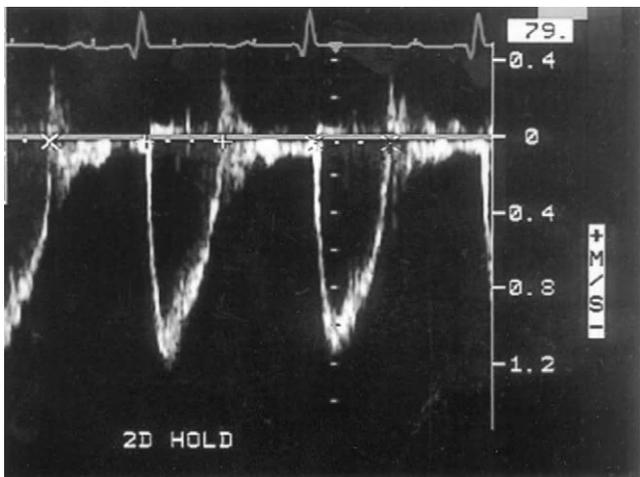

### Doppler Echocardiography

Application of the Doppler principle allows for determination of the velocity and direction of moving objects. Because blood and myocardial tissue both are in motion

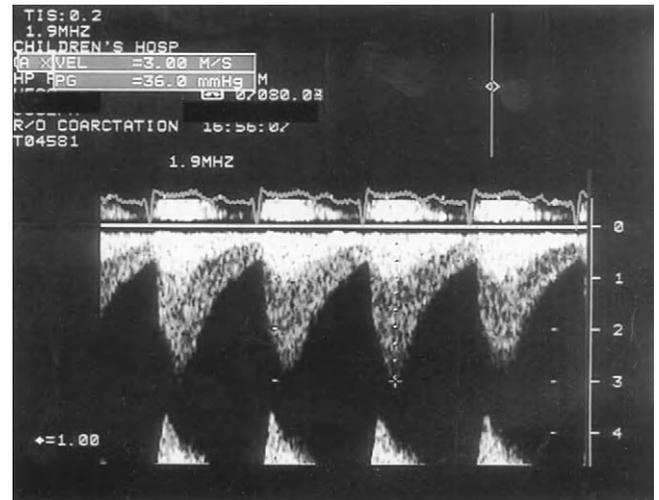

throughout the cardiac cycle, either can be assessed by Doppler echocardiography. Doppler imaging can be performed in a number of ways. In pulsed wave Doppler echocardiography, transducer crystals alternately fire pulses of energy and then “listen” for reflected signal return. This mode allows for determination of spatial signal position but limits the ability to measure increased velocities. In continuous wave Doppler echocardiography, half of the transducer crystals fire continuously while the other half “listen” continuously. This mode allows for unambiguous assessment of increased velocities but limits the ability to pinpoint precise spatial position of these velocities. In combination, pulsed wave and continuous wave Doppler modes provide a complete picture of blood flow direction and velocity (Fig. 54-4).

Color Doppler echocardiography utilizes pulsed wave principles to create a two-dimensional sector display of all velocities within a given region of interest. A sector within a two-dimensional image is identified and pixels of color are displayed overlying the area of interrogation. Each color pixel reflects the direction of motion; the shade of color reflects the velocity. By convention, “warm” colors such as red and orange designate direction of flow toward the transducer, and “cold” colors such as blue and white designate flow away from the transducer. Recently, Doppler techniques have been applied to tissue motion of the myocardium.

Although tissue signals move at much lower velocities than blood signals, determination of Doppler-derived tissue velocities can aid in understanding complex states of systolic and diastolic dysfunction. Distinct patterns of

A

B

**FIGURE 54-4.** (See also Color Plate 54-4.) **A**, Example of a pulsed wave Doppler signal. Time is on the  $x$ -axis, and velocity is in meters/second on the  $y$ -axis. Note the central clearing of the signal, with a fine envelope displayed. The maximal velocity is approximately 1 meter/second. **B**, Example of a continuous wave Doppler signal. Note the filling-in of the signal envelope. The peak velocity is 3 meters/second. This pattern is classic for coarctation of the aorta: There is a run-off of the Doppler signal into diastole, with a double-peak envelope (a smaller peak at 1 meter/second within the larger peak of 3 meters/second). This latter feature reflects the fact that continuous wave Doppler cannot distinguish between the lower velocities proximal to the coarctation from the elevated velocities just distal to the coarctation; hence, both velocities are displayed as a single signal, one overlaid on the other.

normal and abnormal motion of various myocardial segments have been described.

Data derived from Doppler echocardiography are used to provide physiologic information. Utilizing the principles of flow hydraulics across a tubular system with discrete narrowing, velocity data can be translated into pressure data via modification of the Bernoulli equation (Fig. 54–5), in which

$$P_1 - P_2 = 4 \times (V_2 - V_1)^2$$

Normal velocities in the heart are rarely greater than 1 meter/sec. Velocities proximal to areas of narrowing are typically less than 1 meter/sec, and can often be ignored. Hence, the equation can be simplified to

$$\text{pressure change} = 4 \times V_{\text{max}}^2$$

This principle can be applied in a variety of clinical settings. For example, in the presence of tricuspid regurgitation (TR), the peak right ventricle pressure (which will equal the pulmonary artery pressure in the absence of pulmonary stenosis) can be estimated by measuring the regurgitant jet peak velocity. A TR peak velocity of 2 meters/second suggests a right ventricle pressure of 16 mm Hg ( $4 \times (2)^2$ ) greater than the right atrial pressure. One must remember that the Bernoulli equation provides for the pressure difference between two chambers; hence, to assess the absolute pressure in the right ventricle, the right atrial pressure must be added to the difference between the right atrium and right ventricle pressures as measured by the TR jet. In infants and children, right atrial pressure is estimated to be between 3 and 10 mm Hg, with 5 mm Hg typically chosen as an estimated guess. Hence, in the foregoing example, the patient would have a right ventricle pressure of 21 mm Hg, which is within normal limits. Alternatively, an infant with severe chronic lung disease may have a TR peak jet of 4 meters/second. This would translate to a pressure estimate of 64 mm Hg ( $4 \times (4)^2$ ); 64 mm Hg added to the estimated right atrial pressure of 5 mm Hg gives a right ventricle pressure of 69 mm Hg, which suggests pulmonary

hypertension. The Bernoulli equation also is commonly used to assess pressure gradients across stenotic valves such as in valvar aortic or pulmonic stenosis. Using the maximum velocity across the stenotic valve, the clinician can derive the “peak instantaneous” gradient across the outflow tract.

### Three-Dimensional Echocardiography

Integration of multiplanar image data into a real-time 3D display has been a goal of echocardiography for many years. Recently, early systems have been developed that are capable of displaying 3D echocardiographic images. Benefits of 3D echocardiography include an improved way of identifying the spatial relationship of adjacent structures and providing rapid data acquisition times for a large amount of image data. Although in its infancy, 3D echocardiography promises to become an important modality as technologic advances continue.

### LIMITATIONS OF ECHOCARDIOGRAPHY

Although an extremely useful tool that has revolutionized the approach to diagnostic evaluation of the cardiovascular system in the neonate, echocardiography has a number of limitations:

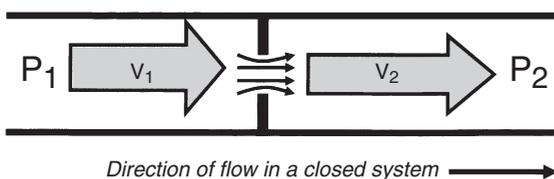

- *Discrepancy between “echo-derived” and “catheter-derived” gradients.* Doppler echocardiography measures the “peak instantaneous” pressure difference at any point in time during flow across a stenotic valve. In the case of a stenotic aortic valve, this may occur during the upstroke of systole, not at the peak of systole. Catheter-based measures of pressure are taken at the peak of systole; hence, echo-derived pressure gradients do not equal, and usually exceed, catheter-derived measures. This discrepancy does not invalidate the measures of either modality but rather highlights the point that they are measures of gradients occurring during two different points in systole. Historically, clinical decision making has been based on catheter-derived information; therefore, echocardiographically derived data should be interpreted in this light. Other factors that may have an impact on differences in echocardiographic versus catheter-based gradients are level of sedation, hydration status, medications (inotropes), and ventilatory strategy.
- *Stress of the test.* Lengthy environmental exposure, temperature instability, and pressure application on the chest or abdomen during transducer contact may result in stress for the premature or hemodynamically unstable infant, often necessitating termination of the procedure or limiting the scope of the ultrasound evaluation.
- *Inadequate visualization of structures.* Lung disease and air trapping can cause acoustic impedance, limiting the ability to visualize structures.
- *Inadequate Doppler signal for velocity measurement.* Small blood volumes in small structures may at times not be seen with echocardiography. Examples are coronary arteries in the very small, premature infant and pulmonary

#### Bernoulli Equation

$$P_1 - P_2 = 4 \times (V_2 - V_1)^2$$

If  $V_1 < 1 \text{ m/sec}$ , then

$$\text{Pressure change} = 4 \times V_{\text{max}}^2$$

**FIGURE 54–5.** Bernoulli equation of flow dynamics describes the relationship between pressure differences and velocity differences across an area of narrowing in a closed fluid system.  $P_1$ , proximal pressure;  $P_2$ , downstream distal pressure;  $V_1$ , proximal velocity;  $V_2$ , distal downstream velocity.

vein flow in patients with severe lung disease, in whom pulmonary blood flow may be limited. Identification of pulmonary venous anatomy and flow in infants on extracorporeal membrane oxygenation also may be difficult owing to blood volume bypass of the pulmonary circulation. TEE may be indicated in these patients.

## INDICATIONS FOR ECHOCARDIOGRAPHY IN THE NEONATE

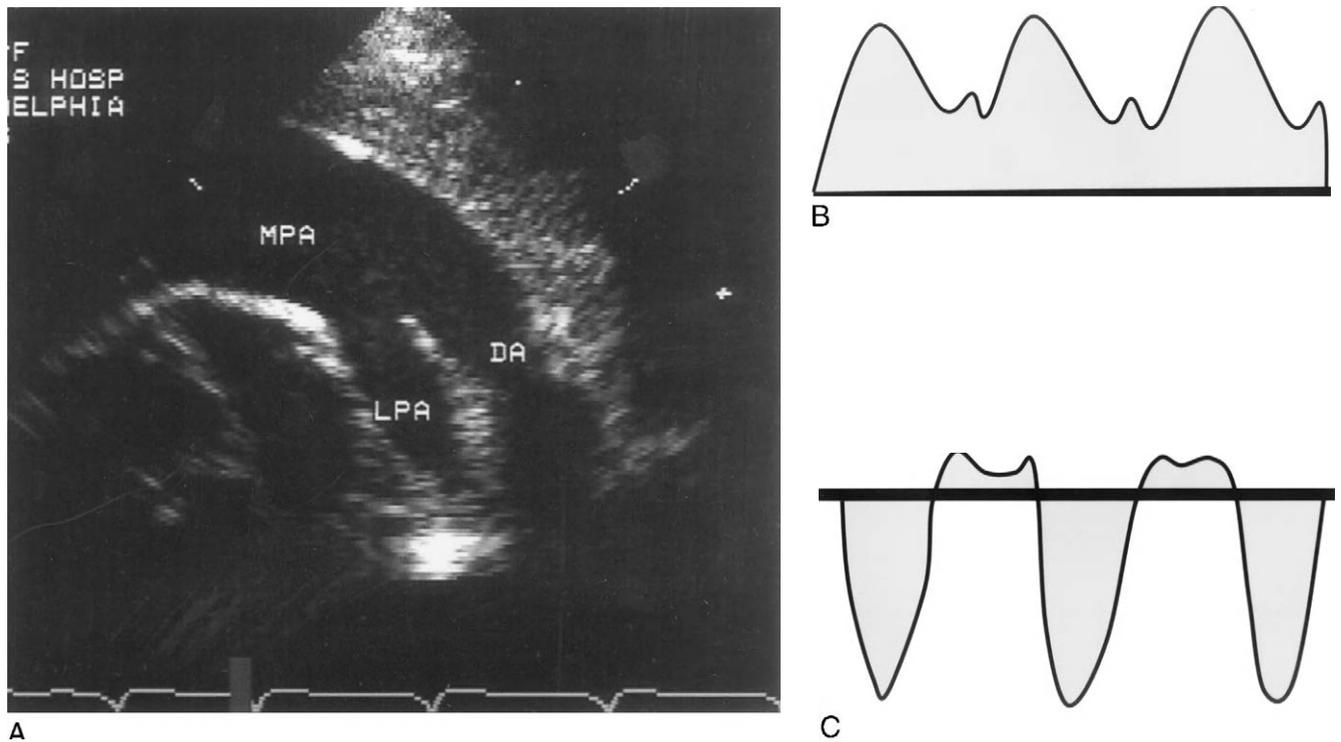

### Suspected Congenital Heart Disease

Echocardiography is the primary imaging modality used to diagnose congenital heart disease. Information concerning structure and physiology can be obtained, thereby obviating the need for further invasive diagnostic tests. Data obtained from echocardiography are frequently sufficient for the development of a surgical plan and manage-

ment strategy for most forms of congenital heart disease (Tworetzky et al, 1999). Detailed review of the application of echocardiography in congenital heart disease is beyond the scope of this chapter and is covered elsewhere (see Snider and Serwer, 1990).

### Assessment of the Ductus Arteriosus

Before the routine use of echocardiography, a hemodynamically significant PDA was diagnosed clinically by the presence of a heart murmur, hyperdynamic precordium, bounding and palmar pulses, need for increased ventilatory support, and radiographic evidence of cardiomegaly with increased pulmonary vascular markings. Unfortunately, the cardiac examination of a critically ill premature infant can be difficult and unreliable. Thus in the present era, a complete transthoracic echocardiogram is recommended before medical or surgical treatment of PDA (Fig. 54–6).

**FIGURE 54–6.** **A**, Two-dimensional echocardiographic image of a large ductus arteriosus, high parasternal view. DA, ductus arteriosus; LPA, left pulmonary artery; MPA, main pulmonary artery. **B**, Schematic of the Doppler flow pattern seen in a neonate with a patent ductus arteriosus and normal pulmonary vascular resistance and left-to-right shunting. Note that all of the flow is above the baseline and, on the high parasternal view, is directed toward the MPA from the aorta. **C**, Schematic of the Doppler flow pattern seen in a neonate with a patent ductus arteriosus and right-to-left shunting in systole and left-to-right shunting in diastole. Flow is below the baseline away from the MPA toward the descending aorta in systole (antegrade) and above the baseline back toward the MPA from the descending aorta (retrograde) in diastole. This pattern is classically seen in critical left-sided congenital heart disease in which ductal support for systemic perfusion is required (hypoplastic left heart syndrome, critical coarctation of the aorta) and in severe pulmonary hypertension of the newborn.

The echocardiogram is important not only to confirm the presence of a PDA but also to ensure that other important structural heart defects are not present. Premature infants with critical left-sided obstructive lesions (e.g., hypoplastic left heart syndrome, critical aortic stenosis, coarctation of the aorta) or right-sided obstructive lesions (e.g., tetralogy of Fallot with pulmonary atresia, pulmonary atresia with intact ventricular septum, tricuspid atresia) rely on a PDA for survival until surgical intervention.

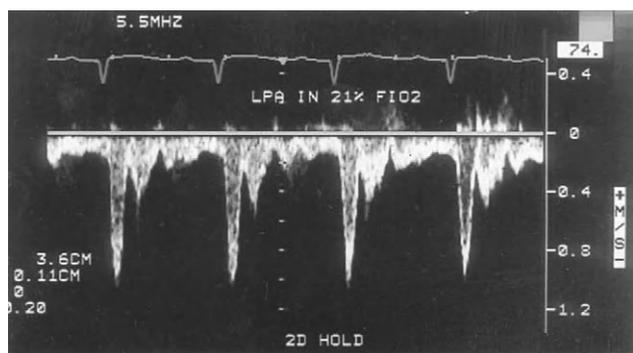

Echocardiographic assessment of the PDA also can be useful in determining the size of the ductus and the impact of the patency on the cardiovascular status of the neonate. Flow across the ductus arteriosus can be purely left to right, purely right to left as seen in association with severe pulmonary hypertension, or bidirectional, with right-to-left flow in systole and left-to-right flow in diastole, as seen in some patients with pulmonary hypertension and in infants with ductus-dependent systemic circulation with normal pulmonary artery pressure (Cloez et al, 1986). When there is isolated left-to-right flow through a PDA, the peak systolic pressure gradient from the aorta to the pulmonary artery (as measured by the modified Bernoulli equation) can be used as a rough estimate of pulmonary artery pressure, if the systolic blood pressure is simultaneously measured (Musewe et al, 1990). However, this method does have limitations and tends to underestimate the true pulmonary artery pressure (Snider, 1990).

PDA closure with indomethacin therapy occurs in approximately 85% of cases (Gersony et al, 1983); however, reopening of the ductus after successful pharmacologic closure has been reported in up to 25% of premature infants so treated (Weiss et al, 1995). In such cases, surgical ligation of the PDA is recommended. Determination of aortic arch “sidedness” via echocardiography is important when surgical thoracotomy is planned (Murdison et al, 1990). Although the majority of patients have a left aortic arch with a left-sided ductus arteriosus, so that surgical access is through a left thoracotomy, there are cases of right aortic arch, right-sided PDA, and/or vascular ring in the premature infant. Identification of one of

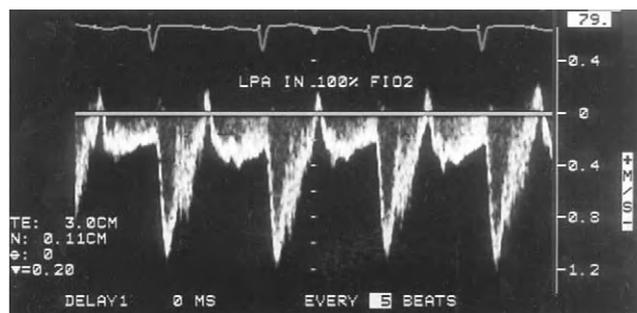

these findings will alter the surgeon’s approach to ductal ligation.

### Evaluation of Pulmonary Hypertension in the Newborn

Infants with persistent pulmonary hypertension of the newborn (PPHN) have severe vasoconstriction of the pulmonary vasculature resulting in elevation of pulmonary artery pressure and pulmonary vascular resistance with normal left atrial pressure. Right-to-left shunting is therefore observed at the level of the ductus arteriosus and foramen ovale (hence the other common term for this disorder—“persistent fetal circulation”). In infants with PPHN, transthoracic echocardiography determines if the heart is structurally normal, demonstrates atrial and ductal level shunting (by color flow mapping), and can provide an estimate of pulmonary artery pressure by measuring the velocity of the tricuspid regurgitation jet, if present. The appearance of the Doppler pattern sampled in the branch pulmonary artery also may provide information about the peripheral vascular resistance and potential response to supplemental oxygen (Fig. 54–7). The velocity of ductal flow also has been used to estimate pulmonary artery pressure. With unidirectional shunting at the ductus, the peak velocity of ductal flow has been correlated with pulmonary artery pressure estimated from the tricuspid regurgitation jet. In addition, with bidirectional shunting at the ductus, duration of right-to-left flow of at least 60% has been associated with systemic level pulmonary artery pressure and resistance and signifies severe PPHN (Musewe et al, 1990). Although some infants may normally exhibit a very short duration of right-to-left shunting early in systole, the presence of right-to-left shunting of significant duration at the ductus arteriosus suggests critical left-sided congenital heart disease or PPHN. When such right-to-left shunting is present, closure of the ductus arteriosus should not be undertaken.

A

B

**FIGURE 54-7.** (See also Color Plate 54-7.) **A**, Doppler flow pattern obtained in the left pulmonary artery of an infant with severe pulmonary hypertension breathing room air (21%). **B**, Doppler flow pattern obtained in the same left pulmonary artery after the addition of supplemental oxygen (100%). Note the increase in area under the Doppler flow envelope with increased flow in both systole and diastole, reflecting pulmonary vasodilatation.

In addition to the assessment of pulmonary artery pressure, echocardiography may be used to assess ventricular function in the infant with PPHN. Neonates with PPHN typically have cardiac dysfunction affecting the right ventricle (Valdes-Cruz et al, 1981). However, the left ventricle can be involved as well, with evidence of myocardial ischemia, abnormal electrocardiogram, and mitral regurgitation (Riemenschneider et al, 1976). Although the etiology of cardiac dysfunction in PPHN is unclear, prenatal constriction of the ductus arteriosus has been suggested as a possible mechanism (Fox et al, 1977; Morin, 1989).

Extracorporeal membrane oxygenation (ECMO) is often utilized to treat infants with severe PPHN whose hypoxemia does not respond to routine methods of mechanical ventilatory support and pulmonary vasodilation. In the decision-making process, an echocardiogram is often crucial to confirm the diagnosis of PPHN and, more important, to rule out congenital heart defects that may mimic PPHN. Many forms of structural heart disease can manifest with severe hypoxemia and pulmonary artery hypertension, which can mimic PPHN. The common finding in these defects is impediment to pulmonary venous return to the left atrium (Long, 1984). Such lesions include total anomalous pulmonary venous connection (TAPVC) with obstruction, cor triatriatum, transposition of the great arteries with intact atrial septum, and hypoplastic left heart syndrome with intact atrial septum. TAPVC can be extremely difficult to diagnose by echocardiography, particularly in the critically ill neonate. TAPVC results in significantly diminished pulmonary blood flow; therefore, it is often difficult to confirm the pulmonary venous connections by noninvasive methods (Kimball et al, 1989). Also, if a patient is on ECMO support before echocardiographic evaluation, diagnosis of TAPVC can be even more challenging, because the volume of blood traversing the pulmonary circulation is markedly diminished. If TAPVC is suspected but not well seen on transthoracic echocardiography, TEE may be useful. Cardiac catheterization is recommended to make the diagnosis if findings of noninvasive methods are inconclusive. Causes for difficulties in circuit flow dynamics while the infant is receiving ECMO often can be elucidated by an echocardiogram. Visualizing an obstructive cannula position, either in the atria or aorta, may explain impaired flow.

Echocardiography can also be useful to document progressive improvement in the patient with PPHN. Aggressive treatment with oxygen, nitric oxide, and other pulmonary vasodilators can be avoided if echocardiography demonstrates a lesser degree of right-to-left or exclusively left-to-right shunting within the heart. Documentation of closure of the PDA also is important because once the ductus is closed, the patient is no longer relying on the right ventricle to augment cardiac output to the systemic circulation. In addition, if tricuspid regurgitation is present, echocardiography can be used to serially monitor the systolic pressure in the pulmonary artery.

### Transitory Myocardial Ischemia of the Newborn

Transitory myocardial ischemia (TMI) occurs in association with severe perinatal asphyxia and may manifest with

tachycardia, tachypnea, poor perfusion, and heart murmur (Barberi et al, 1999; Fox et al, 1977). This clinical presentation is often difficult to distinguish from critical left heart obstruction (i.e., critical coarctation of aorta, hypoplastic left heart syndrome). Typical echocardiographic findings include diminished ventricular function (including wall motion abnormalities), atrioventricular valve regurgitation (most commonly tricuspid regurgitation), and in rare cases, echobright areas within the myocardium consistent with infarction. For the majority of infants with TMI, the cardiac abnormalities are temporary, with return of ventricular function and valve competence to normal within days of birth.

### Assessment of the Neonate with Extracardiac Anomalies

A variety of extracardiac anomalies and conditions are associated with congenital heart disease (Table 54-1). When these anomalies or conditions are suspected or known, an echocardiographic assessment is usually warranted. Confirmation of absence of structural heart disease can be extremely helpful to the neonatologist, the anesthesiologist, and the pediatric surgeon, whereas presence of a congenital heart defect may alter the management strategy and clinical course of the infant. Identification of a significant congenital heart defect in combination with an extracardiac anomaly may require attention to specific details at the

TABLE 54-1

#### Indications for Echocardiographic Evaluation in the Neonate

##### Conditions Associated with Congenital Heart Defects

<i>Syndromes</i>	<i>Non-Syndromes</i>
Trisomies 13, 18, 21	Congenital diaphragmatic hernia
VACTER association	Gastroschisis
CHARGE association	Omphalocele
Holt-Oram syndrome	Tracheoesophageal fistula
Goldenhar syndrome	Absence of radius
Cornelia de Lange syndrome	
Turner syndrome	
Noonan syndrome	
Williams syndrome	
Infantile Marfan syndrome	

##### Conditions Associated with Impact on Cardiovascular System

Congenital diaphragmatic hernia

Twin-twin transfusion syndrome
Arteriovenous malformation
Perinatal asphyxia
Severe anemia

CHARGE, coloboma, heart disease, retarded growth/development and/or central nervous system anomalies, genital hypoplasia, ear anomalies and/or deafness; VACTER, vertebral abnormalities, anal atresia, cardiac abnormalities, tracheoesophageal fistula and/or esophageal atresia, renal agenesis/dysplasia.

time of echocardiographic evaluation. One such extra cardiac anomaly is congenital diaphragmatic hernia (CDH).

CDH is frequently associated with congenital heart disease (prevalence of 10% to 35% of infants with CDH) (Greenwood et al, 1976; Ryan et al, 1994), and the combination frequently is lethal (Cohen et al, 2002). Patients with CDH often have hypoxemia; it is therefore important to distinguish between the cyanosis of severe lung hypoplasia (with PPHN) and that of cyanotic heart disease (e.g., tetralogy of Fallot, pulmonary atresia). If the heart is structurally normal, echocardiography can help in the assessment of the severity of the CDH. Assessment of pulmonary artery pressure and intracardiac shunting (as described for PPHN) can be useful for prognostic purposes. Left ventricular hypoplasia occurs commonly in patients with CDH. This association may be related to prenatal factors such as mechanical compression of the left ventricle by abdominal contents, diminished flow across the foramen ovale, or diminished pulmonary venous return secondary to lung hypoplasia. The degree of left ventricular hypoplasia is a predictor of mortality in infants with left-sided CDH (Baumgart et al, 1998; Schwartz et al, 1994; Seibert et al, 1984). Infants with CDH in association with left ventricular hypoplasia are more likely to require ECMO support after birth. Echocardiographic measurements of mitral annulus, left ventricular length, and aortic dimensions can help establish the viability of the left ventricle as a systemic ventricle in patients with CDH.

### FETAL ECHOCARDIOGRAPHY

Echocardiographic techniques have been applied to the developing human fetal cardiovascular system. Excellent images of fetal cardiac anatomy and flow dynamics can be obtained as early as 16 weeks of gestation. Prenatal detection of congenital heart disease has been shown to improve outcome in the postnatal state by reducing postnatal acidosis and mortality (Tworetzky et al, 2001; Verheijen et al, 2001). Indications for fetal echocardiography can be separated into maternal and fetal and are listed in Table 54–1. Application of Doppler echocardiography in the fetus has been helpful in diagnosing and monitoring a variety of disorders. Evaluation of blood flow patterns in the fetal ductus venosus, umbilical vein, and umbilical artery can provide important information on fetal cardiovascular status and condition of the placenta (Hecher et al, 1995).

Fetal echocardiography can be used to monitor the development and progression of congenital heart disease. Various forms of obstructive disease have been observed to progress in severity, or to evolve into a new category of anomaly, over the period from the second to the third trimester (Hornberger et al, 1995). Moderate forms of pulmonic stenosis may progress to severe stenosis or valvar atresia. Left-sided heart disease such as aortic stenosis diagnosed at 18 weeks of gestation may progress to hypoplastic left heart syndrome, with “arrest” of left ventricular development at 30 weeks of gestation, when flow traversing the left ventricle is impeded. Factors that dictate the presence and rate of progression of congenital heart disease in utero have not yet been determined.

# Stabilization and Transport of the Neonate with Congenital Heart Disease

Bradley S. Marino and Gil Wernovsky

Once a diagnosis of congenital heart disease is suspected, the neonate must be stabilized and arrangements made for a complete evaluation to delineate the anatomic abnormalities. Such evaluation may necessitate transport of the neonate to an intensive care unit at another medical center where a pediatric cardiologist and a pediatric cardiothoracic surgeon are available (Castañeda et al, 1989). The initial hours after diagnosis are crucial in the outcomes of these neonates, as increasing numbers of short- and long-term outcome studies have revealed that the preoperative status of the patient is a major factor in determining mortality risk (Mahle et al, 2000), length of hospital stay (Wernovsky et al, 2000a), and long-term neurologic and developmental outcomes (Mahle and Wernovsky, 2000; Mahle et al, 2000; Wernovsky et al, 2000b). The most important aspects of stabilization and transport are the initial resuscitation, airway management, vascular access, the judicious use of supplemental oxygen, prostaglandin E<sub>1</sub> (PGE<sub>1</sub>) therapy, inotropic support, and the specifics surrounding the transportation of the neonate.

## STABILIZATION

### Initial Resuscitation

For the neonate who presents with hypoxemia unresponsive to supplemental oxygen, congestive heart failure, or shock, simultaneous attention is devoted to the basics of advanced life support and to maintenance of a patent ductus arteriosus. If necessary, a stable airway must be maintained, allowing for adequate alveolar oxygenation and ventilation. In neonates critically ill with congenital heart disease, intubation should be performed following premedication with sedation (with a narcotic or benzodiazepine), preferably with neuromuscular blockade in most cases (as discussed subsequently). Reliable venous access is essential; the umbilical vein should be used if patent. An arterial line assists in monitoring the blood pressure, acid-base status, and oxygenation of the patient. In the neonate, arterial access can be most reliably obtained through the umbilical artery. Volume resuscitation, inotropic support, and correction of metabolic acidosis are required to maximize cardiac output and tissue perfusion.

Blood glucose level and ionized calcium level should be checked to determine if hypoglycemia or hypocalcemia is

present. In the initial evaluation of a newborn with cyanosis or circulatory collapse, a sepsis work-up usually is performed, and the patient is started on appropriate antibiotics.

### Airway Management and Supplemental Oxygen

In general, if respiratory distress or profound hypoxemia is present, the infant should be sedated, paralyzed, intubated, and mechanically ventilated. Although intubation may be “successfully” carried out without sedation and neuromuscular blockade, there are compelling reasons to intubate with the aid of these agents in patients with congenital heart disease. First, the increased secretion of catecholamines with intubation may result in significant dysrhythmias in the at-risk myocardium. Second, vagally mediated bradycardia from hypoxemia, hypercapnia, or laryngeal stimulation may lead to asystole in these neonates, who have little reserve. Finally, sedation and neuromuscular blockade will reduce whole-body oxygen consumption, raising the mixed venous oxygen saturation and improving oxygen delivery. Premedication with atropine 0.02 mg/kg usually is employed to blunt the vagal effects of laryngoscopy. Fentanyl (1 to 2 μg/kg) or midazolam (0.05 to 0.1 mg/kg) may be given, with titration of dose to effect. Chest wall rigidity may occur in the neonate with even low-dose fentanyl, and neuromuscular blockade may be necessary to obtain adequate ventilation. The neonate who has tolerated PGE<sub>1</sub> with stable hemodynamics and little to no apnea may usually be safely transported with a natural airway and spontaneous breathing.

Supplemental oxygen is a potent pulmonary vasodilator and may adversely affect the physiology in neonates with a single ventricle, as well as those with two ventricles with unrestrictive ventricular or great vessel communication (see Chapter 57, on congenital heart disease). An excess of oxygen will decrease pulmonary vascular resistance and increase the pulmonary blood flow at the expense of systemic blood flow. Rather than being managed according to “rules” dictating the concentration of supplemental oxygen, the child with suspected congenital heart disease should receive supplemental oxygen via a nasal cannula or face mask to titrate the peripheral oxygen saturation to 80% to 85%. With a normal hemoglobin level and cardiac output, an oxygen saturation of 80% to 85% will provide adequate oxygen content in the blood and adequate oxygen delivery.

The goal of ventilation generally is to “normoventilate” the neonate with congenital heart disease (to achieve a PCO<sub>2</sub> of 35 to 40 mm Hg). In both the two-ventricle neonate with unrestrictive ventricular or great vessel communication and the neonate with a single ventricle, hyperventilation will decrease pulmonary vascular resistance and increase the pulmonary blood flow at the expense of systemic blood flow.

### Prostaglandin E<sub>1</sub> Therapy

The neonate who “fails” the hyperoxia test without an obvious pulmonary etiology, who has an “equivocal” result on the hyperoxia test but has other signs or symptoms of

congenital heart disease, or who presents in shock within the first 3 weeks of life is highly likely to have complex congenital heart disease. Such neonates are likely to have congenital lesions that depend on blood flow through a patent ductus arteriosus for pulmonary blood flow or systemic blood flow, or they may need a patent ductus arteriosus to promote intercirculatory mixing (Freed et al, 1981). The administration of PGE<sub>1</sub> will open the ductus arteriosus and, depending on the lesion, increase pulmonary blood flow, systemic blood flow, or intercirculatory mixing. In patients with ductus-dependent pulmonary blood flow, as the ductus becomes large and non-restrictive, hypoxemia is lessened, and any metabolic acidosis that resulted from severe hypoxemia is corrected. In patients with ductus-dependent systemic flow and shock, resuscitation of the infant will not be successful until the ductus is opened. In neonates with transposition of the great arteries, maintenance of a patent ductus arteriosus improves intercirculatory mixing (Paul and Wernovsky, 1995; Wernovsky and Jonas, 1998).

The timing of diagnosis and the degree of ductal patency determine the dose of PGE<sub>1</sub>. A dose of 0.01 to 0.025 µg/kg/minute usually is sufficient for stabilization of neonates with an echocardiographically demonstrated patent ductus arteriosus, as well as for those with a prenatal diagnosis in whom PGE<sub>1</sub> is given in the delivery room. Neonates presenting with significant ductal restriction may require doses of PGE<sub>1</sub> as high as 0.1 µg/kg/minute. Rarely, an older neonate (1 to 2 weeks of age) may require a higher dose of PGE<sub>1</sub> to initially reopen the ductus. Once a therapeutic effect has been achieved, the dose may often be decreased to as low as 0.01 µg/kg/minute without loss of therapeutic effect. The response to PGE<sub>1</sub> is often immediate if patency of the ductus is important for the hemodynamic state of the infant. Failure to respond to PGE<sub>1</sub> may mean that the initial diagnosis is incorrect; that the ductus is unresponsive to PGE<sub>1</sub> (which occurs in the older infant); that the ductus is absent; or that there is obstruction to pulmonary venous return.

Rarely, the patient with congenital heart disease may become progressively more unstable after the institution of PGE<sub>1</sub> therapy. This clinical deterioration after the institution of PGE<sub>1</sub> is an important diagnostic finding that identifies the congenital heart defect as involving obstructed blood flow out of the pulmonary veins or left atrium. Lesions with impairment of blood flow out of the left atrium include:

1. Hypoplastic left heart syndrome with a restrictive foramen ovale or intact atrial septum
2. Other variants of mitral atresia with a restrictive foramen ovale
3. Transposition of the great arteries with an intact ventricular septum and a restrictive foramen ovale
4. Total anomalous pulmonary venous return with obstruction of the common pulmonary vein

If there is clinical deterioration despite PGE<sub>1</sub> therapy, then plans for urgent echocardiography and interventional catheterization or cardiac surgery should be made.

PGE<sub>1</sub> administered as a continuous intravenous infusion is associated with adverse reactions that must be anticipated. Adverse reactions are more common in premature

and/or low-birth-weight infants. Common side effects from PGE<sub>1</sub> administration are delineated in Table 55–1.

Apnea and hypotension are two clinically significant side effects of PGE<sub>1</sub> that seem to be dose dependent. Apnea resulting from PGE<sub>1</sub> therapy typically occurs within the first hours of administration but may occur *at any time* during administration of the drug. Therefore, after institution of PGE<sub>1</sub> therapy, infants require continuous cardiorespiratory monitoring. For those neonates with apnea in whom transport to another facility is planned, consideration should be made for control of the airway and mechanical ventilation before transport. Factors that influence the decision for intubation are the severity of hypoxemia and hemodynamic instability, gestational age of the patient, transport distance, and the skill of the transport team in urgent intubation.

The most undesirable side effect of PGE<sub>1</sub> is peripheral vasodilatation, which is manifested as hypotension and/or cutaneous flushing (Lewis et al, 1981). The infant presenting in shock is more likely to need a higher dose of PGE<sub>1</sub>. Due to this phenomenon, a separate intravenous line should be secured for volume administration in infants receiving PGE<sub>1</sub>, especially if transport will be required. If hypotension is noted, a 10 to 20 mL/kg bolus of normal saline, lactated Ringer's solution, or 5% albumin generally will normalize the infant's blood pressure. Serum ionized calcium levels also should be checked and should be normalized if low. If volume resuscitation does not correct hypotension induced by PGE<sub>1</sub>, then dopamine 3 to 5 µg/kg/minute may be given to counter the vasodilatory effects. It is prudent to remeasure arterial blood gases and

TABLE 55–1

### Potential Side Effects of Prostaglandin E<sub>1</sub>: Frequency and Birth Weight

Effect(s)	>2.0 kg	<2.0 kg
<i>Cardiovascular</i> : hypotension, rhythm disturbance, peripheral vasodilation	16%	36%
<i>Central nervous system</i> : seizure, temperature elevation	16%	16%
<i>Respiratory</i> : apnea, hypoventilation	10%	42%
<i>Metabolic</i> : hypoglycemia, hypocalcemia	3%	5%
<i>Infectious</i> : sepsis, wound infections	3%	10%

to reassess the infant's capillary refill and vital signs within 15 to 30 minutes of starting the PGE<sub>1</sub> infusion.

### Vascular Access

Umbilical venous (UVC) and umbilical arterial (UAC) catheters are useful in the stabilization, transport, and preoperative and postoperative management of neonates with congenital heart disease. The UVC should be located centrally in the right atrium. There is controversy over the optimal placement of the UAC. The UAC may be placed in a "high" position, with the tip in the thoracic aorta above the diaphragm (T4 to T10), or may be placed in a "low" position just distal to the take-off of the renal arteries (L3 to L4). Theoretically, high catheter placement may increase the risk of stroke or necrotizing enterocolitis, whereas low catheter placement may be associated with increased vascular complications; case-control studies of umbilical line complications in neonates with congenital heart disease have reported conflicting results. Other than in anecdotal reports, the risk-benefit relation for use of umbilical lines in full-term neonates, or in the neonate with a ductus-dependent circulation, has not been well delineated.

### Inotropic Agents

For the neonate or infant in cardiogenic shock, a continuous infusion of an inotropic agent may improve myocardial contractility and thereby enhance tissue perfusion of the vital organs and peripheral tissues. Care should be taken to replete the intravascular volume before institution of vasoactive agents.

The sympathomimetic amines are the inotropic agents most commonly used for hemodynamic stabilization. Sympathomimetic amines may be endogenous—dopamine and epinephrine—or synthetic—dobutamine and isoproterenol. Dopamine and dobutamine are recommended for the neonate with hypotension and tachycardia, as these agents have less chronotropic properties in low doses. *Dopamine* is a precursor of norepinephrine and stimulates dopaminergic, beta<sub>1</sub>-adrenergic, and alpha-adrenergic receptors in a dose-dependent manner. Dopamine improves myocardial contractility, thereby increasing stroke volume, cardiac output, and mean arterial pressure, as well as urine output, with a low incidence of side effects at doses of less than 10 µg/kg/minute. *Dobutamine*, an analogue of dopamine, stimulates beta<sub>1</sub> receptors predominantly, with relatively weak beta<sub>2</sub> receptor- and alpha receptor-stimulating activity. In comparison with dopamine, dobutamine lacks renal vasodilating properties and does not depend on norepinephrine release from peripheral nerves for its effect. Data concerning the use of dobutamine in neonates are sparse, although clinical experience has been favorable. A combination of low-dose dopamine, up to 5 µg/kg/minute, and dobutamine, up to 10 µg/kg/minute, may be used to minimize the potential peripheral vasoconstriction induced by high doses of dopamine while maximizing the dopaminergic effects on renal perfusion.

Isoproterenol and epinephrine have been clinically utilized in neonates with hypotension and a normal or low heart rate, as these agents have both inotropic and chrono-

tropic effects. *Isoproterenol* stimulates both beta<sub>1</sub> and beta<sub>2</sub> receptors. In comparison with dobutamine, it has a greater chronotropic effect and a stronger vasodilatory effect via its beta<sub>2</sub> mechanism. Because of its strong chronotropic effect, it should be started at a low dose, which is increased slowly, titrated to effect. Chronotropic effects appear before inotropic effects in responsive hearts, and isoproterenol can produce tachyarrhythmias. The heart usually accommodates quickly to the chronotropic properties, allowing the dose to be raised further for inotropic needs. The recommended starting dose for isoproterenol is 0.05 µg/kg/minute. *Epinephrine* has alpha<sub>1</sub>, alpha<sub>2</sub>, beta<sub>1</sub>, and beta<sub>2</sub> effects. It is most commonly used when the previously listed inotropic infusions at high doses and in combination fail to produce the desired cardiac response. The recommended starting dose is 0.05 µg/kg/minute. Adverse reactions to the sympathomimetic amines include tachycardia, atrial and ventricular arrhythmias, and increased afterload due to peripheral vasoconstriction. Tachycardia increases myocardial oxygen consumption, whereas atrial and ventricular arrhythmias and peripheral vasoconstriction decrease cardiac output.

### TRANSPORT

After resuscitation and stabilization are complete, the neonate with suspected congenital heart disease may need to be transferred to an institution with an intensive care unit that provides subspecialty care in pediatric cardiology and pediatric cardiothoracic surgery. A successful transport involves two transitional phases of care for the neonate: (1) from the referring hospital staff to the transport team and (2) from the transport staff to the accepting hospital staff. The need for accurate, detailed, and complete communication of information between the respective teams cannot be overemphasized. If possible, the pediatric cardiologist and/or surgeon at the accepting hospital should be included in formulating the transport management plan while the neonate is still at the referring hospital.

Reliable vascular access should be secured for the neonate receiving continuous infusions of PGE<sub>1</sub> or inotropic agents during transport. Some neonates receiving a PGE<sub>1</sub> infusion will be intubated for transport (see earlier). All intubated patients should have gastric decompression by nasogastric tube or orogastric tube and should not receive anything by mouth or nasogastric tube.

Acid-base status, oxygen delivery, temperature, and serum glucose should be evaluated before transport. Although some patients with structurally normal hearts are transported receiving supplemental oxygen at or near 100%, this is not the inspired oxygen concentration of choice for most neonates with congenital heart disease. Enough oxygen should be used to maintain an oxygen saturation of 80% to 85% (see Chapter 57). This management decision for transport is particularly important in infants with ductus-dependent systemic or pulmonary blood flow and complete intracardiac mixing with single-ventricle physiology, and emphasizes the need to consult with a pediatric cardiologist before transport of the infant for optimal in-transport care.

In neonates, hypotension is a late finding in shock. More sensitive signs of impending decompensation include

persistent tachycardia, poor tissue perfusion, and metabolic acidosis. Treatment of shock should occur before transport during the stabilization phase of management. Before the patient leaves the referring hospital, the hemodynamic status (capillary refill, heart rate, systemic blood pressure, and acid-base status) should be reassessed and relayed to the receiving hospital.

Before transfer, the calcium and glucose status of the neonate should be evaluated. In particular, neonates with conotruncal anomalies have an increased frequency of 22q11 deletion (Goldmuntz et al, 1998), thymic and parathyroid hypoplasia, and problems with calcium homeostasis resulting in hypocalcemia. The neonatal myocardium may be more dependent on calcium for inotropy than the adult myocardium, and ionized calcium levels of less than 1.0 mg/dL may have a significant negative impact on neonatal myocardial contractility. If the ionized calcium concentration is less than 1.0 mg/dL, 50 to 100 mg/kg of calcium gluconate may be given intravenously.

### SUMMARY

The stabilization and transport of the neonate with known or suspected critical congenital heart disease have significant impacts on the child's preoperative condition, potentially contributing to the risk for long-term morbidity. Critical factors in stabilization include the initial resuscitation, airway management, vascular access, and the judicious utilization of oxygen, PGE<sub>1</sub>, and inotropic support. The key to successful transport that will minimize morbidity risk for the infant is accurate detailed communication among the respective staffs of the referring hospital, transport team, and accepting hospital.

## Patent Ductus Arteriosus in the Premature Infant

Ronald I. Clyman

The ductus arteriosus represents a persistence of the terminal portion of the sixth branchial arch. During fetal life, the ductus arteriosus serves to divert blood away from the fluid-filled lungs toward the descending aorta and placenta. After birth, constriction of the ductus arteriosus and obliteration of its lumen result in separation of the pulmonary and systemic circulations. In the full-term infant, obliteration of the ductus arteriosus takes place through a process of vasoconstriction and anatomic remodeling. In the preterm infant, the ductus arteriosus frequently fails to close. The clinical consequences of a patent ductus arteriosus (PDA) are related to the magnitude of the left-to-right shunt through the patent ductus with its associated change in blood flow to the lungs, kidneys, and intestine.

### REGULATION OF DUCTAL CLOSURE

In the full-term infant, closure of the ductus arteriosus occurs in two phases: (1) “functional” closure of the lumen within the first hours after birth by smooth muscle constriction and (2) “anatomic” occlusion of the lumen over the next several days due to extensive neointimal thickening and loss of smooth muscle cells from the inner muscle media.

#### Functional Closure

The initial functional constriction of the ductus depends on alterations in the balance between dilating and contracting forces. The ductus arteriosus normally has a high level of intrinsic tone during fetal life (Kajino et al, 2001). After delivery, an increase in arterial PaO<sub>2</sub> plays an additional important role in ductus arteriosus constriction (Kennedy and Clark, 1942). Oxygen's mechanism of action is still unknown. Although neural and hormonal factors possibly contribute to ductus closure under physiologic conditions, they do not mediate oxygen-induced vessel closure. A cytochrome P-450 hemoprotein that is located in the plasma membrane of the vascular smooth muscle cells appears to act as a receptor in the oxygen-mediated contractile pathway (Coceani et al, 1989b, 1994). Oxygen inhibits K<sup>+</sup> channels (Michelakis et al, 2000; Reeve et al, 2001), which in turn causes membrane depolarization, an increase in smooth muscle intracellular calcium (Nakanishi et al, 1993), and formation of the potent vasoconstrictor endothelin-1 (Coceani et al, 1989a). However, the role of

endothelin-1 in postnatal ductus closure or as a mediator of oxygen-induced ductus constriction has been questioned (Coceani et al, 1999; Fineman et al, 1998; Michelakis et al, 2000). Similarly, the mechanisms that alter membrane potential are still uncertain (Clyman et al, 1988; Reeve et al, 2001).

The fetal ductus also produces several vasodilators that oppose the ability of the intrinsic tone and oxygen to constrict the vessel. Vasodilator prostaglandins (PGs), PGE<sub>2</sub> and PGI<sub>2</sub>, play significant roles in maintaining ductus patency during fetal and neonatal life. PGE<sub>2</sub> appears to be the most important prostanoid regulating ductus patency because it is the most potent prostaglandin produced by the ductus (Clyman et al, 1978; Coceani et al, 1978). The response of the ductus to PGE<sub>2</sub> is unique among blood vessels in that it is extraordinarily sensitive to this vasodilating substance. Inhibition of prostaglandin synthesis, by inhibiting the enzyme cyclooxygenase, produces constriction of the fetal ductus (Moise et al, 1988). Both isoforms of cyclooxygenase—COX-1 and COX-2—are expressed in the ductus arteriosus (Takahashi et al, 2000), and both nonselective (e.g., indomethacin) and selective cyclooxygenase inhibitors constrict the DA. The DA also produces a nitric oxide (NO)-like vasodilator. Competitive inhibitors of nitric oxide synthase (NOS) constrict the newborn ductus, both in vivo and in vitro (Clyman et al, 1998; Seidner et al, 2001).

Following delivery there are several events that promote ductus constriction in the full-term newborn: (1) an increase in arterial PO<sub>2</sub>, (2) a decrease in blood pressure within the ductus lumen (due to the postnatal decrease in pulmonary vascular resistance), (3) a decrease in circulating PGE<sub>2</sub> (due to the loss of placental prostaglandin production and the increase in prostaglandin removal by the lung), and (4) a decrease in the number of PGE<sub>2</sub> receptors in the ductus wall (Bouayad et al, 2001). These factors promote ductus constriction after birth. In contrast with the full-term ductus, the premature ductus is less likely to constrict after birth. The intrinsic tone of the extremely immature ductus (at < 70% of full gestation) is decreased compared with the ductus at term (Kajino et al, 2001). In addition, there is an increased sensitivity of the immature ductus to the vasodilating effects of PGE<sub>2</sub> and NO (Clyman et al, 1998). Inhibitors of prostaglandin production such as indomethacin, ibuprofen, and mefenamic acid have proved to be effective agents in promoting ductus closure. It follows that drugs interfering with NO synthesis or function also could become useful adjuncts, especially in cases in which indomethacin has proved to be ineffective (Seidner et al, 2001).

The endogenous factors that alter the ability of the preterm ductus to constrict with advancing gestation are unknown. Recently, prenatal administration of vitamin A has been shown to increase both the intracellular calcium response and the contractile response of the preterm ductus to oxygen (Wu et al, 2001). Elevated cortisol concentrations in the fetus have been found to decrease the sensitivity of the ductus to PGE<sub>2</sub> (Clyman et al, 1981a); consistent with these findings, prenatal administration of glucocorticoids causes a significant reduction in the incidence of PDA in premature humans and animals (Clyman

et al, 1981b; Collaborative Group on Antenatal Steroid Therapy, 1985; Momma et al, 1981; Thibeault et al, 1978; Waffarn et al, 1983). The postnatal administration of glucocorticoids also has been shown to reduce the incidence of PDA (Early postnatal dexamethasone therapy, 2001). However, postnatal glucocorticoid treatment also seems to increase the incidence of several of the other neonatal morbidities (Early postnatal dexamethasone therapy, 2001).

### Anatomic Closure

In normal, full-term animals, loss of responsiveness to PGE<sub>2</sub> shortly after birth prevents the ductus arteriosus from reopening once it has constricted. This is accompanied by rapid histologic changes that ultimately lead to obliteration of the vessel lumen and loss of smooth muscle cells from the inner muscle media. The loss of vasodilator regulation of the ductus and the “anatomic” remodeling that leads to permanent ductus closure both appear to be related to the intensity of the initial ductus constriction. Constriction produces ischemic hypoxia of the vessel wall (Clyman et al, 1999). In the full-term newborn ductus, the ischemic hypoxia that accompanies constriction is due to a marked reduction in intramural vasa vasorum flow. Profound ductus wall hypoxia occurs even before luminal flow has been eliminated (Kajino, 2001). Loss of vasa vasorum flow produces a threefold increase in the diffusion distance for oxygen across the ductus wall.

Following delivery, the profound ductus wall hypoxia inhibits local production PGE<sub>2</sub> and NO, produces smooth muscle apoptosis, and induces local production of growth factors such as transforming growth factor- $\beta$  (TGF- $\beta$ ) and vascular endothelial growth factor (VEGF), which play early roles in ductus remodeling. Experimental genetic models that alter the ability of the ductus to contract at term also prevent the normal histologic changes that occur after birth (Loftin et al, 2001; Mason et al, 1999; Nguyen et al, 1997).

In preterm infants, the ductus frequently remains open for many days after birth. Even when it does constrict, the premature ductus frequently fails to develop profound hypoxia and to undergo anatomic remodeling. Therefore, the immature ductus is susceptible to vessel reopening. When the ductus arteriosus reopens after initial successful closure, the most frequent cause is the effects of endogenous PGE<sub>2</sub>. Consequently, in 70% of cases of ductal reopening, the ductus can be closed again with a second course of indomethacin. However, the relative importance of the two vasodilators, PGE<sub>2</sub> and NO, also can change after birth. Both the flow of oxygenated arterial blood through the narrowed ductus lumen (with its increased shear stress) and the ingrowth of vasa vasorum (which contain NOS), increase the amount of NO produced within the ductus wall. As NO production increases in the ductus, it is likely that ductus patency becomes less dependent on prostaglandin generation. With increasing ductal dependency on NO, inhibitors of prostaglandin production (such as indomethacin) would become less likely to produce ductus constriction. These findings fit with clinical observations that indomethacin is much more likely to achieve ductus closure if given on the first day after birth; its

effectiveness wanes with increasing postnatal age (Clyman, 1996; Schmidt et al, 2001) (see later). In premature baboons, the combined use of an NOS inhibitor and indomethacin produces a much greater degree of ductus constriction than is achieved with indomethacin alone (Seidner et al, 2001). It follows that drugs interfering with NO synthesis could become a useful adjunct, especially in cases in which indomethacin has proved to be ineffective.

Preterm infants seem to require more ductus constriction to produce the same level of wall hypoxia as that found at term. In contrast with the full-term ductus, the thin-walled preterm ductus does not depend on intramural vasa vasorum to provide oxygen and nutrients to its wall. As a result, the preterm ductus requires complete obstruction of luminal flow before it can develop the same degree of hypoxia as that found at term. If this degree of hypoxic ischemia can be induced in the preterm ductus, then most of the anatomic changes seen at term will occur (Kajino et al, 2001; Seidner et al, 2001).

### HEMODYNAMIC AND PULMONARY ALTERATIONS

The pathophysiologic features of a PDA depend both on the magnitude of the left-to-right shunt and on the cardiac and pulmonary responses to shunting. There are important differences between immature and mature infants in the heart's ability to handle a volume load. Immature infants have less cardiac sympathetic innervation. Before term, the myocardium has more water and less contractile mass. Therefore, in the immature fetus the ventricles are less distensible than at term and also generate less force per gram of myocardium (even though they have the same ability to generate force per sarcomere as the ventricles in more mature infants) (Friedman, 1972). The relative lack of left ventricular distensibility in immature infants is more a function of the ventricle's tissue constituents than of poor muscle function. As a result, left ventricular distention secondary to a large left-to-right PDA shunt may produce a higher left ventricular end-diastolic pressure at smaller ventricular volumes. The increase in left ventricular pressure increases pulmonary venous pressure, causing pulmonary congestion.

Studies in preterm lamb and human newborns (Clyman et al, 1987; Shimada et al, 1994) have shown that despite these limitations, preterm newborns are able to increase left ventricular output and maintain their “effective” systemic blood flow, even with left-to-right PDA shunts equal to 50% of left ventricular output. With shunts greater than 50% of left ventricular output, “effective” systemic blood flow falls, despite a continued increase in left ventricular output. The increase in left ventricular output associated with PDA is accomplished not by an increase in heart rate but by an increase in stroke volume (Clyman et al, 1987; Shimada et al, 1994). Stroke volume increases primarily as a result of the simultaneous decrease in afterload resistance on the heart and the increase in left ventricular preload. Despite the ability of the left ventricle to increase its output in the face of a left-to-right ductus shunt, blood flow distribution is significantly rearranged. This redistribution of systemic blood flow occurs even with small shunts (Clyman et al, 1987). Blood

flow to the skin, bone, and skeletal muscle is most likely to be affected by the left-to-right ductus shunt. The next most likely organs to be affected are the gastrointestinal tract and kidneys. These organs receive decreased blood flow as a result of a combination of decreased perfusion pressure (due to a drop in diastolic pressure) and localized vasoconstriction. These organs may experience significant hypoperfusion before there are any signs of left ventricular compromise (Meyers et al, 1990; Shimada et al, 1994). This decrease in organ perfusion contributes to some of the morbid conditions caused by PDA: necrotizing enterocolitis (NEC) and decreased glomerular filtration rate (Cassady et al, 1989; Clyman, 1996).

The decreased ability of the preterm infant to maintain active pulmonary vasoconstriction (Lewis et al, 1976) may be responsible in part for the earlier clinical manifestation of a "large" left-to-right PDA shunt (Gersony et al, 1983; Jacob et al, 1980). In addition, therapeutic maneuvers (e.g., surfactant replacement) that lead to a more rapid drop in pulmonary vascular resistance can exacerbate the magnitude of left-to-right shunt in preterm infants with respiratory distress syndrome (RDS), leading to pulmonary hemorrhage (Alpan and Clyman, 1995; Raju and Langenberg, 1993). Although the mechanisms responsible for pulmonary hemorrhage after surfactant are uncertain, a retrospective cohort study found that a clinically detectable PDA was associated with the onset of the hemorrhage (Garland et al, 1994). Early ductus closure has been shown to decrease the incidence of significant pulmonary hemorrhage (Clyman, 1996; Domanico et al, 1994).

A wide-open ductus arteriosus exposes the pulmonary vasculature to systemic blood pressure, and when pulmonary vascular resistance is less than systemic vascular resistance, to increased pulmonary blood flow. Because the premature infant with RDS frequently has low plasma oncotic pressure and may have increased capillary permeability, increases in pulmonary microvascular pressure increase interstitial and alveolar lung fluids. If plasma proteins leak into the alveolar space, surfactant function will be inhibited and pulmonary compliance will fall (Ikegami et al, 1983). The increased fraction of inspired oxygen ( $FI_{O_2}$ ) and mean airway pressures required to overcome these early changes in compliance may explain why a persistent PDA increases the risk of developing chronic lung disease (Brown, 1979; Clyman, 1996; Cotton et al, 1978).

In the preterm infant, there is a delicate balance between PDA-induced lung fluid filtration and lung lymphatic fluid reabsorption. A PDA that closes by 72 hours after birth usually has no effect on the newborn's respiratory condition (Alpan et al, 1989; Clyman, 1996; Krauss et al, 1989; Pérez Fontán et al, 1987; Shimada et al, 1989). However, if PDA persists for longer than 72 hours or if lymphatic drainage is impaired (as it is in the presence of pulmonary interstitial emphysema or fibrosis), the likelihood of edema increases dramatically. In infants with a persistent PDA, pulmonary edema and alterations in pulmonary mechanics usually develop at 7 to 10 days after birth. In these infants, improvement in lung compliance occurs following closure of the PDA (Clyman, 1996; Gerhardt and Bancalari, 1980; Johnson et al, 1978; Naulty et al, 1978; Stefano et al, 1991; Yeh et al, 1981).

## DIAGNOSIS

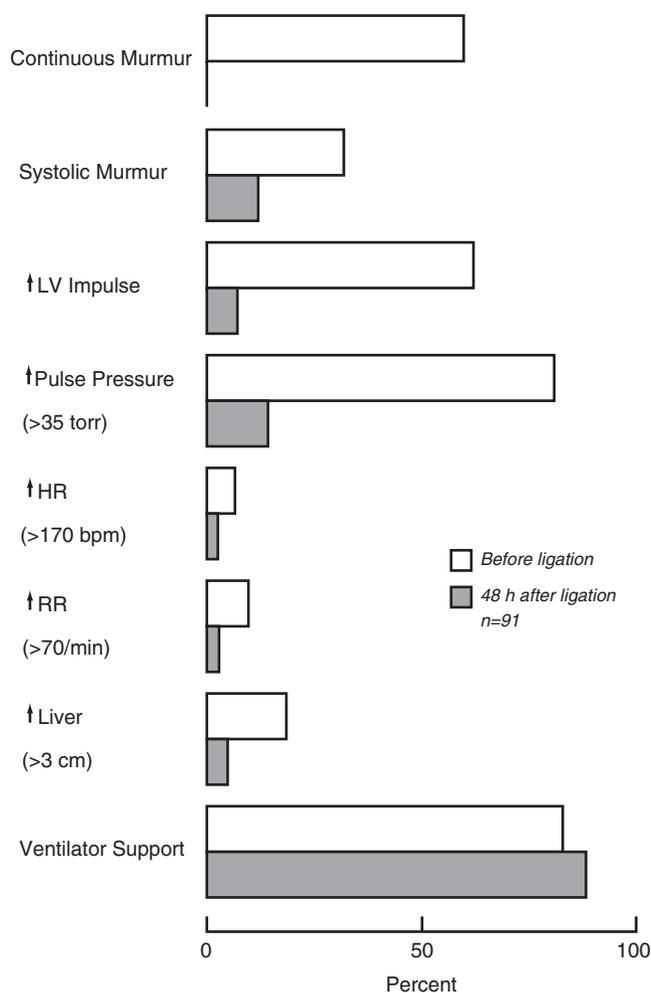

The combination of two-dimensional echocardiographic visualization of the ductus with either pulsed wave, continuous wave, or color Doppler measurements appears to be not only very sensitive but also specific for identifying ductus patency (Drayton and Skidmore, 1987; Gentile et al, 1981; Huhta et al, 1984; Mellander et al, 1987; Stevenson et al, 1980). This combination may also be useful in determining pressure gradients across the ductus (see also Chapter 53) (Musewe et al, 1987). Unfortunately, determining the size of the lumen of the ductus arteriosus and the magnitude of the Doppler signal from the shunt give only qualitative measures of the size of the shunt. M-mode measurements of LA:Ao ratio (diameter of the left atrium to that of the aortic root) of greater than 1.4 (Johnson et al, 1983), Doppler-derived measurements of cardiac output (Walther et al, 1989), and/or evidence of diastolic retrograde flow in the descending aorta help to determine when moderate-to-large PDA shunts are present (Ellison et al, 1983; Evans and Iyer, 1994; Iyer and Evans, 1994; Mellander et al, 1987; Serwer et al, 1982).

Clinical signs of a PDA usually appear later than echocardiographic signs but have a higher correlation with the development of PDA-associated neonatal morbidity. Ellison and colleagues (1983) attempted to evaluate several commonly used criteria for diagnosing a large left-to-right shunt through the ductus arteriosus by noting the occurrence of each sign both before and 36 to 48 hours after surgical ligation (Fig. 56-1). No single criterion alone sufficed as an indicator of PDA. Certain signs, such as continuous murmur or hyperactive left ventricular impulse, were specific for PDA but lacked sensitivity; conversely, ventilatory support criteria were very sensitive but lacked specificity. On the other hand, the appearance of three or more of these clinical signs—systolic murmur, hyperdynamic precordial impulse, full pulses, widened pulse pressure and/or worsening respiratory status—correlated well with the subsequent development of PDA-related morbidity (see "Treatment" later).

## INCIDENCE

Pulsed Doppler echocardiographic assessments of full-term infants indicate that functional closure of the ductus has occurred in almost 50% by 24 hours, in 90% by 48 hours, and in all by 72 hours. The rate of ductus closure is delayed in preterm infants; however, in essentially all healthy preterm infants of 30 weeks of gestation or greater, ductus closure will have occurred by the fourth day after birth (Table 56-1). RDS also delays ductus closure; however, in most infants of 30 weeks of gestation or greater, the actual impact of RDS on ductal shunting may be less than has been commonly assumed (see Table 56-1). On the other hand, preterm infants of less than 30 weeks of gestation with severe respiratory distress have a high incidence of persistent PDA (see Table 56-1).

The introduction of exogenous surfactant therapy has altered both the incidence and the presentation of PDA. Although surfactant has no effect on the contractile behavior of the ductus, its effects on pulmonary vascular

**FIGURE 56-1.** Clinical signs associated with a patent ductus arteriosus. (Data from Ellison RC, Peckham GJ, Lang P, et al. *Evaluation of the preterm infant for patent ductus arteriosus. Pediatrics* 71:364-372, 1983.)

resistance lead to earlier clinical manifestation of the left-to-right shunt in preterm animals (Clyman et al, 1982; Shimada et al, 1989) and humans (Alpan and Clyman, 1995; Kaapa et al, 1993; Reller et al, 1991, 1993). Infants

who receive excessive fluid administration during the first days of life also are more likely to develop a clinically symptomatic PDA (Bell and Acarregui, 2001).

## TREATMENT

In some centers, conservative measures including fluid restriction, diuretics, and digitalis have been advocated to treat the symptoms associated with a PDA. Although excessive fluid administration has been associated with an increased incidence of PDA (Bell and Acarregui, 2001), fluid restriction is unlikely to cause ductus closure (Green et al, 1980). In addition, the combination of fluid restriction and diuretics frequently leads to electrolyte abnormalities, dehydration, and, most important, caloric deprivation. Digitalis would not be expected to be very useful because myocardial contractility is increased rather than reduced in infants with PDA. Moreover, there may be an interaction between digoxin and indomethacin that increases the patient's susceptibility to the toxic effects of digoxin (Berman et al, 1978; Koren et al, 1984; Wilkerson and Glenn, 1977).

The addition of positive end-expiratory pressure has been found to be useful in managing infants with a PDA. When end-expiratory pressure is added, the degree of left-to-right shunting through the ductus arteriosus decreases; as a result, effective systemic blood flow increases (Cotton et al, 1980). A low hematocrit has been shown to aggravate left-to-right shunting by lowering the resistance to blood flow through the pulmonary vascular bed (Lister et al, 1982). Higher hematocrits diminish excessive shunting through the PDA and help ensure adequate systemic oxygen delivery when perfusion is limited. Similarly, demands on left ventricular output should be minimized in infants with PDA by maintaining adequate oxygenation and by keeping the patient in a neutral thermal environment. Nevertheless, such therapies usually only delay, rather than prevent, the ultimate need for PDA closure.

Cotton and associates (1978) demonstrated that failure of the ductus to close after significant clinical symptoms of cardiovascular compromise have developed (approximately 7 to 10 days after birth) significantly increases the neonatal morbidity risk. Ligation of a symptomatic PDA

RDS, respiratory distress syndrome.

Data from the following references: Dudell and Gersony, 1984; Gentile et al, 1981; Hammerman et al, 1986; Reller et al, 1993.

in premature infants now can be done in the neonatal intensive care unit, with low mortality and morbidity rates (Mikhail et al, 1982; Wagner et al, 1984). However, respiratory compromise, blood pressure fluctuations, intracranial hemorrhage, infection, chylothorax, recurrent laryngeal nerve paralysis, and death are still significant risks among infants of less than 28 weeks of gestation.

Inhibition of prostaglandin synthesis with nonselective cyclooxygenase (COX-1 and COX-2) inhibitors (such as indomethacin and ibuprofen) appears to be an effective alternative to surgical ligation (Gersony et al, 1983). At this time, indomethacin is the only nonselective cyclooxygenase inhibitor approved for the treatment of PDA. Its efficacy and toxicity have been explored extensively, and it appears comparable to surgical ligation in preventing the complications associated with PDA: bronchopulmonary dysplasia (BPD), NEC, and intolerance of enteral feedings (Gersony et al, 1983). In most intensive care nurseries, indomethacin has replaced surgery as the preferred therapy for persistent PDA. However, indomethacin has been associated with several adverse effects in the newborn: alterations in renal function (Betkerur et al, 1981; Gersony et al, 1983), NEC, and gastrointestinal hemorrhage (Rennie et al, 1986). Indomethacin produces significant reductions in renal (Pezzati et al, 1999; Rennie et al, 1986) and mesenteric (Coombs et al, 1990; Van Bel et al, 1990) blood flow, which may play a role in the pathogenesis of adverse effects. Indomethacin also reduces cerebral blood flow velocity (Austin et al, 1992; Edwards et al, 1990; Laudignon et al, 1988; Patel et al, 2000; Pryds et al, 1988; Van Bel et al, 1989) and cerebral oxygenation (McCormick et al, 1993; Patel et al, 2000), which could lead to cerebral ischemia; however, indomethacin has not been shown to have a negative impact on neurodevelopmental outcome (Couser et al, 2000; Merritt et al, 1982; Peckham et al, 1984; Yeh et al, 1982). Unlike its effects on the ductus arteriosus, indomethacin's action on these other organ systems may not be due entirely to its inhibition of prostaglandin synthesis (Chemtob et al, 1991; Malcolm et al, 1993; Speziale et al, 1999). Indomethacin also has effects on lipoxygenase activity and on histamine and endothelin release (Docherty and Wilson, 1987; Konig et al, 1987; Therkelsen et al, 1994), although the relevance of these effects to observed neonatal morbidity is still unknown.

Ibuprofen, another nonselective cyclooxygenase inhibitor, also has been shown to close the ductus arteriosus in animals (Coceani et al, 1979). However, ibuprofen does not appear to affect mesenteric blood flow (Malcolm et al, 1993; Pezzati et al, 1999; Speziale et al, 1999) and has less of an effect on renal perfusion than indomethacin (Malcolm et al, 1993; Pezzati et al, 1999; Speziale et al, 1999). Similarly, ibuprofen does not decrease cerebral blood flow and may even extend its autoregulatory range (Chemtob et al, 1990; Mosca et al, 1997; Patel et al, 2000; Speziale et al, 1999). Animal studies suggest that ibuprofen may even have cytoprotective effects in the intestinal tract (Grosfeld et al, 1983). Early clinical trials have shown that ibuprofen is as effective as indomethacin for treatment of PDA but is associated with a significantly lower incidence of renal toxicity (Van Overmeire et al, 2000).

## Indomethacin

### Dose

Although there may be general consensus regarding the efficacy of indomethacin for the treatment of PDA, questions about proper dosage, treatment duration, and optimal timing of treatment remain quite controversial. Indomethacin's plasma clearance depends on postnatal age (Brash et al, 1981; Smith et al, 1984; Thalji et al, 1980; Yaffe et al, 1980; Yeh et al, 1989). Therefore, a dosage regimen recommended for infants at the end of the first week (when the half-life of the drug is 21 hours) (Yaffe et al, 1980; Yeh et al, 1989) may lead to elevated and prolonged plasma concentrations when this agent is used in infants on day 1 (when the half-life is 71 hours) (Smith et al, 1984). Conversely, a single loading dose of indomethacin (0.2 mg/kg), without subsequent maintenance doses, can be effective in preventing clinical symptoms associated with a PDA when administered within the first 24 hours following delivery (Krueger et al, 1987). Many variations in dosage regimens have been reported. Table 56-2 outlines one successful approach. Serious side effects are uncommon with these doses; however, oliguria and dilutional hyponatremia are frequent and may necessitate interruption of a full course of treatment. Isolated bowel perforation is unusual (although the incidence has been shown to increase markedly if indomethacin and stress doses of glucocorticoids are administered concurrently) (Early postnatal dexamethasone therapy, 2001). There is no clear evidence that the incidence or severity of NEC is affected by indomethacin treatment.

### Duration

Prostaglandin production is only transiently suppressed following indomethacin therapy. Within 6 to 7 days following completion of therapy, circulating prostaglandin E<sub>2</sub> concentrations return to the normal range (Seyberth et al, 1982). This interval may not allow enough time for anatomic remodeling of the ductus in the most immature infants. A prolonged maintenance course of low-dose indomethacin (0.1 mg/kg every 24 hours for 5 to 7 days) appears to both increase the success of the initial closure rate and decrease the relapse rate when compared with a shorter course (two or three doses over 24 hours) (Hammerman and Aranburo, 1990; Rennie and Cooke, 1991; Rhodes et al, 1988). This dosage regimen still needs further evaluation because, in some reports (Rennie and Cooke, 1991; Rhodes et al, 1988), a higher mortality rate was observed in the infants receiving prolonged maintenance indomethacin.

In addition to its effects on the ductus, indomethacin also is associated with vasoconstriction of other vascular beds (e.g., cerebral, mesenteric, renal). Prolonging the rate of indomethacin infusion (20 to 30 minutes) alleviates some of the drop in organ blood flow (Colditz et al, 1989); a continuous indomethacin infusion, of the same total daily dose, appears to decrease indomethacin's detrimental effects even further (Hammerman et al, 1995).

TABLE 56-2

**Dosage Schedule for Indomethacin in Premature Infants with Patent Ductus Arteriosus**

Age at Onset of Treatment	Initial Dose	IV Dose (mg/kg)*			
		Time after Initial Dose			
		12	24	36	48
<b>Infants &lt;1200 g</b>					
<24 hours	0.2		0.1		0.1
>48 hours	0.2	0.1		0.1	
<b>Infants ≥1200 g</b>					
>48 hours	0.2	0.2		0.2	

\*Three doses of indomethacin usually are given by intravenous (*never* intra-arterial) administration over 20-30 minutes.

### Timing

The postnatal age at which indomethacin is administered plays an important role in determining its effectiveness. Several investigators have suggested that the relative ineffectiveness of indomethacin in treating infants of advanced postnatal age may be due to rapid drug clearance with a resultant inability to maintain “desired” plasma concentrations (Brash et al, 1981; Thalji et al, 1980). However, even when indomethacin concentrations have been maintained in the “desired” range, the drug’s ability to produce ductus closure remains inversely proportional to the postnatal age at the time of treatment (Achanti et al, 1986; Rennie et al, 1986; Rheuban et al, 1987). With advancing postnatal age, dilator prostaglandins play a lesser role in maintaining ductus patency (see earlier). As a result, indomethacin becomes less effective in producing PDA closure (Achanti et al, 1986). It appears that in some situations, prostaglandins may not be the dominant factor maintaining ductus patency (Cotton et al, 1991).

A second type of indomethacin treatment failure is found in patients in whom the ductus initially constricts following treatment with indomethacin, only to reopen several days later. Recurrence of a symptomatic PDA after initial successful treatment is independent of initial plasma indomethacin concentrations (Brash et al, 1981; Gersony et al, 1983; Ramsey et al, 1987). The rate of reopening, which is greatest among the most immature infants, appears to be related to the timing of treatment with indomethacin and the completeness of initial ductus closure after treatment (Clyman, 1996; Narayanan et al, 2000). Permanent anatomic closure requires tight constriction of the ductus lumen and the development of ductus wall hypoxia (see earlier). Infants delivered at less than 28 weeks of gestation, with a clinically closed ductus following indomethacin treatment, will experience reopening of the ductus with development of clinical symptoms if there is any evidence of luminal patency on the Doppler examination performed at the end of indomethacin treatment. Even when there is echocardiographic evidence of ductus closure, the ductus fails to remodel in a significant number of infants. The more immature the ductus is, the greater the chance of ductus reopening; 23% of infants who were delivered before 26 weeks of gestation demonstrate

reopening in spite of echocardiographic evidence of closure; in contrast, only 9% of those who were delivered between 26 and 27 weeks of gestation demonstrate reopening if the ductus is found after indomethacin treatment to be closed by echocardiography. Early treatment leads to a higher rate of permanent ductus closure. This is due to the greater degree of initial ductus constriction in the early treatment group (Narayanan et al, 2000).

Although indomethacin treatment is most effective when given within the first 24 to 48 hours after delivery, is that necessarily the best time to administer it? Among infants born at 32 weeks of gestation, 90% of those with severe respiratory distress will have echocardiographic evidence of a PDA during the first 24 hours; however, only 40% will subsequently develop symptoms of a hemodynamically large left-to-right shunt that will require intervention with indomethacin or surgery. If this group of infants had been treated during the first 24 hours after delivery, approximately 60% would have been treated unnecessarily. Therefore, such an aggressive approach to therapy can be justified only if early treatment can be demonstrated to significantly alter outcome in these infants. If a group of infants who have a high chance (>50%) of developing a persistent PDA can be identified, then treating the PDA in the first days after delivery will significantly reduce the risk of long-term pulmonary morbidity, pulmonary hemorrhage, NEC, and the ultimate need for surgical ligation (Clyman, 1996). For example, infants who weigh less than 1000 g at birth and who develop a murmur, even without other signs of a PDA, are at high risk (80%) for developing persistent, large PDA shunts. It seems appropriate to treat these very low-birth-weight (VLBW) infants when their PDA first becomes apparent, and before signs of a large shunt become evident (Mahony et al, 1982).

Although prophylactic indomethacin (treatment within 18 hours of birth) reduces the chances of developing a symptomatic PDA, this approach does not appear to offer any additional advantage in reducing pulmonary morbidity risk or decreasing the risk of NEC when compared with an approach that waits for the first symptoms of PDA to appear (around day 3) before initiation of treatment (Clyman, 1996; Schmidt et al, 2001). However, in certain circumstances,

administration of prophylactic indomethacin may be the most appropriate strategy to follow—for example, in identified populations of infants in which (1) either the incidence of grade III or IV intracranial hemorrhage or of severe pulmonary hemorrhage is high (>10%) or (2) indomethacin failure, with the need for surgical ligation, is frequent (>30%) (Clyman, 1996).

### Indomethacin and Intracranial Hemorrhage

Previous studies have shown that indomethacin decreases cerebral blood flow, decreases reactive postasphyxia cerebral hyperemia, accelerates maturation of the germinal matrix microvasculature, and decreases the incidence of intracranial hemorrhage (ICH) in experimental animals (Dahlgren et al, 1981; Ment et al, 1983, 1992). The effects of indomethacin on ICH do not appear to be due to its effects on ductus patency (Ment et al, 1985, 1988). Because most intracranial hemorrhages occur within the first 3 days after birth, one would expect to see beneficial effects only when indomethacin is given in a *prophylactic* strategy (within the first 18 hours after birth). When prophylactic indomethacin is given to infants with normal findings on an echoencephalogram, there is a significant reduction in the incidence of all grades (I to IV) as well as the most severe grades (III and IV) of ICH. The dramatic effect of prophylactic indomethacin in infants with known, *normal* echoencephalographic findings is somewhat tempered when prophylactic indomethacin is administered to populations in which the prior ICH status is unknown. Between 30% and 50% of infants who ultimately develop an ICH have evidence of an ICH on their screening pre-indomethacin echoencephalogram. When indomethacin is administered prophylactically, without knowledge of prior ICH status, there is no longer a difference in the overall incidence of ICH; however, there is still a significant reduction in the incidence of severe (grades III and IV) ICH (Clyman, 1996).

The long-term effects of prophylactic indomethacin on cerebral function have not been fully evaluated. On evaluation at a corrected age of 18 months, there does not appear to be any change in the incidence of neurosensory impairment in infants who received indomethacin prophylaxis at birth (Schmidt et al, 2001).

### Contraindications to the Use of Indomethacin

#### Poor Renal Function

Many clinicians do not use indomethacin if a neonate's serum creatinine is above 1.8 to 2.0 mg/dL, or if urine output is below 1 mL/kg/hour. The reasoning behind this is that indomethacin may decrease urine output further and cause significant water and electrolyte problems. Whether indomethacin administered to a patient with moderate renal failure damages the kidney is uncertain; nevertheless, it is prudent to withhold indomethacin in infants who have significant renal failure. In some infants, administration of indomethacin is followed by a markedly decreased urine output which must be allowed for when replacing fluid and electrolyte losses. Neither dopamine nor furosemide is able

to minimize the renal side effects (Baenziger et al, 1999; Brion and Campbell, 2001; Fajardo et al, 1992).

### Bleeding Disorders and Thrombocytopenia

Frank renal or gastrointestinal bleeding is a contraindication to the use of indomethacin. ICH, however, is not a contraindication to the use of this drug (Ment et al, 1994). As mentioned previously, indomethacin may actually decrease the incidence of ICH.

Indomethacin impairs platelet function for 7 to 9 days (Friedman et al, 1978). Usually, this impairment has not been clinically relevant; however, it is customary to withhold indomethacin if platelet counts are less than 50,000/mm<sup>3</sup>, even in the absence of overt bleeding.

### Necrotizing Enterocolitis

If infants have signs of early necrotizing enterocolitis (NEC), indomethacin is usually contraindicated. Part of the rationale for this is that the NEC may be due to bowel ischemia secondary to PDA shunting, and indomethacin may further decrease blood flow to the bowel.

### Sepsis

Indomethacin should not be used if sepsis is strongly suspected because it impairs white blood cell motility.

### SUMMARY

The clinical consequences of PDA are related to the degree of left-to-right shunting with its associated increase in blood flow to the lungs and decrease in blood flow to the kidneys and intestines. Treatment with indomethacin is effective in closing a PDA, particularly when given within the first few days after birth.

The current use of exogenous surfactant has caused the symptomatic PDA to present earlier than it did during the presurfactant era. The presence of a large, symptomatic PDA that persists through the end of the first week after birth increases the likelihood of pulmonary morbidity, pulmonary hemorrhage, NEC, and the ultimate need for surgical ligation. Early treatment of a clinically symptomatic PDA, in the first days after delivery, will reduce the risk of developing these morbidities if the group of infants treated has a high chance (>50%) of developing a persistent PDA. Several centers have noted that VLBW infants who develop murmurs, even without other signs of a ductus, are at high risk (80%) for developing persistent, large PDA shunts (Mahony et al, 1982, 1985). It seems appropriate to treat these VLBW infants when their PDA first becomes apparent and before signs of a large shunt are evident.

Although prophylactic indomethacin (treatment within 18 hours of birth) reduces the chances of development of a symptomatic PDA, this approach does not appear to offer any additional advantage in reducing pulmonary morbidity or NEC when compared with early symptomatic treatment. This finding is not surprising in light of the fact that less than 40% of the placebo-treated infants in the

prophylactic trials ever developed a symptomatic PDA requiring treatment. On the other hand, administration of prophylactic indomethacin may be the most appropriate strategy to follow in certain populations of infants in which either the incidence of grade III or IV ICH (>10%) or of severe pulmonary hemorrhage (>10%) is high or indomethacin failure, with the need for surgical ligation, is frequent (>30%).

# Common Congenital Heart Disease: Presentation, Management, and Outcomes

Gil Wernovsky and Peter J. Gruber

Cardiac anomalies resulting in congenital heart disease (CHD) constitute the most common birth defect, occurring in nearly 1 in 100 live births. The normal and abnormal formation of the heart during pregnancy, as well as a system of nomenclature for categorizing the multitude of congenital defects of the heart, are discussed in Chapters 52 and 53.

This chapter focuses on the common features of the *neonatal* presentation of CHD, as well as initial stabilization, management, and current data on short- and mid-term outcomes. For a complete compendium of CHD, the reader is referred to extensive texts dedicated solely to congenital and acquired heart disease (Allen et al, 2001; Braunwald, 1997; Fyler, 1992a; Moller and Hoffman, 2000) and its management (Castañeda et al, 1994; Chang et al, 1998; Gravlee et al, 2002; Litwin, 1996; Mavroudis and Backer, 1994).

## GENERAL CONSIDERATIONS

### Epidemiology

The prevalence of structural heart disease in the first year of life confirmed by noninvasive imaging is 6 to 8 cases per 1000 live births. When cases diagnosed solely by clinical means are included, the prevalence is 8 to 10 cases per 1000 live births. The prevalence has been relatively constant over the years and in different areas around the world. Table 57-1 summarizes and compares prevalence data from several large population-based studies. Data from the New England Regional Infant Cardiac Program suggest that approximately 3 infants per 1000 live births have heart disease that results in death or necessitates cardiac catheterization or surgery during the first year of life (Fyler, 1980). A majority of these infants with congenital heart disease are identified by the end of the neonatal period (Fyler, 1980). The most common congenital heart lesions manifesting in the first weeks of life are summarized in Table 57-2. Advances in diagnostic imaging, cardiac surgery, and intensive care have reduced the operative risks for many complex lesions; the hospital mortality rate following all forms of neonatal cardiac surgery has significantly decreased since the early 1990s.

### Effects of the Transitional Circulation in Neonates with Congenital Heart Disease

In the *normal* newborn, a series of rapid physiologic changes occur at birth and in the subsequent days. Separation from the low-resistance placenta results in an increase

in systemic vascular resistance (SVR) to which the systemic (usually left) ventricle needs to adapt. Expansion of the lungs and exposure to oxygen (usually 21%, but occasionally increased with supplemental oxygen in the delivery room) result in a decrease in pulmonary vascular resistance (PVR), resulting in an increase in pulmonary blood flow (PBF) and increased left atrial return via the pulmonary veins. This increase in left atrial pressure and volume tends to close the flap valve of the foramen ovale. In most cases the ductus arteriosus constricts and closes within the first hours to days of life. In the normal heart, these physiologic and anatomic changes result in an effective separation of systemic and pulmonary venous returns, with the elimination of hypoxemia and the establishment of an “series” circulation. Over the subsequent days to weeks, there is a further fall in PVR, improved left ventricular compliance, and increased cardiac output and ventricular reserve. Hematocrit falls (physiologic anemia), which further reduces PVR by virtue of decreased blood viscosity. These physiologic changes are well suited to the transition from fetal to adult circulation.

However, in the newborn with undiagnosed CHD, it is these very changes that typically result in the signs and symptoms of a cardiac malformation. Despite the multiple anatomic variations of CHD, the newborn with CHD—even that due to very complex lesions—typically presents in one of three ways: (1) with cyanosis (the visible sign of hypoxemia); (2) with congestive heart failure (CHF), occasionally in its most severe form of circulatory collapse; or (3) as an asymptomatic or minimally symptomatic newborn with a heart murmur. As is discussed in more detail in subsequent sections on individual lesions, the *fall in PVR* is particularly deleterious in a majority of cases of CHD—those with anatomic connections between the systemic and the pulmonary circuits (e.g., ventricular septal defects [VSDs] and CHD with connections between the pulmonary arteries and aorta, such as a patent ductus arteriosus or truncus arteriosus). In addition, *closure of the ductus arteriosus* is particularly deleterious in patients with duct-dependent PBF or systemic blood flow (SBF), including virtually all patients with single ventricle, as well as those with coarctation of the aorta and interruption of the aortic arch. In these lesions, the open ductus constitutes the proverbial double-edged sword: Although necessary to perfuse the systemic or pulmonary vascular bed, the connection between the systemic and the pulmonary circuits typically results in a “steal” of systemic cardiac output into the lower-resistance pulmonary vascular bed in diastole, resulting in decreased oxygen delivery, a widened pulse pressure, and decreased overall organ perfusion.

### Mimicking the Fetal Circulation

Because in most cases, CHD is associated with stable physiology in utero, the basic principle of initial stabilization in critical CHD is to mimic the fetal circulation by providing PGE<sub>1</sub> to maintain ductal patency, keeping PVR high, keeping SVR low, providing adequate mixing at the atrial level if necessary, and minimizing whole-body oxygen consumption. Following this initial stabilization, however, prompt surgical intervention usually is necessary; although

TABLE 57-1

## Prevalence of Congenital Heart Disease: Summary of Data from Population-Based Studies

Feature	Study					Total	Mean	Approximate No. of Affected Infants per Live Births
	Baltimore Washington Infant Study (Ferencz, 1985)	New England Regional Infant Cardiac Program (Fyler, 1980)	Carlgren (1987)	Dickinson et al (1981)	Laurson (1980)

TABLE 57-2

**Most Common Congenital Heart Lesions Manifesting in the First Month of Life\* (Frequency Distribution Based on Age at Diagnosis)**

Age at Diagnosis		
0-6 Days (n = 1603)	7-13 Days (n = 311)	14-28 Days (n = 306)
D-TGA (15%)	Coarctation (20%)	VSD (18%)
HLHS (12%)	VSD (14%)	TOF (17%)
TOF (8%)	HLHS (9%)	Coarctation (12%)
Coarctation (7%)	D-TGA (8%)	D-TGA (10%)
VSD (6%)	TOF (7%)	PDA (5%)
Other (52%)	Other (42%)	Other (38%)

\*These six lesions account for ~50% of cases of congenital heart disease that manifests in the first month of life.

HLHS, hypoplastic left heart syndrome; PDA, patent ductus arteriosus; TGA, transposition of the great arteries; TOF, tetralogy of Fallot; VSD, ventricular septal defect.

prostaglandin therapy may maintain patency of the ductus for a considerable period of time, long-term medical management cannot overcome the principal physiologic change of the transitional circulation, namely, the expected fall in PVR.

### PHYSIOLOGIC CATEGORIZATION OF CONGENITAL HEART DISEASE

Although the different anatomic variations of CHD are many, the physiologic manifestations in the newborn period are much more limited. Two basic principles apply:

1. Anatomic connections of large enough size between the two atria (e.g., atrial septal defect [ASD]), ventricles (e.g., VSD), or great vessels (e.g., ductus arteriosus) will equalize the pressures on both sides of the defect.
2. Blood flow will be toward the pathway of lower resistance.

#### Pulmonary Hypertension

Pulmonary hypertension—defined strictly as elevated pressure in the pulmonary artery—will result from any nonrestrictive communication at the ventricular or great vessel level. Unfortunately, the term *pulmonary hypertension* frequently is mistakenly used in the neonatal intensive care unit (NICU) to mean “elevated pulmonary vascular resistance”; in fact, however, the terms are not synonymous, as they refer to very different physiologic states. For example, the child with a congenital heart defect such as a large VSD or patent ductus arteriosus will have systemic pressure in the pulmonary artery because of the transmitted systemic pressure into the pulmonary vascular bed. However, the net shunt will be from left to right, and the baby will have symptoms of CHF. This clinical scenario should be distinguished from that in the child with pulmonary hypertension secondary to severely elevated PVR (e.g., congenital diaphragmatic hernia,

meconium aspiration, idiopathic pulmonary hypertension of the newborn [PPHN]), in whom the direction of shunt at the ductus is right to left, resulting in hypoxemia rather than CHF. Both cases demonstrate elevated pulmonary artery pressures—“pulmonary hypertension”—but the physiologic sequelae are very different. Care should be taken to accurately describe a patient with pulmonary hypertension as having either low PVR (as in most cases of CHD) or high PVR (as in most cases of lung disease).

#### Series Circulation: Shunt Physiology

In the absence of associated obstructive lesions, newborns with septal defects or connections between the great vessels will have blood flow shunted from the systemic circulation into the pulmonary circulation. This resultant “left-to-right” shunt results in a higher PBF ( $Q_p$ ) than SBF ( $Q_s$ ). The magnitude of left-to-right shunt is typically expressed as the ratio of SBF to PBF ( $Q_p:Q_s$ ). As PVR falls, an increasing amount of SBF is shunted into the pulmonary circulation, resulting in a volume load in the pulmonary circuit. Compensatory mechanisms to increase SBF occur, including increase in heart rate, increase in stroke volume, and increase in renin and aldosterone production with resultant salt and water retention. The clinical manifestations include tachypnea, tachycardia, and other signs of CHF.

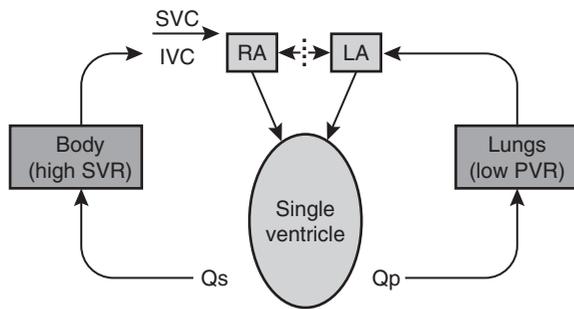

#### Single-Ventricle Physiology

Atresia of an atrioventricular (AV) or semilunar valve results in a physiologic state in which there is complete mixing of the systemic and pulmonary venous circulations. In addition, in some children, there is borderline hypoplasia of an AV valve, outflow tract, or ventricle; in such cases, a separated two-ventricle circulation is ultimately possible. In each of these situations, there is essentially complete mixing of the systemic and pulmonary venous return, typically at the ventricular and/or atrial level (Fig. 57-1). A consequence of the mixing is that the ventricular output must be divided between the pulmonary and systemic arterial circuits: the two parallel circuits. In this situation the pulmonary artery and the aortic oxygen saturations are equal, and the ventricular output is the sum of the PBF ( $Q_p$ ) and the SBF ( $Q_s$ ). The proportion of the ventricular output that goes to the pulmonary or systemic vascular bed is determined by the relative resistance to flow into the two circuits.

In almost all hearts with single-ventricle physiology, one of the two outflows (pulmonary artery or aorta) is obstructed. It is extremely rare to have no outflow obstruction or to have obstruction to the pulmonary *and* the systemic circuits. As a result, patients generally fall into two distinct categories: those with obstructed pulmonary outflow and those with obstructed systemic outflow.

Resistance to *pulmonary* flow is determined by

- the degree of subvalvar or valvar pulmonary stenosis
- the pulmonary arteriolar resistance
- the pulmonary venous and left atrial pressure
- the size of the ductus arteriosus

**FIGURE 57-1.** Single-ventricle physiology. This physiologic variant occurs in several heterogeneous forms of congenital heart disease in which there is complete mixing of the systemic and pulmonary venous returns at the atrial or ventricular level. The ventricular output is divided between the systemic and the pulmonary arterial circulations; the relative distribution is dependent on the relative resistances of the systemic and pulmonary vascular beds, as well as the presence of any anatomic obstruction (see text). IVC, inferior vena cava; LA, left atrium; PVR, pulmonary vascular resistance; Qp, pulmonary blood flow; Qs, systemic blood flow; RA, right atrium; SVC, superior vena cava; SVR, systemic vascular resistance.

The left atrial pressure is determined by the volume of the PBF entering the left atrium and the degree of obstruction to outflow through the left AV valve and atrial septum.

Resistance to *systemic* flow is determined by

- the degree of subaortic or aortic valvar stenosis, arch hypoplasia, or coarctation
- the SVR
- the size of the ductus arteriosus

### **Balancing the Parallel Circulations**

In managing the neonate with single-ventricle physiology, the goal is to balance the ventricular output between the systemic and the pulmonary vascular beds in such a way as to provide for adequate oxygen delivery to prevent acidosis, while minimizing volume load to the single ventricle. Assuming a pulmonary venous saturation of 95% to 100% and a mixed venous oxygen saturation of 55% to 60%, an arterial oxygen saturation of 75% to 80% represents a Qp:Qs of approximately 1.0. This typically results in ventricular volume overload that is twice normal (the ventricle must pump the Qp *plus* the Qs), with minimal AV valve regurgitation and normal systemic blood flow and oxygen delivery.

### **The Transitional Circulation in the Patient with Single Ventricle**

After birth, there is a fall in PVR and a relative increase in the proportion of PBF from the combined ventricular output. As the PVR continues to fall with time, an increasing proportion of the combined ventricular output is committed to the lungs. The normal homeostatic mechanisms to improve systemic output result in an increased stroke volume and an increase in heart rate.

However, the normal fall in PVR over the first few hours to days of life, in the absence of a significant obstruction to PBF, gradually results in elevated PBF at the expense of SBF. As Qp:Qs approaches 2.0, the single ventricle becomes progressively volume overloaded, with mildly elevated end-diastolic and atrial pressures. The neonate may show signs of respiratory distress. The greater proportion of pulmonary venous return in the mixed ventricular blood results in an elevated systemic arterial oxygen saturation (approximately 85% to 90%), and visible cyanosis may be mild or absent.

Before surgical intervention, a number of ventilatory and pharmacologic maneuvers may be employed to “balance” the circulation (to achieve Qp:Qs of approximately 1), resulting in adequate oxygen delivery and SBF. However, in many of these patients, ventilatory and pharmacologic management only temporizes the need for surgical intervention. Cases of “unbalanced” single-ventricle physiology may be divided into two physiologic extremes: (1) inadequate PBF, which results in hypoxemia, and (2) excessive PBF, which results in CHF.

### **Inadequate Pulmonary Blood Flow**

The newborn with single-ventricle physiology and an inadequate oxygen saturation (less than 65%) may have limited PBF as a result of (1) intracardiac obstruction (e.g., severe valvar and/or subvalvar pulmonic stenosis); (2) a restrictive ductus arteriosus in lesions with “duct-dependent” PBF; (3) elevated PVR; or (4) obstruction to pulmonary venous outflow causing pulmonary venous hypertension and secondary pulmonary arteriolar hypertension.

Management strategies to improve PBF in this setting should be tailored to the underlying anatomic or pathophysiologic abnormality resulting in the decreased PBF. For example, in patients with *intracardiac obstruction* to PBF, maneuvers may be performed to increase blood pressure and SVR (e.g., increasing inotropic infusions), “forcing” more blood through the obstructed intracardiac pulmonary outflow. Interventional procedures such as pulmonary valve dilation may also be considered in this group of patients. Patients who are hypoxemic as a result of an obstructive left-sided AV valve and restrictive ASD may undergo transcatheter dilation of the atrial septum. Patients thought to be hypoxemic due to elevated PVR should undergo ventilatory maneuvers to decrease PVR (e.g., increased FIO<sub>2</sub>, hyperventilation/induction of alkalosis, administration of nitric oxide). Most intravenous pulmonary vasodilators are nonspecific and result in unpredictable changes in the PVR and SVR.

### **Excessive Pulmonary Blood Flow**

A more common scenario in nonoperated patients with single ventricle is progressively increasing PBF at the expense of SBF. When the imbalance is severe, systemic hypoperfusion, metabolic acidosis, and shock may result. Once presence of a patent ductus arteriosus is confirmed, maneuvers to minimize SVR and maximize PVR should be employed. Hypotensive patients with a relatively high arterial oxygen saturation (i.e., less than 90%) generally have a severe “steal” of the combined ventricular output

into the pulmonary vascular circuit. In these “overcirculated” patients, excessive inotropic support (particularly at alpha doses) should be minimized, and afterload reduction (e.g., sodium nitroprusside) may be especially helpful in patients with elevated SVR and an adequate blood pressure.

It is important to emphasize that many patients with single-ventricle physiology and “high” arterial oxygen saturations actually have *decreased* oxygen delivery to the tissues. The increased oxygen content comes at the expense of a relative reduction of SBF, which results in inadequate tissue perfusion, metabolic acidosis, and low cardiac output. In addition, ventricular wall tension and oxygen consumption are increased in the dilated, volume-overloaded single ventricle, potentially contributing to myocardial dysfunction and AV valve regurgitation. A progressive metabolic acidosis, even if mild, is a worrisome sign in these patients and requires prompt evaluation and management.

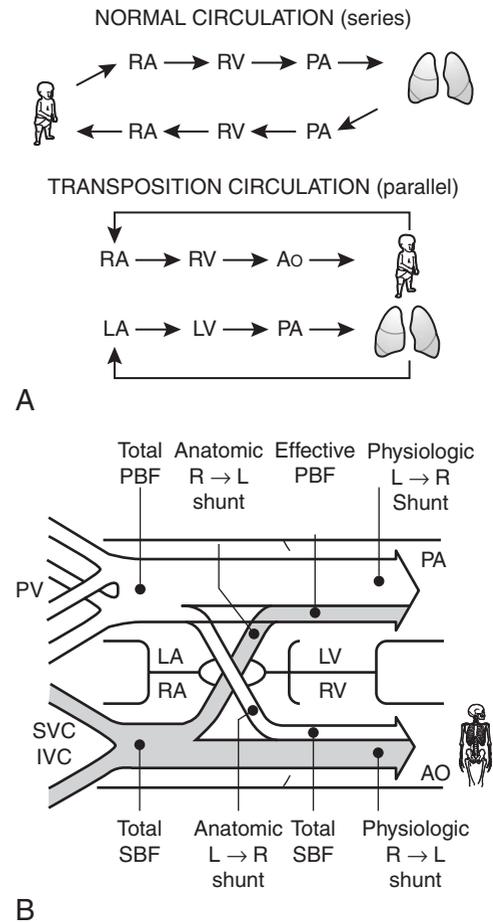

Maneuvers to increase PVR have been shown to be clinically effective in reducing excessive PBF. Supplemental inspired nitrogen or supplemental CO<sub>2</sub> may be used to elevate PVR by inducing alveolar hypoxia (Tabbutt et al, 2001). The hematocrit should be maintained at greater than 40% to 45%, as the increased viscosity also may serve to elevate PVR. Intubation and mechanical ventilation with sedation, paralysis, and permissive hypoventilation can be used to elevate the PCO<sub>2</sub> to the range of 40 to 50 mm Hg. Metabolic acidemia should be corrected with sodium bicarbonate.

It is important to emphasize that preoperative patients with marked overcirculation and systemic hypoperfusion should not undergo a lengthy period of “medical management” of their unstable physiology. If a patient requires intubation and sedation to maintain adequate SBF, relatively urgent surgical management is indicated to achieve a more favorable physiology.

### Transposition Physiology

The dominant physiologic abnormalities in the newborn with transposition of the great arteries (TGA) are a deficiency of oxygen supply to the tissues and an excessive right and left ventricular workload. The systemic and the pulmonary circulations function in parallel rather than in series; hence, the greatest portion of the output of each ventricle is recirculated to that ventricle (Fig. 57–2). In TGA with intact ventricular septum (TGA/IVS), only a relatively small proportion of blood is exchanged by intercirculatory mixing between the two circulations; consequently, only a small proportion of the effective circulation reaches the appropriate vascular bed. The systemic and the pulmonary arterial oxygen saturations are thus dependent on one or more of the following locations for this exchange: *atrial* (patent foramen ovale, ASD); *ventricular* (VSD), and/or *great vessel* (patent ductus arteriosus, bronchopulmonary collateral circulation).

The net volume of blood passing from the pulmonary circulation (left atrium, left ventricle, pulmonary arteries) to the systemic circulation (right atrium, right ventricle, aorta) represents the anatomic *left-to-right* shunt and is the *effective* SBF (i.e., oxygenated pulmonary venous return

**FIGURE 57-2.** **A**, Comparison of the series circulation in the normal newborn with the parallel circulation in transposition of the great arteries (TGA). In TGA, survival after birth is dependent on mixing at either the atrial, ventricular, or great vessel level. **B**, Relative distribution of total and effective flows through the pulmonary and systemic arterial circulations in TGA. See text for details. Ao, aorta; IVC, inferior vena cava; LA, left atrium; LV, left ventricle; PA, pulmonary artery; PBF, pulmonary blood flow; RA, right atrium; RV, right ventricle; PV, pulmonary veins; SBF, systemic blood flow; SVC, superior vena cava. (From Wernovsky G: *Transposition of the great arteries*. In Allen HD, Gutgesell HP, Clark EB, Driscoll DJ [eds]: *Moss and Adams' Heart Disease in Infants, Children, and Adolescents: Including the Fetus and Young Adult*, 6th ed. Philadelphia, Lippincott Williams & Wilkins, 2001, pp 1027-1084.)

perfusing the systemic capillary bed). Conversely, the net volume of blood passing from the systemic circulation to the pulmonary circulation represents the anatomic *right-to-left shunt* and is the *effective* PBF (systemic venous return perfusing the pulmonary capillary bed). The effective PBF, effective SBF, and net anatomic right-to-left and left-to-right shunts all are equal to each other. This volume is the *intercirculatory mixing*, which in TGA is the flow on which survival depends. The net volume exchanged between systemic and pulmonary circulations must be equal over a given short interval of time, because any major differences will result in a depletion of the blood volume of one circulation at the expense of overloading the other.

The volumes of anatomic right-to-left and left-to-right shunted blood (i.e., effective blood flow) that participate in functional gas exchange at the pulmonary and the systemic capillary levels are relatively small in comparison with the large volumes of blood *circulating* (total SBF and PBF) or *recirculating* (physiologic left-to-right and right-to-left shunt flows) within each circulation. The physiologic left-to-right shunt represents the volume of the pulmonary venous blood recirculating through the lungs without having passed through the body, and the physiologic right-to-left shunt is the volume of systemic venous blood reentering the systemic circulation without having passed through the lungs (Paul and Wernovsky, 1995) (see Fig. 57–2B).

The extent of intercirculatory mixing in TGA depends on the number, size, and position of the anatomic communications, and on the total blood flow through the pulmonary circuit. In the neonate with an intact ventricular septum and a closed or closing ductus arteriosus, severe hypoxemia secondary to inadequate mixing at the foramen ovale level is usually present. When the interatrial or interventricular shunting sites are of adequate size, the level of arterial oxygen saturation is influenced primarily by the pulmonary-to-systemic flow ratio, with a high PBF resulting in relatively high arterial oxygen saturation, as long as the ventricles can adequately maintain the high-output state (Wernovsky and Jonas, 1998). If the PBF is decreased by subpulmonary or pulmonary stenosis or elevated PVR, the arterial oxygen saturation will be lowered in spite of adequately sized anatomic shunting sites.

The physiologic mechanisms that precisely control the equalization of interchange between the two circulations remain speculative. The shunting patterns appear to be determined by local pressure gradients, which in turn are influenced by respiratory cycle phase, compliance of the cardiac chambers, heart rate, and the volume of blood flow and the vascular resistance in each of the circulations. With TGA/IVS, the interatrial shunt is from right atrium to left atrium during ventricular diastole, because left ventricular resistance to filling is less than right ventricular. The shunt is from left atrium to right atrium in ventricular systole, because the left atrium is less distensible than the right, and the net pressure in the left atrium is higher during ventricular systole. The pattern is affected by respiration, with the interatrial right-to-left (systemic-to-pulmonary) shunt increasing during inspiration, when the systemic venous return increases and pulmonary venous return decreases. The effects on intercirculatory mixing from positive pressure mechanical ventilation have not been fully studied.

### **Management of Profound Hypoxemia**

In neonates with TGA/IVS, the combination of a very low arterial PO<sub>2</sub> (i.e., less than 20 mm Hg), an elevated PCO<sub>2</sub> (despite adequate chest motion and ventilation), and metabolic acidosis (with or without pulmonary edema on the chest radiograph) constitutes a marker for severely decreased effective pulmonary and systemic arterial flows (“poor mixing”) and requires urgent attention. The initial management of the severely hypoxemic patient with TGA

includes (1) ensuring adequate mixing between the two parallel circuits and (2) maximizing the mixed venous oxygen saturation.

Once the diagnosis of TGA is made, maintaining patency of the ductus arteriosus with prostaglandin E<sub>1</sub> (PGE<sub>1</sub>) will increase PBF and intercirculatory mixing, if PVR is lower than SVR *and* there is an atrial communication. In patients in whom the ductus arteriosus does not respond to prostaglandin infusion with an increased arterial oxygen saturation, the foramen ovale should be emergently enlarged by balloon atrial septostomy, and ventilatory maneuvers should be utilized to decrease PVR and to increase PBF. Balloon atrial septostomy remains an elective procedure in patients with adequate oxygen delivery. Many practitioners find it helpful to perform a balloon atrial septostomy—even in the stable patient on prostaglandin—so that PGE<sub>1</sub> can be discontinued and surgery can take place on a more elective basis.

Even after performance of corrective maneuvers as described, some patients remain hypoxemic despite an open ductus, an adequate-size atrial communication, and hyperventilation. In these patients, it is important to emphasize that a large proportion of SBF is the *recirculated* systemic venous return. In the presence of poor mixing, significant improvements in oxygen delivery can be achieved by increasing the mixed venous oxygen saturation, which is the major determinant of systemic arterial oxygen saturation. Maneuvers include decreasing oxygen consumption (with muscle relaxants, sedation, or mechanical ventilation) and improving oxygen delivery (by increasing cardiac output with inotropic agents or increasing oxygen-carrying capacity by treating anemia). Coexisting causes of pulmonary venous desaturation (e.g., pneumothorax) should be identified and treated. Increasing the fraction of inspired oxygen to 100% will have little effect on the arterial PO<sub>2</sub>, unless this serves to lower PVR and increases total PBF.

### **Summary**

Three mutually exclusive physiologic states, as detailed, may occur in neonates with CHD: shunt physiology, single-ventricle physiology, and transposition physiology. They can easily be distinguished and categorized by the relationship of the pulmonary artery and aortic oxygen saturations. In shunt physiology, and in the normal heart, the pulmonary artery oxygen saturation is *less than* the aortic oxygen saturation. In single-ventricle physiology, the pulmonary artery oxygen saturation is *equal to* the aortic oxygen saturation, and in transposition physiology, the pulmonary artery oxygen saturation is *greater than* the aortic oxygen saturation.

### **BASIC PRINCIPLES OF CARDIAC SURGERY**

Surgery for congenital heart disease encompasses a broad variety of procedures specifically tailored to each disease process. Some can be accomplished through relatively simple surgical manipulations such as with ligation of a patent ductus arteriosus. However, other malformations require highly invasive procedures with complex modes of physiologic support. A balance must be drawn between appropriate

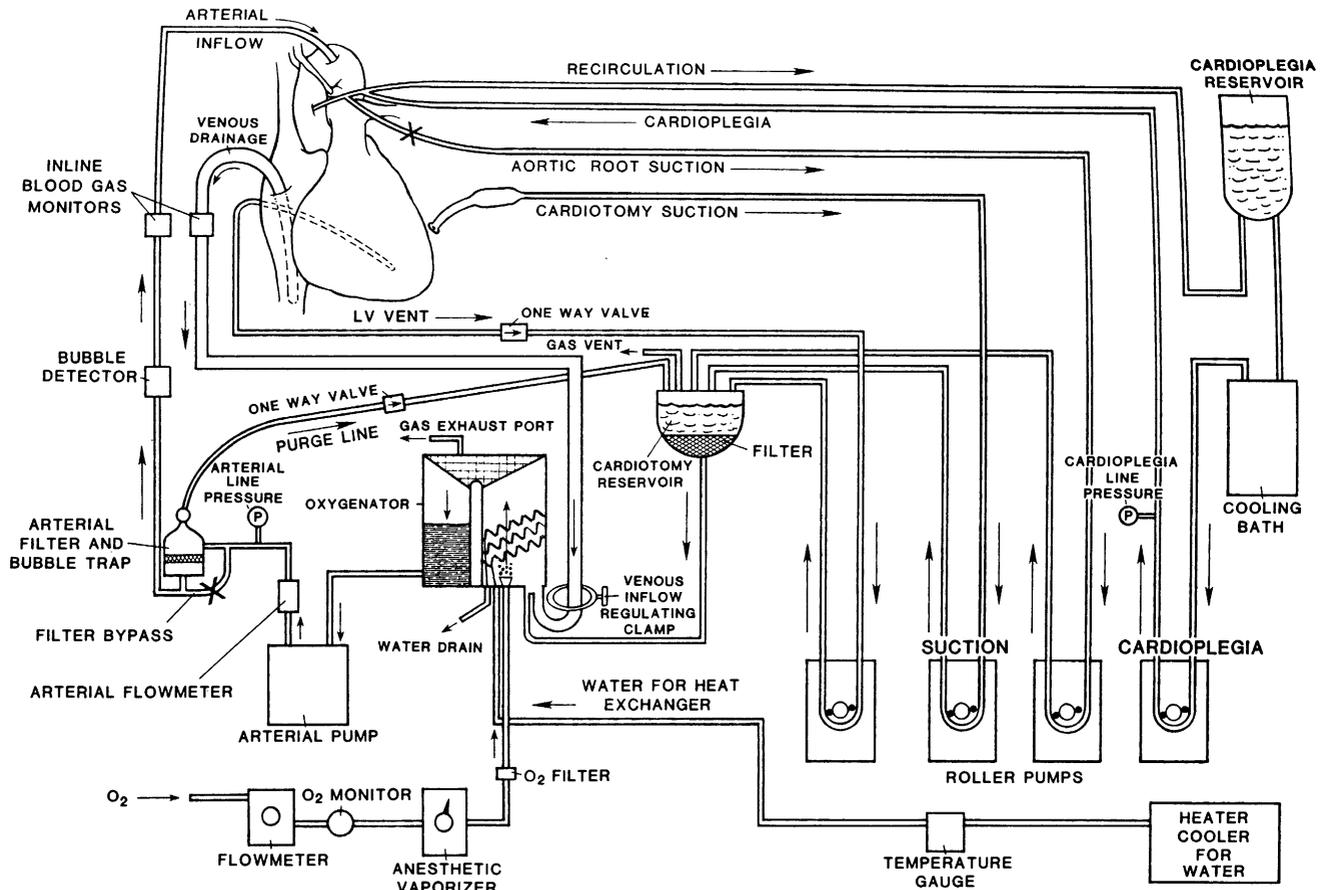

anatomic repair and the child's physiologic condition at the time of surgery. In contemporary practice, one usually proceeds toward complete repair of an anatomic defect, even as early as the immediate neonatal period. However, staged repair is occasionally employed for children in marginal physiologic condition or those with lesions for which a staged operative approach is by now standard, for example, for various forms of single ventricle.

The term *closed procedures* refers to those surgical procedures in which the heart is not opened, and more commonly in which cardiopulmonary bypass is not used. Surgical repairs that can be performed via a closed procedure commonly include ligation of patent ductus arteriosus, repair of juxtaaortic coarctation, pulmonary artery banding, and a variety of systemic-to-pulmonary artery shunt procedures. In general, *“open” procedures* require the use of cardiopulmonary bypass. This modality allows complete cardiopulmonary support of the patient while isolating the heart for repair. Closure of intracardiac defects and/or repair of great vessel abnormalities usually requires the use of cardiopulmonary bypass to provide adequate intracardiac exposure while maintaining support of other organs. Deep hypothermic circulatory arrest (DHCA) is a mode of protection that temporarily interrupts all organ perfusion. This is occasionally necessary because of either patient size or the need to reconstruct the aortic arch.

With increasing frequency, centers are using selective cerebral perfusion, such that DHCA is not strictly necessary. However, at present, an advantage of selected perfusion over circulatory arrest, or vice versa, has not been identified.

For most open procedures, the surgical incision consists of a full, vertical midline sternotomy between the sternal notch and xiphoid process. Dissection is carried down to the sternum, which is opened with either a sternal saw or an electric cautery. A sternal retractor is placed, and the thymus typically is removed in its entirety, enhancing visualization of great vessels. It is important on removal of the thymus to avoid injury to the phrenic nerves, which are tethered near the pleural reflections. The pericardium is opened in a vertical fashion and suspended. It is important at this point to pause and perform an examination of the mediastinal contents. Despite the accuracy of modern imaging techniques, the surgeon occasionally may be surprised by the presence of additional abnormalities. In particular, the unexpected presence of a left superior vena cava can considerably alter the operative and/or cannulation strategy.

The type of cannulation performed depends entirely on the type of procedure to be performed (Fig. 57-3). The principle is to remove blood from the venous system, oxygenate the blood in the bypass machine, and replace

**FIGURE 57-3.** Cardiopulmonary bypass circuit. See text for details. (From Gravlee GP, Davis RF, Kurusz M, et al: *Cardiopulmonary Bypass: Principles and Practice*. Baltimore, Lippincott Williams & Wilkins, 2002.)

the blood into the arterial system. Generally, venous cannulation is performed in one of two ways. Either a single cannula is placed into the right atrial appendage for common atrial drainage, or the superior and the inferior venae cavae are cannulated separately, providing intracardiac isolation. This decision is determined by the need to visualize the inside of the heart or by whether DHCA will be performed. If DHCA is to be used, the cannulae will eventually be removed. Thus, a single atrial cannula is utilized. If bypass is to be continued, however (as in a majority of cases), bicaval cannulation is easily performed. This allows isolation of venous drainage from both the upper and the lower portions of the body, providing a bloodless intracardiac operative field. Arterial cannulation usually is performed in the ascending aorta near the base of the innominate artery. In newborns with a small ascending aorta and/or systemic perfusion maintained through the ductus arteriosus, arterial cannulation is performed through the pulmonary root, with systemic perfusion being maintained through a systemic-to-pulmonary communication, usually a ductus arteriosus.

Heparinization is a critical component of cardiopulmonary bypass. The profoundly procoagulant nature of the bypass circuit requires the use of an anticoagulant. Development of an effective and reversible method to prevent blood clotting began in 1916 with accidental discovery of heparin by a medical student. Twenty years of purification, characterization, and trials resulted in its routine incorporation into regimens requiring an anticoagulant. Although heparin's endogenous physiologic role is not clear, its ability to antagonize antithrombin III, thrombin, and other factors allow its routine use for anticoagulation during cardiopulmonary bypass. There is considerable variability in patient response to heparin; therefore, intraoperative dosing is dependent on the activated clotting time (ACT). In general, ACT of greater than 300 seconds is required before the safe initiation of cardiopulmonary bypass. Intravenous heparin has a number of side effects including serotonin release, platelet release, rare instances of pulmonary edema, heparin-induced thrombocytopenia, and anaphylaxis. ACT is intermittently monitored during the procedure with heparin redosing to ensure appropriate anticoagulation during the procedure. Neutralization of heparin at the completion of cardiopulmonary bypass commonly is performed with administered protamine, a polyanionic protein derived from salmon sperm. Heparin binds to protamine to produce a stable precipitate, thus neutralizing its anticoagulant effect; reversal usually is prompt and complete. Adverse responses to protamine are rare but include severe pulmonary vasoconstriction.

A basic principle of cardiopulmonary bypass management is to minimize the patient's response to a controlled state of shock. Protection of the heart occurs primarily through two mechanisms: unloading the heart to reduce work and cooling to reduce metabolic rate. The vast majority of energy saved is due to arrest of the heart. Hypothermia reduces the metabolic rate and oxygen consumption approximately 5% per degree Celsius. Most procedures utilizing cardiopulmonary bypass and cardiac arrest are performed between 28° and 32° C. However, in those employing DHCA the body is cooled to a temperature of 16° to 18° C. With increasing frequency, studies

are identifying a variety of adverse short- and long-term neurologic effects of cardiopulmonary bypass. DHCA "safe" times are dependent on patient temperature. Arrest times of 10 to 15 minutes can be obtained with moderate hypothermia to 28° C, while arrest times of 45 minutes can generally be obtained safely with patient temperatures of approximately 18° C (Wypij et al, 2003). Cooling to below a temperature of 14° C results in irreversible pulmonary injury.

Myocardial protection is enhanced by cardioplegia, in which a solution is delivered to the heart that results in (1) mechanical arrest, (2) cooling, and (3) metabolic replenishment. Cardioplegia strategies are institutionally based, with good data to support the use of both crystalloid-based and blood-based cardioplegic solutions. In general the simplest, most reproducible procedure is best. The cardioplegic solution usually is injected into the aortic root after the aorta is cross-clamped proximal to the aortic cannula. The clamp separates the heart from warm blood and allows antegrade instillation of cold cardioplegic solution into the coronary arteries. Although this method is adequate in the vast majority of cases, in other cases in which the patient has an incompetent aortic valve or stenotic proximal coronary arteries, alternative methods of cardioplegia delivery are required. Instillation of the solution can be done either in retrograde fashion through the coronary sinus or via direct cannulation of the coronary orifices. In general, a streamlined, reproducible system is usually the best route.

Myocardial injury during cardiopulmonary bypass is due to a number of factors, but it is largely on reperfusion that injury begins. Oxygen radicals are produced through a number of mechanisms including lipid peroxidation, oxidation of catecholamines, and xanthine oxidase pathways. However, the major source is through superoxide and hydrogen peroxide production by activated neutrophils. These neutrophils are stimulated by the complement cascade among other signals, which in turn is activated by the cardiopulmonary bypass circuit. Modulation of these oxygen radicals has been an area of intense investigation since the late 1980s, with disappointingly little progress. Manifestations of reperfusion injury include arrhythmia, myocardial dysfunction, cardiac necrosis, capillary leak, and nitric oxide-mediated endothelial dysfunction.

The neonatal heart differs considerably from that of the older child and adult with respect to the response to myocardial protection with cardioplegia. In general, the young heart has a denser structure than the adult heart, resulting in a less compliant myocardium with less preload reserve. Additionally, the immature heart relies more heavily on active glucose metabolism than on fatty acid metabolism. Calcium stores also are less, resulting in a relative protection during ischemia and reperfusion. Many children with CHD have chronic hypoxemia, which mitigates the recovery of systolic and diastolic function after a period of ischemic arrest and reperfusion. Volume loads associated with intracardiac shunts may progress to the point of hypertrophy or dilation and compromise ventricular function, posing additional stresses. The presence of systemic-pulmonary collaterals in some children with CHD complicates myocardial

protection, with warming and “washout” of the initial cardioplegic solution. A combination of strategies such as hypothermia or reinstallation of cardioplegic solution can alleviate this difficulty.

Cardiopulmonary bypass can have profound effects on other organ systems. Striking morphologic changes in the lung are noted following cardiopulmonary bypass, including intra-alveolar edema and hemorrhagic atelectasis. Mechanical alterations such as atelectasis, diaphragmatic cooling, and airway compression are controlled by anesthetic attention. Microemboli, an inflammatory response, and lung hypoxia all contribute to decrease gas transfer and to alter mechanical properties. Use of blood filtration and membrane oxygenators and careful management of pulmonary vascular distention have helped to reduce the severity of acute lung injury. The use of adjunctive pharmacologic strategies has not resulted in a significant improvement.

Abnormalities in renal function following cardiopulmonary bypass are common, with severe renal failure occurring in up to 5% of all children following cardiac surgery. Multiple studies suggest that creatinine clearance is reduced following cardiopulmonary bypass (Dittrich et al, 2002; Hoffman et al, 2003). Although most of these children recover renal function, some require dialysis or other forms of renal replacement therapy. Among the factors contributing to perioperative renal dysfunction are diminished renal blood flow, nephrotoxic drugs, and hypothermia, especially in combination with hemoconcentration. Hemodilution is one of the most important factors in protecting renal function during cardiopulmonary bypass through its ability to increase renal plasma flow. As in other organ systems, microemboli have the capacity to impede renal function.

Metabolic and splanchnic visceral effects of cardiopulmonary bypass also follow the concepts outlined for other organ systems. Microemboli, hypercalcemia, metabolic substrate loss, and hypoperfusion contribute to visceral malfunction. Although these alterations are largely invisible at the time of surgery, they may become major complicating factors in the early postoperative period.

The neurologic effects of cardiopulmonary bypass have been the focus of significant interest over the last decade or more and are discussed in detail in Chapter 60. Much of the available data are from studies in adults with multiple comorbid conditions, making comparisons with newborn cardiopulmonary bypass difficult. Severe CNS damage secondary to stroke has a low (1% to 5%) but constant incidence following cardiac surgery. In adults, subtle CNS damage was overlooked for a number of years before more sensitive neuropsychological assessment offered a method for detecting subtle changes. These changes may become apparent only during more detailed and serial testing; with use of these methods, greater than 30% of adult patients are demonstrated to have neuropsychological defects a month or later following cardiac surgery. Current data from longitudinal studies following newborn cardiac surgery, reveal that, in general, most school-age survivors have cognitive abilities within the normal range, but nonverbal learning disabilities, attention-deficit hyperactivity disorder, and speech and language delays are common.

## PRINCIPLES OF POSTOPERATIVE CARE

### The Systematic Approach to the Patient

The heterogeneous nature of CHD, combined with the significant interpatient variability in the responses to anesthesia, surgery, and cardiopulmonary bypass, requires that a systematic but individualized approach be used for each patient. Because each patient is slightly different, we discourage “protocol” management in the strictest sense; however, a number of general principles should be followed in all children, especially the neonate. These principles include a constant evaluation of the surgical repair (including potential anatomic, electrophysiologic, and hemodynamic sequelae), the necessary inotropic support and afterload reduction necessary to maintain hemodynamic homeostasis, optimization of mechanical ventilation to reduce pulmonary trauma or hemodynamic impairment, analgesia and sedation, nutritional support, screening for infection, and assessment of secondary organ dysfunction.

### Assessment of the Repair

Perhaps the most important principle of postoperative care is that if the clinical or laboratory findings are at odds with the expected course of recovery, the care team should suspect a problem with either an inaccurate (or incomplete) diagnosis or an imperfect repair. All too often, appropriate interventions for significant residual anatomic defects are delayed as caregivers treat nonspecific states such as “low cardiac output syndrome,” “pulmonary hypertension,” or “sepsis.”

With the advent of portable echocardiography and sophisticated bedside and intracardiac monitoring, frequent, minimally invasive assessment of the repair is possible at the bedside. A checklist should be developed for each repair, reviewing the planned surgical procedure and assessing for possible anatomic or electrophysiologic residual problems. Such problems generally fall into four broad categories: residual shunts, valvular regurgitation, residual obstruction to SBF or PBF, and arrhythmias. Shortly after arrival of the infant in the intensive care unit, the postoperative team should have ascertained, in detail, the preexisting anatomic defect, the surgical procedure used in the operating room, and the results of intraoperative studies such as hemodynamic measurements or echocardiography.

### Monitoring

Accurate measurement of systemic and pulmonary artery pressures, ventricular filling pressures, urine output, alveolar gas exchange, cardiac output, SVR, and PVR allows for precise pharmacologic and ventilatory support in the perioperative period. The neonate in particular demonstrates wide swings in physiologic variables such as heart rate, temperature, glucose metabolism, SVR, and PVR, compared with those in adults, and frequently requires *more* physiologic monitoring, not less, despite the small size of the patient. Use of a variety of invasive catheters has become the mainstay of postoperative care. Invasive

monitoring catheters have two general functions: (1) assessment of the surgical repair and (2) ongoing assessment of hemodynamics. However, although these catheters are generally safe (Gold et al, 1986), they are associated with a number of risks, and their use should be determined on an individual basis.

In general, most patients are monitored in the perioperative period using arterial and urinary catheters, electrocardiographic monitoring, pulse oximetry, and intracardiac monitoring catheters. Following surgery, one to three right atrial (RA) catheters typically are placed through the RA appendage (frequently in the site used for venous cannulation on cardiopulmonary bypass), and a left atrial (LA) catheter may be placed into the right superior pulmonary vein or LA appendage. If necessary (see later), a pulmonary artery catheter is inserted through a pursestring suture in the right ventricular outflow tract, and possibly a single-lumen pressure catheter or a double-lumen catheter with a thermistor for measurement of cardiac output and core temperature.

RA catheters are used to assess the central venous pressure and for measurement of RA oxygen saturation. The RA saturation may not truly reflect the "mixed venous" saturation if the tip of the catheter is close to the renal vein flow (when it will be falsely high) or coronary sinus ostium or hepatic venous flow (when it will be falsely low); x-ray confirmation of tip position is important in correctly interpreting the data. Saline contrast injections through the RA catheter during echocardiography may detect right-to-left intracardiac shunting. RA catheters may be used for delivery of vasoactive and inotropic medications and also may be used for parenteral nutrition. This is particularly important in the low-birth-weight neonate, in whom nutritional reserve is minimal and in whom full caloric enteral feedings may be weeks away from surgery.

LA catheters provide indirect data on the function of the systemic ventricle and may be used for contrast (saline) injections during echocardiography to detect residual left-to-right shunts. Inspection of the pressure tracing allows assessment of the function of the systemic AV valve and may be helpful in distinguishing among various arrhythmias with loss of AV synchrony. The LA catheter is usually removed on the first or second postoperative day; RA catheters may be left in place for up to 2 weeks (or longer) if necessary. Complications with use of these catheters (occurring in approximately 1% in the pediatric population) include bleeding, entrapment, fragmentation, vessel perforation, transient arrhythmias, and infection (Gold et al, 1986)

Continuous monitoring of pulmonary artery pressure is helpful in a small number of patients at risk for reactive pulmonary hypertension following surgical repair of certain congenital lesions (e.g., truncus arteriosus, AV canal, obstructed total anomalous pulmonary venous connection, mitral stenosis). Use of a pulmonary artery catheter also allows for continuous assessment of the effects of respiratory and pharmacologic manipulations on the pulmonary vascular bed.

Continuous monitoring of intra-arterial systemic pressure is routinely employed. Blood pressure measurements by cuff and auscultation are unreliable in an unstable child, and automated Doppler techniques lack accuracy and reliability during low-flow states. Arterial catheters

allow for beat-to-beat analysis of the arterial waveform, which can provide insight into specific disease states such as cardiac tamponade (narrow pulse pressure with pulsus paradoxus) or a large run-off lesion such as a Blalock-Taussig shunt or aortic regurgitation (widened pulse pressure). Pronounced phasic variations in a patient receiving positive pressure ventilation, coupled with low atrial pressures, are typical for significant hypovolemia. The umbilical artery is the most frequently used site for arterial access in neonates.

### Other Monitoring

Continuous monitoring of the heart rate and QRS morphology is standard practice in most intensive care units. Indwelling urinary (Foley) catheters are useful for continuous, hourly assessment of urine output. Transcutaneous oxygen saturation monitors aid in the management of any patient with unstable respiratory status or labile PVR with intracardiac shunting. These monitors are particularly useful in cases in which parallel pulmonary and systemic circulations are supplied by a single ventricle, because variations in SVR and PVR may occur rapidly, with resulting changes in arterial saturation. Also, alterations in arterial oxygen saturation due to pneumothorax, unrecognized extubation, or ventilator failure are rapidly identified. Failure to obtain an adequate signal may be a sign of inadequate peripheral perfusion. Continuous monitoring of the mixed venous oxygen saturation by means of intravascular catheters specifically designed for this use (Oximetric, Abbott Laboratories, Chicago, IL) has been used with increasing frequency, especially in neonates with single ventricle. Finally, there is growing experience with intra-arterial sensors that provide continuous, real time assessment of blood gas data, temperature, and indices of base deficit (Neotrend, Diametrics Corporation, St. Paul, MN), even in low-birth-weight babies. These types of catheters are particularly beneficial in the postoperative low-birth-weight cardiac patient, who requires frequent laboratory assessments but has a more limited blood volume (see Chapter 59).

Temporary epicardial pacing wires are typically placed on the anterior surface of the right ventricle and, with increasing frequency, on that of the right atrium as well. Atrial wires may be used to increase heart rate (in the presence of sinus node dysfunction) while still allowing the ventricles to contract through the AV node and the normal His-Purkinje system. Rapid atrial pacing, occasionally with interposed premature beats, is very effective in converting many types of supraventricular tachycardia to normal sinus rhythm at the bedside, without the need for synchronized direct current (DC) cardioversion. In addition to the therapeutic uses, epicardial atrial wires may be used to record both unipolar and bipolar atrial electrograms for diagnostic purposes. Epicardial ventricular wires are useful in cases of AV node disease (complete heart block), although cardiac output may not be as effective when the ventricles contract dysynchronously (i.e., with the right ventricle contracting before contraction of the left ventricle, rather than through the His-Purkinje system) and without AV synchrony. Dual-chamber pacing

is particularly useful in cases of complete heart block. In patients at risk for complete heart block, the temporary wires should be checked for threshold and sensitivity after arrival in the intensive care unit, and a temporary pacemaker should be at the bedside.

### **The First 24 Hours after Cardiopulmonary Bypass**

The first night after surgery utilizing cardiopulmonary bypass is a period of potentially significant hemodynamic lability. Compared with older children, the neonate is at particular risk because of limited myocardial and pulmonary reserve, immature organ systems, a more severe postoperative (dilutional) coagulopathy and an increased propensity for nosocomial complications of infection, vascular compromise, and central nervous system (CNS) injury. Multiple studies have shown a predictable and reproducible decrease in cardiac output (Hesz and Clark, 1988; Hoffman et al, 2003; Pesonen et al, 1999), thyroid function (Bettendorf et al, 2000), pulmonary function (Nagashima et al, 2000), and renal function (Hoffman et al, 2003), accompanied by increases in PVR and SVR (Hesz and Clark, 1988), complement activation, troponin (Hauser et al, 2001) and endothelin release, and capillary leak resulting in tissue edema and organ dysfunction. These abnormalities peak nearly simultaneously between 6 and 18 hours after surgery, which makes the neonate most vulnerable in the middle of the first night following surgery. In view of this predictable scenario, proactive steps can be taken to minimize the potential risk, including the routine use of inotropic support and afterload reduction (Hoffman et al, 2003; Tweddell et al, 1999), intermittent or continuous neuromuscular blockade, and analgesia, and minimization of stressful procedures during the most at-risk period (such as bathing, suctioning, and handling). It is emphasized, however, that this period of vulnerability is self-limited, and in most neonates, support can be rapidly weaned and discontinued within 24 hours or so of surgery, especially invasive monitoring and mechanical ventilation. A prolonged “weaning” strategy is typically not necessary on physiologic grounds, and longer periods of intensive care, invasive monitoring, and mechanical ventilation expose the neonate to potential nosocomial complications and infections. In the neonate with no other organ dysfunction except the transient effects from the surgical procedure and cardiopulmonary bypass, this “de-intensification” may usually be accomplished with a day or so of surgery. A slightly longer period of mechanical ventilation may be beneficial in neonates with more significant capillary leak and chest wall edema, until adequate diuresis is achieved.

## **CONGENITAL LESIONS WITH A PREDOMINANT LEFT-TO-RIGHT SHUNT**

### **Ventricular Septal Defect**

VSD is the most common form of CHD, occurring in isolation in 1/280 live births, and is a common component of more complex lesions discussed elsewhere in this chapter

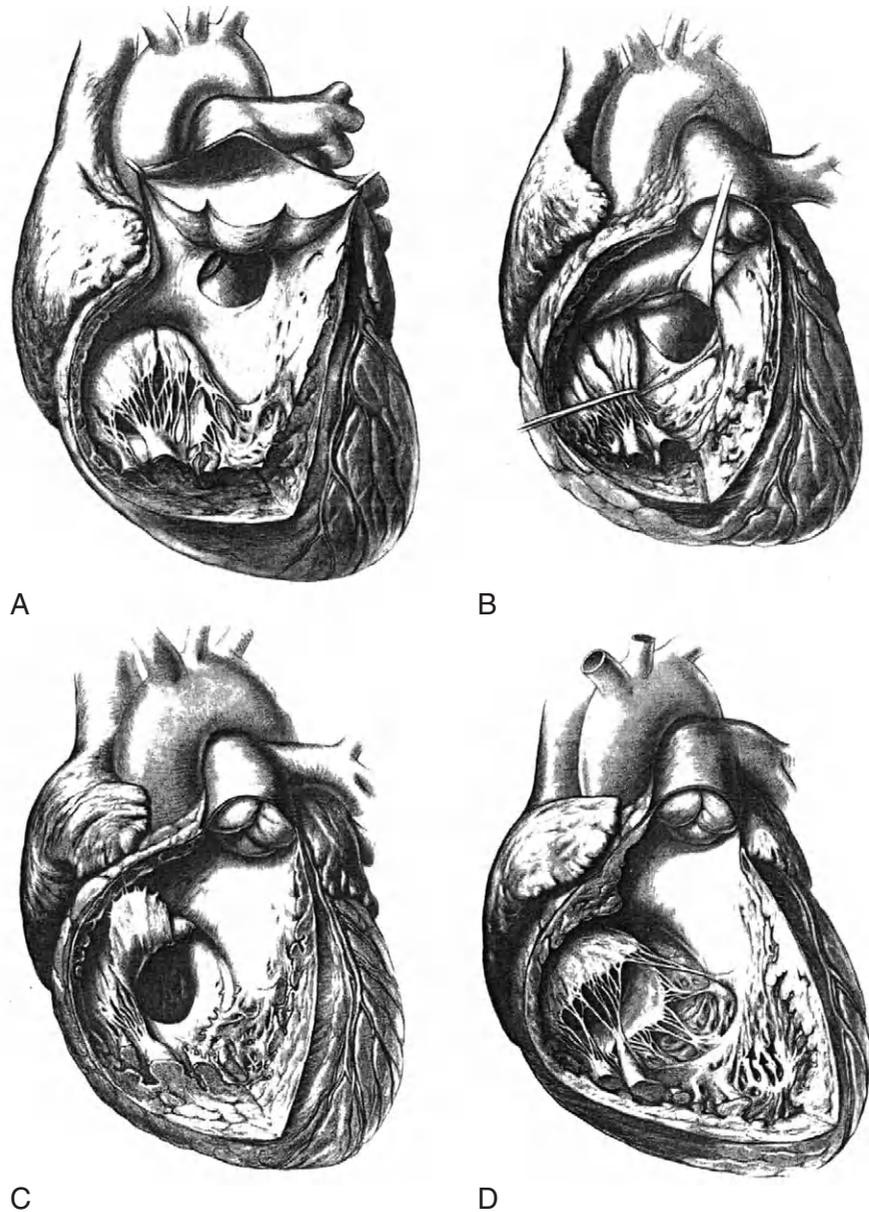

(e.g., tetralogy of Fallot, truncus arteriosus, interrupted aortic arch). VSDs may occur anywhere in the ventricular septum and usually are classified by their location (Fig. 57–4). Defects in the membranous septum are the most common type. The diagnosis of VSD usually is initially suspected on the basis of findings on physical examination of the infant: A harsh murmur develops as PVR falls and a pressure gradient develops across the defect. Echocardiography confirms the diagnosis and localizes the defect in the ventricular septum

VSD is the most common cause of CHF beyond the initial neonatal period. Moderate to large VSDs become hemodynamically significant in the first 4 to 6 weeks of life as the PVR decreases and PBF increases as a result of a left-to-right shunt across the defect. In neonates with an isolated VSD, even if large, development of symptoms of CHF is unusual, as PVR remains modestly elevated and the degree of left-to-right shunting generally is well tolerated. If CHF is present in a neonate with a VSD, additional investigations are indicated to rule out coexisting anatomic abnormalities, such as left ventricular outflow tract obstruction, coarctation of the aorta, or patent ductus arteriosus. (In premature infants, who have a lower initial PVR, clinical symptoms of heart failure may develop earlier and duration of necessary mechanical ventilation may be longer than in term infants with the same-size defect.)

Only a minority of all patients with isolated VSDs ever become clinically symptomatic. Medical management of CHF includes digoxin, diuretics, afterload reduction (typically with an angiotensin-converting enzyme inhibitor), and caloric supplementation. Growth failure is the most common symptom of CHF not fully compensated by medical management. When it occurs, failure to thrive is an indication for surgical repair of the defect, rather than prolonged medical management.

### **Spontaneous Closure of Ventricular Septal Defect**

Depending on the anatomic location, a large number of VSDs may undergo spontaneous closure in infancy and childhood. In particular, defects in the membranous septum (see Fig. 57–4B) may become smaller or even close completely as a result of overlying tissue from the septal leaflet of the tricuspid valve. Defects in the muscular septum (see Fig. 57–4D) also may become smaller with time. Because a large number of VSDs (as many as 50% of such defects, depending on the anatomic type) may close spontaneously in infancy, and symptoms are rare in the first month of life, surgery—if necessary—usually is deferred beyond the neonatal period. As a general guideline, defects that are less than half the size of the aortic valve in the membranous or muscular septum generally are followed conservatively through infancy, as partial or complete closure is likely, and surgery can be avoided in many cases. However, malalignment defects (such as seen in tetralogy of Fallot or interrupted aortic arch), or defects in the inlet (or AV canal) portion (see Fig. 57–4C) of the ventricular septum *never* close spontaneously, and if this diagnosis is made in the neonatal period, surgery will be

**FIGURE 57-4.** Anatomic varieties of ventricular septal defect: **A**, subpulmonary defect; **B**, membranous defect; **C**, inlet (atrioventricular canal type) defect; **D**, apical muscular defects. (From Mavroudis C, Backer CL: *Pediatric Cardiac Surgery*. St. Louis, Mosby-Year Book, 1994.)

inevitable. The timing of surgery will be determined by the clinical status of the patient. Finally, defects in the infundibular septum (“subpulmonary” defects; see Fig. 57-4A) may undergo spontaneous “closure,” although this is usually due to prolapse of one of the cusps of the aortic valve, leading to aortic insufficiency. Therefore, surgery frequently is recommended in early childhood for children with a subpulmonary VSD and signs of aortic valve prolapse with aortic regurgitation.

#### **Surgical Closure of Ventricular Septal Defect**

Surgical closure of VSDs is done utilizing cardiopulmonary bypass; the surgical exposure is dictated by the location of the VSD and the presence of associated defects. In most cases, the VSD can be repaired by performing an atriotomy and closing the defect through the

tricuspid valve. VSDs located under the pulmonary valve (e.g., “supracristal” VSDs, subpulmonary VSDs) may be closed via a small pulmonary arteriotomy, with the operator working through the pulmonary valve. Occasionally, a ventriculotomy is necessary to gain adequate exposure to the VSD, especially of the muscular variety.

Surgical mortality rate for isolated VSDs at present is approximately 1%. Postoperative morbidity includes junctional ectopic tachycardia, and bundle branch block; permanent complete heart block is rare. Residual VSDs are fairly common on intraoperative transesophageal echocardiography; these small VSDs, if less than 3 mm, rarely are hemodynamically significant, and reoperation rarely is required. Reoperation following VSD closure is uncommon; indications include pacemaker implantation (in approximately 1% of cases), residual VSD (in approximately 1%), or the late development of a subaortic membrane or aortic regurgitation (in less than 5%).

### Complete Common Atrioventricular Canal

Complete common AV canal (CAVC) occurs in nearly 1/5000 live births. Although there are many anatomic variations, the most common form consists of a combination of defects in the (1) endocardial portion of the atrial septum and (2) the inlet portion of the ventricular septum and (3) a common, single AV valve. In the immediate neonatal period, affected infants may present with mild cyanosis as a result of the large intracardiac communications and the relatively high PVR. If the defect is not detected in the neonatal period, however, these infants typically present early in infancy with CHF because of the large left-to-right shunt, which increases as the PVR falls; symptoms of CHF may be present earlier if there is associated regurgitation of the common AV valve. Patients with CAVC have a characteristic finding on the electrocardiogram (ECG) of a “superior axis,” and the diagnosis can be made conclusively with echocardiography.

In the absence of associated right ventricular outflow tract obstruction, pulmonary artery pressures are at systemic levels, and pulmonary vascular resistance may remain elevated, particularly in patients with trisomy 21 (nearly 70% of infants with CAVC have trisomy 21). Given the high association of CAVC with trisomy 21, a careful evaluation of phenotype—including a possible karyotype—should be considered in patients with CAVC.

The great majority of patients with CAVC will require medical treatment for symptomatic CHF with digoxin and diuretics, though prolonged medical therapy in patients with failure to thrive and symptomatic heart failure is not warranted. Complete surgical repair is undertaken electively in 3 to 6 months, with earlier repair in symptomatic patients. In the “transitional” form of AV canal, the VSD component may be partially, or nearly completely, covered by AV valve tissue, resulting in less left-to-right shunting, lower pulmonary artery pressure, and minimal symptoms. In these patients, elective repair takes place in the asymptomatic patient in the first few years of life.

#### **Surgical Repair of Common Atrioventricular Canal**

Repair of CAVC is done utilizing cardiopulmonary bypass in all cases (Fig. 57-5). The atrial and ventricular defects are closed—with either one or two separate patches—and the AV valve is reconstructed and resuspended on the VSD portion of the patch. Surgical mortality rate is low (less than 5%) in general but is higher in cases with significant AV valve regurgitation or in those patients with associated lesions (Castañeda et al, 1994). Postoperative complications include arrhythmias (sinus node dysfunction, junctional ectopic tachycardia, complete heart block [occurring in approximately 1% of cases]), AV valve regurgitation, and subaortic obstruction. Reoperation for hemodynamically significant AV valve regurgitation may be necessary in 5% to 10% of patients; surgical options at that time include valvuloplasty and valve replacement.

### Truncus Arteriosus

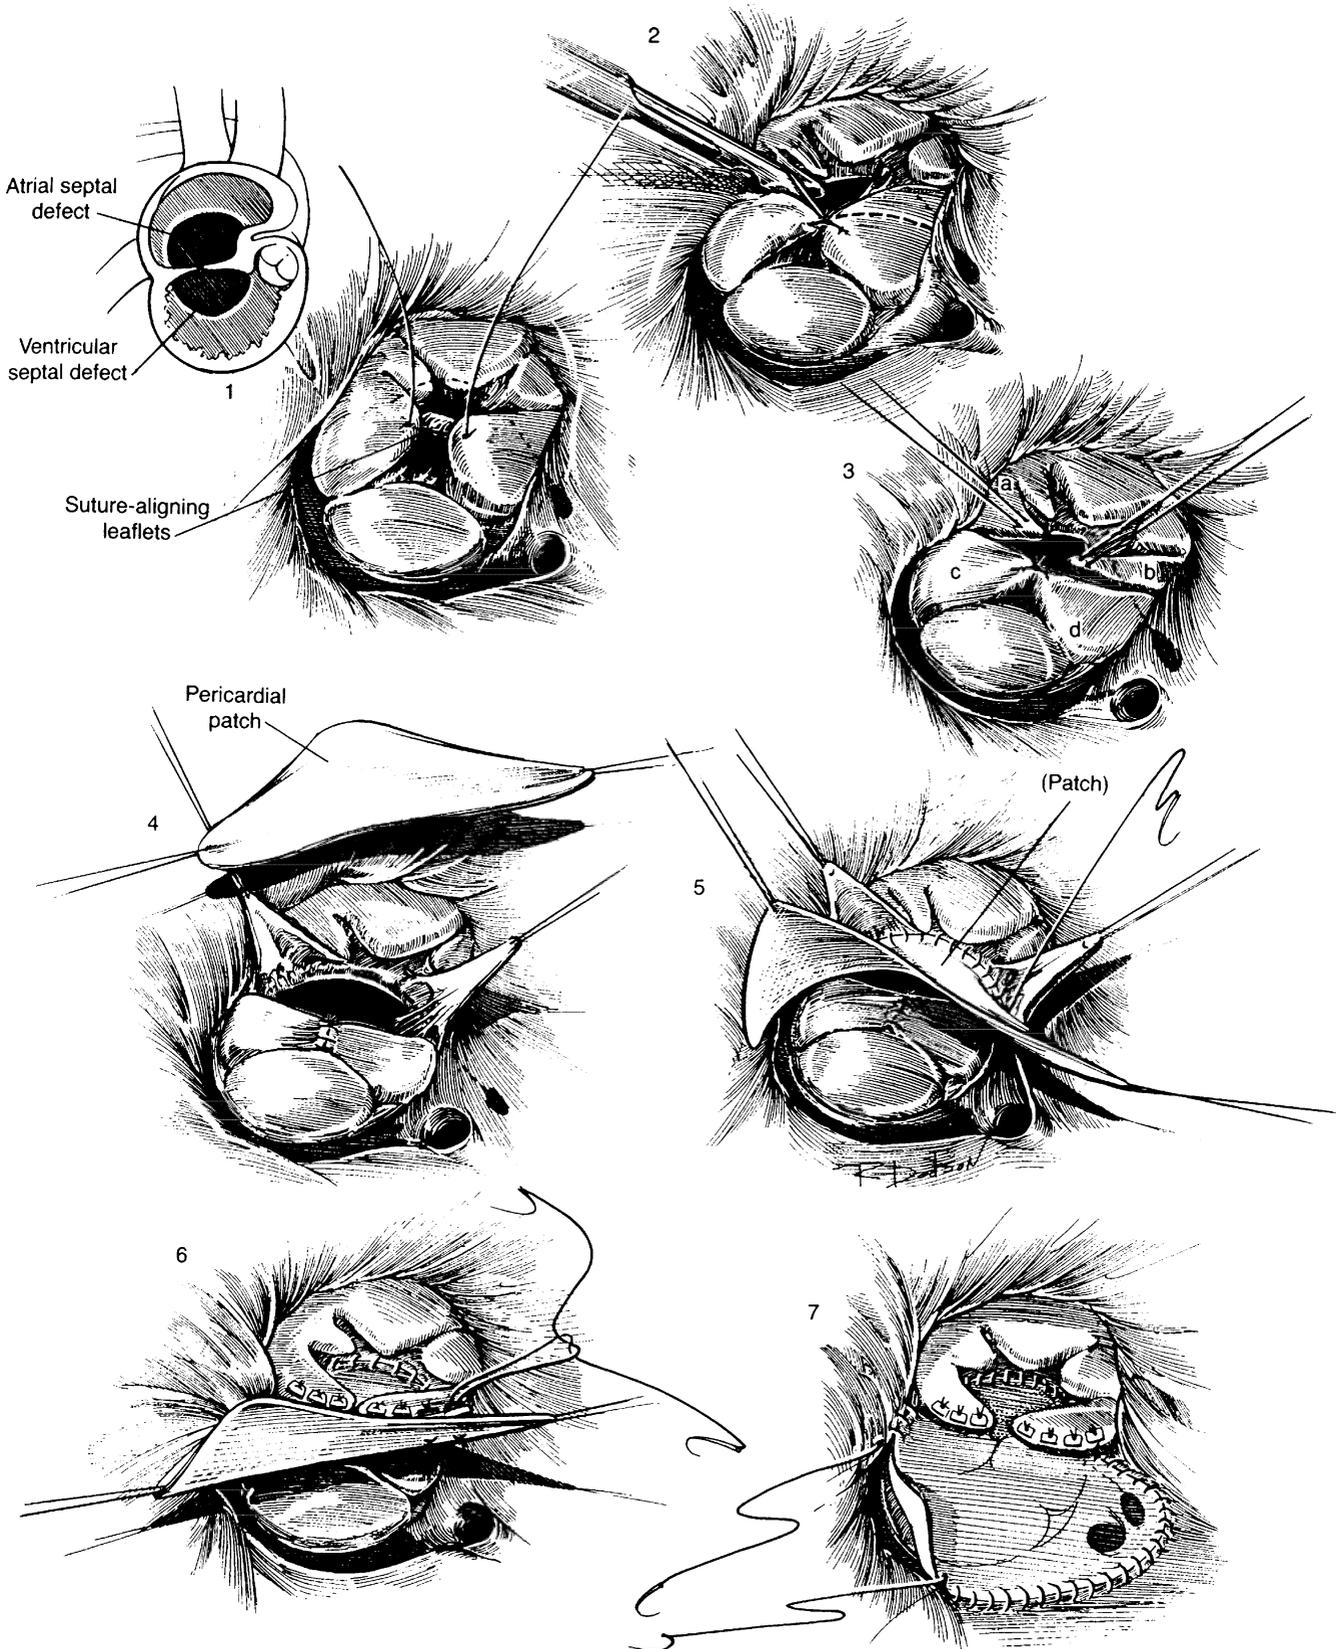

Truncus arteriosus is a relatively rare form of CHD, occurring in 1/16,000 live births. Truncus arteriosus (Fig. 57-6) consists of a single great artery arising from the heart that gives rise to (in order) the coronary arteries, the pulmonary arteries, and the brachiocephalic arteries. The truncal valve is often anatomically abnormal (only 50% are tricuspid) and is frequently thickened, stenotic, and/or regurgitant. A coexisting VSD is present in greater than 98% of cases. The aortic arch is right sided in approximately a third of cases; other arch anomalies such as hypoplasia, coarctation, and interruption are seen in 10% of cases. Extracardiac anomalies are present in 20% to 40% of cases. Recently, microdeletion of chromosome 22 (22q11 deletion—DiGeorge syndrome, velocardial facial syndrome, and so on) has been noted in as many as a third of patients with truncus arteriosus.

The overwhelming majority of infants with truncus arteriosus present with symptoms of CHF in the first weeks of life as PVR falls. The infants may be somewhat cyanotic, but CHF symptoms and signs usually are dominant. In contrast with VSD and CAVC, discussed earlier, CHF occurs earlier and may be more severe, possibly because of the direct connection of the pulmonary arteries to the aorta. In the absence of stenosis at the origins of the pulmonary arteries, the PBF is significantly increased, the pulse pressure is wide, and significant pulmonary hypertension is present. CHF may be more severe, or manifest even earlier, if there is significant stenosis and/or regurgitation of the truncal valve.

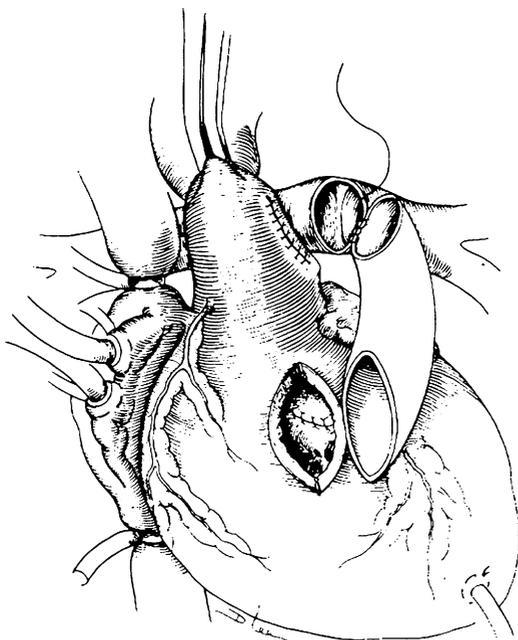

The natural history of truncus arteriosus is quite bleak. If the defect is left unrepaired, only 15% to 30% of affected infants survive the first year of life. Furthermore, among survivors of the immediate neonatal period, the occurrence of accelerated irreversible pulmonary vascular disease is common, making surgical repair in the neonatal period (or as soon as the diagnosis is made) the treatment of choice. “Medical management” of heart failure should be considered only a temporizing measure until surgical correction can be accomplished.

#### **Surgical Correction of Truncus Arteriosus**

Repair is performed utilizing cardiopulmonary bypass (see Fig. 57-6). For unclear reasons, neonates with truncus arteriosus seem to be particularly prone to ventricular fibrillation on opening of the sternum. The pulmonary arteries are removed from the common trunk, and the resultant defect in the aorta is closed either directly or with a patch. Care is taken to inspect and avoid the origin of the left coronary artery, which typically arises near the pulmonary arteries. A ventriculotomy is made to expose the VSD for closure, and to provide the location for the proximal placement of a right ventricle-to-pulmonary artery conduit. The distal end of the conduit, usually homograft, is anastomosed to the pulmonary bifurcation. Surgical mortality rate ranges from 10% to 15%, with increased risk present in older patients, those with abnormal truncal valves, DiGeorge syndrome, or associated obstruction of the aortic arch. Early postoperative complications include ventricular arrhythmias (in approximately

**FIGURE 57-5.** Anatomy and repair of complete common atrioventricular canal (CAVC) defect. Complete CAVC comprises both atrial and ventricular septal defects in addition to the common AV valve. Repair of this complex lesion through the right atrium entails creation of separate right and left AV valves (1 to 3), repair of the ventricular component of the defect (4 to 6), and closure of the atrial defect (6, 7). (From Castañeda AR, Jonas RA, Mayer JE Jr, Hanley FL: *Cardiac Surgery of the Neonate and Infant*. Philadelphia, WB Saunders, 1994.)

**FIGURE 57-6.** Anatomy and repair of truncus arteriosus. After the branch pulmonary arteries are removed from the common trunk (and the resulting aortic defect is closed), a ventriculotomy is performed. The ventricular septal defect is closed through this incision, and a conduit is placed from the right ventricle to the pulmonary arteries. (From Behrendt DM, Dick M: *Truncus repair with a valveless conduit in neonates*. *J Thorac Cardiovasc Surg* 110:1148-1150, 1995).

30% of cases), pulmonary hypertensive “crises,” complete heart block (in 2% to 3%), conduit obstruction, and truncal (“neoaortic”) valve stenosis and/or insufficiency. If the patient has 22q11 deletion, associated metabolic (hypocalcemia), infectious (immunodeficiency), feeding (palatal abnormalities and esophageal dysmotility), and CNS complications may occur as well. Late reoperations are necessary in nearly 100% of operative survivors, principally for conduit revision, but occasionally for neoaortic valve replacement.

### Atrial Septal Defect

ASDs are one of the more common types of CHD, occurring in 1/1000 live births and appearing in association with many other types of more complex CHD. Because the anatomic communication is at the atrial rather than the ventricular level, the fall in PVR has little initial effect on the degree of left-to-right shunting through the defect. The magnitude of left-to-right shunt is determined principally by the relative *compliance* of the two ventricles, rather than their afterload. As the normal newborn right ventricular hypertrophy regresses, typically in the first 3 to 6 months of life, there is a progressive left-to-right shunt at the atrial level. This left-to-right shunt only rarely causes symptoms of CHF, even if left unrepaired into adult life. If symptoms of CHF are present in patients with ASD, and/or there is a very large left-to-right shunt, presence of additional problems in the left side of the

heart, such as mitral hypoplasia or stenosis or left ventricular hypoplasia, should be considered.

ASDs are characterized by their location in the atrial septum (Fig. 57-7). Secundum-type ASDs may spontaneously close in the first few years of life, and symptoms are rare; therefore, these defects generally are not surgically repaired before 2 to 3 years of age. Sinus venous defects (typically associated with anomalous right upper pulmonary venous return) and ostium primum defects do not undergo spontaneous closure, and surgical repair typically is electively performed in the first few years of life. The surgical mortality rate is quite low (less than 1%), and postoperative complications are uncommon. Arrhythmias may develop later in adult life.

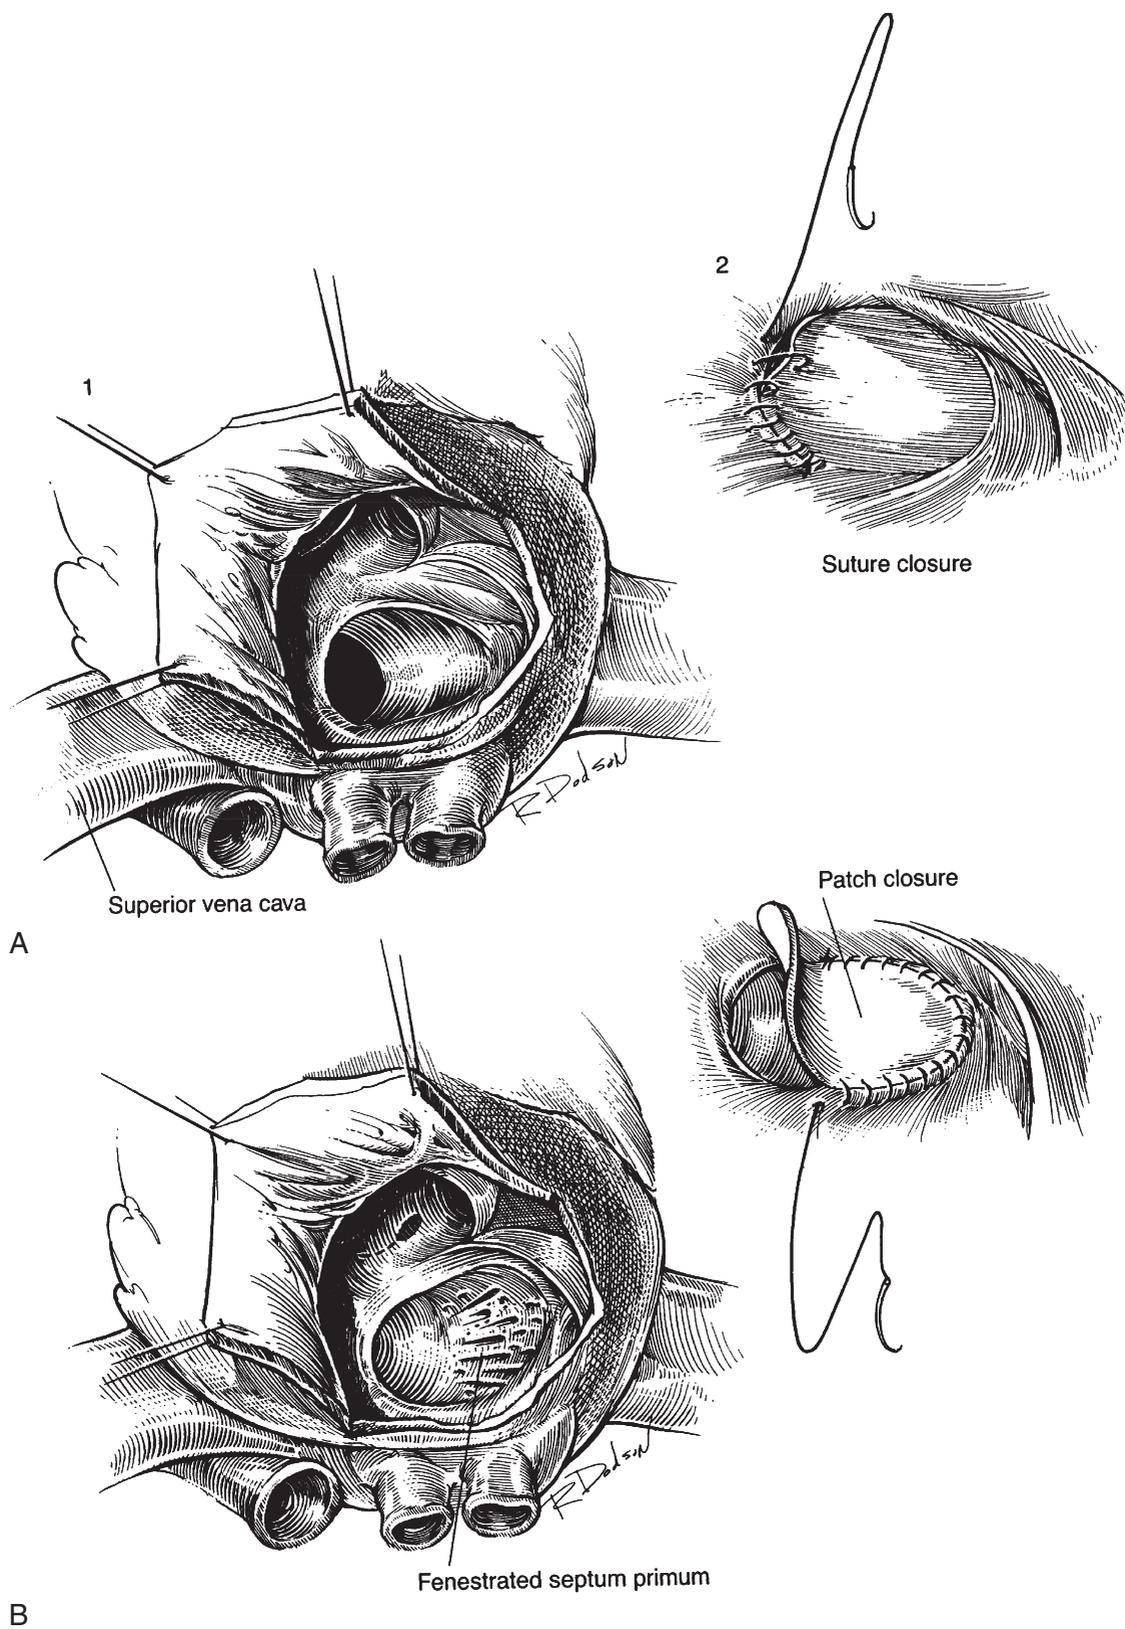

### CONGENITAL LESIONS WITH DUCT-DEPENDENT SYSTEMIC BLOOD FLOW

Commonly referred to as *left-sided obstructive lesions*, congenital lesions with duct-dependent systemic blood flow constitute a group of defects involving hypoplasia of left-sided structures of the heart: critical aortic stenosis, isolated coarctation of the aorta, interruption of the aortic arch, and hypoplastic left heart syndrome (HLHS). These four lesions on the “left side” of the heart share the common presentation of CHF and or shock/circulatory collapse on closure or constriction of the ductus arteriosus. Of the four, critical aortic stenosis usually manifests shortly after birth, with signs of CHF, a gallop rhythm, murmur, and poor perfusion. In the other three left-sided lesions—coarctation of the aorta, interruption of the aortic arch, and HLHS—the most common clinical presentation is the following: A previously well newborn, frequently discharged as “healthy” from the term nursery, presents with poor feeding, poor pulses, tachycardia, perhaps an ashen appearance, or even full cardiac arrest in the first 1 to 2 weeks of life. In many ways, this presentation may mimic that in bacterial sepsis, but it is important to remember that bacterial sepsis in the full-term, noninstrumented newborn beyond the first 24 hours of life is a rare event, occurring in perhaps 1/3000 live births. In contrast, left-sided heart disease occurs in approximately 1/1000 live births, making the presentation of circulatory failure/shock in the first weeks of life three times more likely to be due to heart disease, rather than to sepsis, in the current era (Platt and O’Brien, 2003).

Although all infants with significant left-sided lesions and duct-dependent systemic blood flow require prostaglandin-maintained patency of the ductus arteriosus as part of the initial management, additional care varies somewhat with each lesion.

### Critical Aortic Stenosis

Morphologic abnormalities of the aortic valve may range from a bicuspid, nonobstructive functionally normal valve to a unicuspid, markedly deformed, and severely obstructive valve that greatly limits systemic cardiac output from the left ventricle. By convention, “critical” aortic stenosis is present if the systemic blood flow is dependent on patency of the ductus arteriosus, regardless of the measured

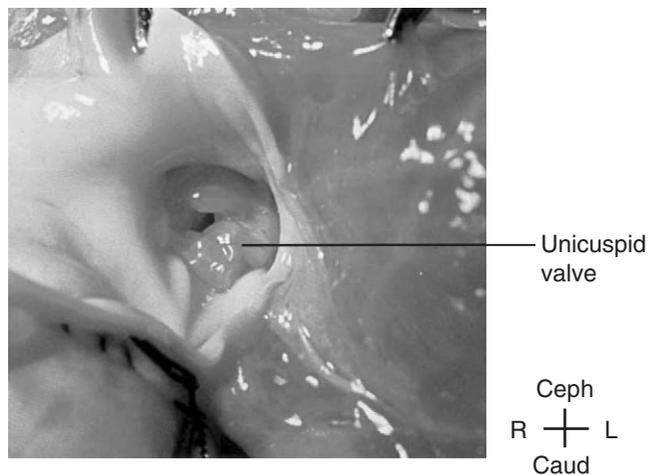

**FIGURE 57-7.** Anatomy and repair of atrial septal defects. **A,** Closure of a patent foramen ovale. **B,** Patch closure of ostium secundum atrial septal defect with fenestrated septum primum. (From Castañeda AR, Jonas RA, Mayer JE Jr, Hanley FL: *Cardiac Surgery of the Neonate and Infant*. Philadelphia, WB Saunders, 1994.)

gradient across the valve. Critical aortic stenosis results from severe anatomic obstruction with accompanying left ventricular failure and/or shock. Because of the severe left ventricular dysfunction, it is not uncommon for the output across the dysplastic aortic valve to be severely reduced. Because of the low-flow state, Doppler-measured gradients may be low—at times only 10 to 30 mm Hg—with this low value greatly underestimating the severity of the anatomic obstruction. In the presence of adequate left ventricular function, the degree of aortic stenosis is *severe* if the peak systolic gradient from left ventricle to ascending aorta is at least 60 mm Hg, *moderate* if the gradient is between 30 and 60 mm Hg, and *mild* if the gradient is less than 30 mm Hg.

Patients with critical aortic stenosis have severe obstruction present in utero (usually due to a unicuspid, plate-like valve) (Fig. 57–8), with resultant left ventricular hypertrophy and, frequently, endocardial fibroelastosis. Associated left-sided abnormalities such as mitral valve disease and coarctation are not uncommon. Following closure of the ductus, the left ventricle must supply all of the systemic cardiac output. In cases of severe myocardial dysfunction, clinical CHF or shock will become apparent.

Initial management of the severely affected infant includes treatment of shock, provision of stable vascular access, airway management and mechanical ventilation, sedation and muscle paralysis, inotropic support, and institution of PGE<sub>1</sub> therapy. Positive end-expiratory pressure is helpful to overcome pulmonary venous desaturation from pulmonary edema secondary to left atrial hypertension. For a patient with critical aortic stenosis to benefit from a PGE<sub>1</sub> infusion, however, there must be a small patent foramen ovale to allow “effective” SBF (pulmonary venous return) to cross the atrial septum and ultimately enter the systemic vascular bed through the ductus. If the atrial septum is severely restrictive or intact, there will be no way for pulmonary venous return to reach the tissues, and profound metabolic acidosis will result; even a PGE<sub>1</sub> infusion

**FIGURE 57-8.** (See also Color Plate 57–8.) Congenital aortic stenosis. Frontal view through opened aorta demonstrates stenotic and dysmorphic aortic valve with commissural fusion. (From Litwin SB: *Color Atlas of Congenital Heart Surgery*. St. Louis, Mosby, 1996.)

to ensure a patent ductus arteriosus will not suffice to stabilize the patient. In such cases, urgent balloon valvuloplasty, as well as a limited balloon atrial septostomy, may be necessary. Inspired oxygen should be limited to an FIO<sub>2</sub> of 50% to 60% unless severe hypoxemia is present.

Following anatomic definition of left ventricular size and of mitral valve and aortic arch anatomy by echocardiography, cardiac catheterization or surgery should be performed as soon as possible to accomplish aortic valvotomy. With either type of therapy, outcome will depend largely on (1) the degree of relief of the obstruction, (2) the degree of aortic regurgitation, (3) presence of associated cardiac lesions (especially left ventricular size), and (4) the severity of end-organ dysfunction secondary to the initial presentation (e.g., necrotizing enterocolitis, renal failure). The initial results from balloon valvuloplasty for critical aortic stenosis have been variable, mainly owing to the associated anatomic and physiologic variables rather than to technical aspects of the procedure. Some investigators have recently advocated a more radical surgical approach for the neonate with critical or severe aortic stenosis: a Ross procedure in the neonatal period (Ohye et al, 2001). In this surgical procedure, the diseased aortic valve is excised, typically with an annulus-enlarging procedure such as a Konno procedure; the patient's anatomic pulmonary valve is inserted in the aortic position; and a homograft is placed *in situ* in the pulmonary position (Fig. 57–9). Short-term results in well-selected patients have been acceptable, although long-term results of the anatomic pulmonary valve in the systemic position are currently unknown, and reoperation to replace the right-sided homograft is inevitable.

Critical aortic stenosis is a lifelong disease—all patients require lifelong follow-up and endocarditis prophylaxis. Restenosis or progressive regurgitation is common, and multiple procedures in childhood frequently are necessary.

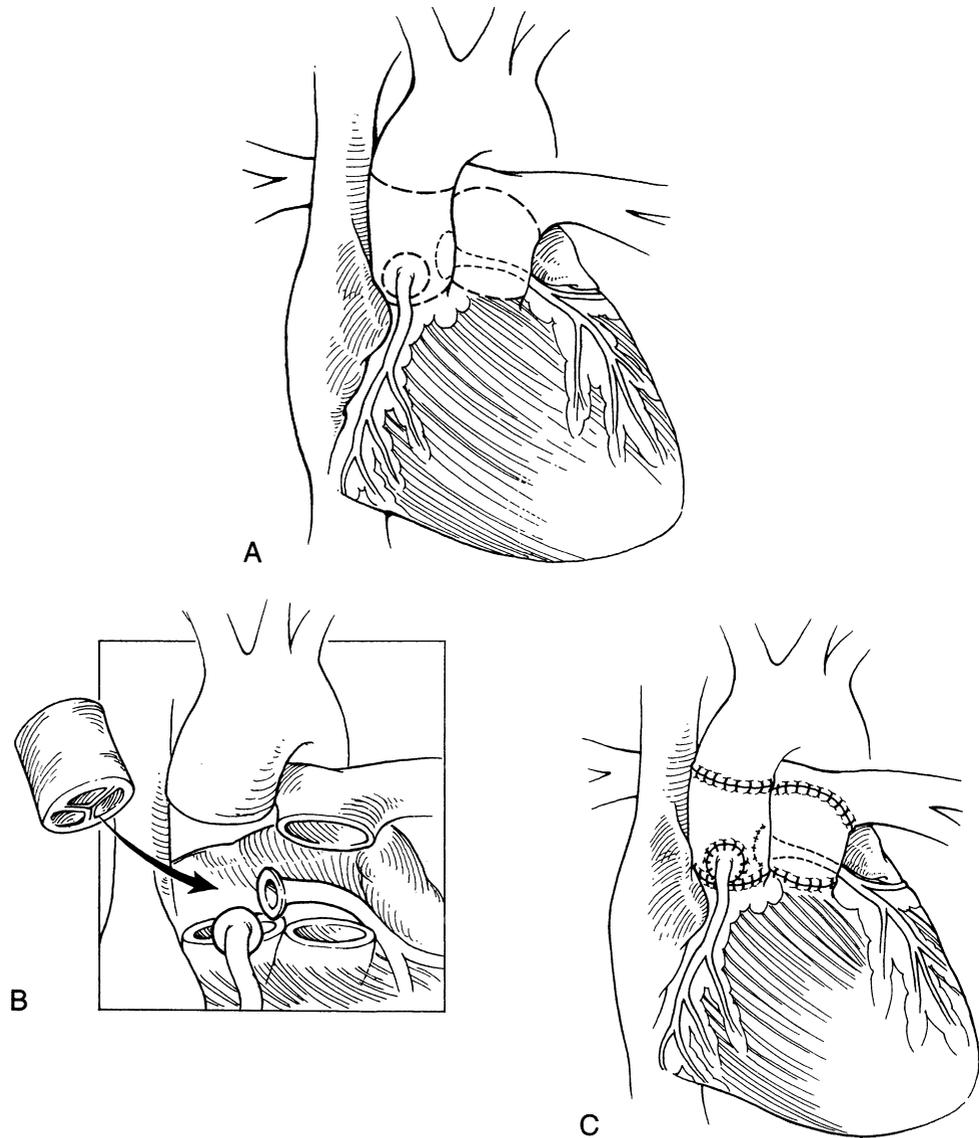

### “Noncritical” Aortic Stenosis

Patients with less severe forms of aortic stenosis—namely, those in whom the ductus is not necessary for systemic perfusion and in whom left ventricular function is for the most part preserved—have a significantly better prognosis. Balloon valvuloplasty has become the procedure of choice and frequently is the only procedure necessary throughout infancy and childhood (Egito et al, 1997; Freedom et al, 2000; Rome, 1995).

### Coarctation of the Aorta

Coarctation of the aorta, present in approximately 1 in 2500 infants, is an anatomic narrowing of the descending aorta, most commonly at the site of insertion of the ductus arteriosus (i.e., “juxtaductal”). Additional cardiac abnormalities are common, including bicuspid aortic valve (which occurs in 80% of patients) and VSD (which occurs in 40% of patients). In addition, hypoplasia and obstruction of other left-sided structures including the mitral valve, the left ventricle, and the aortic valve are not uncommon and must be looked for during the initial echocardiographic evaluation.

**FIGURE 57-9.** Ross procedure: “Autograft” aortic valve replacement. **A,** Dotted lines depict surgical incisions around coronary arteries, aorta, and pulmonary artery. **B,** The patient’s native pulmonary valve (“autograft”) is removed from the pulmonary position. Following removal of the coronary arteries from the diseased native aortic valve root, the aortic valve is removed and replaced by the autograft. **C,** Completed repair, with reimplanted coronary arteries. A cadaveric homograft valve is inserted in the pulmonary position in situ. (From Chang AC, Burke RP: *Left ventricular outflow tract obstruction*. In Chang AC, Hanley FH, Wernovsky G, Wessel DL [eds]: *Pediatric Cardiac Intensive Care*. Baltimore, Williams & Wilkins, 1998, pp 233-256.)

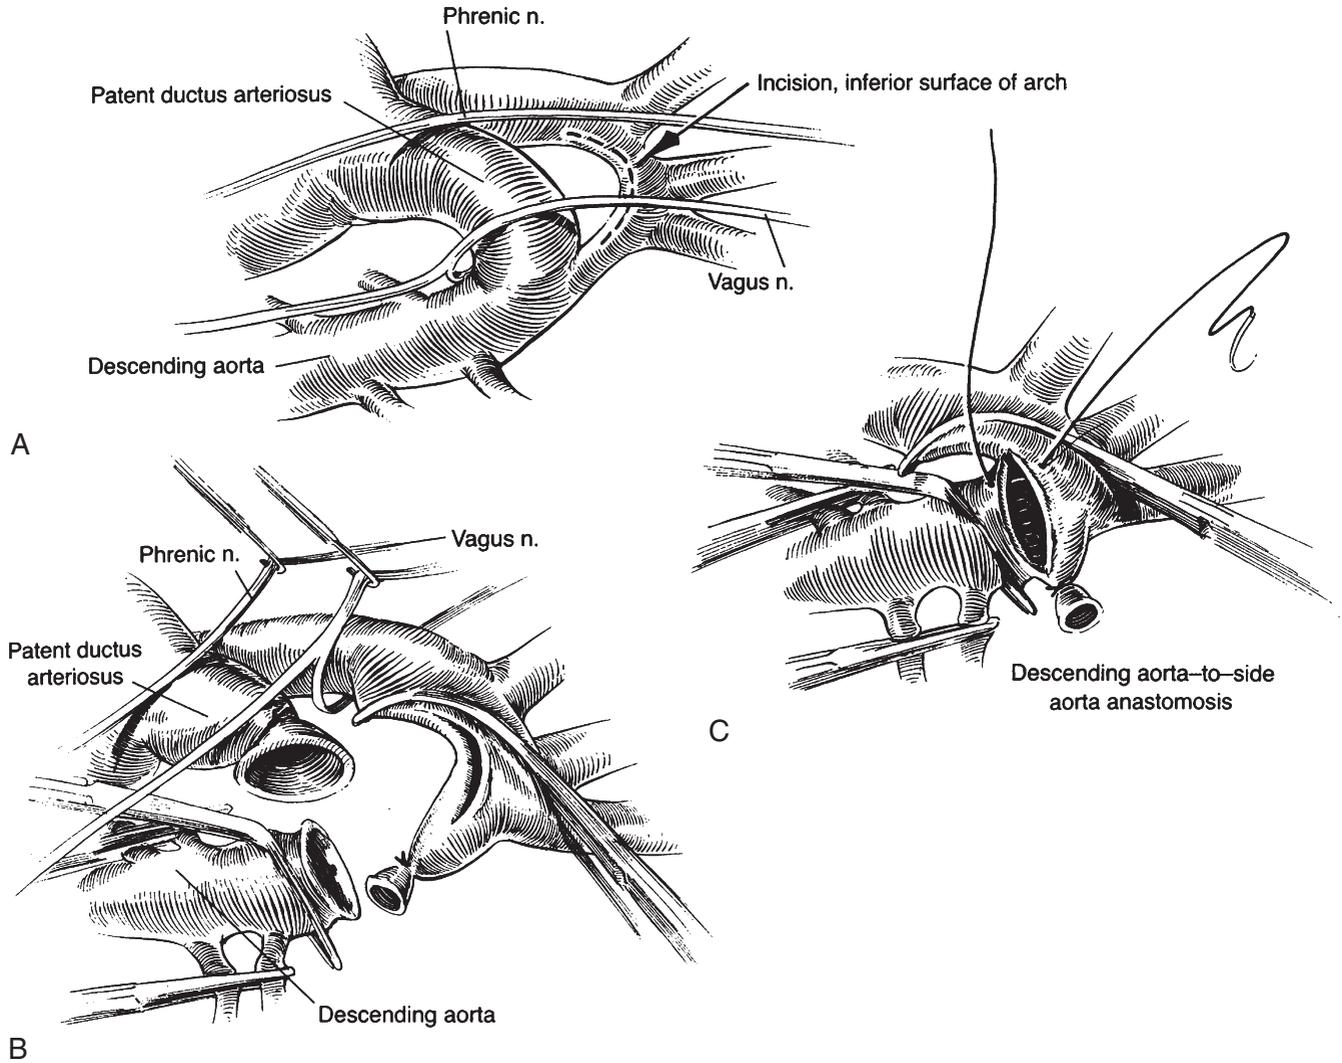

In utero, systemic blood flow to the lower body is via the patent ductus arteriosus. Following ductal closure, in the newborn with a critical coarctation, the left ventricle must suddenly generate adequate pressure and volume to pump the entire cardiac output past a significant point of obstruction. This sudden pressure load may be poorly tolerated by the neonatal myocardium, and the neonate may become rapidly and critically ill because of myocardial dysfunction and/or lower body hypoperfusion.

As in critical aortic stenosis, initial management of the severely affected infant includes treatment of shock, provision of stable vascular access, airway management and mechanical ventilation, moderate supplemental oxygen, sedation and muscle paralysis, inotropic support, and institution of PGE<sub>1</sub> therapy. Positive end-expiratory pressure is helpful to overcome pulmonary venous desaturation from pulmonary edema secondary to left atrial hypertension. In some infants, PGE<sub>1</sub> is unsuccessful in opening the ductus, and urgent surgical intervention is necessary after a brief period of resuscitation. In less severely affected newborns, especially those who are diagnosed

before significant myocardial dysfunction or end-organ damage has occurred, low-dose inotropic support and a PGE<sub>1</sub> infusion may be all that is necessary until surgical intervention can be undertaken.

In symptomatic infants with coarctation, surgical repair is performed as soon as the child has been resuscitated and medically stabilized. Usually the procedure is performed through a left lateral thoracotomy incision. In most cases, the coarctation is resected, and the proximal and distal ends of the aorta are anastomosed to each other. The proximal incision may be extended on the underside of the aorta to manage areas of proximal hypoplasia (“extended end-to-end” anastomosis; Fig. 57-10). In infants with symptomatic coarctation and a large, coexisting VSD, consideration should be given to repair of both defects in the initial procedure via a median sternotomy. The surgical mortality rate for isolated coarctation repair is less than 5% and higher if additional defects are repaired simultaneously using cardiopulmonary bypass. Balloon dilation of native coarctation is not routinely done because of the high incidence of restenosis and aneurysm

**FIGURE 57-10.** View through left lateral thoracotomy of the anatomy and repair of aortic coarctation. **A**, Dotted line depicts the surgical incision; important vascular and nerve landmarks are shown. **B**, The ductus arteriosus is divided and the proximal end is ligated. The coarctation segment and any residual ductal tissue in the descending aorta are resected. An incision in the undersurface of the transverse aortic arch is made. **C**, The descending aorta is brought superiorly and anastomosed to the undersurface of the aortic arch. (From Castañeda AR, Jonas RA, Mayer JE Jr, Hanley FL: *Cardiac Surgery of the Neonate and Infant*. Philadelphia, WB Saunders, 1994.)

formation, especially given the safe and effective surgical alternative.

Recoarctation occurs in 10% to 15% of children, especially if the repair is undertaken in the early newborn period (most likely due to the fact that early repair is necessary in the most severe forms of coarctation). Recoarctation is very effectively managed with balloon angioplasty.

### Interrupted Aortic Arch

Interrupted aortic arch is present in approximately 1/30,000 live births. Although this lesion is similar in many respects to severe coarctation of the aorta, there are a few notable exceptions. The clinical presentation—shock or severe CHF in the first 2 weeks of life—is remarkably

similar. Interrupted aortic arch, however, is not a lesion isolated to the great vessels but is a complex conotruncal defect that occurs in most cases as a result of posterior malalignment of the infundibular septum with the muscular septum—almost a “mirror image” of tetralogy of Fallot, in which there is anterior malalignment. (Also as in tetralogy of Fallot, microdeletion of chromosome 22 is common.) The posterior malalignment results in a narrowed left ventricular outflow tract, sometimes nearly atretic. It is thought that this severe obstruction in utero results in decreased growth, hypoplasia, and eventual interruption of the distal aortic arch. Thus, in addition to the VSD and narrowed subaortic area, there is complete atresia of a segment of the aortic arch. There are three anatomic subtypes of interrupted aortic arch based on the location of the interruption: type A, distal to the left subclavian artery; type B, between the left subclavian artery

and the left carotid artery; and type C, between the innominate artery and the left carotid artery. (Fig. 57–11). Type B is the most common variety. In up to 50% of cases of type B interruption, the right subclavian artery arises aberrantly from the descending aorta *below* the ductus. Thus, all four extremities have equal pressure, even in the presence of ductal constriction or, following repair, making assessment for recoarctation impossible by blood pressure measurements alone.

Infants with interrupted aortic arch are completely dependent on a patent ductus arteriosus for lower body blood flow; thus, they become critically ill when the ductus closes. Immediate management is similar to that described for coarctation; PGE<sub>1</sub> infusion is essential. All other resuscitative measures will be ineffective if blood flow to the lower body is not restored. Oxygen saturations should be measured in the upper body; pulse oximetry readings in the lower body are reflective of the pulmonary artery oxygen saturation, which typically is lower than that distributed to the CNS and coronary arteries. (However, as mentioned previously, those patients with an aberrant right subclavian artery from the descending aorta may have low oxygen saturations in all four extremities, and ear oximetry may be the only location to determine oxygen delivery to the CNS.) High concentrations of inspired oxygen may result in low PVR, a large left-to-right shunt, and a “run-off” during diastole from the lower body into the pulmonary circulation. Inspired oxygen levels should therefore be minimized, aiming for normal (95%) oxygen saturations in the *upper* body.

Surgical reconstruction should be performed as soon as metabolic acidosis (if present) has resolved, end-organ dysfunction is improving, and the patient is hemodynamically

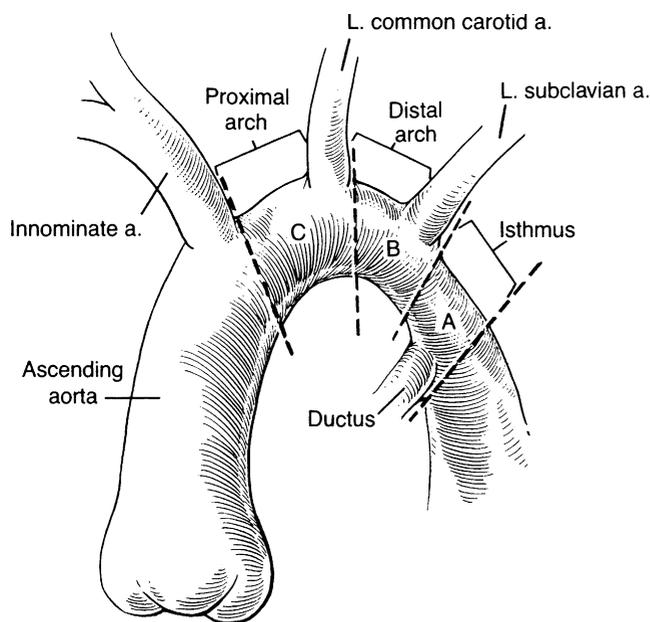

stable. The repair typically entails a corrective approach via a median sternotomy, with the method of arch reconstruction based on the distance between the interrupted segments (short: direct anastomosis [Fig. 57–12]; long: tissue-to-tissue connection with homograft patch augmentation—jump grafts are rarely used), and closure of the VSD. A staged approach (arch reconstruction and a pulmonary artery band via a lateral thoracotomy) generally is not recommended and typically is reserved for patients with multiple VSDs. The surgical mortality rate is less than 10% but higher in patients with multiple anomalies, severe left ventricular outflow tract obstruction, low birth weight, multiple VSDs, or end-organ dysfunction. Repeat operation is necessary in approximately 25% of patients for progressive subaortic obstruction in childhood (Gaynor et al, 2000; Monro et al, 2003), and approximately 10% to 15% of infants require balloon angioplasty of the arch reconstruction for recurrent obstruction.

### Hypoplastic Left Heart Syndrome

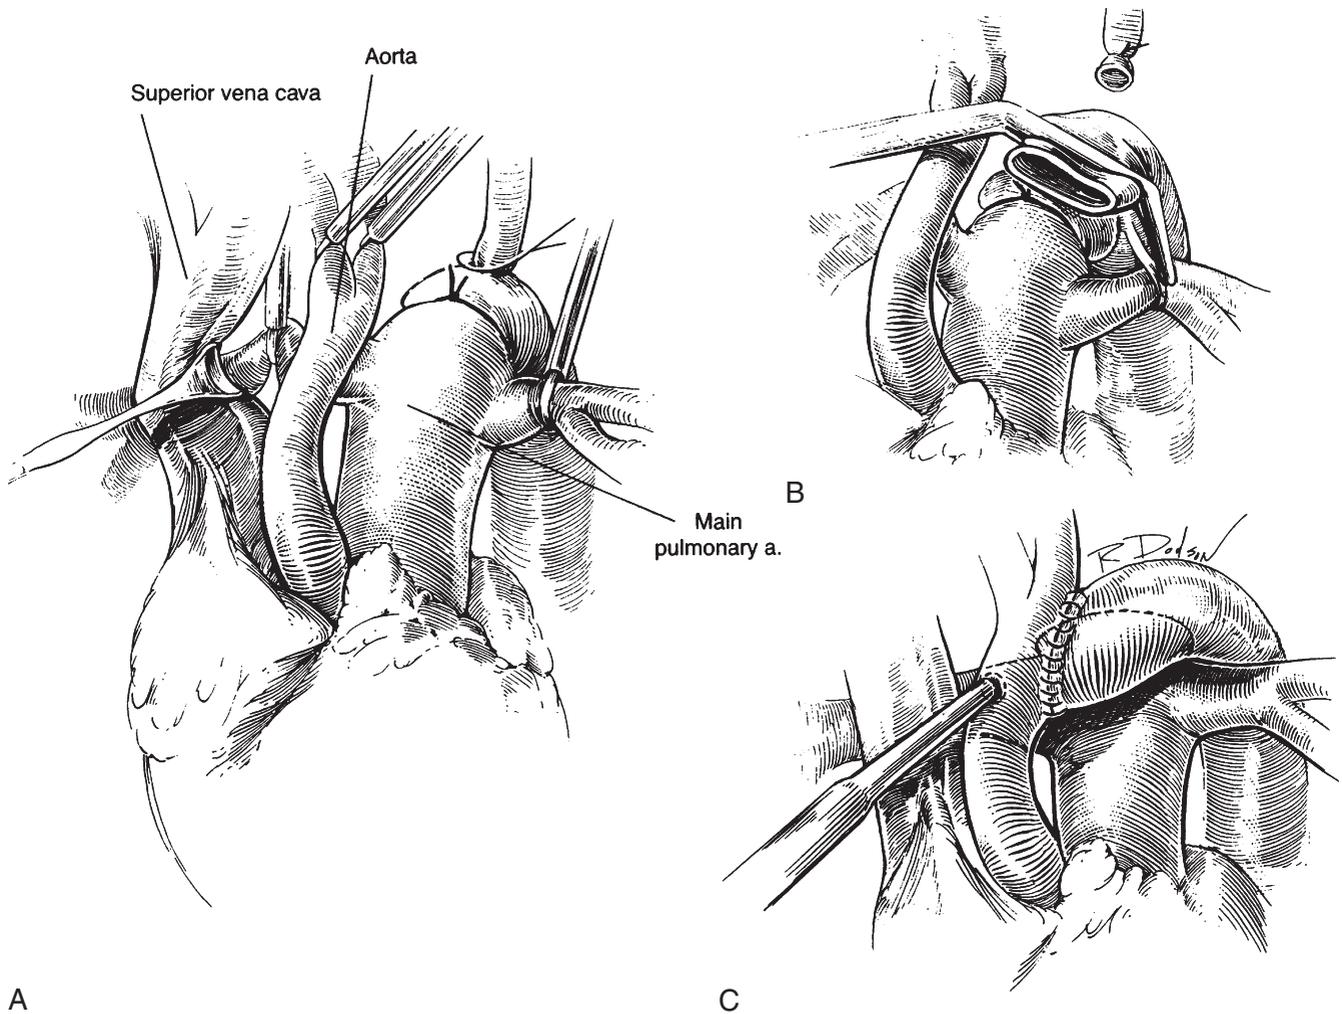

HLHS is a fairly common, heterogeneous group of anatomic abnormalities in which there is a small or absent left ventricle with hypoplastic or atretic mitral and aortic valves. The incidence is 1/5500 live births, although a greater number of children with similar or related conditions are managed in a similar fashion. Although a genetic etiology has not yet been elucidated, there are increasing reports of HLHS occurring in families with other members affected with left-sided disease, such as a bicuspid aortic valve. HLHS is rare in trisomy 21 but has been reported in other trisomies such as 13 and 18, as well as in Turner syndrome.

Single-ventricle physiology and management strategies to optimize systemic oxygen delivery are discussed in detail earlier in this chapter. The presentation of HLHS typically is (1) *prenatal diagnosis*, in which an expectant team of caregivers manages a metabolically stable neonate; (2) *mild CHF* ± cardiac murmur, with no end-organ dysfunction; or (3) *profound circulatory collapse* and multiorgan system failure. In this last presentation, a sudden deterioration takes place with rapidly progressive CHF and shock as the ductus arteriosus constricts. There is decreased systemic perfusion and greatly increased PBF, largely independent of the level of pulmonary vascular resistance. The peripheral pulses are weak to absent. Renal, hepatic, coronary, and CNS perfusion are compromised, possibly resulting in acute tubular necrosis, necrotizing enterocolitis, or cerebral infarction or hemorrhage. A vicious circle also may result from inadequate retrograde perfusion of the ascending aorta (coronary artery blood supply), with further myocardial dysfunction and continued compromise of coronary blood flow. The pulmonary-to-systemic flow ratio approaches infinity as SBF nears zero. Thus, a paradoxical presentation results: a profound metabolic acidosis in the face of a relatively high PO<sub>2</sub> (70 to 100 torr). At the initial presentation, sepsis is frequently suspected before the diagnosis of CHD is made.

Arterial blood gas values may represent the single best indicator of hemodynamic stability and adequacy of systemic oxygen delivery. Although “low” arterial saturation (approximately 75% to 80%) with a normal pH and CO<sub>2</sub> indicates an acceptable balance of SBF and PBF with adequate periph-

**FIGURE 57–11.** Anatomic classification of interrupted aortic arch. Dashed lines indicate the potential areas of discontinuity (interruption) in the aortic arch. See text for details. (From Castañeda AR, Jonas RA, Mayer JE Jr, Hanley FL: *Cardiac Surgery of the Neonate and Infant*. Philadelphia, WB Saunders, 1994.)

**FIGURE 57-12.** Surgical repair of interrupted aortic arch, type B. **A**, The descending aorta is cannulated for cardiopulmonary bypass distal to the ductus arteriosus, and the branch pulmonary arteries are snared. **B**, To adequately mobilize the descending aorta, the left subclavian artery may need to be divided. Following resection of the ductus arteriosus, the proximal (pulmonary artery) end is oversewn. **C**, The distal descending aorta is anastomosed directly to the ascending aorta. An alternative strategy is anastomosis of the left subclavian and left common carotid arteries combined with homograft patch augmentation of the inferior surface of the arch. Ventricular septal defect closure, when present, is also performed (not shown). (From Castañeda AR, Jonas RA, Mayer JE Jr, Hanley FL: *Cardiac Surgery of the Neonate and Infant*. Philadelphia, WB Saunders, 1994.)

eral perfusion, elevated oxygen saturation (greater than 90%) with acidosis represents significantly increased pulmonary and decreased systemic flows, with probable myocardial dysfunction and secondary effects on other organ systems.

### Oxygen

In general, supplemental oxygen should be avoided in the preoperative infant with HLHS. Oxygen will act as a pulmonary vasodilator, decreasing PVR and increasing Qp:Qs. The presence of a lung pathologic process (e.g., atelectasis, meconium aspiration, pneumonia) or of a restrictive ASD may result in an increased oxygen requirement. In the absence of lung disease or a restrictive ASD, most preoperative infants with HLHS have increased PBF with a room air oxygen saturation of 85% to 95% (PaO<sub>2</sub> of 45 to 50 mm Hg). Patients with a mildly restrictive atrial septum and/or elevated PVR will have oxygen saturations in the

high 70s to low 80s. Although the temptation may be to increase the inspired oxygen, the low arterial oxygen saturation actually represents the best balance between Qp and Qs, increasing the supplemental oxygen may paradoxically decrease oxygen delivery to the tissues.

### Indications for Treatment of a “High” Oxygen Saturation

The clinically stable infant may tolerate significantly increased PBF in the preoperative period without significant intervention or obvious untoward effects. When the diagnosis of HLHS is made early, before onset of significant ductal constriction and a low-flow state, acidosis usually is avoided, and intubation may not be needed; the infant often may tolerate mild pulmonary overcirculation on low doses of PGE<sub>1</sub> (0.01 to 0.025 μg/kg/minute). Such infants often have a mild degree of restriction at the atrial septum,

the left atrial hypertension keeping PVR a bit elevated and limiting Qp to some degree, and although tachypneic (respiratory rates of 60 to 80/minute), and well oxygenated (SaO<sub>2</sub> greater than 90%; PaO<sub>2</sub> 40 to 50 mm Hg), they remain clinically stable with minimal intervention. This group of patients maintains adequate SBF despite increased PBF, and further interventions to achieve some arbitrary PO<sub>2</sub>—such as intubation and/or supplemental inspired gases—may not achieve improved patient stability and in fact may increase the potential for iatrogenic complications. In short, the neonate without significant CHF, acidosis, or progressive respiratory distress does not necessarily require significant therapy to treat a “high” PO<sub>2</sub>.

Two subsets of infants with HLHS require aggressive preoperative management of the balance between their PBF and SBF: (1) those who are diagnosed late, following ductal constriction with circulatory collapse, and (2) those with clinically significant pulmonary overcirculation, independent of the timing of diagnosis.

### **Presentation in Shock**

Infants presenting with inadequate systemic cardiac output due to either ductal constriction with severe pulmonary overcirculation have depressed cardiac function, often with significant tricuspid insufficiency, profound metabolic acidosis, usually some degree of hepatic and renal failure, and occasionally bowel ischemia or disseminated intravascular coagulopathy. These infants require rapid and aggressive resuscitation. PGE<sub>1</sub> infusion must be initiated and the dose adjusted for the degree of ductal patency (confirmed by echocardiography). Dopamine at 3 to 5 µg/kg/minute will help augment overall cardiac output. Sedation, paralysis, and endotracheal intubation will allow for controlled ventilation and minimize systemic oxygen consumption. If normoventilation with 21% FIO<sub>2</sub> results in unacceptable pulmonary overcirculation, the addition of inspired CO<sub>2</sub> (20 mm Hg) has been shown to improve systemic oxygen delivery (see later). Most commonly, infants with HLHS presenting in shock benefit from recovery of end-organ function before proceeding to the operating room for surgical reconstruction or transplantation. Infants with persistent metabolic acidosis despite resuscitative efforts should be evaluated by echocardiogram for adequate ductal patency. Rarely, in a preoperative infant with HLHS, medically refractory pulmonary overcirculation persists, necessitating urgent stage I reconstruction.

### **Hypotension**

Although mild preoperative hypotension is common and frequently is thought to be caused by increased PBF at the expense of systemic flow, other causative disorders play a role as well. PGE<sub>1</sub> is a potent pulmonary and systemic vasodilator, and adequate volume resuscitation is indicated after the institution of PGE<sub>1</sub> therapy. It is important for the clinician to remember the neonatal myocardium's sensitivity to intracellular calcium and glucose, and serum levels of both should be monitored periodically. Myocardial dysfunction may coexist, and although small to moderate doses of inotropic agents frequently are

beneficial, large doses of these agents may have a deleterious effect, depending on the relative effects on the systemic and pulmonary vascular beds. Preferential selective elevations of systemic vascular tone will secondarily increase PBF, and careful monitoring of mean arterial blood pressure and arterial oxygen saturation is warranted. Tricuspid regurgitation from an anatomically abnormal valve or secondary to ventricular dysfunction may contribute as well, and low doses of phosphodiesterase inhibitors such as milrinone—which may seem counterintuitive for the mildly hypotensive patient—may actually improve overall tissue perfusion and oxygen delivery. Finally, patients with refractory hypotension despite implementation of all of the foregoing measures should undergo echocardiography to confirm that the ductus remains widely patent and nonrestrictive; occasionally, inadvertent or unrecognized problems with PGE<sub>1</sub> administration result in a constricting ductus.

### **Inspired Gases**

The use of inspired gas mixtures to balance PBF and SBF in preoperative infants with HLHS or other single-ventricle physiologic defect is a topic of interest and controversy (Keidan et al, 2003; Tabbutt et al, 2001; Wessel, 1996). Several retrospective case reports and small series support the use of inspired CO<sub>2</sub> (14 to 35 mm Hg) to induce hypercarbia to stabilize preoperative infants with HLHS. Similarly, reports of small series of preoperative infants with HLHS have demonstrated clinical improvement or aortic Doppler measurements suggestive of lower Qp:Qs with increasing inspired nitrogen (to achieve 14% to 19% FIO<sub>2</sub>) to induce alveolar hypoxia.

Until recently, prospective, controlled data comparing hypoxia and hypercarbia were limited to studies in shunt-dependent, single-ventricle animal models. The most elegant model is that of Reddy and colleagues (1996), who created a fetal sheep model of single ventricle. Two to three days after delivery, the lambs were anesthetized, intubated, and ventilated and underwent median sternotomy with ligation of the patent ductus arteriosus and placement of vascular pressure and flow probes. With use of both induced alveolar hypoxia and increased inspired CO<sub>2</sub>, Qp:Qs was significantly decreased in both conditions compared with baseline. Tabbutt and associates (2001) recently compared the effects of hypoxia, achieved by adding increased inspired nitrogen (to achieve FIO<sub>2</sub> of 17%), with those of hypercarbia, achieved by adding increased inspired CO<sub>2</sub> (20 mm Hg inspired CO<sub>2</sub>), in preoperative infants with HLHS under conditions of anesthesia, paralysis, and fixed minute ventilation. In this prospective, crossover study, systemic venous, arterial, and mixed cerebral oxygen saturations were measured, with each condition compared with baseline values in room air. Both inspired nitrogen (hypoxia) and CO<sub>2</sub> (hypercarbia) decreased Qp:Qs, although the decrease did not reach significant significance for hypoxia ( $P = .056$ ). Under these conditions of anesthesia and fixed mechanical ventilation, however, only hypercarbia increased cardiac output and mixed cerebral oxygenation.

In our practice at The Children's Hospital of Philadelphia, we tend to not use inspired gases preoperatively in most circumstances. If a child has significantly increased PBF but adequate SBF and oxygen delivery without acidosis, and is otherwise a good candidate for surgery, surgery is undertaken as soon as medically and logistically possible. However, for the neonate presenting with circulatory collapse and pulmonary overcirculation who is already intubated and mechanically ventilated, inspired CO<sub>2</sub> is utilized until surgery is undertaken. In these situations, minute ventilation is kept fixed, and CO<sub>2</sub> is added to the inspiratory limb of the ventilator to achieve an arterial PCO<sub>2</sub> of approximately 55 mm Hg, with a normal pH. Although increased inspired CO<sub>2</sub> has been shown to improve oxygen delivery in the anesthetized infant under conditions of controlled ventilation, similar studies have not yet been reported in the spontaneously breathing infant. The increased oxygen consumption associated with the CO<sub>2</sub>-induced tachypnea could potentially negate the benefits observed in the anesthetized patient. Thus, for patients in whom surgery must be delayed and there is clinically significant pulmonary over circulation with low systemic blood flow, inspired nitrogen may be utilized in the spontaneously breathing patient, and inspired CO<sub>2</sub> reserved for the mechanically ventilated patient, until surgery is undertaken. Between January 2001 and December 2002, 106 newborns underwent stage I reconstruction; 5 received supplemental inspired CO<sub>2</sub> and 4 received supplemental nitrogen.

### ***Restrictive Atrial Septum***

In contrast, a severely restrictive atrial septum limits outflow from the pulmonary veins and, if coupled with mitral atresia, results in profound left atrial outlet obstruction, pulmonary hypertension, and hypoxemia following birth. The newborn with HLHS and an intact atrial septum will be difficult to manage immediately following birth; however, if the intact atrial septum is suspected prenatally, delivery of the infant should take place at the delivery center associated with the surgical referral center and with a surgical team or catheterization laboratory team available. The infant should be intubated, umbilical access obtained, and PGE<sub>1</sub> infusion initiated in the delivery room, followed by direct transportation to the operating room or catheterization laboratory where the planned septectomy or catheter intervention is to be performed. In the absence of a prenatal diagnosis, the clinical scenario is identical to that in obstructed total anomalous pulmonary venous return or severe "lung disease." From a management standpoint, the strategy is quite similar: intubation, positive end-expiratory pressure, supplemental oxygen as needed to maintain an oxygen saturation of approximately 80%, umbilical access, inotropic support, isotonic volume as necessary, and base replacement.

Anticipation of the potential diagnosis of CHD is critical. Having an echocardiographer, catheterization team, and operating room (OR) team available when the patient arrives at the tertiary care center provides the best chance of survival. On arrival of an infant in extremis with a clinical picture of obstructed pulmonary venous return but without a definitive diagnosis, obtaining a brief echocar-

diogram is of utmost importance. Obstructed pulmonary veins can be stabilized only with venovenous extracorporeal membrane oxygenation (ECMO) or corrective surgery. HLHS with intact atrial septum is best stabilized by septectomy (in the operating room or catheterization laboratory) or palliative surgery. Neck cannulation for venoarterial ECMO for unrepaired HLHS is impossible due to the size of the diminutive aorta and requires transthoracic cannulation with ligation of the patent ductus arteriosus to provide adequate SBF.

Unfortunately, the association of a severely restrictive or intact atrial septum with HLHS carries a significantly worse short- and long-term prognosis compared with other forms of HLHS, mainly because of the secondary changes that occur in the pulmonary vascular bed from in utero obstruction of pulmonary venous outflow (Rychik et al, 1999). The pulmonary vascular tree is abnormal in all patients with HLHS: There is an increase in the number of arteries per unit area of lung, and the arteries themselves have a considerable increase in muscularity. Increased medial arterial wall thickness is present, as well as extension of muscle into smaller and more peripheral arteries than is normal. These abnormalities may explain the predilection toward extreme sensitivity of the pulmonary vascular bed to vasoactive agents. The pulmonary veins are typically dilated, with thickened walls. The degree of restriction at the atrial level influences the histopathologic findings within the pulmonary vascular tree. Increased arterial tortuosity and arteriopathy consistent with grade III Heath-Edwards classification have been noted in patients with a severely restrictive (or absent) ASD. Marked thickening of the pulmonary veins with the appearance of multiple elastic laminae—so-called arterIALIZATION of the pulmonary veins—has been noted in patients with intact atrial septum (Rychik et al, 1999). Impediment to drainage from the left atrium in utero may be the reason for development of the histopathologic features seen in the pulmonary veins of infants with intact atrial septum. These pulmonary venous abnormalities further contribute to the pathophysiology once these infants are born and may explain why most of them continue to do poorly, with a high mortality rate despite creation of a large and effective interatrial communication at birth. Even if the newborn survives stage I reconstruction (for which the mortality rate is greater than 50% among those with an intact atrial septum), the underlying pulmonary vascular pathology may preclude a later Fontan procedure.

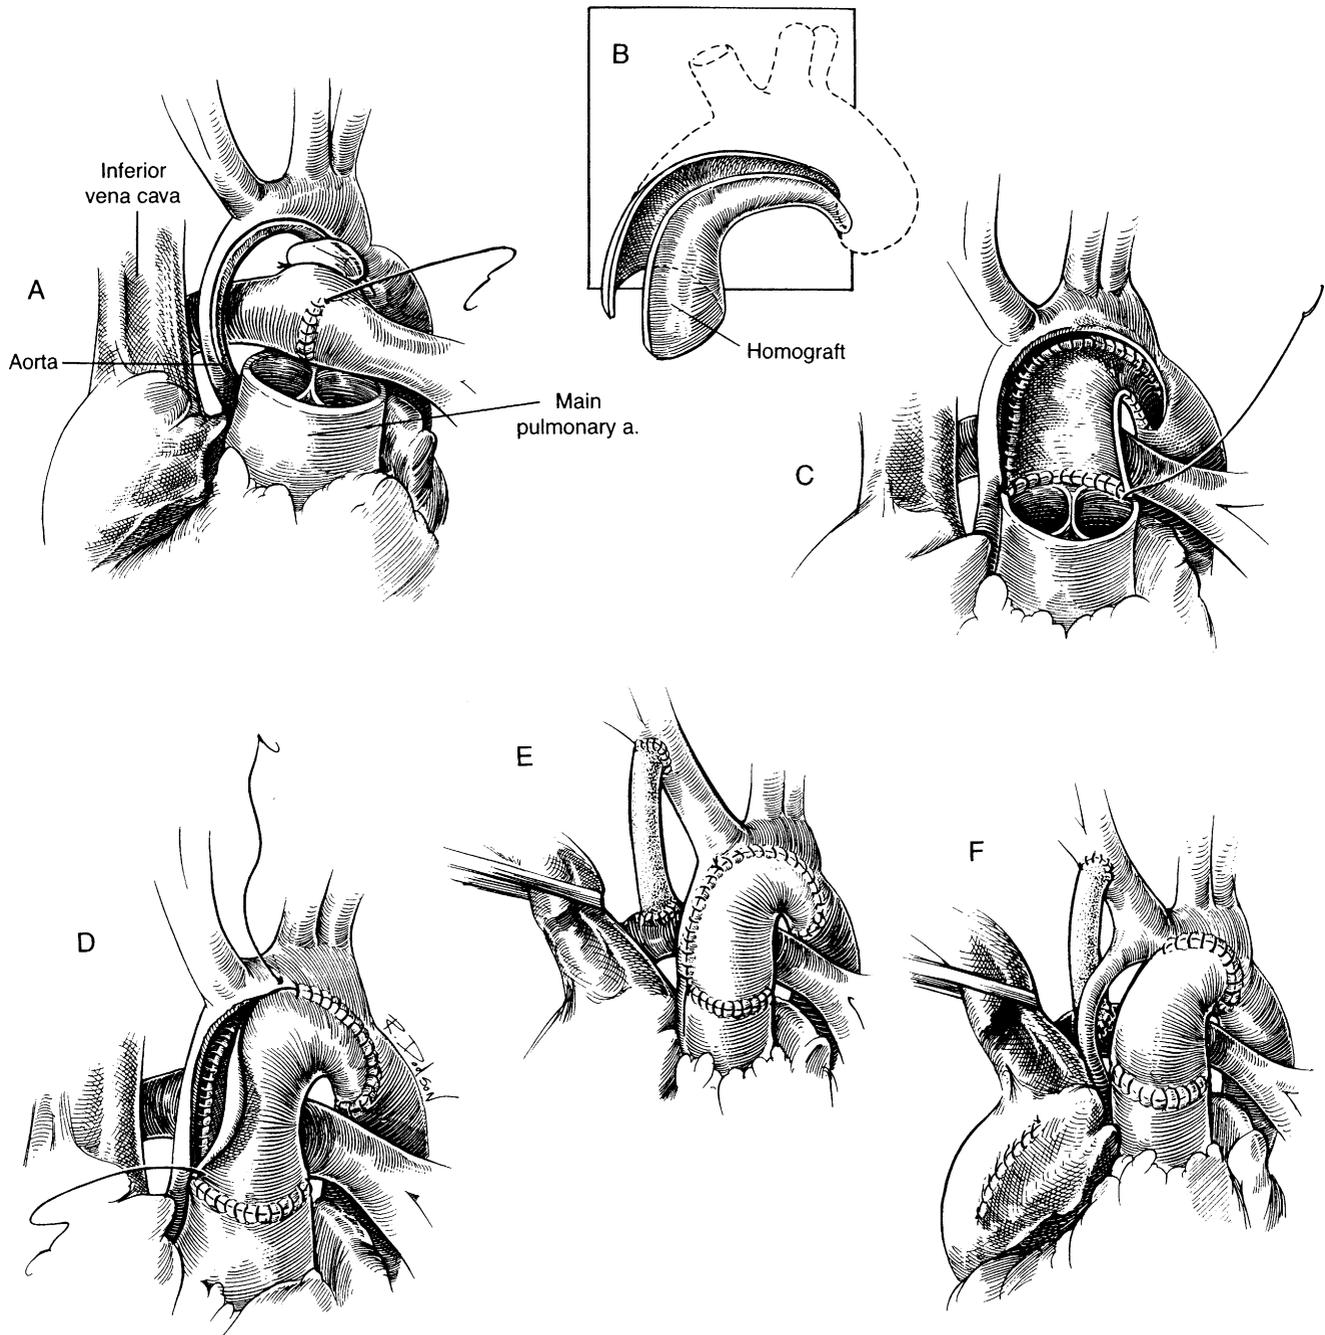

### ***Surgical Therapy for Hypoplastic Left Heart Syndrome***

Although medical stabilization is important in the overall outcome in these children, ultimately surgical therapy is necessary for survival. After a period of medical stabilization and support to allow recovery of ischemic organ system injury (particularly of the kidneys, the liver, the CNS, and the heart itself), surgical relief of left-sided obstruction is required. The surgical management of HLHS remains controversial; surgical intervention involves either staged reconstruction (with a neonatal Norwood procedure followed by a staged

Fontan operation later in childhood) or neonatal cardiac transplantation. Recent results from both reconstructive surgery and transplantation have vastly improved the outlook for infants born with this previously 100% fatal condition (Bailey et al, 1993; Gaynor et al, 2002; Mahle et al, 2000).

### Stage I Reconstruction

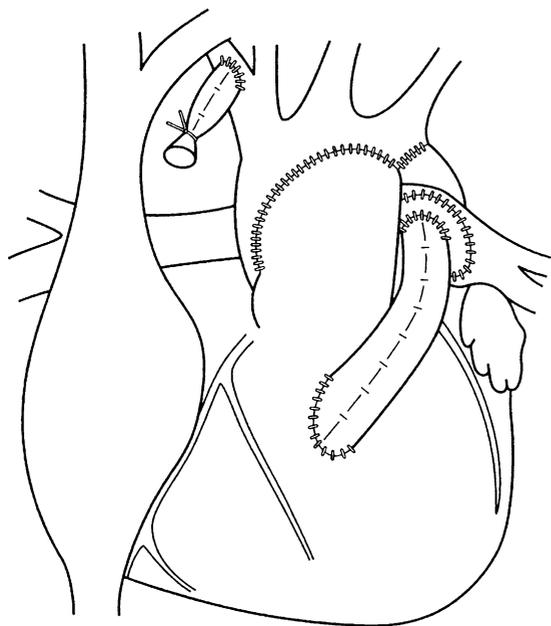

The first stage reconstruction for HLHS with the classic Norwood operation (Fig. 57-13) is typically performed with a median sternotomy incision and use of DHCA, although some groups have recently utilized selective

**FIGURE 57-13.** Stage I reconstruction for hypoplastic left heart syndrome: Classic Norwood procedure. **A**, The main pulmonary artery is transected, and the distal end oversewn. The ductus arteriosus is ligated, and an incision is made from the proximal ascending aorta around the aortic arch to the level of the ductus. **B**, A pulmonary homograft is utilized to create a patch to reconstruct the neo-aorta. **C** and **D**, This homograft patch is used to connect the proximal main pulmonary artery and pulmonary (neo-aortic) valve to the ascending aorta and transverse arch. **E**, A modified Blalock-Taussig shunt is placed from the base of the innominate artery to the right pulmonary artery. **F**, An alternative technique utilizing a circumferential tube graft from the proximal main pulmonary artery to the distal transverse aortic arch. *Not shown*: Atrial septectomy is performed to provide unobstructed egress from the pulmonary veins to the right ventricle. (From Castañeda AR, Jonas RA, Mayer JE Jr, Hanley FL: *Cardiac Surgery of the Neonate and Infant*. Philadelphia, WB Saunders, 1994.)

cerebral perfusion during cardiopulmonary bypass. The main pulmonary artery is transected just proximal to the branch pulmonary arteries, and the defect in the distal pulmonary arteries is closed. The pulmonary valve and proximal pulmonary artery become the systemic outflow, after anastomosis to the reconstructed aortic arch, usually following augmentation with pulmonary artery homograft. An atrial septectomy is performed to ensure adequate pulmonary venous outflow, and a shunt is created to provide PBF. Classically, this is a modified Blalock-Taussig shunt from the base of the innominate artery. Recently, there has been interest in creation of the shunt from the right ventricular infundibulum to the central pulmonary arteries, popularized by Sano and colleagues (2003) and others (Mahle et al, 2003; Malec et al, 2003; Pizarro et al, 2003) (Fig. 57-14). The theoretical advantages of a right ventricle–pulmonary artery shunt are a higher postoperative diastolic pressure (Pizarro et al, 2003), improved coronary artery flow, pulsatile end-organ perfusion, and improved growth of the central pulmonary arteries (Maher et al, 2003). However, this technical modification employs a small incision in the systemic right ventricle, and the long-term effects on ventricular function and/or arrhythmia are unknown. Follow-up studies examining the theoretical advantages of the right ventricle–pulmonary artery conduit modification are under way but short-term in duration. Decades of follow-up study are likely to be necessary to determine the better overall surgical strategy to be used in the neonatal period.

The surgical results of first-stage reconstruction for HLHS have progressively improved after the initial successes reported in the early 1980s. In the current era, it is

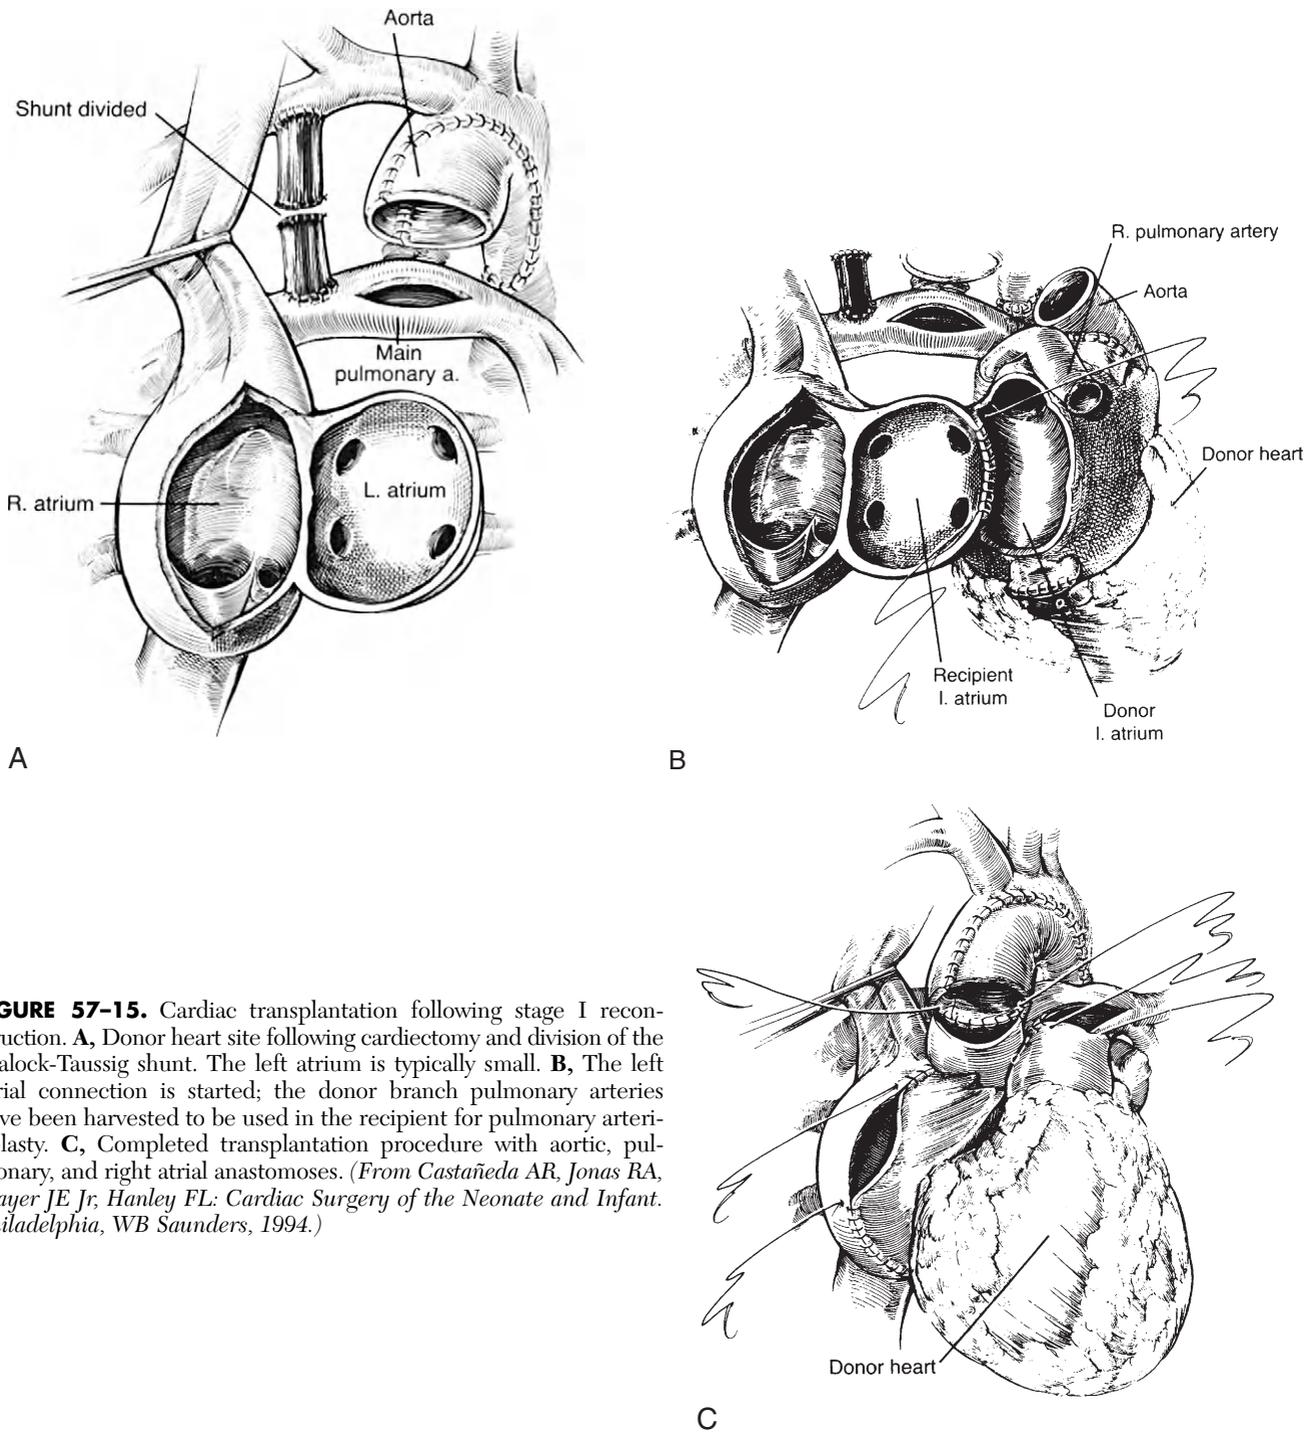

**FIGURE 57-14.** Right ventricle–pulmonary artery (RV-PA), or Sano, modification of stage I reconstruction. The arch repair is similar to that shown in Figure 57-13. The Blalock-Taussig shunt is replaced with a Gore-Tex tube inserted from the right ventricle to the main pulmonary artery. (From Sano S, Ishino K, Kawada K, et al: *Right ventricle–pulmonary artery shunt in first-stage palliation of hypoplastic left heart syndrome*. *J Thorac Cardiovasc Surg* 126:504-510, 2003.)

increasingly recognized that there are “standard-risk” and “high-risk” patients; risk factors for first-stage operation include low birth weight (less than 2.5 kg) and the association of other cardiac (e.g., severe tricuspid regurgitation, intact atrial septum) or genetic anomalies. Standard-risk patients have an approximately 5% to 10% mortality risk, whereas infants with additional risk factors have incrementally increased risk (Gaynor et al, 2002). There is an approximately 5% to 10% interstage mortality rate (Mahle et al, 2001), but recent success with home monitoring programs may reduce this risk (Ghanayem et al, 2003). The expected operative mortality risks for the second (superior cavopulmonary connection) and third (Fontan operation) procedures are currently in the range of 1% to 2%. Thus, a majority of the deaths that occur in newborns with HLHS are concentrated in the newborn and early infancy period: from birth through the second-stage operation.

### Infant Heart Transplantation

In recent years, heart transplantation survival has improved in children and remains an important surgical option for patients with acquired and congenital forms of heart disease in whom medical and surgical treatment schemes are exhausted (Bailey et al, 1993). In neonates, HLHS remains the most common indication for heart transplantation either as initial therapy or as a treatment for those patients in whom surgical reconstruction has failed. The overall survival rate for pediatric cardiac transplantation worldwide is 73% at 1 year and 70% at 4 years after transplantation (Wernovsky and Chrisant, 2004). The biggest drawback to the routine use of transplantation as primary therapy for HLHS is a lack of donors. Even with most centers in North America performing staged reconstruction as primary therapy, thus limiting the number of babies with HLHS waiting for an organ at any given time (approximately 2000 neonates are born each year with HLHS, with approximately 200 neonatal and infant heart transplantations annually), approximately 25% to 30% of children never receive a transplant because of a limited donor supply. Risk factors for early death after transplantation in children (for any underlying cause) include CHD, pretransplantation use of a ventricular assist device, younger age, requirement for intensive care, retransplantation procedure, and performance of transplantation in a low-volume center.

The surgical technique for implantation of a donor heart in a newborn with HLHS is relatively straightforward; the primary technical consideration is reconstruction of the aortic arch. The procedure is a bit more technically demanding if prior stage I reconstruction has been performed (Fig. 57-15). Several reconstructive techniques have been used; however, in a majority of cases, the donor aorta is harvested with a greater length than is typical and the undersurface of the arch of the donor aorta is utilized to reconstruct the aortic arch in the recipient after ligation or excision of the diminutive ascending aorta, which functions as a common coronary artery in patients with aortic atresia and HLHS. The remainder of the implantation of the donor heart involves standardized techniques including anastomosis of the donor left atrium and recipient left atrium and anastomosis of the pulmonary trunk to the pulmonary bifurcation in the recipient. The right atrium can

**FIGURE 57-15.** Cardiac transplantation following stage I reconstruction. **A**, Donor heart site following cardiectomy and division of the Blalock-Taussig shunt. The left atrium is typically small. **B**, The left atrial connection is started; the donor branch pulmonary arteries have been harvested to be used in the recipient for pulmonary arterioplasty. **C**, Completed transplantation procedure with aortic, pulmonary, and right atrial anastomoses. (From Castañeda AR, Jonas RA, Mayer JE Jr, Hanley FL: *Cardiac Surgery of the Neonate and Infant*. Philadelphia, WB Saunders, 1994.)

be connected by either a cuff of right atrium of the recipient left in place or by utilizing bicaval anastomoses. Because implantation of a donor heart in HLHS requires arch reconstruction, residual coarctation or subsequent development of stenosis at the anastomotic site is possible; either may be treated with balloon angioplasty.

Rejection of the graft can occur at any time (hyperacute, acute, and chronic); nearly 75% of children will have at least one episode of rejection. Infectious complications are common, occur most often in the immediate period after transplantation, and are a major cause of early morbidity and death, especially in the first year after transplantation. Longer-term sequelae include lympho-

proliferative disease (in 2% to 10% of cases, possibly more in younger recipients) and graft vasculopathy (in 8% to 10%).

#### **Transplantation Versus Staged Reconstruction**

As mentioned previously, the management of HLHS from a surgical perspective remains highly controversial. At present, the overall mortality risks are very similar, if one assumes continued organ availability at the current rate and no significant shift in the percentage of centers that adopt one or another strategy.

However, if transplantation is performed as an “intent to treat” strategy at more centers, and the donor supply does not change, the pretransplantation mortality rate will invariably increase. Thus, the optimal strategy will depend on the long-term mortality risks and morbidity associated with each strategy. Certain morbid conditions are inherent to transplantation (immunosuppression, lymphoproliferative disease, graft vasculopathy), and others are inherent to staged reconstruction culminating in a Fontan operation (arrhythmias, protein-losing enteropathy, thromboembolism). A number of such comorbid conditions, however, occur with nearly identical frequency with *either* strategy, including growth retardation, exercise limitations, chronic medication use, developmental delay, and psychological factors related to a “chronic” disease. Further research is necessary to determine which strategy is ideal for individual patients and their families (Wernovsky and Chrisant, 2004).

## LESIONS WITH DUCT-DEPENDENT PULMONARY BLOOD FLOW

### Tricuspid Atresia

Tricuspid atresia involves complete absence of the tricuspid valve and thus no direct communication from right atrium to right ventricle. The right ventricle may be severely hypoplastic or completely absent. An atrial-level communication is necessary for blood to exit the right atrium; there is an obligatory right-to-left shunt at this level. More than 90% of patients have an associated VSD, allowing blood to pass from the left ventricle to the right ventricle and its associated great vessel. In patients with normally related great arteries, accounting for 70% of cases of tricuspid atresia (Fig. 57–16A, B), PBF is derived from the right ventricle; if the right ventricle (or its connection with the left ventricle via a VSD) is severely diminutive, the PBF may be duct dependent; closure of the ductus leads to profound hypoxemia and acidosis. In

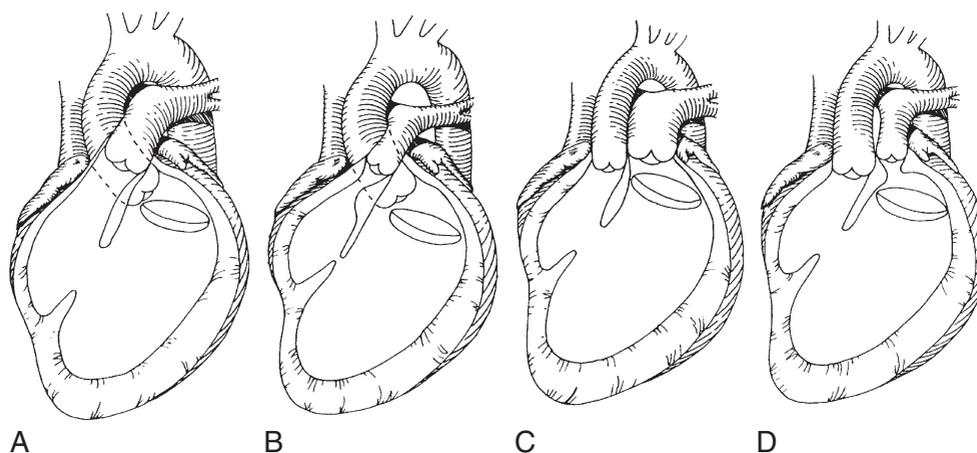

the remaining 30% of cases, the great arteries are transposed (see Fig. 57–16C, D), with the aorta aligned with the small right ventricle. In these cases with transposition and tricuspid atresia, the VSD usually is smaller than the aorta, and the newborn may have limited SBF in the absence of a patent ductus arteriosus. Many patients have an associated coarctation as well.

Immediate medical management is aimed primarily at maintenance of adequate PBF. In the usual case of severe pulmonary stenosis and limited PBF, PGE<sub>1</sub> infusion maintains PBF via the ductus arteriosus. Surgical creation of a more permanent source of PBF (usually via a Blalock-Taussig shunt) is undertaken as soon as possible. More complex cases (e.g., with transposition) may require more extensive palliative procedures (Daebritz et al, 2000) similar to stage I reconstruction for HLHS.

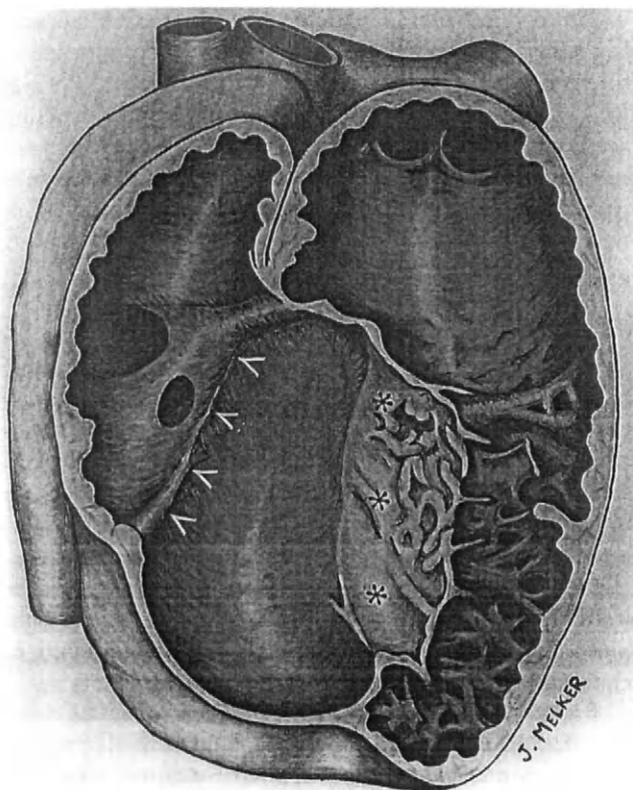

### Ebstein Anomaly

Ebstein anomaly is an uncommon (1/25,000 live births) but grave anatomic lesion when presenting in the neonatal period (Knott-Craig et al, 2000). Anatomically, there is “downward displacement” of the tricuspid valve into the body of the right ventricle (Fig. 57–17). The tricuspid valve is frequently regurgitant resulting in marked right atrial enlargement, cardiomegaly, and CHF in utero; the resultant inadequate forward flow from the right ventricle (to the ductus arteriosus and placenta) results in hydrops fetalis, with a high rate of fetal demise. Following birth, right ventricular afterload increases further (temporarily, following removal from the placenta), and although PVR remains high, there is greatly diminished forward flow from the right ventricle, a large right-to-left shunt at the atrial level, and profound hypoxemia, acidosis, and CHF.

Medical management is aimed at supporting the neonate through the initial period of the transitional circulation. PGE<sub>1</sub> is used to maintain a patent ductus arteriosus while other measures aimed at decreasing PVR and

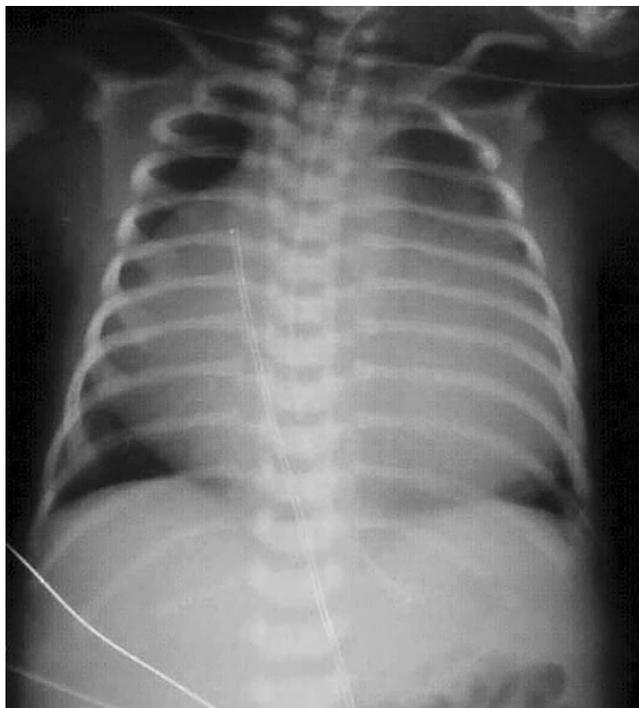

**FIGURE 57–16.** Anatomic variants in tricuspid atresia. **A**, Normally related great vessels with a large ventricular septal defect (VSD) and normal-sized pulmonary arteries (PAs). **B**, Normally related great vessels with a small VSD and PAs. **C**, Transposed great arteries (left ventricle aligned with the PA, right ventricle with the aorta) with a relatively small VSD and aorta. Many patients with this variant have coarctation as well (see text). **D**, Transposed great vessels with a VSD, subpulmonary obstruction, and small PAs. (From Fyler DC: *Tricuspid atresia*. In Fyler DC [ed]: *Nadas' Pediatric Cardiology*. Philadelphia. Hanley & Belfus, 1992b, pp 659-667.)

**FIGURE 57-17.** Inferior displacement of tricuspid valve leaflet (\*) into the right ventricular cavity. The *white arrowheads* indicate the normally positioned tricuspid valve annulus. The area between the true annulus and the displaced valve leaflet is considered “atrialized”. (From Epstein ML: *Congenital stenosis and insufficiency of the tricuspid valve*. In Allen HD, Gutgesell HP, Clark EB, Driscoll DJ [eds]: *Moss and Adams’ Heart Disease in Infants, Children and Adolescents: Including the Fetus and Young Adult*. Philadelphia, Lippincott Williams & Wilkins, 2001, pp 810-819.)

promoting antegrade PBF are employed (such as a high level of supplemental oxygen and maintaining a mild respiratory alkalosis). Recently, nitric oxide has been utilized with limited success (Atz et al, 2003). Following a few days of medical management, a trial of discontinuing PGE<sub>1</sub> may be considered. Weaning from nitric oxide and/or PGE<sub>1</sub> may take 2 to 3 weeks. Weaning may be unsuccessful in some infants, who then may require a systemic-to-pulmonary shunt or more aggressive surgical reconstruction with a high mortality risk (Knott-Craig et al, 2000).

An important contributor to the high mortality rate in the neonate with severe Ebstein anomaly is the associated pulmonary hypoplasia (due to the massive enlargement of the right side of the heart in utero) (Fig. 57-18). The prognosis for neonates presenting with profound cyanosis due to Ebstein anomaly has been very guarded (Epstein, 2001; Knott-Craig et al, 2000). Surgical options are controversial and generally reserved for the severely symptomatic child. Systemic-to-pulmonary shunts have been used with limited success, and complicated neonatal tricuspid repairs have not been particularly successful. Further complicating the medical condition, Ebstein anomaly is associated with Wolff-Parkinson-White syndrome and supraventricular tachycardia in up to 50% of cases.

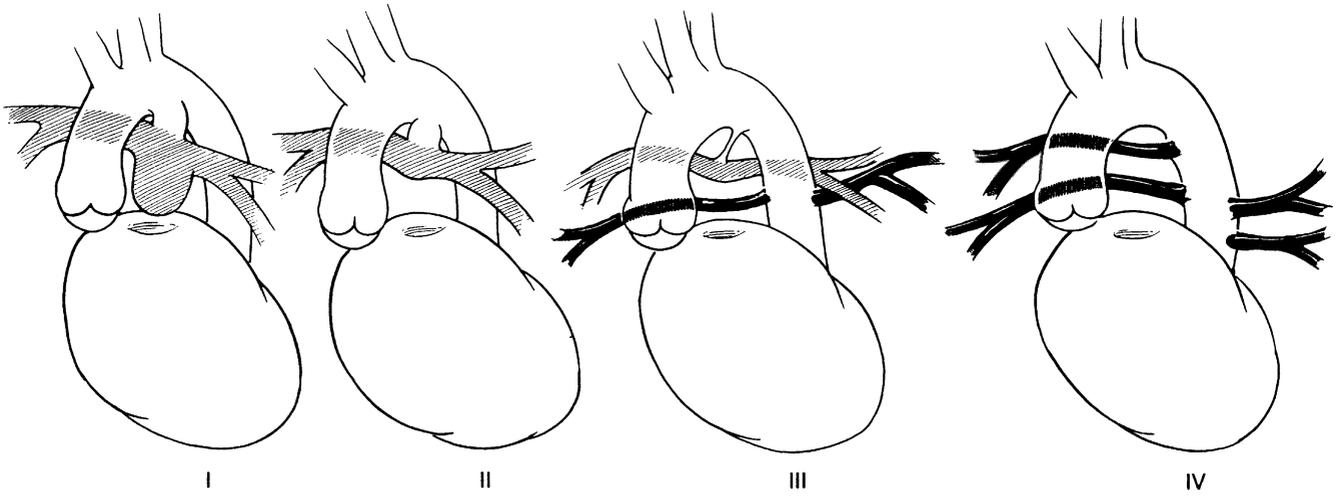

**FIGURE 57-18.** Chest radiograph in a 1-day-old newborn with Ebstein anomaly of the tricuspid valve. Note the massive cardiomegaly and relative pulmonary oligemia and hypoplasia.

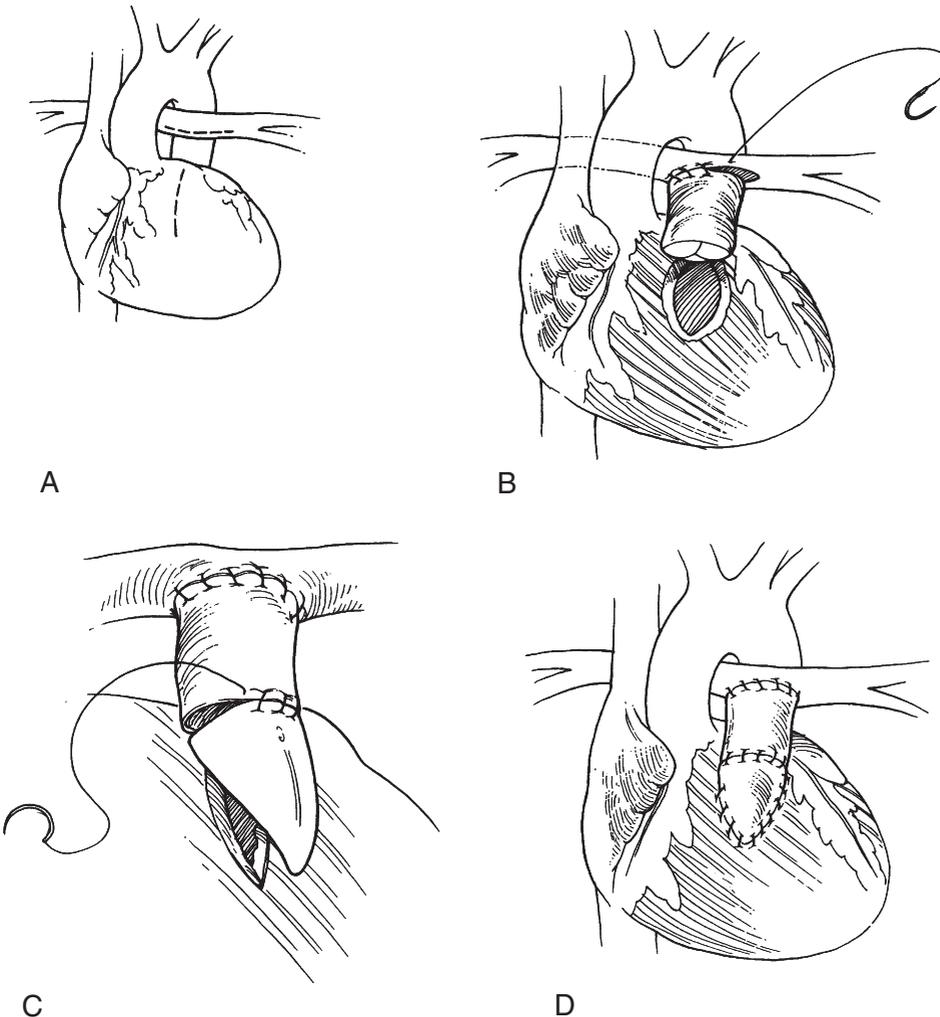

### Pulmonary Atresia with Ventricular Septal Defect

Pulmonary atresia with VSD (PA/VSD) is sometimes also known as *tetralogy of Fallot with pulmonary atresia* (TOF/PA), as the VSD is almost always of the malalignment type with severe obstruction of the right ventricular outflow tract (tetralogy of Fallot with pulmonary stenosis is discussed later in this chapter). PA/VSD (or, alternatively, TOF/PA) is a heterogeneous anomaly with respect to the source(s) of PBF. Inside the heart, there is typically one VSD; the ventricles are of normal size, and there usually is a severely hypoplastic infundibulum with complete atresia of the pulmonary valve. The pulmonary vascular bed architecture is much more variable, ranging from normal-sized pulmonary arteries supplied by the ductus arteriosus, to diminutive pulmonary arteries and a small ductus, to discontinuous pulmonary arteries supplied by bilateral ductus, to virtually absent central pulmonary arteries with the PBF supplied by multiple aortopulmonary collateral arteries (MAPCAs) (Fig. 57-19).

Initial management is based on the source of PBF, as well as the size and branching pattern of the distal pulmonary arteries. In cases with a patent ductus arteriosus and normal branch pulmonary arteries, newborn surgery may consist of a systemic-pulmonary artery shunt followed by eventual shunt takedown, VSD closure, and placement of a right ventricular-pulmonary artery conduit (sometimes considered to be a Rastelli procedure); alternatively, the complete repair may be done in the neonatal period (Fig. 57-20). Complete repair in the neonate usually is dependent on good-sized pulmonary arteries and an adequately developed infundibulum to allow transannular patch

**FIGURE 57-19.** Variability in the pulmonary artery architecture in tetralogy of Fallot with pulmonary atresia (pulmonary atresia with ventricular septal defect). In types I and II, the pulmonary arteries are well developed and supplied by a single source, the ductus arteriosus. In type III, the ductus supplies small central pulmonary arteries and is either absent or diminutive. In type IV, there are no mediastinal pulmonary arteries, and aortopulmonary collateral arteries supply all bronchopulmonary segments. (From Castañeda AR, Jonas RA, Mayer JE Jr, Hanley FL: *Cardiac Surgery of the Neonate and Infant*. Philadelphia, WB Saunders, 1994.)

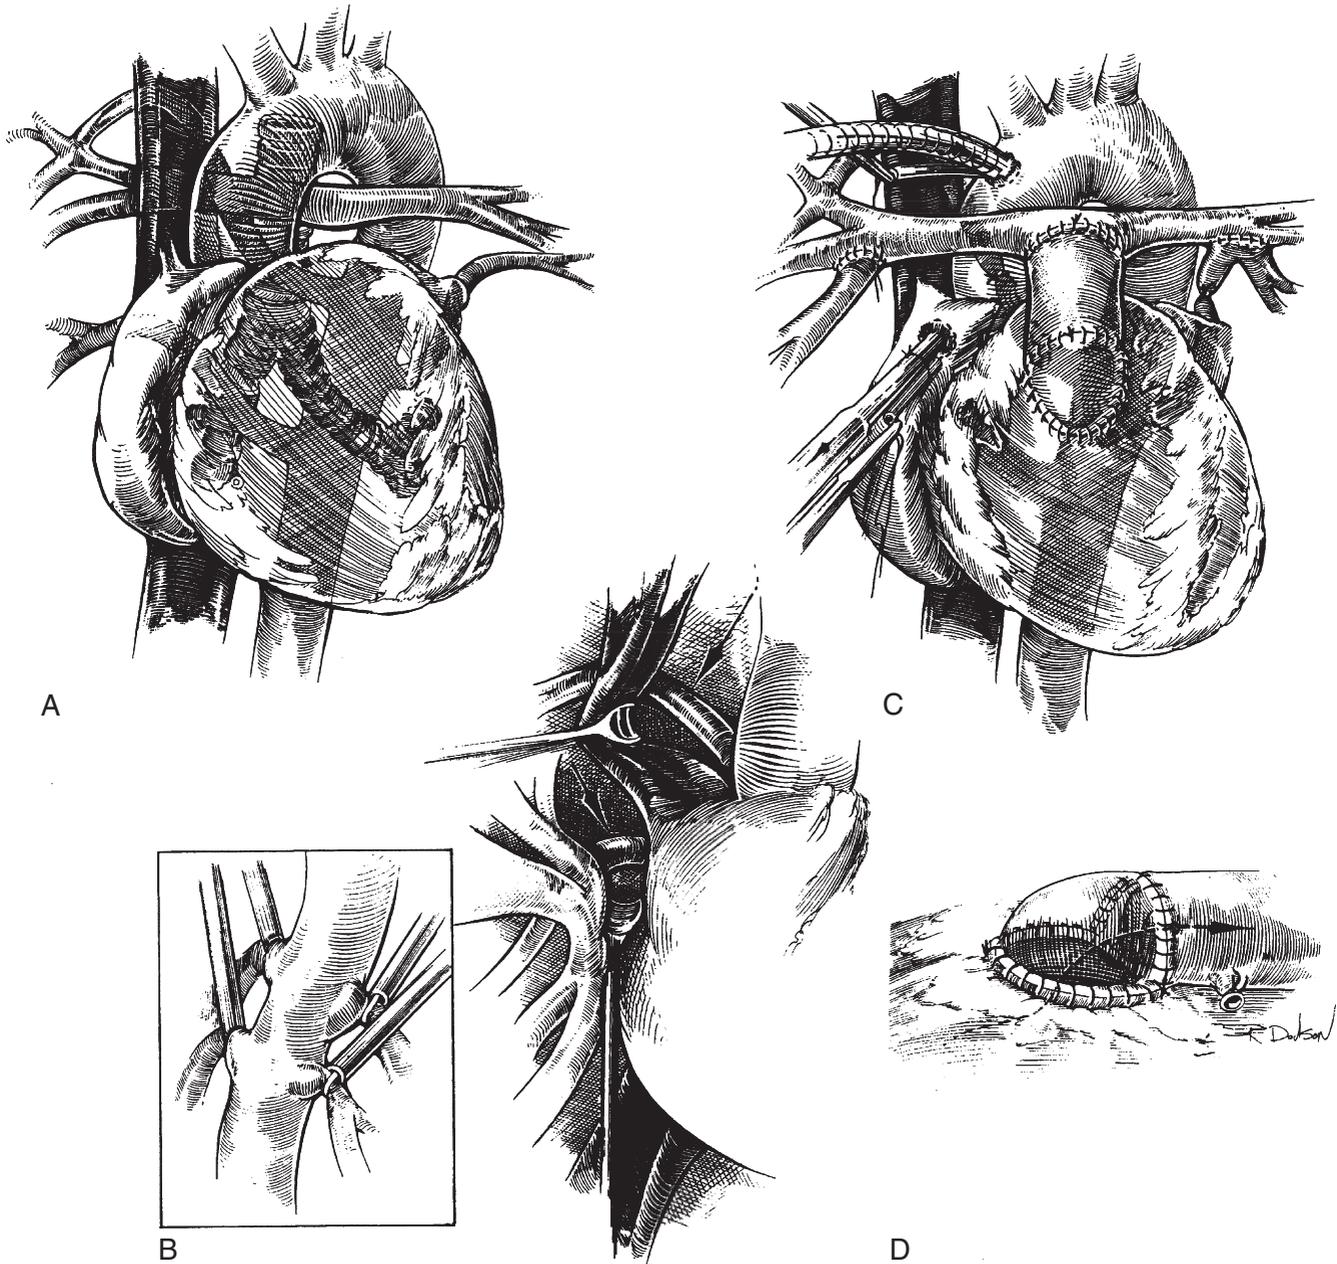

**FIGURE 57-20.** Repair of pulmonary atresia with ventricular septal defect and normal pulmonary arteries. **A**, Dotted lines depict the location of the ventriculotomy and pulmonary arteriotomy. **B**, The ventricular septal defect is closed through the ventriculotomy, and a valved homograft conduit is anastomosed to the distal pulmonary arteries and superior aspect of the ventriculotomy. **C** and **D**, A “hood” of pericardium is used to complete the repair. (From Spray TL, Wernovsky G: *Right ventricular outflow tract obstruction*. In Chang AC, Hanley FH, Wernovsky G, Wessel DL [eds]: *Pediatric Cardiac Intensive Care*. Baltimore, Williams & Wilkins, 1998, pp 257-270.)

placement and the absence of a conduit. In cases with diminutive pulmonary arteries and MAPCAs, amalgamation of the multiple mediastinal vessels into a common confluence (“unifocalization”) may be considered, with placement of a right ventricle-to-pulmonary artery conduit. If the branch pulmonary arteries are too hypoplastic to accept the

full cardiac output without unacceptable pulmonary hypertension, the VSD may be left open until the branch pulmonary arteries can undergo angioplasty (“rehabilitation”) to increase the total cross-sectional area (Fig. 57–21).

The long-term outcomes are highly dependent on the status of the pulmonary vascular bed at birth. If the pul-

**FIGURE 57-21.** Example of complete repair of pulmonary atresia with multiple aortopulmonary collaterals. **A**, Three large aortopulmonary collaterals are seen arising from the descending aorta behind the heart. **B**, In some cases a preliminary thoracotomy may be necessary to identify posterior collaterals to either temporarily or permanently interrupt these vessels (*inset*). **C**, Following cannulation for bypass, the three collaterals are unifocalized to the true mediastinal pulmonary arteries. The operation is completed by performing a ventriculotomy to close the ventricular septal defect (see also Fig. 57–20) and interposing a valved homograft from the ventriculotomy to the unifocalized pulmonary arteries. **D**, The proximal conduit anastomosis is augmented with a pericardial hood. (From Castañeda AR, Jonas RA, Mayer JE Jr, Hanley FL: *Cardiac Surgery of the Neonate and Infant*. Philadelphia, WB Saunders, 1994.)

monary arteries are essentially normal in size, the long-term outcomes are highly similar to those for “straightforward” tetralogy of Fallot. If there are diminutive pulmonary arteries, or MAPCAs, the prognosis is much more guarded (Permut et al, 1994; Rome et al, 1993).

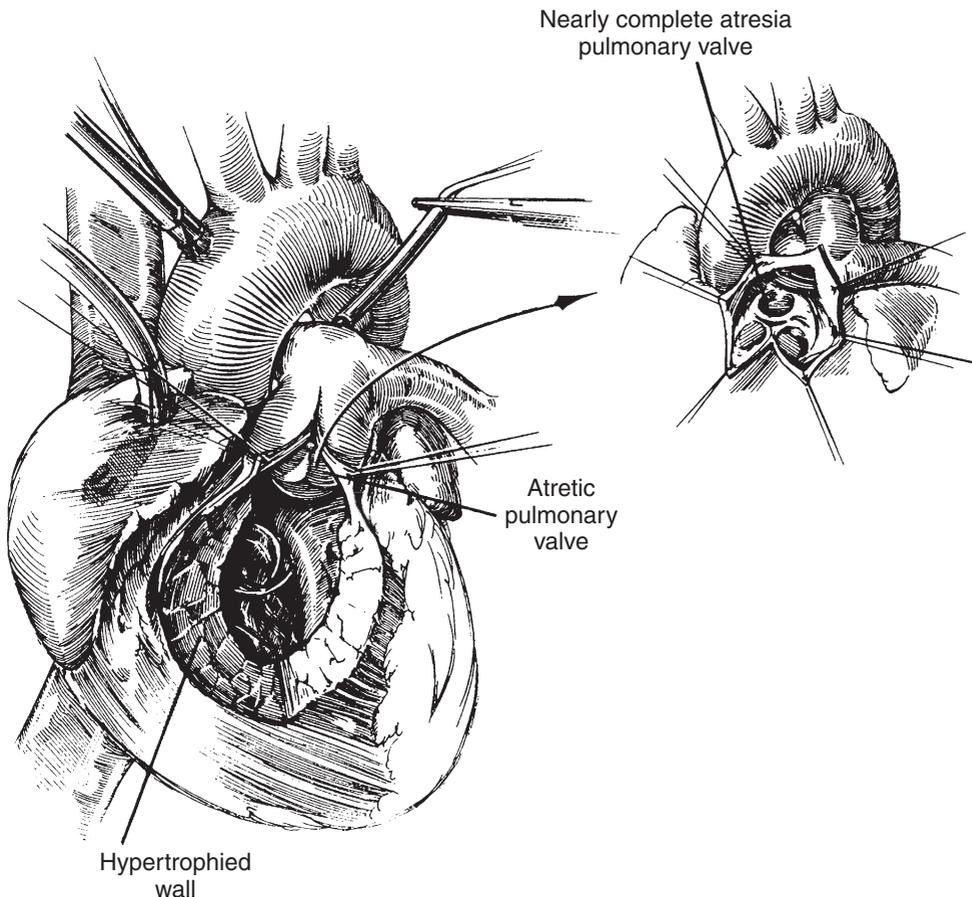

### Pulmonary Atresia with Intact Ventricular Septum

Sometimes referred to as “hypoplastic right heart syndrome,” pulmonary atresia with an intact ventricular septum is a heterogeneous disease. In all cases, there is absent antegrade flow from the right ventricle to the pulmonary arteries, with PBF supplied by a ductus arteriosus after birth. Right-sided hypoplasia is present in variable degrees, ranging from a nearly normal-sized right ventricle and tricuspid valve to severe hypoplasia (virtual atresia) of the tricuspid valve and a diminutive, muscle-bound right ventricle (Fig. 57–22). In the most severe cases, coronary artery blood flow is derived not from the aortic root but from the hypertensive, muscle-bound right ventricle (Fig. 57–23). These abnormal connections between the right ventricular sinus and coronary arteries develop in the fetus, possibly because of the suprasystemic pressure generated by the right ventricle during systole. Very abnormal coronary sinusoids, and even areas of complete coronary interruption, may be present at birth. These

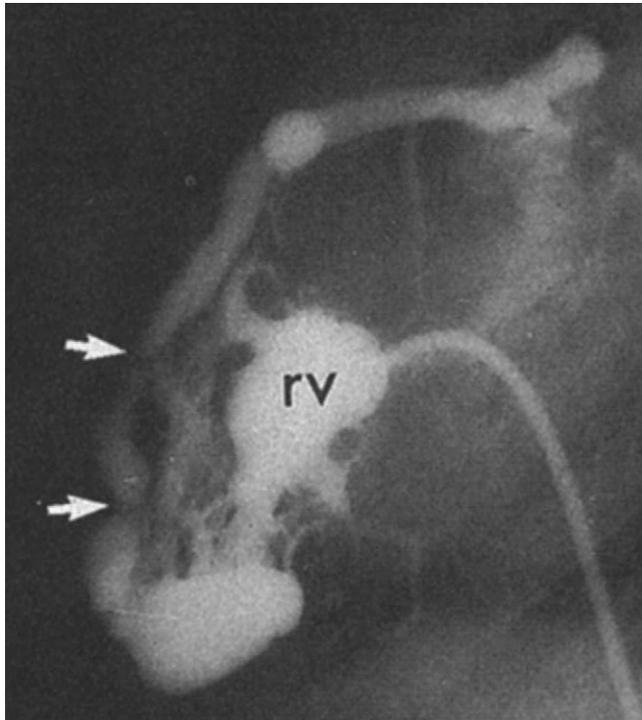

abnormal connections may represent the predominant source of coronary blood flow to the myocardium. In these cases with so-called right ventricle–dependent coronary circulation, relieving the pulmonary outflow tract obstruction would result in a fall in right ventricular pressure and hence coronary insufficiency and myocardial ischemia or infarction (Giglia et al, 1992).

Although the cornerstone of initial management is prostaglandin infusion to maintain ductal patency, a more permanent and reliable form of PBF must be surgically created for the infant to survive. Surgical management is often preceded by catheterization to define the coronary artery anatomy. In patients with right ventricle–dependent coronary arteries, creation of a systemic-to-pulmonary shunt is the typical initial surgical procedure in the neonate, with postoperative management similar to that with other forms of single-ventricle disorders. This procedure is followed by further staged reconstruction culminating in either a Fontan operation or cardiac transplantation.

In patients without significant coronary abnormalities, however, PBF is established by creating an outflow for the right ventricle by catheterization (valvoplasty, after valve perforation), surgical pulmonary valvotomy or right ventricular outflow tract augmentation. If surgery is performed, a systemic-to-pulmonary artery shunt (most often a Blalock-Taussig shunt) is constructed to also augment PBF (Fig. 57–24). Following this procedure, the patient may develop

**FIGURE 57-22.** Exposure of the hypertrophied, diminutive right ventricle in pulmonary atresia with an intact ventricular septum. The inset shows the diminutive pulmonary valve with abnormal tissue and commissural fusion. (From Castañeda AR, Jonas RA, Mayer JE Jr, Hanley FL: *Cardiac Surgery of the Neonate and Infant*. Philadelphia, WB Saunders, 1994.)

**FIGURE 57-23.** Lateral angiogram from a newborn with pulmonary atresia and intact ventricular septum. Following injection of contrast through the hypertrophied and diminutive right ventricle (RV), there is retrograde filling of tortuous coronary arteries through sinusoidal connections to the RV (arrows).

low cardiac output, either from unrecognized coronary abnormalities or from a “circular shunt” (see Fig. 57-24).

Surgical mortality risk is highly dependent on the heterogeneous anatomy of this disease, in particular, the presence or absence of coronary abnormalities; the presence of sinusoidal connections between the right ventricle and the coronary arteries is associated with poorer long-term survival. In cases with adequate coronary arteries and minimal right ventricular hypoplasia, however, the prognosis is considerably more favorable. If the right ventricular outflow tract obstruction is adequately relieved and the tricuspid valve and right ventricle are of “adequate” size, within 2 to 3 months hypertrophy regresses, compliance improves, and the right ventricle can increase its contribution to PBF. At this time, the shunt can be closed surgically (or coil-embolized in the catheterization laboratory), and any residual shunting at the atrial level can be closed with either surgical or transcatheter techniques, resulting in a normal “series” circulation.

### “Critical” Pulmonary Stenosis

In contrast with pulmonary atresia with intact ventricular septum, isolated pulmonary valve stenosis (Fig. 57-25) typically coexists with a normal-sized right ventricle and tricuspid valve and normal distal pulmonary arteries. By convention, “critical” pulmonary stenosis is the terminology used when adequate oxygenation cannot be achieved

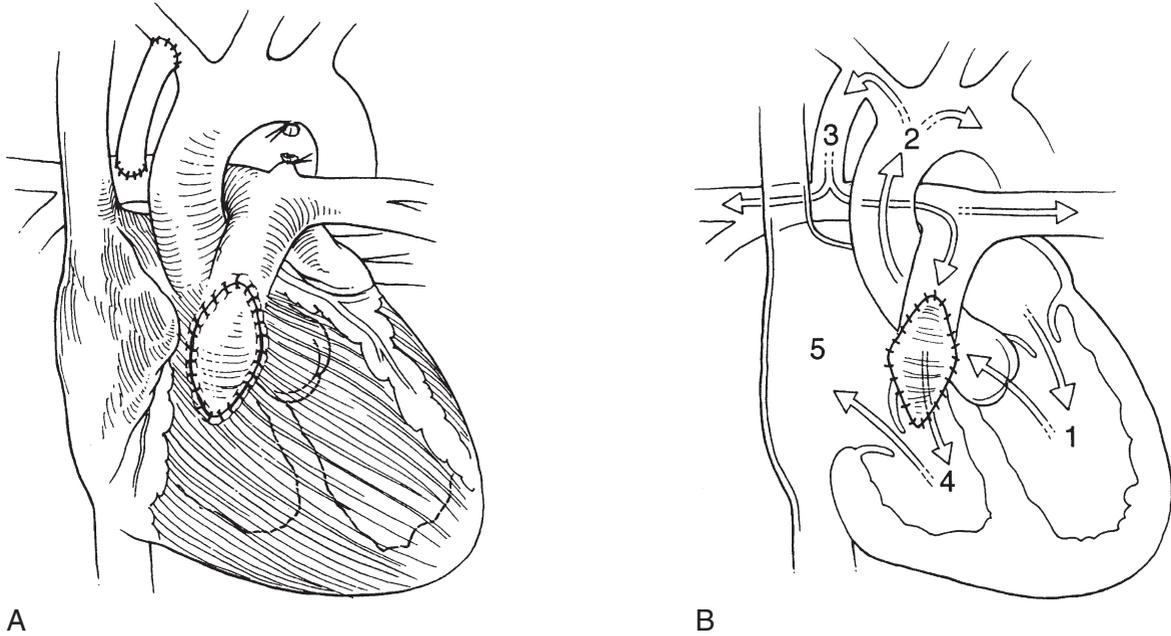

without patency of the ductus arteriosus. Prostaglandin therapy may be necessary in some cases of severe hypoxemia. “Noncritical” pulmonary stenosis may result in very high (e.g., suprasystemic) right ventricular pressures, and there may even be a component of right-to-left atrial shunting and hypoxemia, but PBF is not completely dependent on the ductus. In most cases of severe or critical obstruction, right ventricular hypertrophy is considerable, and the noncompliant right ventricle creates a preferential right-to-left shunt at the atrial level, resulting in arterial hypoxemia. Balloon valvuloplasty has become the procedure of choice in this disease, with excellent short- and mid-term results (Planche et al, 1988). It is important to emphasize that in most cases of critical pulmonary stenosis, even after the valvar obstruction is relieved, there is persistent right-to-left atrial shunting and hypoxemia. However, regression of hypertrophy will occur over the next 3 to 6 months, and atrial-level shunting will decrease over time.

## OTHER COMMON LESIONS MANIFESTING IN THE NEONATAL PERIOD

### Heterotaxy Syndrome

Arguably, there is no more confusing nomenclature than that associated with the heterotaxy syndrome, and there is no larger group of heterogeneous congenital heart lesions. Alternatively, this group of structural heart lesions has been called *atrial isomerism* and *asplenia* or *polysplenia syndrome* (Fig. 57-26). It is beyond the scope of this chapter to detail all of the subtleties of the multiple anatomic variants and the corresponding surgical strategies for correction; the reader is referred to more comprehensive texts in cardiology and cardiac surgery (Allen et al, 2001; Fyler, 1992a).

This group of rare lesions (1/10,000 live births) (Lin et al, 2002) shares the common abnormality of failure of “right-left” differentiation, leading to ambiguities of atrial and visceral “sidedness,” abnormalities of the conduction system, and characteristic anomalies of systemic and pulmonary venous return. Reported risk factors have included a family history of malformations, maternal diabetes, maternal cocaine use, and genetic microdeletions (Kuehl and Loffredo, 2002; Lin et al, 2002). Although some cases have trivial abnormalities of systemic venous return (e.g., bilateral superior venae cavae) and abdominal positioning abnormalities, a majority of cases have a functional single ventricle. These are usually of right ventricular morphology, with an endocardial cushion defect and a common AV valve. The conduction system frequently is abnormal, with dual sinus and/or AV nodes, and supraventricular tachycardia, sinus node dysfunction, or AV block may occur. The branching pattern of the pulmonary arteries and bronchi is variable and generally assumes one of two forms: bilateral right-sidedness (asplenia) with an eparterial bronchus and first branch of the pulmonary artery to the upper lobe or bilateral left-sidedness (polysplenia) with bronchi below the pulmonary artery at the hilum and bilateral, bilobate lungs. Frequently there is obstruction to PBF, as a result of muscular subvalvar pulmonary

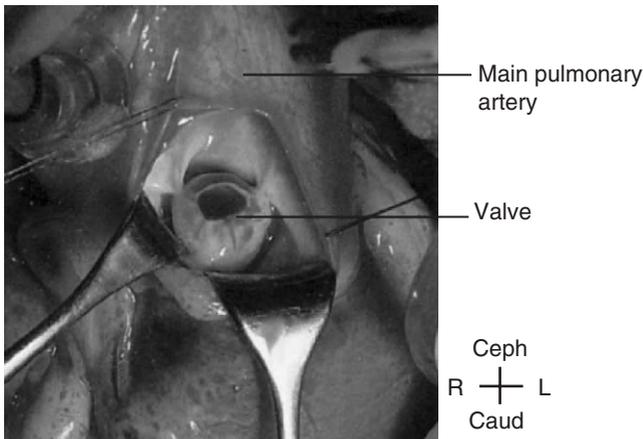

**FIGURE 57-24.** **A**, Newborn surgical palliation for pulmonary atresia with intact ventricular septum and normal coronary arteries. A right ventricular outflow tract patch is placed, the ductus is ligated and divided, and a modified Blalock-Taussig (BT) shunt is placed. **B**, Circular shunting following palliative surgery. Presence of a BT shunt in combination with obligate pulmonary insufficiency, associated tricuspid valve insufficiency, and atrial septal defect can result in flow patterns as shown (arrows) in this diagram. Blood from the left atrium enters the left ventricle (1) and the aorta (2) and then passes through the BT shunt (3) into the pulmonary artery, then retrograde across the right ventricular outflow tract (4) and retrograde across the tricuspid valve into the right atrium (5), and then across the right atrium back to the left atrium. See text for details (From Wernovsky G, Hanley FL: *Pulmonary atresia with intact ventricular septum*. In Chang AC, Hanley FL, Wernovsky G, Wessel DL [eds]: *Pediatric Cardiac Intensive Care*. Baltimore, Williams & Wilkins, 1998, pp 265-270.)

stenosis or plate-like valvar atresia, and prostaglandin therapy may be necessary to maintain ductal patency before placement of a Blalock-Taussig shunt. Although a majority of neonates with heterotaxy have obstruction to PBF, some may have obstruction to SBF, with subaortic obstruction

and/or coarctation, necessitating neonatal palliation similar to that for HLHS.

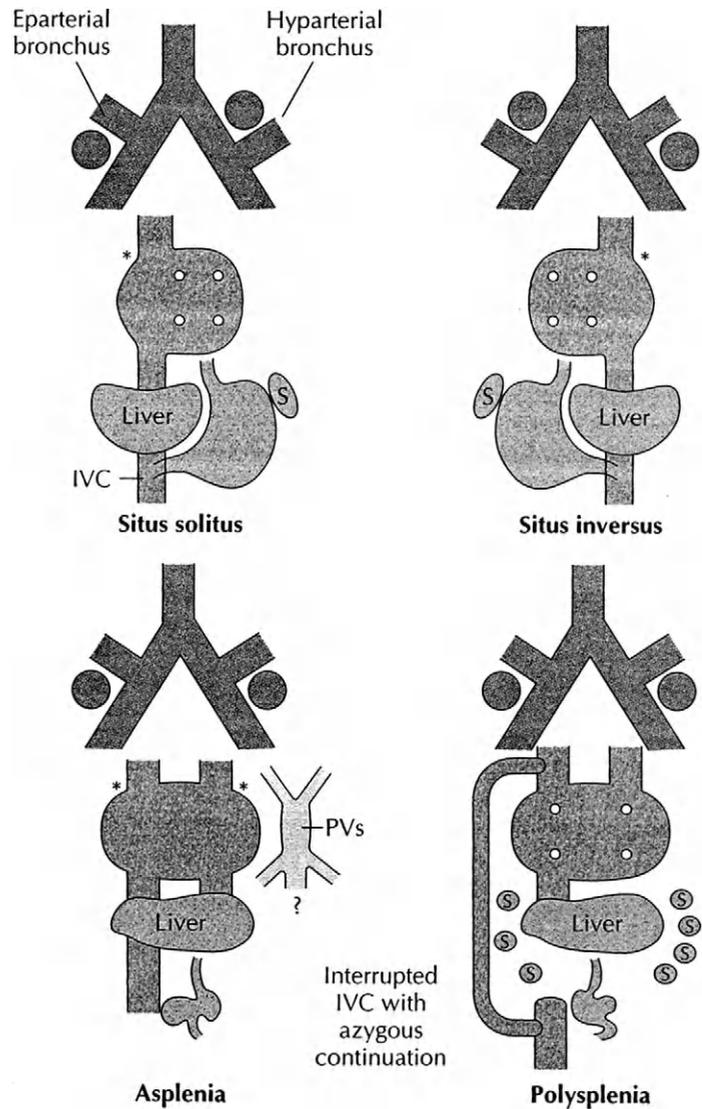

Splenic function (even in *polysplenia syndrome*) is typically abnormal and can be diagnosed by the presence of an increased number of Howell-Jolly bodies in the routine blood smear. There is no strong evidence to support treatment for heterotaxy patients similar that for patients with functional asplenia from other medical or surgical conditions; nevertheless, many practitioners maintain patients with heterotaxy on life-long ampicillin, and immunization against encapsulated organisms is considered important.

**FIGURE 57-25.** (See also Color Plate 57-25.) Exposure of a severely stenotic pulmonary valve through a pulmonary arteriotomy. (From Litwin SB: *Color Atlas of Congenital Heart Surgery*. St. Louis, Mosby, 1996.)

**Total Anomalous Pulmonary Venous Return**

Total anomalous pulmonary venous return occurs in 1/15,000 live births. This condition is characterized by failure of incorporation of the common pulmonary vein/venous confluence into the posterior aspect of the left atrium. The fetal (and postnatal) pulmonary venous return is thus directed to the systemic venous circulation through a number of potential vestigial venous structures, with complete mixing of pulmonary and systemic venous returns. The anomalous connections of the pulmonary veins may be (1) supracardiac (usually into the right superior vena cava or to the innominate vein via a persistent vertical vein), (2) cardiac (usually to the right atrium or

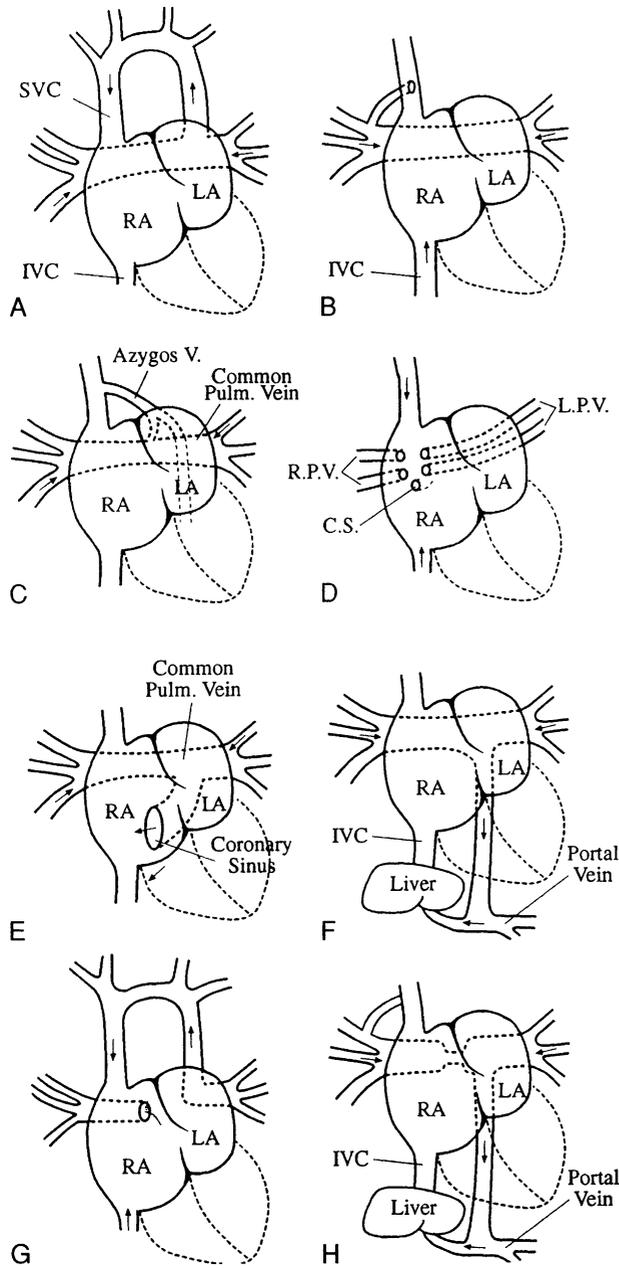

**FIGURE 57-26.** Situs and looping abnormalities: “Heterotaxy syndrome.” See text for details. IVC, inferior vena cava; PVs, pulmonary veins; S, spleen. (From Lacro RV: *Genetics, teratology, and syndromes of congenital heart disease*. In Braunwald E [ed]: *Atlas of Heart Diseases*. Philadelphia, Mosby-Year Book, 1997, pp 2.1-2.12.)

coronary sinus), (3) infracardiac (usually into the portal system), or (4) mixed drainage (Fig. 57-27). Filling of the left ventricle is thus dependent on an obligate shunt through the patent foramen ovale into the left heart to provide adequate cardiac output.

Patients may be physiologically categorized as either those with no obstruction to pulmonary venous return or those with anatomic narrowing of the connection or pathway of the pulmonary venous confluence to the systemic venous circulation. In those with no obstruction (or only a mild degree of obstruction), there may be no symptoms or visible cyanosis, with many neonates escaping recognition of their condition until later in infancy. However, in patients with obstruction of pulmonary venous return, findings include severe pulmonary venous hypertension, severe restriction to antegrade PBF, pulmonary hypertension, and profound hypoxemia. Most of these cases will have an obstructed pathway from the pulmonary venous chamber inferiorly below the diaphragm through the liver (subdiaphragmatic type) or from the pulmonary venous chamber superiorly, with narrowing between the bronchus

and pulmonary artery (supracardiac type). In patients with moderate obstruction, there is adequate PBF and mixing of systemic and pulmonary venous returns to achieve adequate oxygen delivery to the tissues. Many of these patients will benefit from supplemental oxygen, mechanical ventilation with positive end-expiratory pressure, and sedation to reduce oxygen consumption.

In cases of severe obstruction with significantly reduced PBF, the diagnosis may be difficult to make non-invasively by echocardiography. In these cases, the pulmonary veins may be small, and when little flow is present, they are difficult to visualize with color Doppler. In addition, the congested appearance of the lungs on radiographs and a right-to-left shunt at the ductus arteriosus may suggest lung disease with elevated PVR as the etiology of hypoxemia. Many neonates are so severely ill from profound hypoxemia that they are initially treated with ECMO before definitive diagnosis of obstructed pulmonary venous return. Even in the current era of prostaglandin therapy, echocardiography, improved ventilatory support, and advanced medical intensive care,

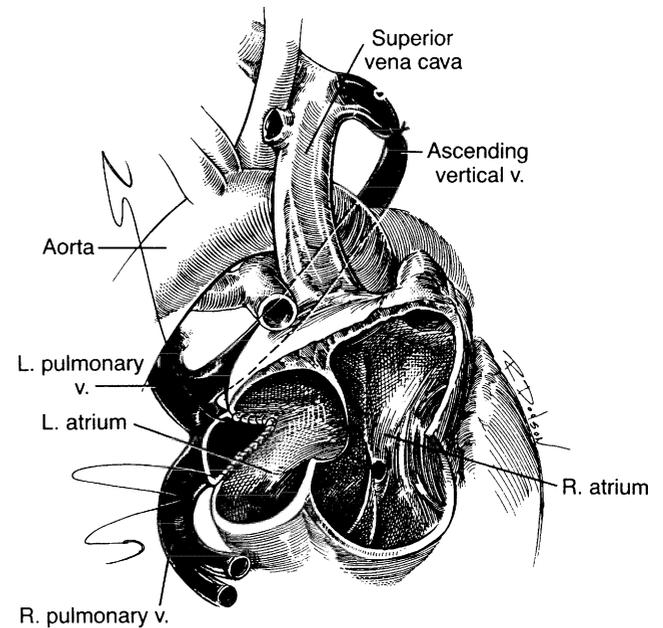

**FIGURE 57-27.** Anatomic varieties of total anomalous pulmonary venous return: **A-C**, supracardiac; **D** and **E**, cardiac; **F**, infracardiac; **G** and **H**, mixed. See text for details. C.S., coronary sinus; IVC, inferior vena cava; LA, left atrium; L.P.V., left pulmonary vein; RA, right atrium; R.P.V., right pulmonary vein; SVC, superior vena cava. (From Eimbeck F, Enriquez G, Gomez O, Zilleruelo R: Total anomalous pulmonary venous connection. In Moller JH, Hoffman JIE [eds]: *Pediatric Cardiovascular Medicine*. Philadelphia, Churchill Livingstone, 2000, pp 409-420.)

severely obstructed total anomalous pulmonary venous return represents one of the few remaining congenital heart lesions that may require emergent, “middle of the night” surgical intervention. Severe obstruction represents a surgical emergency, with minimal beneficial effects from medical management. Although PGE<sub>1</sub> will maintain ductal patency, the limitation of PBF in these

patients is due *not* to limited antegrade flow into the pulmonary circuit but rather to outflow obstruction at the pulmonary veins. Early recognition of the problem and prompt surgical intervention are necessary for the infant to survive.

Whether or not obstruction to pulmonary venous return exists, in virtually all cases there is a common pulmonary venous confluence behind the left atrium. Surgical repair consists of a direct anastomosis of this chamber to the left atrium, with division and/or ligation of the accessory venous connection to the systemic venous return (Fig. 57-28). Surgical mortality risk is principally dependent on the anatomic and physiologic variability in this disease; the surgical mortality rate is less than 5% in patients with uncomplicated, unobstructed anatomy, and incrementally higher in cases of complex connections and/or obstruction. In cases with severe preoperative obstruction, the postoperative course is frequently marked by pulmonary vascular lability, right ventricular hypertension, and low cardiac output syndrome.

Late pulmonary venous obstruction may occur in upwards of 20% of cases (especially if obstruction exists at presentation) and, if present, is very difficult to treat surgically. Pulmonary venous hypoplasia, in addition to suture line narrowing, complicates many of these cases (Kirshbom et al, 2002). In addition, interventional catheterization procedures to dilate the confluence or to place expandable stents also have been met with little success. Lung transplantation may need to be considered in some cases. In children in whom late obstruction does not develop, functional outcomes are good, with little limitation to daily activities and no need for frequent follow-up or long-term medications.

**FIGURE 57-28.** Repair of supracardiac total anomalous pulmonary venous return by connecting the horizontal pulmonary venous confluence into the left atrium. (From Castañeda AR, Jonas RA, Mayer JE Jr, Hanley FL: *Cardiac Surgery of the Neonate and Infant*. Philadelphia, WB Saunders, 1994.)

### Transposition of the Great Arteries

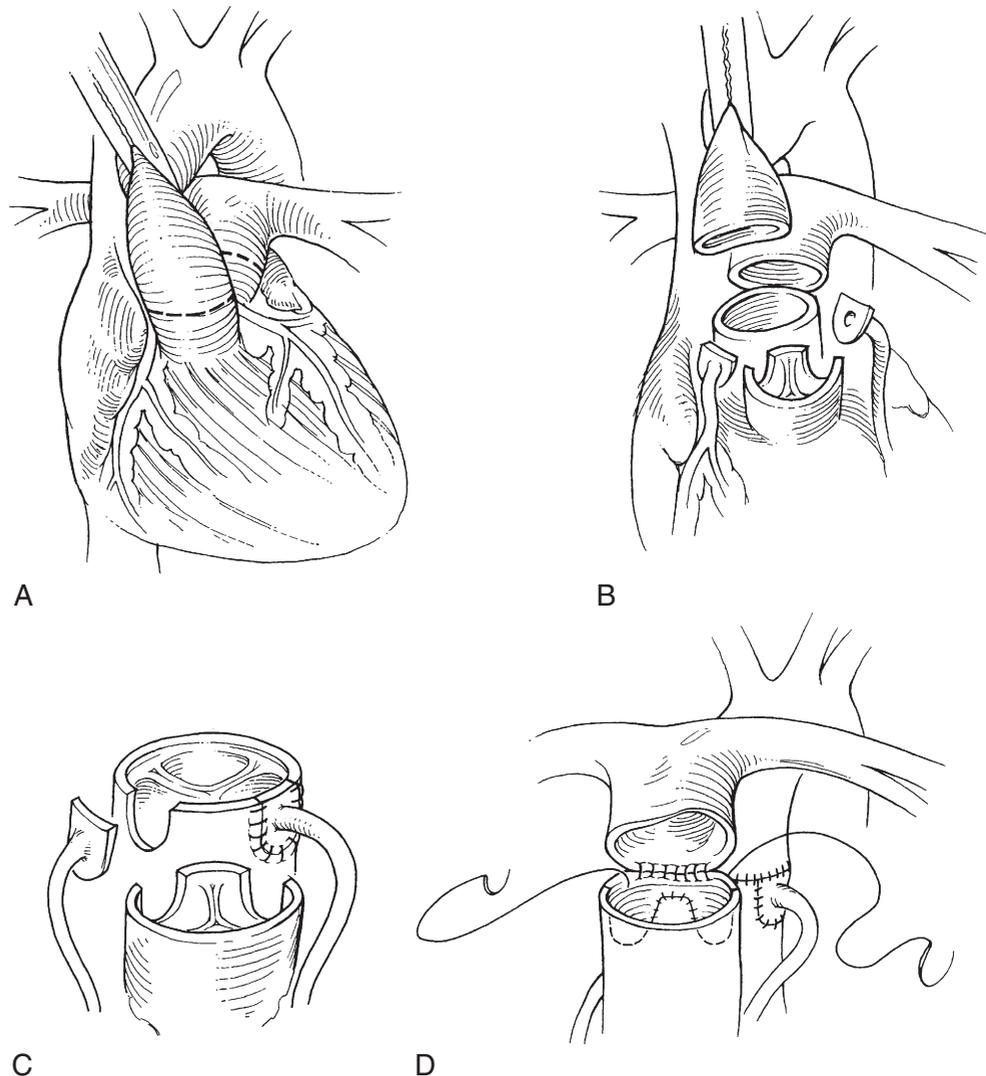

TGA occurs in approximately 1/3500 live births, is more frequent in males, and is not typically associated with additional noncardiac anomalies or genetic syndromes. *Transposition* is defined as an aorta arising from the morphologically right ventricle and the pulmonary artery from the morphologically left ventricle. About half of the patients have an associated VSD, and perhaps 10% have either obstruction to systemic blood flow (usually coarctation) or obstruction to PBF (usually subpulmonary and valvar pulmonary stenosis).

In the usual arrangement this creates a situation of “parallel circulations” with systemic venous return being pumped via the aorta back to the systemic circulation, and pulmonary venous return being pumped via the pulmonary artery to the pulmonary circulation. Following separation from the placenta, neonates with transposition are dependent on mixing between the parallel systemic and pulmonary circulations in order for them to survive. In patients with an intact ventricular septum, this communication exists through the patent ductus arteriosus and the

patent foramen ovale. These patients are usually clinically cyanotic within the first hours of life, leading to early diagnosis of TGA. Those infants with an associated VSD typically have somewhat improved mixing between the systemic and pulmonary circulations and may not be as severely cyanotic. See the earlier sections on the transitional circulation and the physiologic classification of heart disease for a full description of transposition physiology, mixing, and initial management.

In the current era, definitive management in patients with two normal-sized ventricles and no obstruction to PBF is surgical correction with an arterial switch operation in the early neonatal period (Wernovsky and Freed, 1997; Wernovsky et al, 1995) (Fig. 57–29). In uncomplicated cases, the surgical mortality rate is less than 5%, with higher risk in patients with low birth weight, additional cardiac anomalies (e.g., coarctation, dextrocardia), and/or abnormal coronary artery origins or distribution. The postoperative course is frequently marked by a transient period of low cardiac output, and the multiple suture lines at systemic pressure are at risk for bleeding. Mid-term

**FIGURE 57-29.** Repair of *d*-transposition of the great arteries by the arterial switch procedure. **A**, The dashed lines depict the planned location of transection of the great vessels. **B**, The coronary arteries are removed with surrounding aortic wall as “buttons.” **C**, Following a counterincision in the neo-aorta, the coronary buttons are translocated to the posterior semilunar root. **D**, The Lecompte maneuver brings both pulmonary arteries anterior to the neo-aorta. The aortic suture line is completed, incorporating the coronary buttons. The coronary donor sites are filled in with patches of autologous pericardium, and the pulmonary anastomosis is completed. (From Wernovsky G, Jonas RA: *Transposition of the great arteries*. In Chang AC, Hanley FL, Wernovsky G, Wessel DL [eds]: *Pediatric Cardiac Intensive Care*. Baltimore, Williams & Wilkins, 1998, pp 289-301.)

follow-up studies (Haas et al, 1999; Hovels-Gurich et al, 2003; Hutter et al, 2002; Wernovsky et al, 1995; Williams et al, 2003) reveal a late reintervention rate of 10% to 15%, typically for supervalvar pulmonary stenosis. Rarely, late deaths have occurred, presumably from coronary events. As the earliest survivors of this operation now are approaching young adulthood, there is a growing recognition of late dilation of the neo-aortic root and neo-aortic regurgitation in as many as 50% of patients.

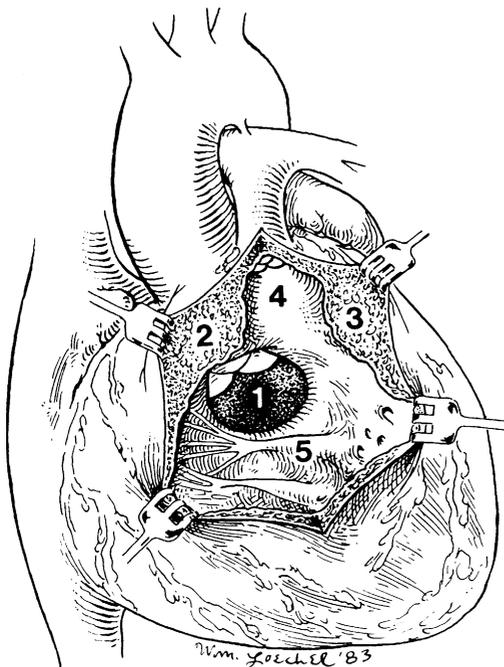

### Tetralogy of Fallot

Originally described in the early 19th century, tetralogy of Fallot remains one of the most common and well-described congenital heart lesions. Fallot originally recognized the common association of VSD, subvalvar and valvar pulmonary stenosis, right ventricular hypertrophy, and a location of the aortic root so that it appeared to “override” the ventricular septum (Fig. 57–30). Current thinking is that this constellation of morphologic observations results from a single anatomic defect: anterior deviation of the infundibular septum. This “malalignment” of the infundibular (or conal) septum with the muscular septum results in incomplete separation of the right and left ventricles (VSD), a narrowed right ventricular outflow tract (subvalvar obstruction to PBF), and an aortic valve that is more rightward and anterior than usual, thus “overriding” the muscular ventricular septum. Right ventricular hypertrophy develops not because of the obstruction to PBF but from the fact that the VSD is nonrestrictive, thus

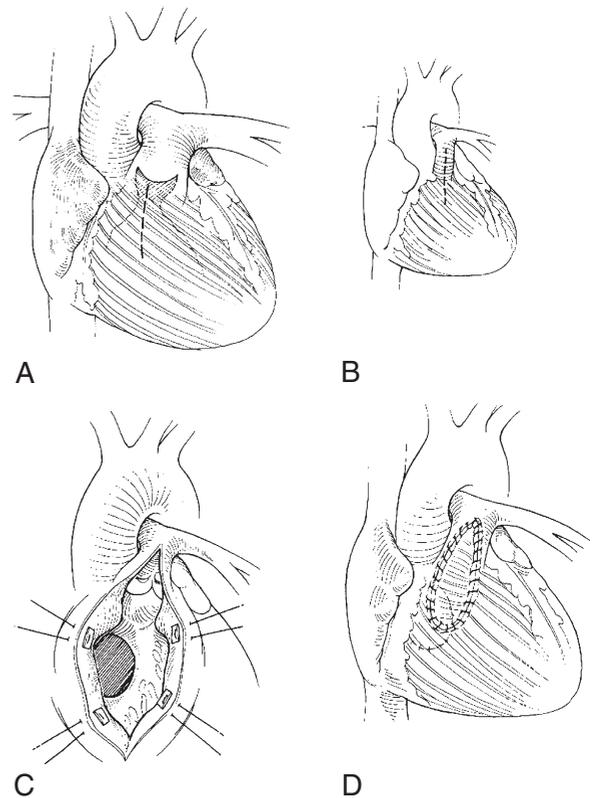

maintaining systemic-level pressure in the right side of the heart. The severity of pulmonary obstruction is variable, but all patients with tetralogy of Fallot will have right ventricular hypertrophy, even in the face of relatively mild pulmonary stenosis.

Most children with tetralogy of Fallot are asymptomatic and present in the early newborn period with a harsh murmur across the right ventricular outflow tract. Rarely, obstruction to PBF is quite severe, resulting in visible cyanosis; rare patients have such severe obstruction to PBF that they require stabilization with PGE<sub>1</sub>. In these children, management options include palliation with a systemic-to-pulmonary shunt (e.g., modified Blalock-Taussig shunt) and complete anatomic correction in the newborn period. In older children without significant hypoxemia or symptoms, elective repair in the first 6 months of life is recommended (Fig. 57–31).

Surgical mortality risk is quite low (1% to 2%) in patients without additional comorbid conditions (e.g., prematurity) (Hirsch et al, 2000). Reintervention is uncommon in childhood, usually being limited to angioplasty of

**FIGURE 57–30.** Anatomy of tetralogy of Fallot. Principal anatomic components include malalignment ventricular septal defect with aortic override (1), obstruction of the right ventricular outflow tract (2, 3) with pulmonary stenosis (4) and right ventricular hypertrophy (5). (From Mavroudis C, Backer CL: *Pediatric Cardiac Surgery*. St. Louis, Mosby-Year Book, 1994.)

**FIGURE 57–31.** Repair of tetralogy of Fallot. **A**, Dashed line depicts non-transannular incision, used when the pulmonary valve and annulus are of adequate size. **B**, A transannular incision (dashed line) is used when there is annular hypoplasia. **C**, An example of transventricular exposure of the ventricular septal defect (VSD). Alternatively, the VSD may be closed via a right atriotomy through the tricuspid valve. **D**, External view of patch closure of the transannular incision. (From Spray TL, Wernovsky G: *Right ventricular outflow tract obstruction*. In Chang AC, Hanley FH, Wernovsky G, Wessel DL [eds]: *Pediatric Cardiac Intensive Care*. Baltimore, Williams & Wilkins, 1998, pp 257-270.)

narrowing in the branch pulmonary arteries or surgical closure of residual VSD (Kaulitz et al, 2001). Increasingly, as these patients enter adulthood, pulmonary valve replacement is becoming necessary to correct right ventricular dilation and/or dysfunction (Ternstedt et al, 2001; Warner et al, 2003).

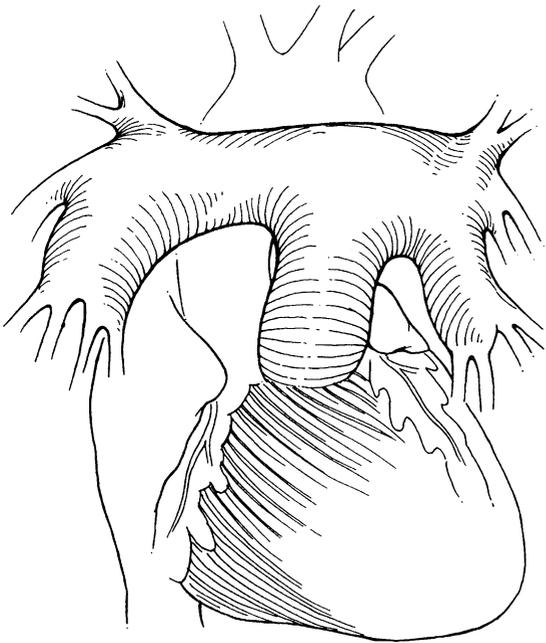

### Tetralogy of Fallot with Absent Pulmonary Valve

Alternatively called *absent* (or *dysplastic*) *pulmonary valve syndrome*, tetralogy of Fallot with absent pulmonary valve (TOF/APV) represents a spectrum of conditions in which there is an abnormally formed pulmonary valve with varying degrees of (1) annular hypoplasia, (2) valvar stenosis, and, most significant, (3) pulmonary regurgitation. Virtually all reported cases are associated with a malalignment type of VSD morphologically identical to that seen in tetralogy of Fallot (hence the term *TOF/APV*), but rare cases with intact ventricular septum have been reported. The principal hemodynamic burden to the fetus in this lesion is pulmonary regurgitation. The regurgitant fraction increases right ventricular volume work and results in aneurysmal dilation of the branch pulmonary arteries with abnormal muscularization of branch pulmonary arteries and the large and small airways (Fig. 57-32).

There are two distinctly different groups of patients with TOF/APV, with minimal overlap: (1) severely symptomatic neonates with hypoxemia and respiratory distress and (2) relatively asymptomatic neonates and young infants

with a cardiac murmur and mild hypoxemia (McDonnell et al, 1999). In the severely affected neonate, signs and symptoms related to the intracardiac pathology are worsened by coexisting *airway compression*, which manifests as hyperinflation, CO<sub>2</sub> retention, hypoxemia, and respiratory distress. It is sometimes difficult to determine whether the hypoxemia is due principally to intracardiac right-to-left shunting from severe right ventricular outflow obstruction or to intrapulmonary shunting from the airway disease. (In most cases, the hypoxemia results from a combination of these factors.) Because of the extrinsic airway compression, intubation and mechanical ventilation frequently do not improve the gas exchange and abnormal respiratory mechanics; a long expiratory phase, increased positive end-expiratory pressure, and occasionally prone positioning may be necessary. However, urgent surgery often is required in these patients.

In both the severely symptomatic neonate and the minimally symptomatic infant, surgery consists of VSD closure, plication of the pulmonary arteries, relief of the right ventricular outflow tract obstruction, and in most cases, insertion of a valve or monocusp in the right ventricular outflow tract (Fig. 57-33). The mortality risk and both short- and long-term outcomes are related principally to the severity of pulmonary artery dilation and airway compression; severely affected neonates have a high mortality risk, and most of the survivors require long-term mechanical ventilation, progressing to tracheostomy and home ventilation and/or airway stenting in some (Dodge-Khatami et al, 1999; McDonnell et al, 1999). In contrast, children with less significant pulmonary artery dilation and airway symptoms have a low mortality risk and a long-term course similar to that in tetralogy of Fallot.

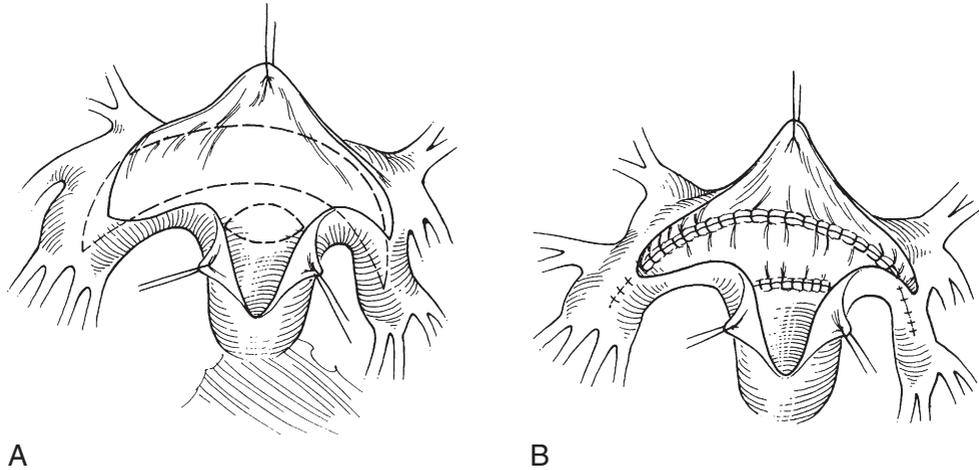

**FIGURE 57-32.** Tetralogy of Fallot with absent pulmonary valve is marked by severe dilatation of the main and branch pulmonary arteries, frequently with associated bronchial compression and large and small airway disease. The intracardiac anatomy is usually similar to that in standard tetralogy of Fallot. (From *Spray TL, Wernovsky G: Right ventricular outflow tract obstruction. In Chang AC, Hanley FH, Wernovsky G, Wessel DL [eds]: Pediatric Cardiac Intensive Care. Baltimore, Williams & Wilkins, 1998, pp 257-270.*)

### Aorticopulmonary Window

*Aorticopulmonary window* is defined as a connection between the ascending aorta and main pulmonary artery; the presence of two separate semilunar valves separates this disease from truncus arteriosus. Aorticopulmonary window is a rare disease sometimes associated with 22q deletion syndrome. More than 50% of the patients have associated lesions, especially ASDs and VSDs, or, more rarely, interruption of the aortic arch distal to the left subclavian artery (type A) with an associated VSD.

The developmental mechanisms leading to aorticopulmonary window are not clear. Anatomic classification of aorticopulmonary window depends on the location of the defect with respect to the semilunar valves. A proximal defect, type 1, occurs just above the sinuses of Valsalva leaving essentially no inferior rim. Distal defects, type 2, are located in the upper ascending aorta and have little upper rim but a well-formed inferior rim, whereas total defects, type 3, have neither upper nor lower rims, with near-complete absence of aorticopulmonary separation.

Affected infants usually demonstrate symptoms of CHF in the first few weeks of life following a fall in PVR. The anatomic communication typically is large and unrestrictive, with a resultant large left-to-right shunt and transmitted pulmonary hypertension; if the defect is left unrepaired, irreversible pulmonary vascular obstructive

**FIGURE 57-33.** Repair of tetralogy of Fallot with absent pulmonary valve, along with closure of the ventricular septal defect and establishment of continuity between the right ventricle and pulmonary arteries. An important component of repair for tetralogy of Fallot with absent pulmonary valve is plication of the redundant pulmonary arteries. **A**, Upper dashed line depicts area of posterior pulmonary arterioplasty. **B**, Completed posterior suture line, prior to anterior pulmonary arterioplasty. (From Spray TL, Wernovsky G: Right ventricular outflow tract obstruction. In Chang AC, Hanley FH, Wernovsky G, Wessel DL [eds]: *Pediatric Cardiac Intensive Care*. Baltimore, Williams & Wilkins, 1998, pp 257-270.)

disease may result. Physiologically, this lesion is much like a patent ductus arteriosus, although the shunt is usually larger. The anatomic diagnosis is usually straightforward by echocardiography; catheterization is rarely necessary for anatomic diagnosis alone. Preoperative management should address the risks of pulmonary hypertension. Repair should be done in most cases shortly after the diagnosis is made. Intermediate forms can sometimes be repaired via catheter-based device closure, although most defects are repaired by surgery. Surgical repair usually is uncomplicated and typically involves patch closure of the defect (Backer and Mavroudis, 2002). The mortality rate is low in the absence of complicated comorbid conditions (Fig. 57-34).

### Vascular Rings and Pulmonary Artery Sling

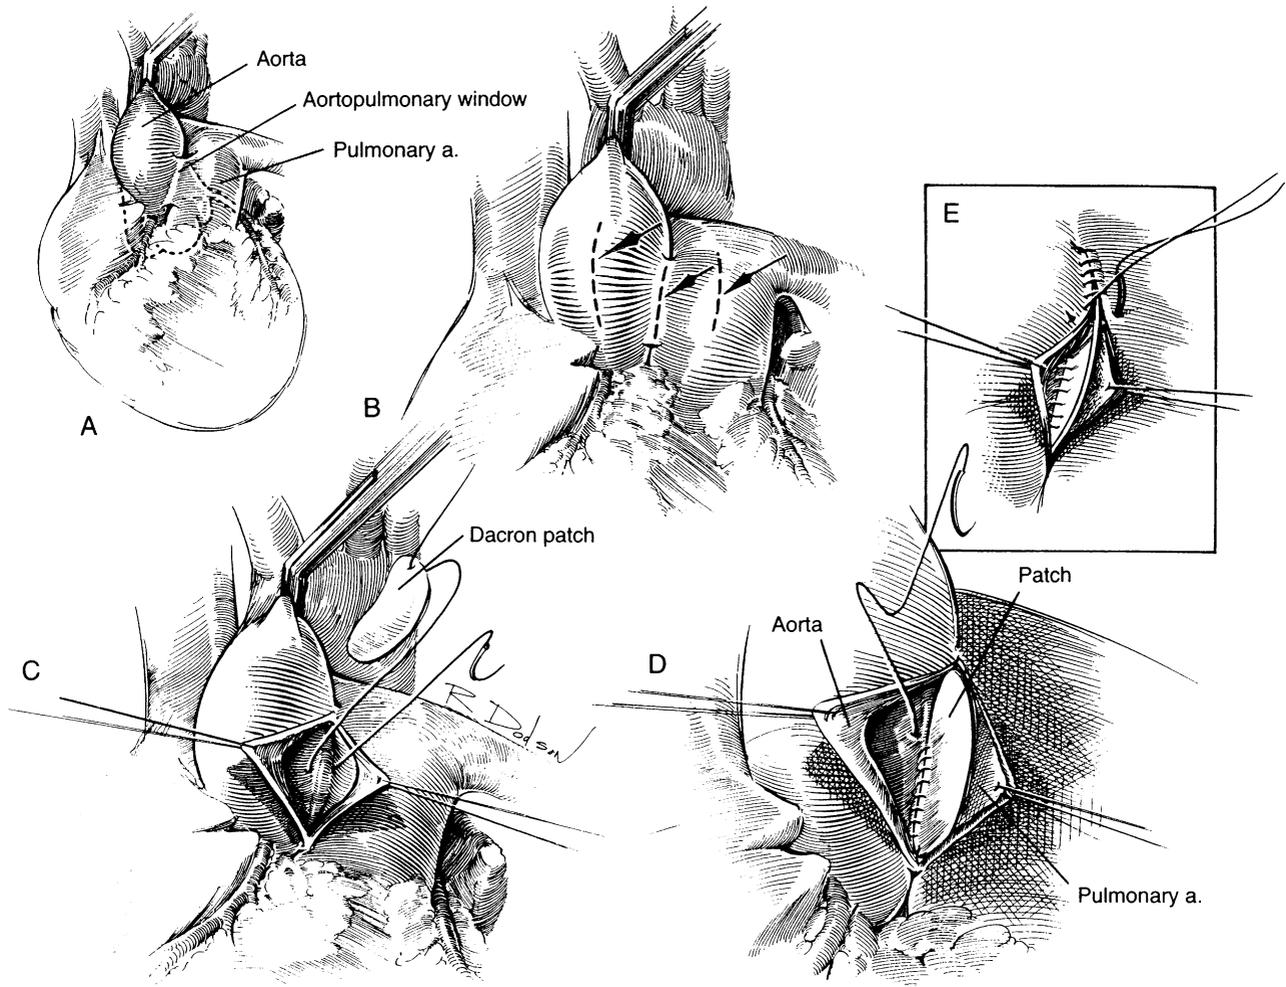

Abnormalities of branching of the aortic arch vessels may cause compression of the airway and/or esophagus. In the most common form of vascular ring, there is a right-sided aortic arch, but the first branch is not a left innominate artery but an isolated left common carotid artery. The left subclavian artery arises from the descending aorta, passing behind the esophagus. The ligamentum arteriosum connects the posterior left subclavian artery to the anterior left pulmonary artery, “completing” the ring. The second most common variety is a double aortic arch (Fig. 57-35). Pulmonary artery sling is a very rare condition that results from an abnormal origin and course of the left pulmonary artery (LPA). In LPA sling, the artery initially proceeds directly posteriorly and then proceeds leftward in between the trachea and esophagus (Fig. 57-36). Complete cartilaginous rings may be present in the area where the LPA crosses behind the trachea, adding a fixed component of airway obstruction to the dynamic airway compression

due to the LPA abnormality. The presentation is variable and related to the degree of airway compression; additional intracardiac pathology is very rare. In the absence of tracheal rings, repair typically is performed by division of the LPA followed by reimplantation anterior to the airway. However, if tracheal rings are present in association with an abnormal airway diameter, repair is much more extensive and complicated. In these cases, either the airway is transected with removal of the rings and end-to-end anastomosis (similar to repair for coarctation of the aorta), or a posterior incision is made in the airway followed by patch augmentation using gluteraldehyde-treated pericardium or artificial material over the posterior portion of the airway. Depending on the anatomy and geometry of the repair, the LPA may not require division but is brought anterior to the reconstructed airway (Bove et al, 2001; van Son et al, 1999) (Fig. 57-37).

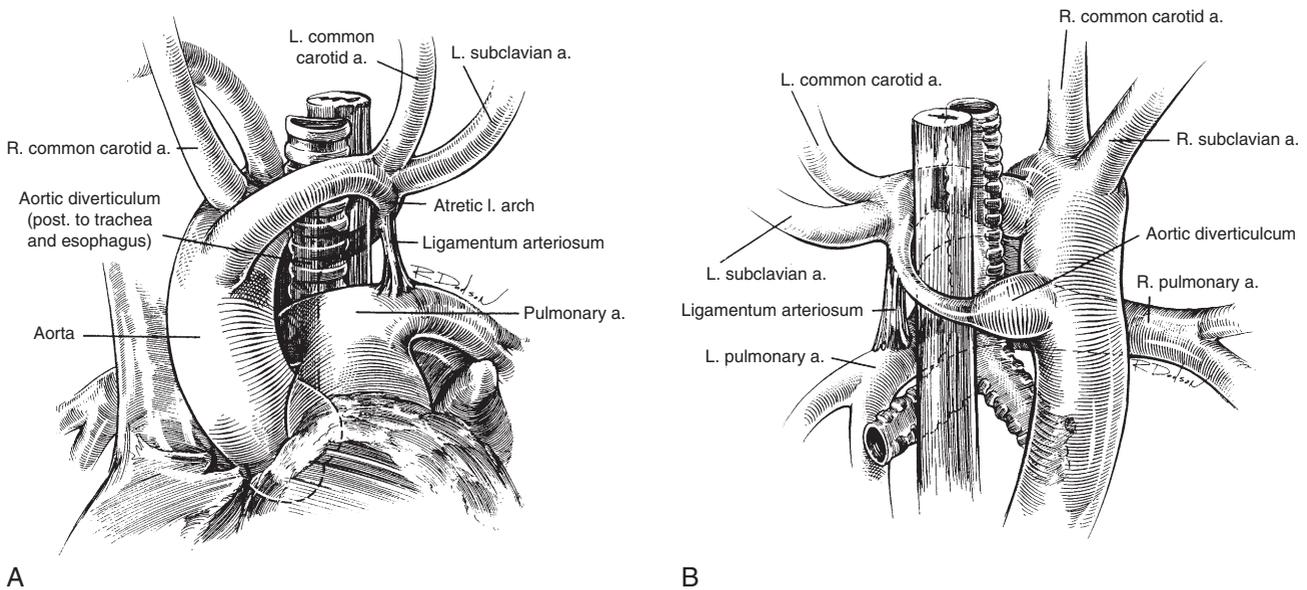

If tracheal rings do not complicate the sling, the long-term outcomes are very good, with rare patients requiring balloon angioplasty of the origin of the LPA for late postoperative stenosis. However, if tracheal surgery is necessary, the long-term outcomes are much more variable and complicated and depend primarily on the length and caliber of the reconstructed airway, and whether airway scarring complicates long-term growth.

### Double-Outlet Right Ventricle

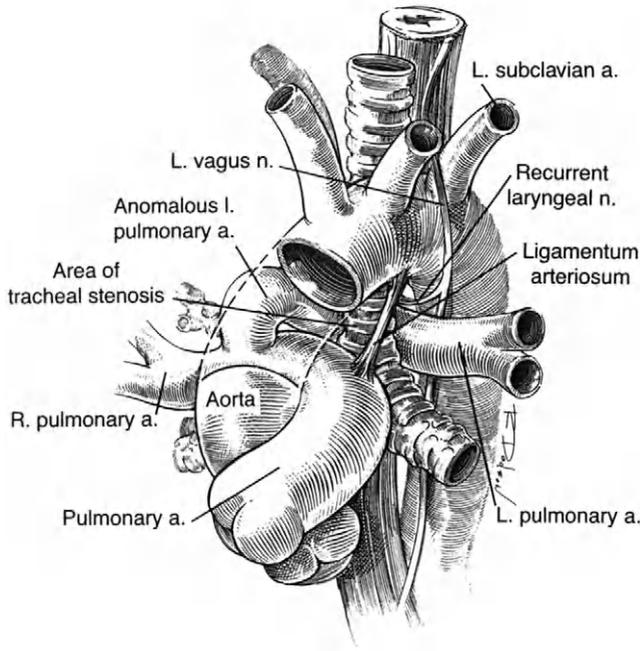

The term *double-outlet right ventricle* (DORV) (Fig. 57-38) refers to a heterogeneous group of lesions that share two principal characteristics: (1) both the aorta and pulmonary artery arise from the right ventricle, and (2) a muscular conus or infundibulum below each great artery connects it to the right ventricle. It is beyond the scope of this chapter to describe the multiple different anatomic subtleties of this

**FIGURE 57-34.** Aorticopulmonary window. **A**, Surface view. **B**, Dashed lines depict possible surgical incision lines based on individual anatomic variation. **C-E**, Patch closure of the defects. Care must be taken to avoid the coronary arteries. (From Castañeda AR, Jonas RA, Mayer JE Jr, Hanley FL: *Cardiac Surgery of the Neonate and Infant*. Philadelphia, WB Saunders, 1994.)

**FIGURE 57-35.** Vascular ring caused by a double aortic arch. **A**, Anteroposterior view; **B**, Posteroanterior view. The most common form of double aortic arch consists of a dominant, posterior right aortic arch and a smaller, anterior arch, usually in combination with a left ligamentum arteriosum. The ligamentum arteriosum contributes to the compression from the ring. (From Castañeda AR, Jonas RA, Mayer JE Jr, Hanley FL: *Cardiac Surgery of the Neonate and Infant*. Philadelphia, WB Saunders, 1994.)

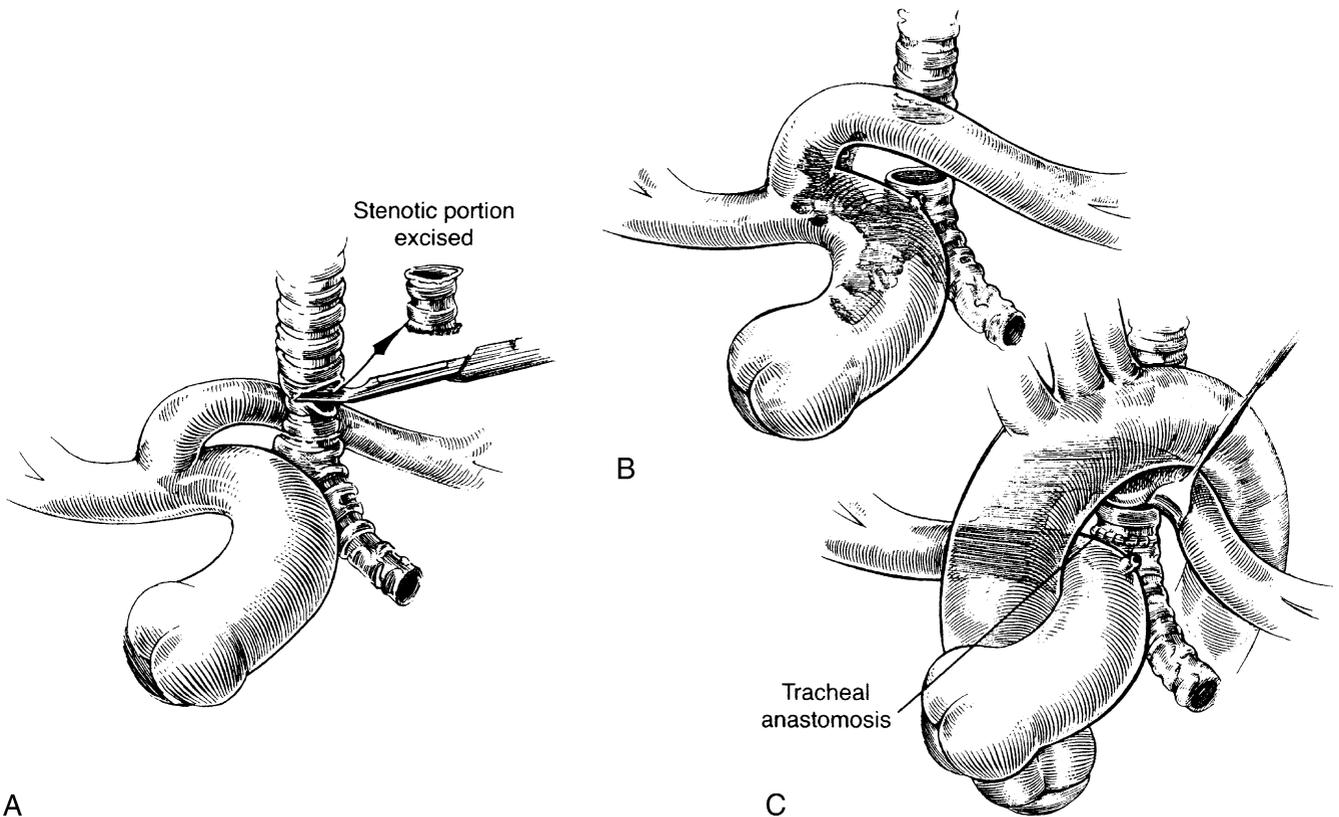

**FIGURE 57-36.** Anatomy of pulmonary artery sling. The left pulmonary artery passes behind the trachea, frequently resulting in tracheal compression.

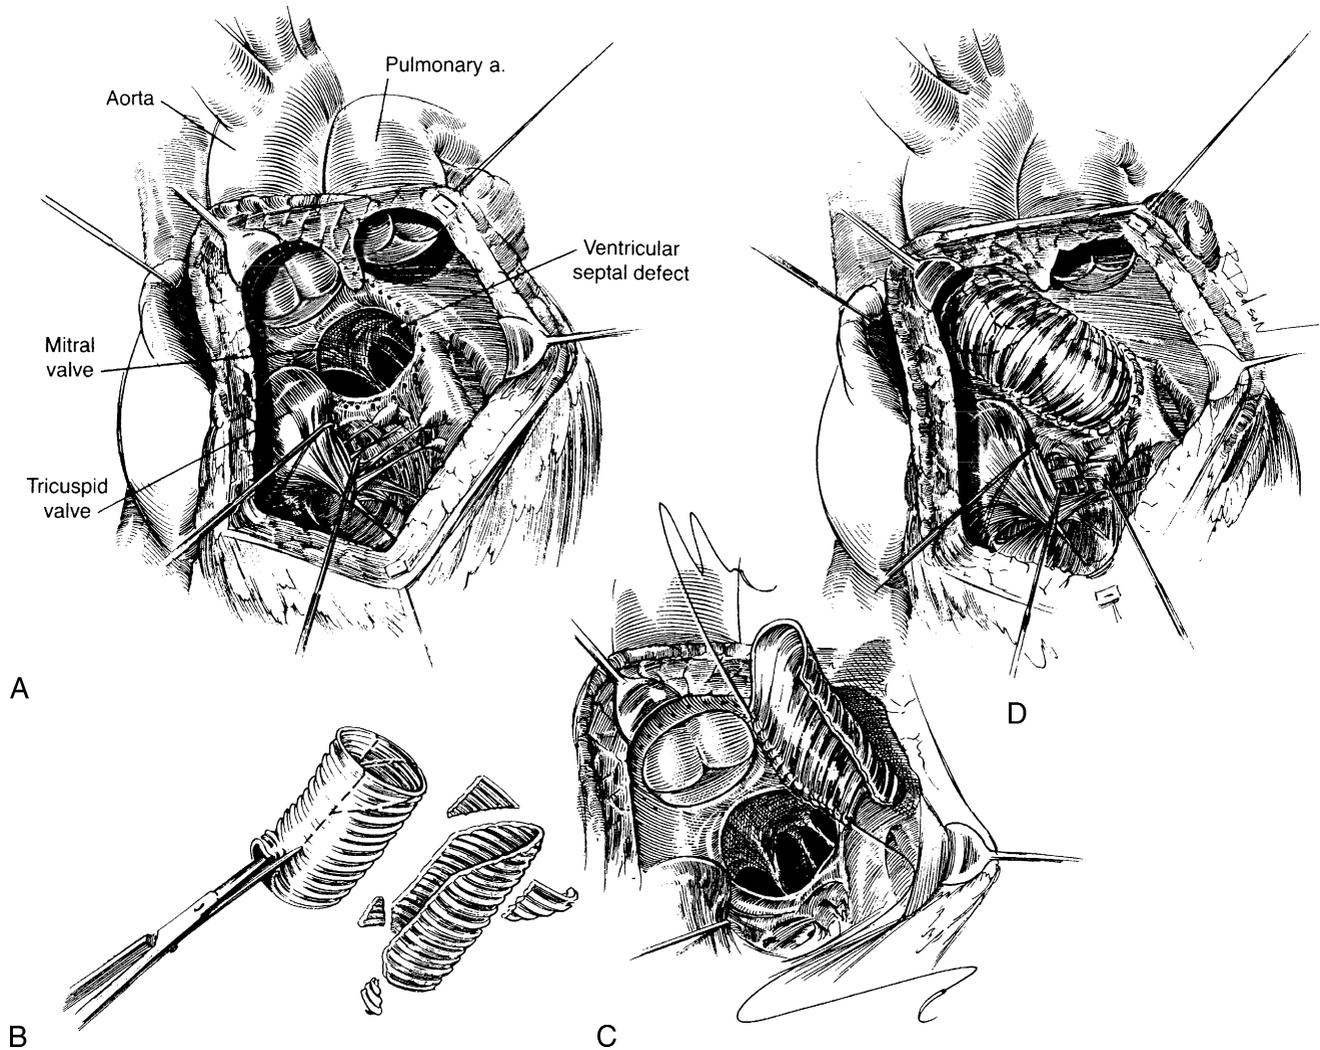

lesion; entire book chapters and reviews have been dedicated to this one anatomic diagnosis alone (Anderson et al, 1996; Stellin et al, 1991). However, it is useful to characterize DORV into a classification scheme that is related to surgical management and outcome. Some patients have one functional ventricle and are managed with staged reconstruction similar to that for HLHS; these patients typically have a small or atretic mitral valve, a restrictive ASD, a small left ventricle connected to the right ventricle through a VSD, and a high prevalence (perhaps 20% to 25%) of an associated left superior cava to the coronary sinus.

In a larger group of patients with non-single-ventricle physiology, DORV typically is divided into four types related to the location of the VSD vis-à-vis the great arteries and the relationship of the great arteries to each other.

1. In DORV of the *tetralogy* type, the great vessels are normally related to each other, with the aorta-pulmonary artery conotruncus “pulled” anterior and rightward over the right ventricle. The VSD directs blood primarily toward the aorta (subaortic VSD); the pulmonary artery and its supporting conus are typically smaller than the aorta, and the physiology and repair are similar to those in tetralogy of Fallot.
2. In DORV of the *transposition* type, the great vessel relationship is more similar to that in transposition of the great arteries, with the aorta anterior to or directly on

**FIGURE 57-37.** Repair of pulmonary artery sling associated with tracheal stenosis. **A**, The stenotic tracheal segment is resected. **B**, The left pulmonary artery is brought anterior to the tracheal reconstruction. **C**, Completion of the tracheal suture line. (From Castañeda AR, Jonas RA, Mayer JE Jr, Hanley FL: *Cardiac Surgery of the Neonate and Infant*. Philadelphia, WB Saunders, 1994.)

**FIGURE 57-38.** Double-outlet right ventricle with “doubly committed” ventricular septal defect (VSD) (see text). **A**, The *dotted line* depicts the location of the synthetic baffle that will direct blood from the left ventricle through the VSD to the aorta. **B**, Construction of the baffle. **C**, Beginning of suture line around the superior rim of the VSD. **D**, Completed intracardiac baffle (“tunnel”). The right ventriculotomy is then closed, typically with a patch of material to enlarge the right ventricular-to-pulmonary artery pathway. (From Castañeda AR, Jonas RA, Mayer JE Jr, Hanley FL: *Cardiac Surgery of the Neonate and Infant*. Philadelphia, WB Saunders, 1994.)

the right of the pulmonary artery. Again, the aorta-pulmonary artery conotruncus sits directly over the right ventricle, but in contrast with the tetralogy type of DORV, the VSD directs blood toward the pulmonary artery (subpulmonary VSD); the aorta and its supporting conus are typically smaller than the pulmonary artery, and the physiology and repair are similar to those in transposition of the great arteries. An associated coarctation is present in up to 25% of patients with DORV of the transposition type. The so-called Taussig-Bing malformation fits into this variety of DORV, with side-by-side great arteries (with the aorta more rightward), a subpulmonary VSD, and arch hypoplasia.

3. In DORV with a “doubly committed” VSD, a large VSD is present below *both* great arteries, with variable physiology depending on the relative degrees of obstruction from the subaortic or subpulmonary infundibulum or

conus. Surgical repair in this subgroup must be customized in order to baffle the VSD to one of the great vessels without causing obstruction to the other. If the VSD is more easily “connected” to the pulmonary artery, an arterial switch operation may be necessary as well. If the VSD is more easily “directed” to the aorta, unobstructed flow to the pulmonary arteries may be achieved only with a right ventricle-to-pulmonary artery conduit.

4. Finally, the least common variety of DORV with two ventricles is that associated with a VSD that is *remote* from both great vessels, most typically in the inflow or posterior portion of the ventricular septum. Although there are two anatomically normal ventricles, this uncommon anatomy is most frequently palliated with a single-ventricle approach. Because the VSD is posterior, and both great vessels are anterior over the right ventricle

(typically with interposed chordae of the tricuspid valve), the only effective way to separate the circulation is by means of a Fontan operation. As this is not possible in the newborn period, a pulmonary artery band may be necessary to limit PBF and pressure in the newborn period, followed by staged reconstruction toward a Fontan operation.

The long-term outlook for most patients with DORV is good (Brown et al, 2001), with early and late postoperative sequelae principally related to the type of repair that is possible, which is determined by the location of the VSD and the interrelationship of the great vessels.

## Arrhythmias in the Fetus and Newborn

Mitchell I. Cohen and Roy Jedeikin

Brady- and tachyarrhythmias may occur at any point during the perinatal period. This chapter reviews those arrhythmias occurring during fetal and early neonatal life.

Although the atrioventricular (AV) node and the His bundle develop as separate entities, they appear to join by the eighth week of gestation. By week 16 the conduction system of the fetus is fully developed and sinus rhythm can be detected on screening fetal echocardiograms. Although changes in the heart rate are seen throughout gestation, by the third trimester heart rates typically range from 120 to 160 beats/minute. Bradycardia is defined as a rate of less than 100 beats/minute, and tachycardia as a rate greater than 180 beats/minute. Fetal arrhythmias may develop at any time after the conduction system has completed development, although they are typically seen after 22 weeks of gestation.

Fetal arrhythmias are often the same arrhythmias that are seen in postnatal life. These include, but are not limited to, premature atrial and ventricular beats, automatic tachycardias (e.g., sinus tachycardia), reentrant tachycardias (e.g., supraventricular tachycardia [SVT] or ventricular tachycardia [VT]), and associated bradycardia in the form of either sinus node dysfunction or AV block. It is estimated that the incidence of fetal arrhythmias is 1% to 2% (Clavin et al, 1992). Arrhythmias in the developing fetus may be completely benign, without any hemodynamic sequelae, or in 6% to 7% of fetuses result in significant cardiovascular decompensation, hydrops, and possibly intrauterine death (Allen et al, 1983; Kleinman, 1987; Reed, 1989). Although a majority of fetal arrhythmias are nonsustained events, such as premature atrial depolarizations, they may be associated with underlying congenital heart disease. Additionally, both brady- and tachyarrhythmias may represent underlying noncardiac pathology such as maternal drug abuse or placental insufficiency.

### ASSESSMENT OF FETAL ARRHYTHMIAS

Fetal echocardiography can be performed as early as 16 weeks of gestation and is used to assess structural, functional, and rhythm abnormalities of the fetal heart. Examination techniques have been well described (Cyr et al, 1986; Silverman and Globus, 1985), with emphasis on the importance of a systematic approach to the echocardiographic assessment of the cardiac anatomy. The segmental approach to the anatomic integrity of the fetal heart is the mainstay of accurate and complete diagnosis of fetal cardiac abnormalities (see Chapter 52).

Fetal echocardiography using M-mode (Fig. 58-1) and Doppler (Fig. 58-2) techniques has been well described in the evaluation of fetal cardiac arrhythmias (Allen et al, 1983; Kleinman et al, 1995; Silverman et al, 1988). These modalities allow assessment of atrial rate, ventricular rate, and the AV relationship to help define the exact type of dysrhythmia present.

More recently, tissue Doppler imaging in fetal cardiac arrhythmias has been used as a methodology allowing simultaneous recording and analysis of mechanical activity of the atrial and ventricular tissues at high temporal and spatial resolution (Rein et al, 2002).

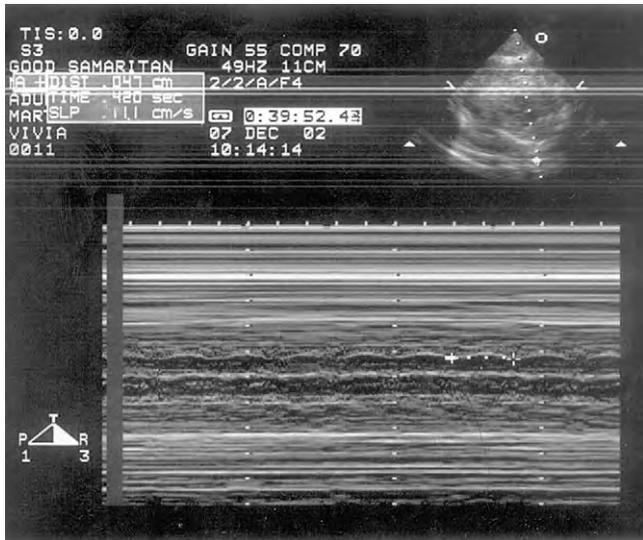

Congenital complete heart block (CCHB) in the setting of maternal collagen vascular disease is associated with significant morbidity and mortality (Groves et al, 1996; Jaeggi, et al, 2002; Michaelsson and Engle, 1972; Schmidt et al, 1991). The diagnosis in utero of AV dissociation can be well established by using current Doppler and M-mode techniques (Fig. 58-3). It is known that once autoimmune CCHB has been established, this process is irreversible. Case reports have suggested that maternal steroid and other therapies may reduce the development of permanent injury to the AV node in these high-risk fetuses (Theander et al, 2000; Yamada et al, 1999).

Doppler echocardiography can now be used to estimate the P-R interval (mechanical interval [MI]). Normal measurement data indicate that in the unaffected fetus this interval is less than 150 msec; intervals longer than 150 msec suggest first-degree AV block (Glickstein et al, 2000). The MI can be obtained by placing the Doppler signal in the area between the aortic and the mitral valves. The MI is the interval from the onset of the atrial contraction (A-wave) to the onset of the ventricular contraction (V-wave) in the left ventricular outflow tract (see Fig. 58-2). Another tool to assess AV temporal relationships is the simultaneous recording of Doppler flow signals in the superior vena cava (retrograde A-wave flow during atrial systole) and the ascending aorta/antegrade ejection (V-wave) (Andelginfer et al, 2001). With systematic utilization of these physiologic/mechanical principles, electrical disturbances of the fetal heart can be defined, allowing appropriate in utero diagnosis and therefore appropriate treatment strategies.

### FETAL BRADYCARDIA

#### Premature Atrial and Ventricular Ectopy

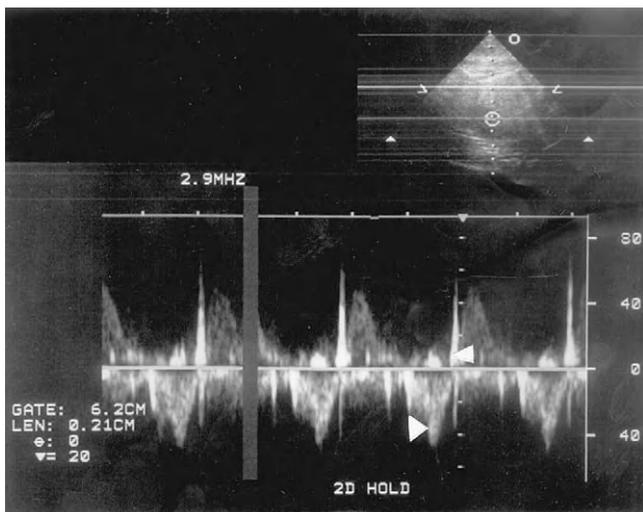

Irregularity is frequently seen during the third trimester of pregnancy and typically is a result of either premature atrial or ventricular contractions. Premature atrial contractions (PACs) are generally considered a benign entity, provided that there is no evidence of structural heart disease and that the premature beats do not initiate a sustained reentrant tachycardia. If a PAC occurs prior to ventricular myocardial recovery (early diastole), the PAC is unable to depolarize the ventricle and will reset the sinus node (blocked PAC). Care must be taken to ensure that blocked premature atrial beats are not mistaken for complete AV block. Although atrial ectopy is considered to have a

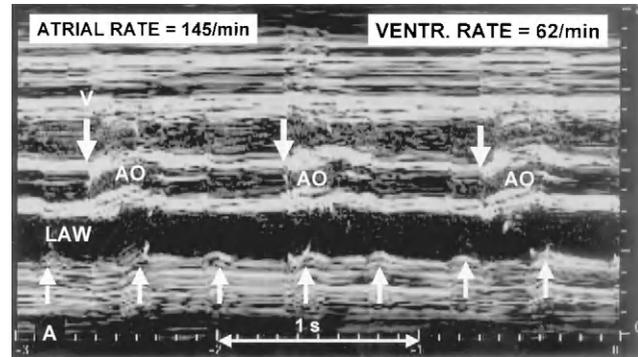

**FIGURE 58-1.** M-mode echocardiogram demonstrating ventricular wall motion. Hatch marks represent a ventricular cycle length of 420 msec (143 beats/minute).

benign prognosis, it is crucial that blocked PACs are *not* falsely identified as sinus bradycardia, a potentially more ominous sign of fetal demise necessitating early delivery. A small percentage of fetuses with isolated atrial ectopy may develop an in utero or postnatal form of SVT such as atrial flutter or orthodromic reentrant SVT. Our practice has been to closely follow newborns with isolated premature atrial beats for the first few months of life to be certain that there has not been a progression to a more sustained dysrhythmia warranting antiarrhythmic therapy.

Premature ventricular contractions (PVCs) are less frequently seen than their atrial counterpart; in isolation they also are thought to carry a benign prognosis. Associated

**FIGURE 58-2.** Doppler waveforms demonstrating atrioventricular synchrony. Mitral inflow (atrial systole) is shown below baseline, and left ventricular outflow tract (ventricular systole) signal is above baseline. Mechanical interval (MI) is shown between the two arrows.

**FIGURE 58-3.** M-mode echocardiogram demonstrating complete heart block with dissociation between atria (left atrial wall motion, upward arrows) and ventricular systole (aortic valve opening, downward arrows).

conditions such as the long Q-T syndrome, congenital heart disease, or electrolyte abnormalities should be excluded if PVCs are identified. Neither atrial nor ventricular ectopy necessarily signifies fetal distress, and delivery should not be expedited on the basis of these findings. Frequent monitoring of fetal heart tones, for both PACs and PVCs, should be performed bimonthly by the obstetrician to be certain that progression of the arrhythmia, albeit rare, has not taken place. If there is any concern that a fetus is developing sustained or nonsustained episodes of SVT, follow-up discussions with the pediatric cardiologist are warranted.

### Fetal Heart Block

Congenital complete heart block (CCHB) is often detected by evaluation of a slow heart rate on a routine obstetric examination. Congenital complete heart block results from complete discontinuity between the atrium and the ventricle, with the atrial rate exceeding the ventricular rate (see Fig. 58-3). The QRS complexes are almost always narrow and normal. The Q-T interval may be prolonged. The incidence of CCHB is approximately 1 in every 15,000 to 20,000 live births (Michaelsson and Engle, 1972). In a study from Finland, Siren and colleagues (1998) found that the incidence during the last decade has increased to 1 in 11,000 births. This increase may be secondary to improved diagnostic capabilities as well as more effective antenatal care. Alternatively, the increase may reflect a higher obstetric success rate among gravid mothers with known connective tissue disorders.

Congenital AV block has been associated with structural heart defects in approximately 50% of cases (Schmidt et al, 1991). The etiology of the AV block probably resides in both the abnormal position and course of the conduction tissue. Malformations that are typically associated with CCHB include L-transposition of the great arteries (L-TGA), left atrial isomerism typically with AV septal defects, and other forms of AV discordance. However, in the absence of structural heart defects, CCHB is typically associated with maternal connective tissue disorders.

### Isolated Congenital Complete Heart Block

Although Stokes-Adams attacks were originally described by Morquio in 1901, it was not until the 1960s that the association of CCHB with maternal systemic lupus erythematosus (SLE) became well recognized (Hull et al, 1966; McCue et al, 1977). The pathogenesis of lupus-associated CCHB results from transplacental transfer of maternal antibodies (IgG Ro [SS-A] and IgG La [SS-B]), which initiates an inflammatory reaction within the AV node proper, resulting in tissue necrosis and fibrous replacement (Thomas et al, 1996). The majority of cases of CCHB are detected between 16 and 23 weeks of gestation coincident with the placental transfer of these antibodies. Congenital AV block associated with maternal connective tissue disorders is often complete, though cases of incomplete or transient AV block have been reported (Esscher and Scott, 1979).

Aside from transplacental AV node disruption, maternal antibodies may also cause an immunomyocarditis and dilated cardiomyopathy (Scott et al, 1983; Udink ten Cate et al, 2001). Whereas only 1% of fetuses born to mothers with maternal SLE develop CCHB, nearly 100% of the affected fetuses are positive for anti-Ro (SS-A) antibodies (Buyon et al, 1993). However, of pregnancies in mothers who are known to be anti-Ro positive, only 5% will result in a fetus with CCHB (Jones, 1994). Aside from maternal SLE, other maternal connective tissue disorders (e.g., Sjögren's syndrome) may result in CCHB. Of interest, despite the association of maternal connective tissue disorders with CCHB, most mothers are asymptomatic, without clinical evidence of a rheumatologic process, and the maternal diagnosis is often made retrospectively after the fetus is found to have high-grade AV block. Risk factors associated with the development of fetal heart block include (1) prior pregnancy resulting in CCHB, (2) a direct relationship between CCHB and titers of anti-SS-A, (3) presence of both maternal anti-SS-A and anti-SS-B antibodies, and (4) HLA-DR3-positive haplotype (Olah and Gee, 1991). As reported in the Association of European Pediatric Cardiologists Collaborative Study, of the 67 children with CCHB whose mothers had documented connective tissue disorders, 22 other siblings were affected (Cyr et al, 1986). Prior pregnancy resulting in fetal CCHB appears to be the single greatest risk factor (approximately 30%) for third-degree AV block in babies born subsequently (Waltuck and Buyon, 1994). Finally, the in utero environment or actual timing of transplacental antibody transference may also play a large role in the development of CCHB.

Outcome in the fetus with isolated CCHB appears to be directly related to the heart rate. Of fetuses with a heart rate less than or equal to 50 beats/minute, nearly 45% succumb to an intrauterine death; of the remaining patients, almost all require pacemaker implantation (Groves et al, 1996). In comparison, among fetuses with heart rates greater than 60 beats/minute, the mortality rate is only 6%, with few (3/16, or 18.8%) requiring a pacemaker (Groves et al, 1996). Fetuses with heart rates between 51 and 60 beats/minute tend to have an intermediate mortality rate (27%). Although heart rates generally remain stable during fetal life, a decline of more than 5 beats/minute portends a poorer prognosis (Groves et al, 1996).

### Congenital Complete Heart Block with Structural Heart Disease

The second possible cause of in utero congenital complete AV block relates to the malposition of the normal AV nodal conduction tissue secondary to underlying structural heart disease. Approximately 50% of fetuses with congenital heart block have structural heart disease, the most common forms of which are congenitally corrected transposition of the great arteries (L-TGA), left atrial isomerism, and atrioventricular septal defects (Reed, 1989). Third-degree AV block is present at birth in approximately 5% to 10% of patients with L-TGA, although it develops insidiously at a rate of approximately 2% per year or may occur during surgical correction of an associated lesion such as a ventricular septal defect (Friedberg and Nadas, 1970; Huhta et al, 1983). The etiology of CCHB in L-TGA relates to the anterior malposition of the AV node, which places the conduction system at high risk as the penetrating bundles encircle the subpulmonary (left ventricular [LV]) outflow tract. An alternative explanation may relate to abnormal development of the central fibrous body or a lack of union between the AV node and penetrating bundle (Lev, 1972). The clinical outcome of congenital heart block diagnosed in utero carries a poorer prognosis with concomitant congenital heart disease (CHD). In a multicenter study of 55 fetuses with CCHB (29 structural, 26 isolated), intrauterine death occurred in 7 (24%) with heart disease and 3 (11%) without associated congenital heart defects (Schmidt et al, 1991). Similarly, the incidence of neonatal death was quite high in the group with heart disease: Among infants born alive with CCHB/CHD, the mortality rate was 4/29 (13.8%); among those born alive with isolated CCHB, it was 22/26 (84.6%) (Schmidt et al, 1991). The surviving neonates with CCHB tended to have higher resting ventricular rates than nonsurvivors ( $68 \pm 8$  versus  $53 \pm 8$  beats/minute) (Schmidt et al, 1991).

### Diagnosis of Fetal Heart Block

In order to maintain cardiac output, the fetus adapts to marked bradycardia with ventricular dilatation and an augmented stroke volume. Failure of the fetus to maintain an acceptable cardiac output in light of these hemodynamic perturbations results in congestive heart failure and hydrops fetalis. The degree of bradycardia appears to be directly related to the development of hydrops. Nearly 85% of fetuses having rates of less than 55 beats/minute exhibit signs of hydrops such as ascites, anasarca, pleural effusions, tricuspid regurgitation, and/or hepatopathy (Schmidt et al, 1991). Fetal electrocardiography, either through transabdominal auscultation or via electrodes placed directly on the fetal scalp, has largely been abandoned since the advent of fetal echocardiography. Fetal echocardiography allows for a noninvasive assessment of the heart's rate and rhythm by timing mitral valve opening with ventricular contractions. Fetuses can be followed noninvasively by echocardiography with particular attention to not only the junctional/ventricular escape rate but also, of more importance, clinical manifestations such as fetal growth, presence or absence of hydrops, and any associated malformations. Surface

electrocardiography is all that is required to make the diagnosis postnatally.

### Management of Fetal Heart Block

Treatment for CCHB varies. In utero treatments for CCHB are designed not only to reduce the symptoms of congestive heart failure but to achieve a more stable intrauterine environment conducive to a successful term pregnancy. Therapeutic options include (1) sympathomimetics, (2) plasmapheresis, (3) steroids, (4) premature delivery, and (5) fetal pacing.

Sympathomimetics, either oral or intravenous, have had occasional anecdotal success in raising the fetal heart rate in both hydropic and nonhydropic fetuses (Groves et al, 1995; Yoshida et al, 2001). However, to date, there have been no controlled or large studies evaluating this therapy. Although plasmapheresis has been successful in reducing the maternal antibody load, there has been only one documented case reversing complete heart block (Kaaja et al, 1991). Both betamethasone and dexamethasone can cross the placenta and suppress the symptoms of hydrops, ascites, and effusions but, as with plasmapheresis, do not reverse the heart block. However, there is evidence that early (at approximately 20 to 23 weeks of gestation) use of dexamethasone (4 mg PO daily) in mothers carrying a fetus with CCHB may improve fetal cardiac contractility by reversing the often associated myocarditis component of this disease process (Copel et al, 1995). Additionally, anecdotal experience has illustrated rare cases of conversion from incomplete AV block (Wenckebach or 2:1 AV block) to sinus rhythm (Theander et al, 2000; Yamada et al, 1999). Fetal echocardiography can measure the mechanical P-R interval and may offer an avenue for institution of prophylactic therapy prior to the development of complete heart block. Studies are currently in progress to decide if early use of steroids in pregnancies with high-risk fetuses, before the development of CCHB, can in actuality prevent the progression to complete heart block. As a last resort, expedited delivery can be considered, although this approach carries significant morbidity and mortality risks, especially in the premature neonate. Although pacemaker implantation has been reported in a few fetuses with severe hydrops, the technique is currently not available in the majority of centers and is in essence experimental (Carpenter et al, 1986). Direct pacing is generally performed via a maternal transabdominal approach; lead dislodgement is likely to result from fetal movement. In addition, the possibility of pacemaker-mediated infection is a consideration (Silverman et al, 1997; Walkingshaw et al, 1994).

The prognosis for the fetus with structural heart disease is much poorer, with an estimated 80% to 90% mortality rate, with death occurring either in utero or during the first year of life (Machado et al, 1987; Schmidt et al, 1991). Fetal heart rates of less than 55 beats/minute in the cohort with structural heart disease carry an excessively high mortality rate; therefore, this group would be likely to benefit the most from in utero pacing (Schmidt et al, 1991). In most clinical settings, single-ventricle heart disease and congenital AV block are universally fatal even

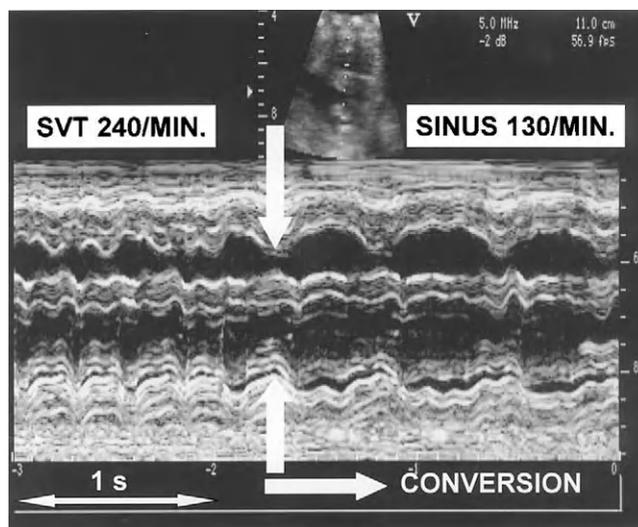

with the institution of pacing in the first hours of life. Postnatal CCHB therapy is discussed later (see Neonatal Bradycardia).

### FETAL TACHYCARDIA

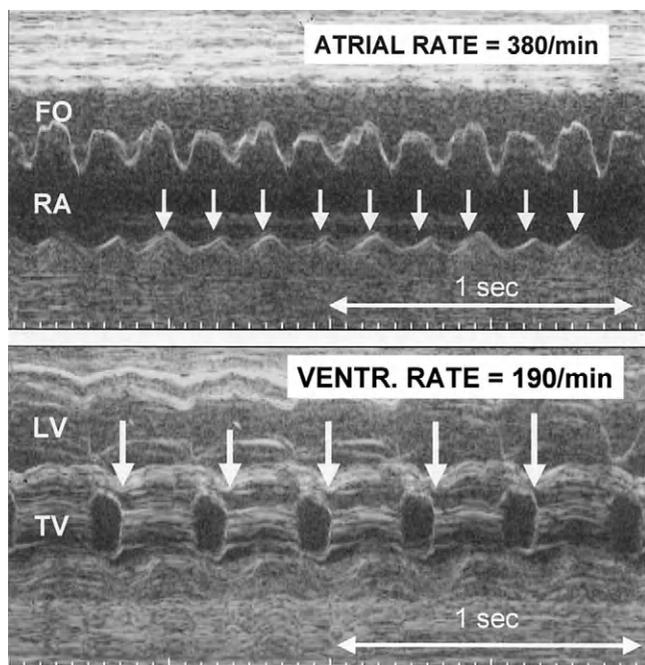

#### Fetal Supraventricular Tachycardia

The types of fetal tachycardia are comparable with those found in neonates and include both supraventricular tachycardia (SVT) and ventricular tachycardia (VT). SVT using an accessory bypass tract between the atrium and ventricle is the most common form of fetal tachycardia, with heart rates generally between 240 and 300 beats/minute. The tachycardia circuit tends to be orthodromic, with normal antegrade AV nodal conduction and retrograde conduction via the bypass tract. M-mode echocardiography will show equal atrial and ventricular rates exceeding 200 beats/minute with a fixed relationship (Fig. 58-4). Hydrops in association with reentrant SVT has been reported in 50% of fetuses (Machado et al, 1987; Walkingshaw et al, 1994). The development of nonimmune hydrops fetalis probably relates to several factors: the ventricular rate (Van Engelen et al, 1994), the length of time the fetus has been in the abnormal rhythm, and the onset of SVT at an earlier gestational age (Naheed et al, 1996).

The second most common form of SVT seen in fetuses is atrial flutter. Atrial tachycardias originate in the atrium without either the AV node or ventricle needed to complete the circuit. Because fetuses have rapid AV nodal conduction, 1:1 conduction with ventricular rates of 350 to 480 beats/minute can be seen (Lisowski et al, 2000). More commonly, however, AV nodal block results in either 2:1 conduction (Fig. 58-5) or a Wenckebach pattern. Automatic atrial tachycardia with a classic “warm-up” and “cool-down” phase is similar to sinus tachycardia and can also be seen in fetuses at any point in the second or third trimester. Although less common than atrial flutter, automatic atrial

**FIGURE 58-4.** M-mode echocardiogram demonstrating ventricular wall motion at a rate of 240 beats/minute, with spontaneous conversion (arrows) to a physiologic rate of 130 beats/minute.

**FIGURE 58-5.** Upper panel, Atrial wall motion at a rate of 380 beats/minute. FO, foramen ovale; RA, right atrial wall. Lower panel, Ventricular response at 190 beats/minute consistent with 2:1 AV node conduction. LV, left ventricle; TV, tricuspid valve.

tachycardias (ectopic or chaotic) tend to be incessant and more difficult to control with primary drug therapy. As with all forms of SVT, fetuses may exhibit no signs of heart failure or have marked ascites, skin edema, effusions, or abnormal umbilical venous pulsations with imminent fetal demise. The development of hydrops is known to decrease the effectiveness of antiarrhythmic therapy and to increase the mortality rate.

### Management of Fetal Supraventricular Tachycardia

Management of the fetus with SVT should be based on the gestational age, frequency of the dysrhythmia, and the presence or absence of hydrops. Although management strategies vary by center, there are generally four approaches to management of fetal SVT: (1) observation, (2) expedited delivery of the fetus, (3) maternal drug therapy, and (4) fetal therapy. Observation is generally reserved for term or near-term fetuses or in those experiencing nonsustained bouts of SVT without any compromise. Expedited delivery is a reasonable consideration in the term neonate, thus avoiding the potential side effects of many of the antiarrhythmic agents. Delivery of the preterm fetus with SVT has been met with a high incidence of complications related to the prematurity, including lung disease, intraventricular hemorrhage, necrotizing enterocolitis, and sepsis (Hansmann et al, 1991; Maxwell et al, 1988).

The rationale in treating fetal SVT is to prevent the development of hydrops and fetal death. The exact timing of drug initiation (Table 58-1) or early delivery needs to be individually tailored. Fetuses without hydrops and

intermittent tachycardia can be closely followed for development of hydrops or sustained arrhythmia. However, it is unknown which arrhythmia will become sustained and what interval may elapse before hydrops ensues. For fetuses with a nonhydropic clinical picture and a sustained dysrhythmia, drug therapy should be initiated unless the pregnancy is full term and the mother can be considered for early delivery. In all fetuses with a documented sustained arrhythmia and even in those with frequent intermittent tachyarrhythmias, weekly follow-up with particular attention to fetal well-being should be considered as part of routine obstetric care. If a sustained arrhythmia results in nonimmune hydrops, the fetus is at high risk for demise, and drug therapy or delivery needs to be implemented.

The treatment of fetal tachycardia requires the use of the mother as the vehicle to deliver therapy to the patient. Effectiveness of drug therapy requires successful transplacental absorption, stability of fetal and maternal hemodynamics, and knowledge of the actual mechanism of the arrhythmia (automatic versus reentrant). Fetal pharmacokinetics of drug absorption, distribution, metabolism, and elimination is variable and different from that in adults. Second, the placenta may be a barrier to successful drug delivery, and the actual antiarrhythmic concentration in the maternal serum is not necessarily reflective of fetal levels. Once cardiac failure develops, the success of fetal drug delivery diminishes because of poorer placental transfer and fetal absorption. In multiple studies, the presence or absence of fetal hydrops has consistently been the single greatest predictor of survival, with a nonhydropic fetal mortality rate between zero and 4% and a mortality rate in hydropic fetuses of 13% to 35% (Frohn-Mulder et al, 1995; Hansmann et al, 1991; Maxwell et al, 1988; Simpson and Sharland, 1998; Van Engelen et al, 1994).

In the nonhydropic infant, digoxin is the first-line agent and has achieved excellent safety and efficacy. Digoxin levels may be decreased by as much as 50% in the hydropic fetus, which may warrant an alternative treatment strategy (Younis and Granat, 1987). Maternal digoxin may be administered via either an oral or an intravenous route. The advantage of intravenous administration is the rapidity with which the fetus typically responds to the medication, but use of this route requires that the mother be hospitalized. Oral administration is generally more convenient, but therapy given by this route should continue for at least 1 or 2 weeks before it is deemed a failure. Using ultrasound guidance, direct administration of the drug to the fetus by an intramuscular, intraperitoneal, intra-amniotic, or umbilical venous route has been previously described (Hallak et al, 1991; Weiner and Thompson, 1988; Wiggins et al, 1986). As a result of the increased volume of distribution, maternal drug levels in the high range (1.5 to 2.5 ng/mL) are generally required. Such levels can typically be achieved with a maternal loading dose of 1 to 2 mg and a maintenance dose between 0.5 and 1.0 mg daily. If digoxin is unsuccessful, a combination of digoxin and verapamil has been reported to give 91% efficacy; however, side effects of both hypotension and asystole have made this treatment less frequently utilized in recent years (Hansman et al, 1991). Flecainide also has been used, but in view of the potential for proarrhythmic side effects, our approach has been to reserve this therapy for fetuses with SVT-related hydrops.

TABLE 58-1

## Drugs Used in the Treatment of Fetal Arrhythmias

Medication	Maternal Dose	Fetal/Maternal Plasma Ratio	Adverse Effects	Comments
Digoxin	0.5-1 mg/day (M serum levels 1.5-2.5 ng/mL)	0.1-0.9	Safe	Adjust dose on basis of serum levels
Procainamide	3-6 g/day	0.3-1.3	Proarrhythmia (F), uterine contractions, preterm labor, Q-T prolongation (M/F)	Adjust dose on basis of serum procainamide, NAPA levels
Propranolol	40-320 mg/day	0.2-1.3	Hypoglycemia (F), IUGR, myocardial depression (F), respiratory depression (F), hyperbilirubinemia (F)	Serum levels not readily available
Lidocaine	1 mg/kg/dose (bolus); 20-40 µg/kg/min (infusion)		Safe	Adjust dose on basis of serum levels; lower dose if Cr elevated
Flecainide	100-450 mg/day	0.5-0.8	(?)Proarrhythmia (M), fetal demise, Q-T prolongation (M/F)	No intravenous form
Sotalol	80-320 mg/day	0.5-1.0	Q-T prolongation (M/F)	More effective for atrial flutter than for AV reciprocating SVT
Amiodarone	<i>Load:</i> 600 mg infused over 6 hr <i>Maintenance:</i> 800 mg/day	0.1-0.4	IUGR, prematurity, thyroid dysfunction (F), Q-T prolongation (M/F) neurologic dysfunction (F)	Direct fetal delivery may be required secondary to prolonged oral loading, slow clearance

AV, atrioventricular; F, fetal; Cr, creatinine; IUGR, intrauterine growth restriction; M, maternal; NAPA, *N*-acetyl-procainamide; SVT, supraventricular tachycardia.

Data from Ito S, Magee L, Smallhorn J: Drug therapy for fetal arrhythmias. *Clin Perinatol* 21:543-572, 1994; Simpson JM, Sharland GK: Fetal tachycardias: Management and outcome of 127 consecutive cases. *Heart* 79:576-581, 1998; Tanel RE, Rhodes LA: Fetal and neonatal arrhythmias. *Clin Perinatol* 28:187-208, 2001.

In the hydropic fetus, isolated use of digoxin has had limited efficacy (10% to 20%); this result may be related to poor absorption across the placenta (Frohn-Mulder et al, 1995; Hansmann et al, 1991; Simpson and Sharland, 1998; Van Engelen et al, 1994). Direct fetal therapy with intraumbilical adenosine has been used to successfully terminate SVT (Friedman et al, 1993). Although the half-life of adenosine is quite short, a dose-dependent constriction of placental blood flow has been reported, which urges caution with this therapy (Omar et al, 1996).

Flecainide has been used extensively as a second-line agent for treatment of fetal arrhythmias. Flecainide is a class IC antiarrhythmic drug that blocks conduction through sodium channels with little to no effect on the refractory properties of the tissue. Flecainide is typically given by the oral route, with a maternal-to-fetal placental transference of 65% to 95% (Allan et al, 1991; Wren and Hunter, 1988). Although there are no known teratogenic side effects of flecainide, caution must be exercised because of the potential for fetal proarrhythmic effects. A decrease in heart rate variability occurs with flecainide and appears to be dose-related (Van Gelder-Hasker et al, 1995). The typical starting dose for oral flecainide is 200 to 300 mg/day; with adequate control of the SVT, the fetus can be weaned to the lowest possible dose with continued efficacy.

Although amiodarone (class III) is an effective antiarrhythmic agent, reports of thyroid gland suppression and neurologic motor delay make this drug less appealing (Magee et al, 1995; Plomp et al, 1992).

Sotalol is a potent  $\beta$ -blocking agent with additional class III antiarrhythmic properties (increases the action potential duration). Sotalol appears to have minimal negative inotropic effects with excellent transplacental properties. In a recent multicenter study, regimens using sotalol and the combination of sotalol and digoxin were very successful in fetuses with atrial flutter (Oudjik et al, 2001). The conversion rate was 80%, with a relatively low recurrence rate. However, the results with sotalol in the treatment of fetal SVT were not as promising, with only 6 of 10 fetuses converting to sinus rhythm, but more alarming was the intrauterine demise of three fetuses. All of the intrauterine deaths occurred within the first week of therapy, bringing into question the known proarrhythmic side effects of this medication (Oudjik et al, 2001). Other drugs utilized in the treatment of fetal SVT with hydrops include propranolol, verapamil, and procainamide (Teuscher et al, 1978; Wolff et al, 1980).

Failure of either oral or intravenous maternal drug therapy to convert the fetal heart to sinus rhythm warrants consideration of direct fetal therapy by an intraumbilical, intramuscular, intraperitoneal, or intracardiac approach.

This more aggressive approach avoids the need for transplacental absorption but carries a significant risk to both the fetus and the mother. It is important to remember that infusion of a drug directly into the fetal circulation still mandates a background level of drug (achieved with maternal oral or intravenous administration) to avoid recurrences of SVT once the direct fetal dose is diminished. Finally, direct overdrive fetal pacing is potentially possible either by trans-ventricular puncture (Strasburger et al, 1986) or through the umbilical vein. The potential hazards of this more aggressive approach include wire dislodgement, infection, premature labor, and degeneration of a reentrant SVT into atrial fibrillation.

### Fetal Ventricular Tachycardia

The prenatal diagnosis of VT is rare in the fetus. The importance of diagnosing VT rests in the coexistent association of structural heart defects, ventricular dysfunction, and ventricular tumors. VT does not require the atrium or the AV node as part of the circuit and is typically diagnosed by M-mode demonstration of AV dissociation with the ventricular rate exceeding the atrial rate. Congenital junctional ectopic tachycardia cannot be distinguished from VT, although it is exceedingly rare. Treatment for VT is relatively similar to SVT management, with the exception of the need to avoid digoxin. In addition to beta-blockers, procainamide and intravenous lidocaine can be used, although levels need to be closely followed in the latter two choices.

### NEONATAL BRADYCARDIA

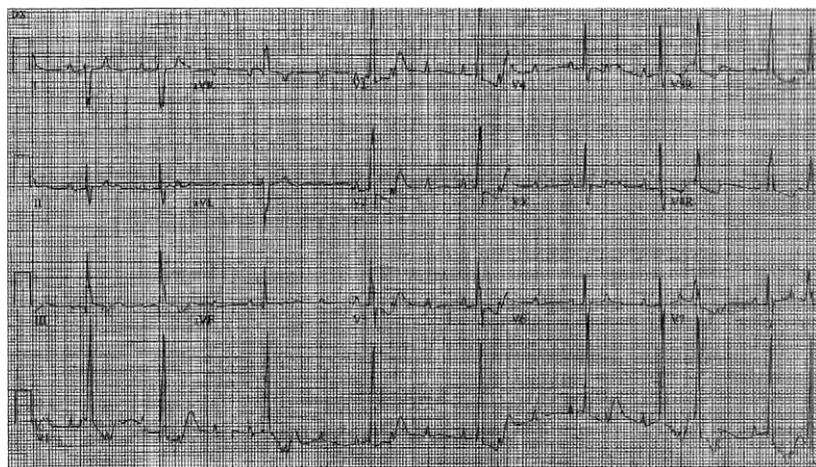

Bradycarrhythmias in the neonate are similar to those in the fetus. Either sinus or AV node dysfunction may cause neonatal bradycardia. As in the fetus, bradycardia may be associated with structural heart defects ranging from simple septal defects to complex single-ventricle lesions. Symptoms related to marked bradycardia in the infant include poor growth, feeding intolerance, dyspnea, and on rare occasions syncope. Congenital complete heart block in the neonate (Fig. 58-6) is typically a result of transplacental passage of anti-Ro and anti-La antibodies with concomitant fibrosis of the AV nodal conduction system. This process is

not reversible after birth, and the typical decision for the managing physician is not *if* to pace but *when* to pace. Alternatively, congenital heart block may be seen in association with structural heart defects such as L-transposition of the great vessels, heterotaxy syndrome, or atrioventricular septal defects (Fig. 58-7).

Guidelines from the American College of Cardiology and the American Heart Association recommend permanent pacemaker implantation for infants with congenital third-degree AV block with a ventricular rate of less than 50 to 55 beats/minute or with congenital heart disease and a ventricular rate of less than 70 beats/minute (Gregoratos et al, 1998). However, more often than not, the decision regarding pacing is very difficult, as in an infant with a structurally normal heart and a ventricular rate of 59 beats/minute, or with a rate of 72 beats/minute in association with heart disease. Aside from the ventricular rate, several reviews of CCHB have identified a wide escape rhythm, prolonged Q-T, cardiomegaly, right atrial enlargement, ventricular dysfunction, and ventricular ectopy as risk factors that might prompt consideration for early permanent pacing (Gregoratos et al, 1998; Michaelsson et al, 1995; Pinsky et al, 1982; Sholler and Walsh, 1989). Despite the early institution of pacing, some infants with CCHB develop a cardiomyopathy, and it is critical that patients be followed closely not only for rate assessment but for overall myocardial performance (Moak et al, 2001; Udink ten Cate et al, 2001).

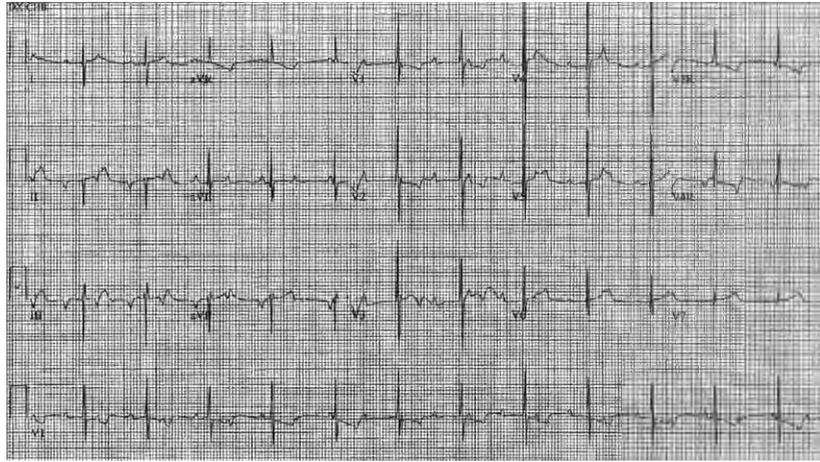

Isolated atrial premature depolarizations are frequently seen in the newborn period and typically require no treatment. They may be blocked within the AV node resulting in a pause, conduct normally, or aberrantly conduct. The development of symptoms in affected infants is unlikely, although a small percentage will go on to have SVT or atrial flutter. Drug therapy is not required to treat isolated benign premature atrial beats.

Idiopathic long Q-T syndrome is a rare disorder that may lead to syncope, seizures, and sudden death. The long Q-T syndrome is an abnormality in ventricular repolarization secondary to an abnormal sodium or potassium ion channel. Patients with long Q-T syndrome are at risk for the development of life-threatening ventricular arrhythmias (e.g., torsade de pointes). As a result of the findings of the International Study of the Pediatric Electrophysiology Group, in which sudden death was the presenting

**FIGURE 58-6.** A 12-lead electrocardiogram demonstrating complete heart block with atrioventricular dissociation. Evidence of right atrial enlargement and right ventricular hypertrophy with a strain pattern and isolated premature ventricular complexes are also noted.

**FIGURE 58-7.** A 12-lead electrocardiogram demonstrating complete heart block with atrio-ventricular dissociation. Note the presence of a left superior axis and an abnormal P wave axis consistent with heterotaxy syndrome.

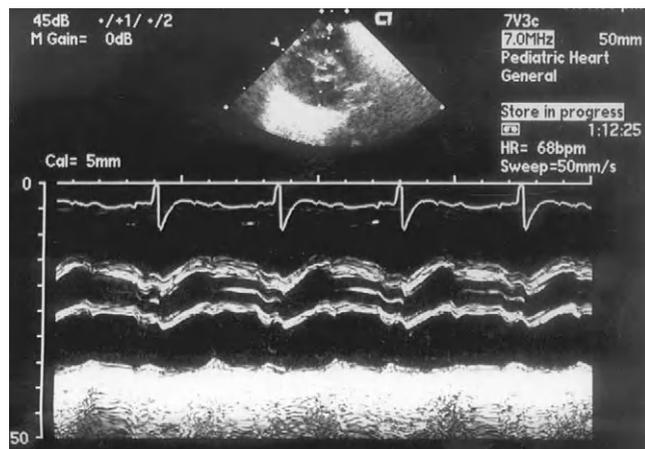

symptom in 9% of children without any preceding symptoms, prophylactic therapy with beta-blockers is now standard (Garson et al, 1993). Congenital long Q-T syndrome is associated with neonatal sinus bradycardia, and there is now some clinical evidence that this may be associated with sudden infant death syndrome (Hofbeck et al, 1997; Schwartz et al, 1998). Congenital long Q-T syndrome has also been seen as a presentation with bradycardia secondary to 2:1 AV nodal conduction (Fig. 58-8). A careful family history with particular attention to sudden death, near drowning, and seizures should be obtained in all neonates with bradycardia and/or ventricular ectopy.

## NEONATAL TACHYCARDIA

### Neonatal Supraventricular Tachycardia

Rate alone is insufficient to diagnose a tachydysrhythmia. Neonates can have sinus tachycardia with rates of 230 to 240 beats/minute secondary to pain, fever, anemia, hyperthyroidism, infection, or related to intravenous inotropic medication. Interpretation of the electrocardiogram should

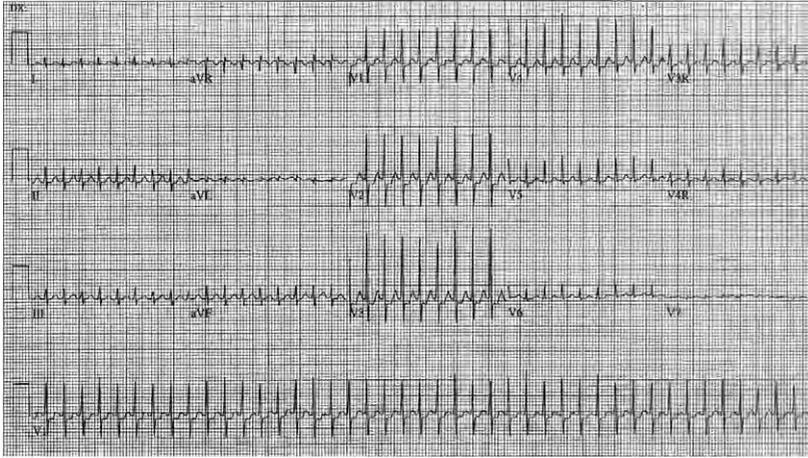

**FIGURE 58-8.** M-mode echocardiogram and postnatal electrocardiogram depict prolonged Q-T interval (580 msec) with 2:1 AV conduction in a 1-day-old infant with a history of fetal bradycardia.

be performed methodically, with careful attention to regularity, P wave axis, and the relationship of each P wave to QRS complex. Although supraventricular tachycardias are typically narrow-complex, it is not unusual for the first few beats to demonstrate aberrancy before narrowing of complexes. Our general approach has been to obtain an echocardiogram in all neonates presenting with sustained SVT or VT, as 25% of infants may have associated structural heart disease.

The clinical presentation of the newborn with either SVT (Fig. 58-9) or VT generally depends not only on the tachycardia rate but also the duration of tachycardia and on the presence of any associated structural heart defects that may further compromise systemic output. Newborns with sustained SVT or VT may present with irritability, feeding intolerance, pallor, diaphoresis, tachypnea, decreased urine output, or shock. The mechanisms of SVT that are seen in the newborn are similar to the fetus, although diagnosis is easier because direct electrocardiographic analysis can be performed on the patient, as well as assessment of therapeutic vagal maneuvers.

SVTs may be reentrant or automatic. Reentrant arrhythmias generally manifest with a sudden onset and termination. These types of tachycardia respond well to maneuvers that block the AV node and interrupt the circuit, such as administration of adenosine or digoxin. The most common form of reentry in the newborn involves an accessory bypass tract. If the bypass tract has the potential to conduct antegrade, the diagnosis is Wolff-Parkinson-White (WPW) syndrome (Fig. 58-10). Anatomic lesions such as Ebstein's anomaly of the tricuspid valve, ventricular inversion, and hypertrophic cardiomyopathy can be associated with WPW syndrome; therefore, all newborns with WPW syndrome should undergo a screening echocardiogram. If, however, the bypass tract conducts only in retrograde fashion, the accessory pathway is "concealed" and does not have the typical delta wave on the resting electrocardiogram. During orthodromic SVT, no distinction can be seen on the electrocardiogram between these two types of dysrhythmia. The mechanism of the tachycardia appears to be antegrade conduction through the AV node and His-Purkinje system with retrograde conduction via the bypass tract. Occasionally, patients with WPW syndrome can have antegrade conduction via the accessory pathway with retrograde AV nodal

**FIGURE 58-9.** A 15-lead electrocardiogram demonstrating a narrow-complex tachycardia with a ventricular rate of 265 beats/minute. Note absence of P wave secondary to rapid retrograde conduction.

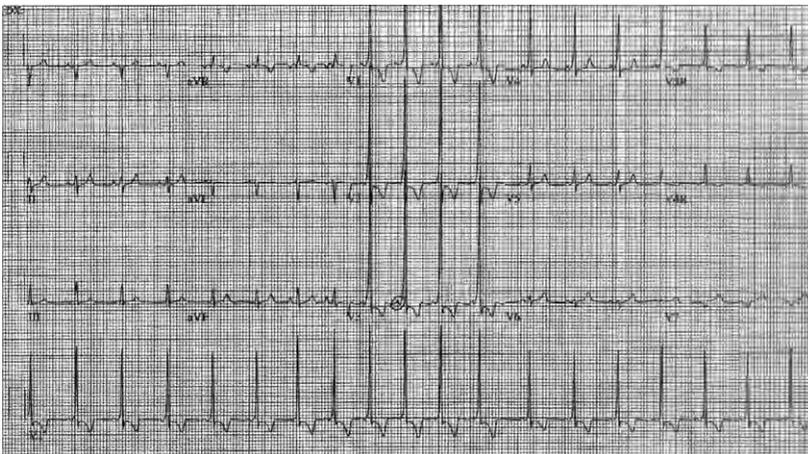

conduction (antidromic SVT). In this instance, unlike in the former, the tachycardia is of the wide-complex type and is indistinguishable from VT. In AV reciprocating (narrow-complex) SVT, the onset and termination are sudden and characterized by a fairly fixed heart rhythm with rates between 240 and 300 beats/minute, with often unidentifiable P waves, as they are superimposed upon the T wave.

AV nodal reentrant tachycardia is rarely seen in neonates and more commonly diagnosed in adolescents and young adults. Another form of reentrant SVT is permanent junctional reciprocating tachycardia (PJRT), which tends to be slower (less than 200 beats/minute) and incessant. The electrocardiogram typically demonstrates a narrow-complex tachycardia, with easily identifiable P waves secondary to the long R-P interval from the slowly conducting retrograde limb of the circuit (Fig. 58-11). Because of the incessant nature of PJRT, infants may present with a dilated cardiomyopathy and congestive heart failure.

### Management of Neonatal Supraventricular Tachycardia

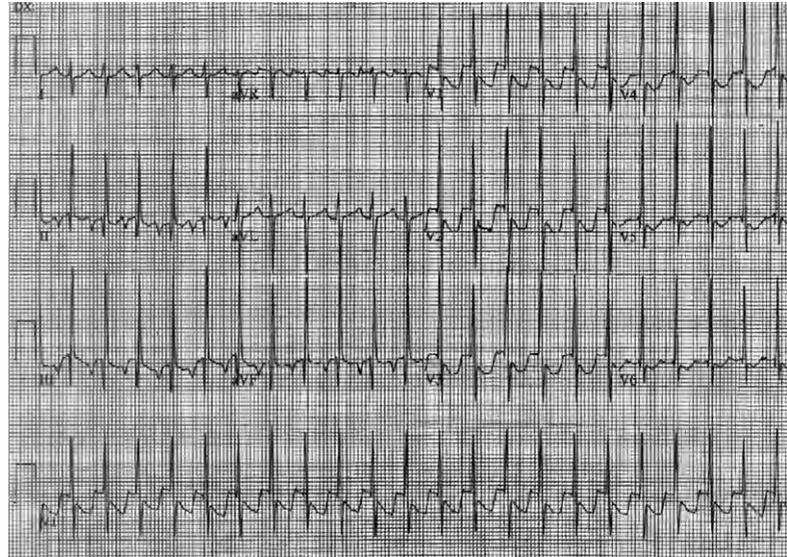

The treatment of reentrant SVT entails both acute therapy and more long-term treatment (Table 58-2). Acute treatments can be broken down into (1) reflex vagal maneuvers,

(2) drug therapy, and (3) electrical conversion. Vagal maneuvers transiently block AV conduction by upregulating parasympathetic (vagal) input and terminating the tachycardia. Our general approach in the neonate is to use a bag filled with a water-ice mixture, or a bag of frozen vegetables (e.g., peas), to cover the forehead to the brim of the nose. Rectal stimulation is another successful vagal modality that has been used for reentrant SVT. If the tachycardia terminates and returns almost immediately, additional vagal maneuvers will be no more effective, and in essence the patient needs to begin an antiarrhythmic medication. In our experience, vagal maneuvers are safe and effective, although of somewhat limited effectiveness in patients with high levels of circulating catecholamines. Although numerous antiarrhythmic medications including digoxin, beta-blockers, procainamide, amiodarone, flecainide, and sotalol have been utilized for the acute treatment of neonatal SVT, adenosine is the most effective short-term pharmacologic agent available. Adenosine given in rapid intravenous bolus form (100 to 300  $\mu\text{g}/\text{kg}$ ) blocks AV nodal conduction and effectively stops the reentrant circuit. Side effects of adenosine include flushing, chest discomfort, bronchospasm, and rarely induction of atrial fibrillation. In patients with low cardiac output and poor systemic blood flow, a higher dose of adenosine may be required to circumvent the rapid metabolism in the vascular endothelium and erythrocytes.

**FIGURE 58-10.** Electrocardiogram from a newborn with Wolff-Parkinson-White (WPW) syndrome. During sinus rhythm there is a short P-R interval, with obvious delta waves in leads V<sub>1</sub>-V<sub>3</sub> (circle).

**FIGURE 58-11.** Narrow-complex tachycardia (permanent junctional reciprocating tachycardia) with a long R-P interval and classically inverted P waves in the inferior leads (II, III, aVF).

Direct current cardioversion should be reserved for the hemodynamically compromised (hypotensive) neonate. Transesophageal overdrive atrial pacing has also been shown to be highly efficacious and safe in neonates, with an excellent conversion rate (Schwartz et al, 1998).

Once the acute tachycardia has been terminated, prophylactic antiarrhythmic therapy is prescribed for most infants, given the high recurrence risk of AV reciprocating tachycardias in the first year of life (Benson et al, 1987; Perry and Garson, 1990). In fact, Perry and Garson (1990) reported that of infants presenting with WPW syndrome prior to 2 months of age, 93% experienced disappearance of the tachycardia, although 31% had recurrent SVT at an average age of 8 years. This finding was corroborated by Wu and associates (1994); in their study, 40% of children who presented with SVT in infancy were still symptomatic by age 5 years. Although digoxin has often been considered the first-line antiarrhythmic, its use in patients with WPW syndrome is controversial and potentially contraindicated. Digoxin may impair AV nodal conduction and enhance more rapid antegrade bypass conduction, and even ventricular fibrillation.

Digoxin is generally regarded as a safe and effective antiarrhythmic medication, but the dose must be decreased in the premature neonate and in patients with renal insufficiency. Beta-blockers (e.g., propranolol) can be used safely in the neonate with SVT, especially if the WPW pattern is seen on the resting electrocardiogram. Because of the potential hypoglycemic effect of beta-blockers, our recommendation is to usually give the medication during or shortly after a feeding. Beta-blockers act as competitive antagonists at catecholamine-binding sites and slow AV nodal conduction. Beta-blockers may also impair myocardial contractility and should be used with caution in the newborn with depressed ventricular function. Beyond digoxin and/or beta-blockers, drug therapy should be individualized and often varies depending on the practitioner. Whereas verapamil is an excellent drug in older children, it should be *avoided* in neonates because of its potent negative inotropic effect (Epstein et al, 1985). Procainamide is a class IA antiarrhythmic medication that has been used

extensively in the treatment of neonatal SVT. Procainamide is a negative inotrope and has vasodilating properties, especially during the intravenous loading infusion. The bolus (5 to 15 mg/kg) is generally given over 30 to 45 minutes; adjustments in the bolus infusion rate and need for additional volume should be individualized according to the patient's cardiac status. Amiodarone is a class III drug that is also effective in the treatment of neonatal SVT. The intravenous dose is usually 5 mg/kg given over 30-60 minutes, with close observation needed secondary to potential hypotension from acute vasodilatation. Chronic oral amiodarone has a rather extended half-life, and in our experience, 2 to 3 weeks or longer may be needed to achieve full therapeutic levels in newborns. Side effects of amiodarone include photosensitivity, hypothyroidism, hyperthyroidism, hepatitis, and proarrhythmia.

If available, overdrive esophageal atrial pacing can be effective in terminating AV reciprocating tachycardias. A flexible 4 or 5 F lead can be advanced into the nares and situated in the esophagus posterior to the left atrium. Electrical stimulation allows capture of the left atrial myocardium, and pacing slightly faster than the atrial rate should terminate the dysrhythmia. Sedation with a medication such as midazolam is usually helpful. As with any attempt at atrial pacing, there is the potential for initiating atrial fibrillation, which would require an alternative treatment strategy and possible direct current cardioversion. Finally, direct current cardioversion should be readily available if the patient is hemodynamically unstable or is resistant to medications, or if overdrive esophageal pacing fails to correct the dysrhythmia. Synchronized cardioversion (using 0.25 to 2 J/kg) is recommended for patients with an organized reentrant tachycardia, whereas asynchronous defibrillation should be performed in the pulseless patient or if the rhythm is disorganized. Sedation, if not general anesthesia, is always warranted for an elective cardioversion/defibrillation. Radiofrequency ablation is used infrequently in infants and is more commonly reserved for older children and adolescents.

Atrial flutter represents another form of SVT seen in infants and results from a single reentrant focus in the

TABLE 58-2

## Drugs Used in the Treatment of Neonatal Arrhythmias

Medication (Class)	Route of Metabolism/ Excretion	Oral Dose	IV Dose	Therapeutic Level	Common Adverse Effects
Adenosine	RBCs, vascular endothelium		0.05 mg/kg; may increase to 0.25 mg/kg if no effect (IV push)		Hypotension, flushing, chest pain, heart block, Afib
Digoxin	Renal	Load: Preterm: 20 µg/kg in 3 doses; full-term: 30 µg/kg in 3 doses Maintenance: Preterm: 5-7.5 µg/kg div q12h; full-term: 6-10 µg/kg div q12h 15-50 mg/kg/day in 4-8 div doses	75%-80% oral dose Load: Preterm: 15 µg/kg in 3 doses; full term: 20 µg/kg in 3 doses Maintenance: Preterm: 3-4 µg/kg div q12h; full-term: 6-8 µg/kg div q12h	0.8-2.0 ng/mL	AV, SA block, bradycardia, nausea/vomiting, toxicity with hypocalcemia or K abnormality
Procainamide (IA)	Renal, hepatic	3.5-7.5 mg/kg q6h	Load: 3-6 mg/kg/dose over 5 minutes; repeat dose over 10 minutes up to a maximum of 15 mg/kg. Maintenance: 20-80 µg/kg/min	Procainamide, NAPA levels = 10-20 µg/mL	Hypotension, AV block, nausea/vomiting, lupus-like syndrome
Disopyramide (IA)	Renal, hepatic			2-5 µg/mL	Negative inotropy, AV block, anti-cholinergic effects, hypoglycemia, ventricular arrhythmias
Lidocaine (IB)	Renal, hepatic		1 mg/kg/dose (bolus); 20-50 µg/kg/min (infusion); decrease with hepatic or renal dysfunction	2-5 µg/mL	Hypotension, heart block, CNS effects, respiratory depression
Mexilitine (IB)	Hepatic	1.4-5 mg/kg/dose q8h		0.5-2.0 g/L	CNS effects, nausea/vomiting, bradycardia, hepatopathy
Flecainide (IC)	Renal, hepatic	0.3-2 mg/kg q8h; decrease with hepatic or renal dysfunction		0.2-1.0 µg/mL	Bradycardia, conduction block, VT, nausea, CHF; avoid in CHD
Propranolol (II)	Hepatic	0.25 mg/kg/dose q6-8h, usual dosage range	0.01 mg/kg over 10 min; repeat q6-8h, may increase slowly to 0.15 mg/kg/dose q6-8h		Hypotension, bradycardia, conduction block, hypoglycemia, bronchospasm, weakness
Esmolol (II)	RBC esterases	2-4 mg/kg/day divided q6-q8h	Load: 100-500 µg/kg/min over 1 min Maintenance: 40-300 g/kg/min		Same as for propranolol
Sotalol (II/III)	Renal	20-120 mg/m <sup>2</sup> BSA q12h			Bradycardia, conduction block, VT/torsades, nausea, CHF
Amiodarone (III)	Hepatic	5 mg/kg q12h for 7 days, then 2-5 mg/kg/day; decreased with liver dysfunction	5 mg/kg/dose over 30 min; may repeat up to 15 mg/kg on day 1 Maintenance: 3-10 µg/kg/min	Follow reverse T <sub>3</sub>	Thyroid/hepatic dysfunction, AV block, hypotension, corneal deposits, proarrhythmia

Afib, atrial fibrillation; AV, atrioventricular; BSA, body surface area; CHD, congenital heart disease; CHF, congestive heart failure; CNS, central nervous system; IV, intravenous; NAPA, *N*-acetyl-procainamide; RBC, red blood cell; SA, sinoatrial; T<sub>3</sub>, triiodothyronine; VT, ventricular tachycardia.

atrium, typically around vena caval orifices or the tricuspid valve. Atrial rates in the newborn will range from 240 to 360 beats/minute, and the typical “saw-toothed” P wave pattern will be seen in the inferior leads. Typically, AV nodal conduction block allows for 2:1 conduction and better-tolerated hemodynamics. Newborn atrial flutter is not typically associated with structural heart defects (occurring in approximately 8% of cases by report) but can on occasion be seen in the setting of systemic illness, with the presence of a central venous catheter, or in association with a rare defect, septum primum aneurysm (Mendelsohn et al, 1991; Moller et al, 1969; Rice et al, 1988). Atrial flutter, like the other reentrant forms of SVT, responds well to overdrive esophageal pacing and, in addition, may spontaneously resolve. Results on long-term follow-up evaluation of neonates with isolated atrial flutter are exceedingly promising, and often acute and chronic digoxin therapy is probably unnecessary. If the diagnosis cannot be made by a standard 12-lead electrocardiogram, either an esophageal recording or administration of intravenous adenosine during recording of the 12-lead electrocardiogram may be used for diagnostic purposes. Intravenous adenosine will block the AV node, and if atrial flutter is present, will unmask the typical flutter pattern.

Automatic atrial tachycardias are a result of enhanced automaticity resulting from a microfocus within the atrial wall itself. The rate of automatic ectopic atrial tachycardia (EAT) is faster than the sinus rate but may vary among patients and even within an individual patient. A characteristic feature of EAT is a “warm-up” and a “cool-down” phase, without the need for either the AV node or the ventricle to contribute to the circuit. Variable degrees of AV block may be seen, and patients typically have no evidence of structural heart disease, although they may present with or develop a dilated cardiomyopathy (Garson et al, 1990). Chaotic atrial tachycardia is a similar automatic atrial rhythm that typically has a minimum of three P wave morphologies and tends to be more incessant than EAT. Automatic tachycardias do not respond to typical vagal maneuvers, adenosine, or direct current cardioversion. Medical therapy for patients with automatic atrial tachycardias usually revolves around ventricular rate control rather than termination of the tachycardia. Although

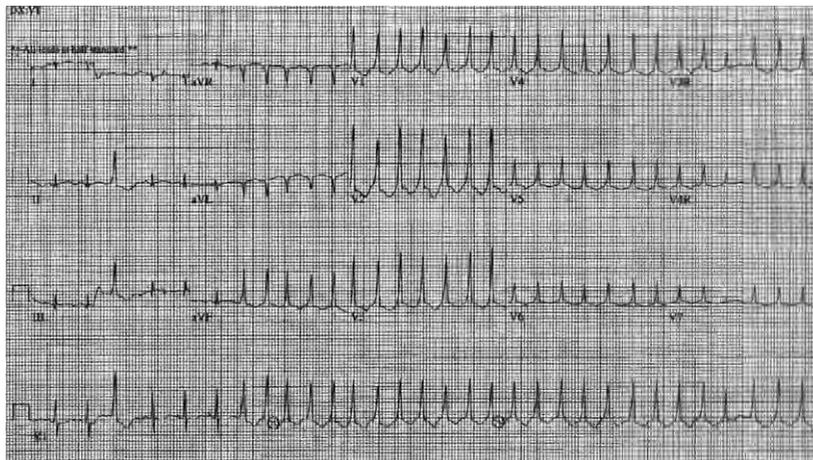

digoxin and beta-blockers remain first-line agents for the treatment of EAT/CAT, better control seems to occur with amiodarone or flecainide (Garson et al, 1990; Von Bernuth et al, 1992). Often, combination drug therapy is required. Pacing to achieve 2:1 block will result in a slower ventricular response but is a more invasive strategy.

### Neonatal Ventricular Tachycardia

VT and accelerated ventricular rhythm are uncommon in newborns, although they may be related to a number of causes including right- or left-sided cardiac obstructive lesions, myocarditis, electrolyte abnormalities, cardiac tumors, or proarrhythmia from a variety of antiarrhythmic medications (Fig. 58–12). Although the prognosis is generally good in the infant with a structurally normal heart (Pfammatter and Paul, 1999), cases of deterioration to ventricular fibrillation and sudden death have been seen in those with the long Q-T syndrome (Pfammatter and Paul, 1999) or cardiac hamartomas. Pfammatter and associates observed that infants with VT tend to be less symptomatic than older children and have nearly a 90% spontaneous resolution rate. VT associated with a left bundle branch pattern (originating from the right ventricle) carries a more favorable prognosis than that for right bundle branch (left ventricular origin) VT (Pfammatter and Paul, 1999). Accelerated ventricular rhythm (more than 20% above the sinus rate) in infants younger than 1 month of age usually portends an excellent prognosis, and antiarrhythmic therapy is probably not warranted (Van Hare and Stanger, 1991). In our experience, PVCs in healthy newborns typically resolve by 12 weeks of age and do not require treatment once the presence of a structurally normal heart and normal QTc interval and the absence of symptoms have been confirmed. Both isolated PVCs and idiopathic neonatal VT probably result from developmental factors related to the autonomic nervous system.

It is important that all neonates presenting with ventricular ectopy or VT, especially if polymorphic, be evaluated for possible long Q-T syndrome. A careful family history should be obtained, with particular attention to syncope, deafness, seizures, drowning, or sudden death. The QTc should be measured on the electrocardiogram in

**FIGURE 58–12.** Onset of a wide-complex tachycardia (ventricular tachycardia) slightly faster than the sinus rate. Atrioventricular dissociation is seen during ventricular tachycardia (circled P waves).

a region (typically lead II) free of PVCs. Normal values for children are less than 450 msec.

### Management of Neonatal Ventricular Tachycardia

The therapies discussed for treating SVT can be used in managing patients with VT, with the sole exception of the need to avoid digoxin and adenosine. Degeneration to ventricular fibrillation has been reported in patients being digitalized for presumptive SVT with aberrancy, when in reality the underlying rhythm was VT. Intravenous lidocaine (bolus dose of 1 mg/kg; infusion of 20 to 50  $\mu$ g/kg/minute) is effective in the treatment of neonatal VT, with good results. In the setting of renal failure, the dosing of lidocaine needs to be adjusted on the basis of the creatinine clearance. Amiodarone, procainamide, and beta-blockers are also effective in the treatment of neonatal VT. Calcium channel blockers in newborns should be avoided because of the potential for hypotension, myocardial depression, and even cardiac arrest. As in any patient presenting with an arrhythmia and hemodynamic instability, cardioversion (1 to 2 J/kg) and airway control should be considered as first-line therapy. Because VT can degenerate into ventricular fibrillation, it is important that *any* neonate presenting with a wide-complex tachycardia be treated first and foremost as having VT. More often than not, a wide-complex tachycardia is VT, and error typically occurs if the patient is wrongly and prematurely diagnosed as having SVT with aberrancy.

### CONCLUSIONS

In general, fetal and neonatal arrhythmias encompass a broad spectrum ranging from benign isolated atrial ectopy to malignant polymorphic ventricular tachycardia. The management of the fetus or newborn with an arrhythmia depends on a host of factors related to the type of dysrhythmia, ventricular rate, the presence of any associated structural cardiac defect, and also the overall clinical status of the patient. Many medications are available to the fetus via delivery to the mother as well as to the newborn. In the absence of congenital heart defects, most newborn tachy- and bradyarrhythmias are well tolerated and can be managed medically. Finally, most arrhythmias seen in newborns spontaneously resolve within the first year of life and carry an excellent long-term prognosis.

# Management of Congenital Heart Disease in the Low-Birth-Weight Infant

Gil Wernovsky, Anne M. Ades,  
and Thomas L. Spray

Low birth weight may coexist in upward of 35% of neonates with critical congenital heart disease (CHD) (Levin et al, 1975), either associated with prematurity or secondary to other factors that make the neonate small for gestational age. The optimal management strategy for these newborns is controversial and has not been fully evaluated.

## GENERAL CONSIDERATIONS IN MANAGEMENT

The preterm low-birth-weight (LBW) neonate with associated complex CHD presents many intricate clinical problems in management, more so than either the preterm neonate without complex heart disease or the term neonate with a complex cardiac malformation. Therapies utilized for the preterm neonate without heart disease frequently need to be altered in the presence of heart disease, and those needed for management of heart disease may need to be altered because of prematurity. Optimal management requires a collaborative approach among many disciplines, including input from neonatologists, cardiologists, surgeons, anesthesiologists, perfusionists, and nurses.

The goals of therapy should be as follows:

1. Initial stabilization, including establishment of reliable vascular access
2. Determination of a complete anatomic diagnosis non-invasively, with minimal stress to the infant
3. Monitoring of the physiology associated with the transition from in utero to ex utero life, which may be more problematic in the preterm infant
4. Evaluation of the newborn for additional congenital defects
5. Early surgical correction of the cardiac defect when technically and logistically possible
6. Establishment of enteral feedings and removal of invasive support and monitoring as rapidly as possible, to minimize hospital-related morbidity

In the past, therapeutic plans for preterm or small-for-gestational age (SGA) neonates with complex heart disease relied on a “conservative” medical approach to attain those goals. It is important to recognize that the secondary effects of uncorrected CHD in the preterm infant may be more severe than in a full-term infant with the same lesions. For example, lesions associated with increased

pulmonary blood flow may complicate lung disease of prematurity, and hypoxemia secondary to intracardiac right-to-left shunting may be more deleterious to the immature central nervous system (CNS). In addition, low systemic blood flow may result in an increased risk of significant renal impairment or of necrotizing enterocolitis (NEC) in the preterm infant. Anecdotally, we have found that the hypertrophic response to pressure and volume overload in the postnatal preterm infant appears to be more severe than in the full-term child with the same lesion. With recent technical improvements in cardiopulmonary bypass, anesthesia, and neonatal intensive care, as well as improved (and perhaps more aggressive) surgical techniques, correction of abnormal cardiac anatomy can now be accomplished at an earlier postnatal age and smaller weight. Of importance, this approach restores a more normal cardiac physiology as early as possible, minimizing the secondary effects of the abnormal physiology associated with the CHD, such as increased pulmonary blood flow, pulmonary hypertension, hypoxemia, low systemic blood flow as well as low myocardial pressure, and/or volume overload. In turn, this may shorten hospital length of stay and diminish associated morbidity.

We believe that postponing surgery while waiting for an LBW neonate to gain weight and grow to a desired—though clearly arbitrary—size is an approach not worth taking in the great majority of cases. The requisite stay in the intensive care unit (ICU) for the infant with unrepaired CHD is associated with significant morbidity, and the eventual repair may be no easier from a technical perspective. In fact, the secondary effects of long-standing CHD on the lungs, pulmonary vasculature, and myocardium may render the infant *more* unstable following surgery. Finally, even in optimal circumstances, significant weight gain is rare with critical CHD, even in full-term neonates and infants.

However, it must be recognized that cardiac surgery in LBW neonates—especially procedures involving cardiopulmonary bypass (CPB)—has a complication rate that is significantly higher than in infants and older children, and the risk for mortality and morbidity increases with lower body weight (Heinle et al, 1997; Jacobs et al, 1998; Jonas et al, 1994; Reddy et al, 1999; Wernovsky et al, 2000a). The causes of this increased mortality and morbidity are multifactorial and may include the following:

- Technical issues related to small cardiac structures
- Technical issues related to cannulation for CPB
- Immaturity of organ systems, especially the lungs
- Decreased nutritional reserve
- Limited ability to increase cardiac output secondary to a relatively fixed stroke volume
- Increased risk of bleeding from an immature germinal matrix compounded by the dilutional coagulopathy and thrombocytopenia after CPB
- Increased risk of infection, including NEC
- Abnormal chest wall mechanics, especially after median sternotomy or thoracotomy

For all of these reasons, neonates with complex heart disease and low birth weight have been thought to be at too great a risk for surgery and traditionally have been managed “conservatively” with the hope of weight gain.

However, the rates of complications and of comorbid conditions that may occur in LBW newborns with critical CHD who do *not* undergo surgery—the effects of chronic hospitalization, intravenous access, abnormal cardiovascular physiology, and cardiopulmonary interaction—have not been reported. It is rare in surgical reports to include a consideration of preoperative mortality associated with the CHD. For example, studies that describe the mortality risk for a certain surgical procedure typically do not include the mortality rate for LBW newborns who died while waiting for surgery.

Thus, it is important to carefully categorize and describe critical CHD in the newborn, and to understand the natural history of the unrepaired state (see also Chapter 57). The largest groups of infants with these lesions are those with *duct-dependent pulmonary blood flow* (as in tricuspid atresia, pulmonary atresia, many forms of heterotaxy, and severe forms of tetralogy of Fallot), those with *duct-dependent systemic blood flow* (as in coarctation, hypoplastic left heart syndrome [HLHS], or interrupted aortic arch), or others in whom maintenance of a patent ductus arteriosus improves overall circulatory stability or oxygenation (as in most forms of transposition of the great arteries). The underlying pathophysiology in all of these lesions results in congestive heart failure (CHF), hypoxemia, or both. In these newborns, intravenous prostaglandin is necessary for maintenance of ductus patency, with the attendant risks of infection, apnea, vasodilatation, seizures, and NEC. The benefit of waiting for surgery until some arbitrary weight has been achieved versus performing surgery at a lower body weight with increased risk (i.e., the risk-benefit ratio) has not been evaluated. However, it is important to note that studies in LBW newborns with HLHS suggest that weight gain is *not* achieved with time (Weinstein et al, 1999).

Thus, in our center, we recommend cardiac surgery shortly after birth in *any* child with a duct-dependent lesion, essentially regardless of weight. This recommendation is based on the following considerations:

- The known complications of long-term prostaglandin use
- The morbidity associated with in-hospital intensive care
- The fact that weight gain is unlikely
- The abnormal physiology present in all of these children (volume overload, CHF, hypoxemia) with its significant but difficult-to-quantify secondary effects on the heart, pulmonary vasculature, mesenteric and renal circulations, and CNS

We believe it is likely that the *combined* risks associated with the unrepaired physiology, ICU-related complications, and eventual surgery (at a weight that is typically not much different from birth weight) are greater than the risks for mortality and morbidity with surgery shortly after birth. In addition, we recommend surgery for neonates with noncritical lesions that result in increased ventricular work—regardless of weight—at the first signs of CHF and failure to thrive. However, there are many issues that must be addressed and anticipated in this high-risk group of neonates.

A second large group of patients are those with large left-to-right shunt lesions and pulmonary hypertension, as with large ventricular septal defects, truncus arteriosus,

complete atrioventricular canal, patent ductus arteriosus, and aortopulmonary window. Following the expected fall in pulmonary vascular resistance, pulmonary blood flow will increase, resulting in CHF, failure to thrive, and/or ventilator dependence. In essentially all of these children, the abnormal circulatory physiology results in increased total energy expenditure, making weight gain even in optimal conditions unlikely. Struggling to “get weight on the baby” may not be worth the risk. For example, a 1.9-kg baby with CHF who might only gain 10 to 15 g/day (requiring high-caloric feeds, anticongestive medications, possible tube feedings, or even mechanical ventilation) will take 1 to 3 months to achieve a weight of 2.5 kg. The risks to the baby during that time may be considerable, especially if hospitalization is required, and include infection, long-standing increased pulmonary blood flow and pulmonary artery pressure (making the postoperative course *more* risky), and an uncertain promise of weight gain. Of importance, the relative risk for surgery for a baby of 1.9 kg who has *not* had a prolonged period of CHF versus that for a baby of 2.5 kg who has been in CHF for 2 additional months is unclear.

## SURGICAL ISSUES

As diagnostic, intensive care, and intraoperative cardiac surgical techniques have improved, the technical issues related to operating on LBW infants (with birth weights of <2.5 kg) have become less of a consideration. Philosophically, the surgical team may be faced with a decision to perform palliative procedures initially, followed by corrective surgery at a later date, or to proceed with corrective “open” procedures with use of CPB. In general, for the LBW infant, if palliative procedures can be performed to allow control of CHF without compromising the patient’s nutrition or other organ systems, palliation may be preferable to an open repair with the attendant risks of CNS bleeding, hypoxemic-ischemic damage, and activation of the inflammation cascade.

“Closed” operations may include shunt placement, pulmonary arterial banding, coarctation repair, and ductus ligation. Although vessels are small, it is certainly possible to consider repair of coarctation of the aorta even in very small neonates weighing less than 1 kg. Ductus ligation has been performed frequently in newborns of this weight (Perez et al, 1998), and coarctation repair also can be performed with reasonable safety. As a practical matter, however, it is unusual to require coarctation repair in very small neonates with noncritical coarctation, in whom the blood pressure generally can be well controlled after ductal closure with antihypertensive medication until an older age and higher weight are achieved. In the presence of a coexisting ventricular septal defect, however, it may be necessary to address the distal aortic obstruction in addition to performing pulmonary artery banding at a very low weight to allow for satisfactory growth and development.

Lesions with duct-dependent pulmonary blood flow (e.g., severe forms of tetralogy of Fallot, pulmonary atresia with intact ventricular septum) may be treated temporarily by short-term prostaglandin infusion and placement of aortopulmonary artery shunts. In general, it is preferable

to create an aortopulmonary shunt rather than to continue prostaglandin therapy indefinitely during postnatal life, because the long-term complications of intravenous access and continuous prostaglandin therapy are considerable. Shunts may be physiologically quite large in very small babies, and determining the appropriate size of the shunt is of prime importance. Generally, a modified Blalock-Taussig shunt 3 mm in diameter can be used for babies weighing 1 to 1.5 kg, and a 3.5-mm shunt may be adequate for babies weighing greater than 1.5 kg, with the length altered to allow for additional resistance in children at the lower end of that weight range. Central shunts may be more advisable for patients with suitable anatomy; however, a short central shunt may actually provide excessive pulmonary blood flow. To reemphasize, shunting in patients at a very low birth weight is a temporary palliative procedure to allow for weight gain and to avoid CPB, followed by either conversion to a complete repair in patients with two ventricles when the baby achieves an acceptable weight, or conversion to a cavopulmonary shunt in patients with a single ventricle at 4 to 6 months of age.

However, true "correction" of most cardiac defects in LBW infants requires the use of CPB. In these neonates, technical modifications related to cannulation and to bypass technique are necessary. Even with current miniaturization of CPB circuits, the relative volume of the circuit will dilute clotting factors in the very small infant to a significant degree. Addition of clotting factors to the bypass circuit may be necessary. Our current method for dealing with this problem is the use of fresh whole blood added to the bypass circuit, and following separation from CPB while in the ICU (Manno et al, 1991). Although significant hemodilution may be tolerated in older babies, the use of a very hemodiluted bypass prime in LBW babies adds to the difficulty in supplying adequate red cell mass after completion of the operation. Even with the use of modified ultrafiltration techniques (Skaryak et al, 1995), the hematocrit may not be able to be raised to a suitable level following the operation if severe hemodilution is used. Therefore, we prefer to use only moderate hemodilution in very small babies with use of modified ultrafiltration to eliminate as much free water as possible following the operation. This approach allows the venous pressures to be brought as low as possible, thereby providing "room" to infuse additional clotting factors after separation from the bypass circuit. If hemodilution is too great, it may not be possible to give clotting factors and blood following the operation without excessively raising venous pressures, which may contribute to intracranial bleeding and lead to hemodynamic instability.

It is important in LBW babies, especially premature infants, to maintain blood pressures in the lower range of normal. Particular care should be taken to prevent mean arterial pressure elevations during CPB in the heparinized patient. Hypertension in association with a post-bypass coagulopathy may result in generalized oozing at the intracardiac suture lines, but the combination of hypertension and coagulopathy may be particularly disastrous, given the increased risk of intracranial bleeding in the preterm neonate. We therefore institute systemic vasodilatation after weaning from bypass—typically with milrinone and/or sodium nitroprusside.

Because of the technical difficulties and size of bypass cannulae during CPB in very small babies, deep hypothermic circulatory arrest is frequently utilized. With circulatory arrest techniques, accurate repairs can be performed in even very small babies weighing less than 1 kg, but use of these techniques may increase the long-term risk of neurologic morbidity (see also Chapter 60) (Bellinger et al, 1999; Rappaport et al, 1998; Wernovsky et al, 2000b). Even in the absence of CHD, long-term follow-up evaluation of very LBW (VLBW) neonates has revealed an increased incidence of neurologic abnormalities; therefore, long-term follow-up is particularly warranted in this group of patients with CHD (Borowski et al, 1997; Vohr et al, 2000).

## RESULTS

An increasing number of studies are reviewing the overall surgical outcomes in LBW infants who have undergone cardiac operations (Beyens et al, 1998; Borowski et al, 1997; Bove and Lloyd, 1996; Chang et al, 1994; Malec et al, 2000; Numa et al, 1992; Pawade et al, 1993; Reddy and Hanley, 2000; Reddy et al, 1999; Rossi et al, 1998; Weinstein et al, 1999). The overall survival rate for infants undergoing corrective or palliative reconstruction for CHD in these series was 80% to 87% but was lower than for babies of normal weight with similar cardiac lesions. In addition, although most studies have confirmed the increased morbidity (and slightly greater early mortality) for surgery in infants in these weight ranges compared with that associated with surgery in babies of normal birth weight, the combined effect of prolonged attempts at weight gain on chronic morbidity would seem to favor primary repair in most patients, especially those with two-ventricle physiology. Even complex reconstructions such as the arterial switch repair and truncus arteriosus correction can be accomplished in very small babies with acceptable operative risk.

A major question is "How small is too small?" when complex palliative operations such as stage I reconstruction for HLHS are under consideration. Although early survival after the first stage of reconstructive surgery for HLHS has steadily improved, with rates now approaching 95% among standard-risk patients at our institution, early survival for HLHS remains significantly less than for other cardiac defects requiring neonatal surgery. In addition, low birth weight and being small for gestational age (below the 10th percentile for birth weight) are more common in these infants, and there is an increased incidence of extracardiac anomalies (Glauser et al, 1990), both increasing the surgical risk for stage I reconstruction. Only a few patients with HLHS have been included in previously published studies on the results of cardiac surgery in LBW infants (Beyens et al, 1998; Bove and Lloyd, 1996; Chang et al, 1994; Malec et al, 2000; Pawade et al, 1993; Rossi et al, 1998).

Not surprisingly, prematurity and low weight in infants with HLHS have been found to be risk factors associated with higher mortality (Jacobs et al, 1998; Razzouk et al, 1996; Weinstein et al, 1999). A review of overall surgical results for HLHS from Bove and Lloyd (1996) recognized low birth weight as a significant risk factor for in-hospital mortality. Because of these outcomes, some authors have suggested that LBW patients might best be referred for

cardiac transplantation. However, in a Congenital Heart Surgeons Society study, low birth weight was found to be an incremental risk factor for death in both staged reconstruction and transplantation protocols (Jacobs et al, 1998), and in the largest series of infants receiving transplants reported from Loma Linda, the average weight was 3.7 kg and the smallest patient who underwent transplantation weighed 2.0 kg (Razzouk et al, 1996). Thus, the availability of hearts for VLBW babies is probably limited, and low birth weight may in fact be a contraindication to transplantation as the primary surgical strategy.

We have previously reported on the experience with 67 children weighing less than 2.5 kg undergoing first-stage reconstruction for HLHS between January 1, 1990, and December 31, 1997 (Weinstein et al, 1999). Mean age at surgery was 10.1 days, with a median of 8 days, and mean weight was 2.2 kg, with a median weight of 2.2 kg. Fourteen patients weighed less than 2.0 kg and two patients weighed less than 1.5 kg. Early mortality rate (death within 30 days or before hospital discharge) was 51%. No patient-, procedure-, or time-related variables correlated with increased mortality. However, there was a trend toward increased mortality with increased cardiopulmonary bypass time ( $P = .08$ ) and decreased preoperative ventricular performance ( $P = .1$ ). Babies in whom surgery was delayed did not experience a statistically significant increase in weight before the date of surgery, suggesting that delay in surgery to permit weight gain is not justified and exposes the patient to prolonged risks of pulmonary overcirculation, long-term mechanical ventilation, and other ICU-related complications.

We also recently retrospectively analyzed LBW infants with congenital heart disease who had cardiac surgery at our institution between July 2000 and July 2002. Patients were excluded if they had atrial or ventricular septal defects not requiring surgical closure during the initial hospitalization or isolated patent ductus arteriosus. Fifty-four LBW infants underwent cardiac surgery at our institution in the specified time period. For the overall population, the median gestational age and weight were 35 weeks and 2061 g, respectively. Thirteen infants (24%) were also small for gestational age. The median gestational age and weight of the SGA infants were 37 weeks and 1845 g, respectively. Nineteen (35%) of the patients had HLHS and its variants. Postoperative mortality rates were 25.9% (14/54) overall and 36.8% in patients with HLHS. There was no influence of SGA status ( $P = .31$ ) or associated major congenital anomalies ( $P = .53$ ) on mortality. Common postoperative morbidity included blood culture-positive sepsis (22.6%), proven NEC (5.7%), suspected NEC (15.1%), periventricular echodensities (37%), and severe intracranial hemorrhage (ICH) in 3.8% of infants.

## NUTRITION

During the third trimester of pregnancy, which is foreshortened in the preterm baby, the transplacental accretion rate of metabolic and growth fuels is incredibly high. It is extremely difficult to successfully reproduce this function of placental transfer in the extrauterine environment. The task of supplying fuel for growth becomes even more diffi-

cult when necessary limits are placed on the total amount of fluid that may be administered either parenterally or via the enteral route in these preterm neonates with CHD. In the neonate being enterally nourished, formula concentrated to a caloric density in excess of 30 calories per ounce is sometimes utilized for growth but may present a hyperosmolar load to the gastrointestinal tract or provide calories in a nonphysiologic distribution of protein, fat, and carbohydrate. Hyperosmolar feedings have been associated with an increased risk of NEC in the preterm neonate or, more rarely, in the neonate born at term who has decreased splanchnic blood flow from any cause, such as left-sided obstructive lesions (see later). If nutritional needs are met by the parenteral route, as is frequently the case in the preterm neonate with complex heart disease, administration of highly concentrated parenteral nutrition fluid into a large central vein is required, to maximize caloric administration while limiting infusion volumes.

When composing the parenteral nourishment, one must be aware of the increased risk of precipitation of its constituents when the solution is concentrated to the degree necessary for the fluid-restricted preterm neonate. Crucial for growth is administration of calories in the correct proportions of protein, lipid, and carbohydrates; also crucial but problematic can be intravenous access with a centrally placed catheter.

In the preoperative patient, the preferred method of placing central catheters is via the percutaneous route (peripherally inserted central catheters [PICCs], transumbilical lines), rather than operative placement of Broviac catheters; however, preterm neonates with central catheters placed by either route frequently have complicated hospital courses with catheter-related problems. In particular, thrombosis of central vessels or bacteremia is particularly problematic in patients awaiting cardiac surgery. Complications include nosocomially acquired bacteremia, thrombosis, sympathetic effusions, and rarely, perforation through a vessel wall. Hydrothorax, hemothorax, and pericardial effusions with or without tamponade are not rare events. The use of central catheters in VLBW neonates (<1500 g) without congenital heart disease is clearly associated with sepsis; upward of 20% of those neonates with central catheters in place have at least one episode of sepsis. This risk is likely to be higher in patients with CHD, especially in the postoperative period with increased numbers of monitoring and drainage catheters. Although hospital-acquired infections have been associated with a myriad of etiologic agents (e.g., sporadic reports of contaminated intravenous fluids, suction catheters, thermometers, use of artificial nails by caregivers, overuse of antimicrobial agents), the risk factors that repeatedly correlate with neonatal infection are (1) the use of central catheters and (2) the use of mechanical ventilation. Every attempt must be made to wean patients to spontaneous ventilation and to start enteral feeds as rapidly as possible to minimize these complications.

## MECHANICAL VENTILATION

Mechanical ventilation is frequently necessary in caring for the preterm neonate with complex CHD, especially in those babies with malformations that either produce or are

associated with increased pulmonary blood flow or pulmonary venous engorgement of any cause. Such cardiac lesions are associated with decreased pulmonary compliance, compelling the most fragile babies to breathe with the greatest of effort and generate greater-than-normal inspiratory pressures. This increased work of breathing can be sustained for only a limited period without the use of mechanical ventilatory support. In addition, the chest wall and airways of these preterm neonates are far more compliant than their non-compliant lungs, further decreasing effective tidal volumes and minute ventilation. Dead space ventilation as a proportion of tidal volume increases, promoting further respiratory failure with the need for both endotracheal intubation and initiation of mechanical ventilation. Both of these interventions have been associated with lung inflammation and the subsequent release of inflammatory mediators, recently suggested as the initiating events in the etiology of the chronic lung disease affecting the lungs of preterm neonates known as bronchopulmonary dysplasia (BPD). In addition, the pulmonary toxicity of high concentrations of inspired oxygen in the pathogenesis of this disease should not be forgotten. The presence of BPD is likely to be detrimental to surgical outcomes. Whenever possible, early correction may be advantageous for these prematurely born neonates.

Following sternotomy or thoracotomy, intermittent positive-pressure ventilation is almost always necessary; preterm neonates in particular do not spontaneously ventilate well because of the added chest wall instability induced by the surgical approach. Even when pre-extubation cardiac and pulmonary parameters appear appropriate for a trial of extubation, re-intubation for respiratory failure in these children is not uncommon, being required in up to 25% of cases in our experience. This is in stark contrast to a low re-intubation rate for full-term neonates and infants (<5%) after similar cardiac surgical procedures. It is important to recognize and investigate the possibility of phrenic nerve injury contributing to the difficulty with attempts at extubation in these babies, especially following procedures with placement of a Blalock-Taussig shunt (deLeeuw et al, 1999), arch reconstruction, and/or hilar dissection of the pulmonary arteries (e.g., coarctation repair, stage I reconstruction for HLHS, arterial switch operation, repair or palliation of tetralogy of Fallot).

Preterm or LBW neonates may particularly benefit from nasal continuous positive airway pressure (CPAP) as a “wean” from continuous positive-pressure mechanical ventilation. Permissive hypercarbia is currently under research study in preterm neonates as a means of minimizing both “volutrauma” and “barotrauma”; although the evidence is not yet finalized, use of this modality may be an effective and safe way to decrease the incidence of BPD. If true, and *if the cardiac physiology does not preclude or contraindicate its use*, mechanical ventilation that produces PCO<sub>2</sub> values of 50 to 55 mm Hg may be less detrimental to the pulmonary outcome in these neonates.

### NECROTIZING ENTEROCOLITIS

NEC is a disease of the neonate in which the mucosal barrier of the gut is typically damaged and breached by pathogenic enteric bacteria, resulting in intestinal injury

that may progress to bowel necrosis, sepsis, and death. The risk of developing NEC is inversely related to gestational age at birth. In addition, CHD has been found in several studies to be a predisposing factor for the development of NEC in neonates born at or close to term (Martinez-Tallo et al, 1997; Wiswell et al, 1988). A recent report by McElhinney and colleagues (2000) described a cohort of 643 neonates with complex CHD admitted to our cardiac intensive care unit (CICU). The incidence of NEC in this cohort was 3.3%, which is substantially (10- to 100-fold) higher than the reported population-wide rates of 0.3/1000 to 3/1000 term newborns. In a case-control analysis of data for infants matched by diagnosis and age at admission to the CICU, risk factors for the development of NEC were prematurity (<36 weeks), episodes of poor systemic perfusion, and a maximum dose of prostaglandin of greater than 0.05 µg/kg/minute. By multivariable analyses, lesions with significant aortic “run-off” into the lungs (e.g., HLHS, truncus arteriosus, aortopulmonary window), lower gestational age, and episodes of low cardiac output (based on laboratory criteria suggesting end-organ damage) were found to be independently significant risk factors. Although prostaglandin use and, to a lesser extent, indwelling umbilical catheters and cardiac catheterization have been reported as probable causative factors for NEC, it may in fact be the underlying CHD and its management, rather than the prostaglandin or umbilical lines per se, that are most contributory. Thus, the LBW baby with CHD has two major risk factors for the development of NEC, adding to the surgical risk and overall morbidity. Strategies aimed at minimizing preoperative prostaglandin dose and maximizing preoperative and postoperative cardiac output and oxygen delivery and prompt surgical intervention in the neonate with high-risk anatomy may reduce these risks in the future.

### POSTOPERATIVE CONSIDERATIONS

Ideal postoperative care of the patient following either reparative or palliative operations requires a thorough understanding and systematic evaluation of the following:

1. The underlying anatomic defect
2. The pathophysiology of the preoperative state (including secondary effects on other organ systems from altered cardiac output preoperatively)
3. The anesthetic regimen used during surgery
4. CPB issues (e.g., duration of bypass and circulatory arrest, if utilized)
5. The details of the operative procedure and any concerns of the surgeon regarding the potential for residual defects
6. Data available from monitoring catheters, echocardiography, and cardiac catheterization

Optimal management of these critically ill children can best be achieved through a harmonious “team” approach, combining the expertise of cardiologists, cardiac surgeons, neonatologists, anesthesiologists, intensivists, nurses and respiratory therapists.

In general, when the clinical course, postoperative hemodynamic measurements, or laboratory data do not correspond to the expected postoperative recovery, it is prudent

to suspect both the accuracy of the preoperative diagnosis and the adequacy of the surgical repair, rather than to presume that the preoperative diagnosis and surgical repair were entirely complete and that the patient is failing for some ill-defined reason (such as “low-cardiac output syndrome”). Decreased cardiac output does occur following CPB (Wernovsky et al, 1995) but usually can be anticipated and adequately managed (Hoffman et al, 2002). When significant residual anatomic defects are suspected, complete investigation, including echocardiography and/or catheterization, should be pursued. It is important to emphasize that echocardiography in the postoperative patient—particularly in the LBW neonate—is not entirely a benign, “noninvasive” procedure (see Chapter 54). Abnormal respiratory mechanics and changes in preload and afterload should be expected and anticipated during the study. A caregiver *not* involved in the performance or interpretation of the echocardiogram should be present to perform ongoing assessment of the baby’s airway, ventilation, perfusion, and metabolic stability.

### Pain Control and Sedation

Stress responses to pain and other noxious stimuli are profound in even the youngest neonates, regardless of gestational age (Anand and Hickey, 1987). These hormonal and metabolic stress responses may have pathologic and deleterious consequences (Anand and Hickey, 1992), and the hypertensive sequelae of pain and agitation are to be particularly avoided (see earlier). Regardless of which medications are chosen, it is important on physiologic grounds alone to give children of all ages adequate anesthesia or analgesia for suppression of the responses to noxious stimulation. The neonate responds to stressful perioperative stimuli with altered hemodynamics and stress hormone levels (Anand and Hickey, 1987).

Evidence of the adverse cardiorespiratory effects of stress is provided in reports of bradycardia, hypoxia, systemic blood pressure lability, and increased intracranial pressure in newborns undergoing the stress of awake intubation. Patients with CHD who are recovering from surgical reconstruction are especially sensitive to stressful interventions and have marginal organ system reserves and insufficient compensatory mechanisms to respond adequately.

Evidence is accumulating that extending anesthesia for a short time in the immediate postoperative period may blunt the adverse hemodynamic lability and hormonal stress response and improve outcome without complicating or extending postoperative care (Wernovsky et al, 1995). The postoperative myocardium that has been exposed to the effects of CPB, aortic cross-clamping, deep hypothermia, or myocardial ischemic damage may not be capable of increasing stroke volume during a bradycardic episode or of maintaining cardiac output during an acute increase in afterload following surgical procedures. This is especially true if myocardial performance is impaired by a ventriculotomy as required for repair of a variety of CHDs. Therefore, we typically use intermittent neuromuscular blockade and analgesia with fentanyl (2 to 4  $\mu\text{g}/\text{kg}/\text{hour}$ ) for the first 12 to 24 hours following neonatal repairs that utilize CPB.

Wakefulness, agitation, and stress responses in mechanically ventilated children may increase the work of breathing, exacerbate asynchrony between patient and ventilator, and cause an increase in arterial  $\text{PCO}_2$ . The associated decrease in pH significantly raises pulmonary vascular resistance (PVR) in children following CPB. Endotracheal suctioning causes sympathetic stimulation and marked elevation in PVR which can be attenuated by pretreatment with high doses of narcotic (Hickey et al, 1985). In an infant with a healthy heart and normal cardiovascular reserve, a painful or stressful stimulus may produce tachycardia, hypertension, and a transient decrease in arterial  $\text{PO}_2$  (Tanner et al, 1985). However, in a postoperative cardiac surgical patient, the tachycardia may evolve into a hemodynamically compromising tachyarrhythmia, and the hypertension may present a critical and intolerable increase in ventricular afterload or may complicate hemostasis. Hypoxia may be profound and prolonged if the child has cyanotic heart disease or experiences intermittent right-to-left shunting during periods of agitation, when intrathoracic pressure and right ventricular afterload are increased.

This sensitivity to stimuli and lability in hemodynamic response may be expressed as sudden death during the first postoperative night following apparently successful and uncomplicated congenital heart surgery. This appears to be especially true among patients with labile pulmonary artery hypertension and in palliated single-ventricle patients, in whom the balance between systemic and pulmonary vascular resistance plays an important role in hemodynamic stability.

### Monitoring

Accurate measurement of systemic and pulmonary arterial pressures, ventricular filling pressures, urine output, alveolar gas exchange, cardiac output, and systemic and pulmonary vascular resistances allows for precise pharmacologic and ventilatory support in the perioperative period. Monitoring techniques and risks and benefits are detailed in Chapter 57. In the LBW neonate undergoing cardiac surgery, invasive, transthoracic intracardiac monitoring is well tolerated and reduces the risk of central vein thrombosis associated with use of transcutaneous catheters in small babies. Because the LBW neonate has such wide swings in physiologic variables such as heart rate, blood pressure, temperature, and glucose metabolism, frequently *more* physiologic monitoring, not less, is required, despite the baby’s small size. In particular, *continuous* monitoring of important hemodynamic and respiratory parameters is gaining widespread acceptance in postoperative cardiac patients. In addition to the routine use of systemic intra-arterial catheters, typically in the umbilical artery, there is growing experience with intra-arterial sensors that provide continuous, real-time assessment of blood gas data, temperature, and calculated base deficit (Neotrend, Diametrics Medical, St. Paul, Minnesota), even in LBW babies. These types of catheters are likely to be particularly beneficial in the LBW postoperative cardiac patient, who requires frequent laboratory assessments but has a more limited blood volume.

Finally, *cranial ultrasonography* should be performed in LBW babies preoperatively to identify intracranial

hemorrhage, which may influence the timing of surgery or the CPB strategy. Cranial ultrasound examination also is useful to diagnose periventricular leukomalacia in this at-risk population. In premature infants, we also perform a postoperative head ultrasound examination 2 to 3 days after surgery in view of their increased risk of intracranial hemorrhage, or if there are neurologic or hematologic concerns.

## SUMMARY

LBW infants with CHD are likely to be at a higher risk for postoperative death and complications than that observed in their normal-sized counterparts owing to the combined effects of prematurity and of the unrepaired CHD on organ system function and technical issues related to the repair. However, current experience does not suggest that waiting until the baby attains an arbitrary weight before surgery significantly improves outcome. Survival rates for LBW infants undergoing complex repairs such as those for interruption of the aortic arch and HLHS are less than those for larger babies undergoing the same operation at the same institution; however, the absolute survival rates are still acceptable (given the alternative of death). Weight alone should therefore not be considered a contraindication to surgery for complex CHD. A careful investigation for the *cause* of the low birth weight must be undertaken (e.g., prematurity, intrauterine infections, multiple congenital anomalies, genetic syndromes) and appropriate options discussed and therapies initiated. The medical and surgical teams should collaborate to determine the optimal timing and type of surgery, with body weight being only of minor importance.

## Long-Term Neurologic Outcomes in Children with Congenital Heart Disease

J. William Gaynor and Gil Wernovsky

An estimated 30,000 to 40,000 children are born in North America each year with congenital heart disease (CHD), and approximately one third require surgical intervention during the first year of life. In the past 2 decades, there has been a dramatic reduction in surgical mortality, which has been accompanied by increasing recognition of adverse neurodevelopmental sequelae in some children. Evaluation of preschool- and school-aged children following neonatal and infant repair of CHD demonstrates a pattern of neurodevelopmental sequelae characterized by mild cognitive impairment; expressive speech and language abnormalities; impaired visual-spatial and visual-motor skills; attention-deficit/hyperactivity disorder (ADHD); motor delays; and learning disabilities (Table 60–1). The need for early intervention, rehabilitative services, and special education reduces the quality of life for the children and their families, as well as resulting in significant costs to society.

Central nervous system (CNS) injury in children with CHD is a result of a complex interaction of patient-specific factors (diagnosis, genetic susceptibility) and environmental influences (cardiac surgery, socioeconomic status) (Table 60–2). The risk of a poor developmental outcome varies according to the specific cardiac defect. In addition, there is significant interindividual variation in developmental outcome, even among children with the same cardiac defect. Cerebral ischemia before, during, and after the surgical repair of CHD has been proposed to be a primary mechanism of CNS injury. However, many factors may contribute to neurologic dysfunction: congenital or acquired structural CNS abnormalities; hypoxemia and acidosis secondary to uncorrected CHD; and associated anomalies or genetic syndromes. Immaturity of the developing CNS also may be a factor. Perioperative events at the time of reconstructive surgery have been implicated as important factors in postoperative neurologic dysfunction. Factors that possibly contribute to intraoperative neurologic injury include the type of support during surgery (deep hypothermic circulatory arrest [DHCA] or continuous cardiopulmonary bypass [CPB]), use of hemodilution, the degree of cooling, and type of blood gas management. Hemodynamic instability with impaired cerebral perfusion in the postoperative period or fever with increased oxygen consumption may exacerbate cerebral injury. However, these potential risk factors do not

fully explain either the high frequency or the pattern of neurodevelopmental dysfunction described following infant cardiac surgery, suggesting that other patient-specific factors may be important determinants of neurologic injury.

It may be very difficult to completely define the etiologic factors leading to CNS injury in patients with CHD. The neurologic sequelae of cardiac surgery can be subtle in very young infants. The full extent of an injury is often not fully recognized until long after the event, when certain cognitive and higher executive skills are required. Neurologic examination of neonates and infants is limited; and developmental testing, even at 1 year of age, has imprecise predictive value for long-term neurodevelopmental outcomes. Investigators have evaluated potential surrogate measures such as electroencephalographic monitoring and magnetic resonance imaging (MRI) of the brain. However, the predictive value of these tests in isolation for long-term neurodevelopmental outcome is uncertain. Examination of preschool- and school-aged children provides greater sensitivity and specificity in determination of neurologic defects and remains the standard for evaluation of the neurologic sequelae of infant cardiac surgery.

### GENETIC SUSCEPTIBILITY TO NEUROLOGIC INJURY AND DEVELOPMENTAL DYSFUNCTION

Intellectual development and cognitive function are highly heritable and probably are dependent on multiple genes, as well as on environmental factors. Numerous inherited defects or syndromes that are associated with compromised mental development and intellectual capacity (e.g., Down syndrome, Williams syndrome, DiGeorge syndrome) may have CHD as one of the phenotypic outcomes. Although the genetic basis for most cardiac defects has not been delineated, specific genetic anomalies have been implicated in the pathogenesis of some defects. For example, microdeletions of chromosome 22 are associated with DiGeorge syndrome and a variety of heart defects, including tetralogy of Fallot (TOF), truncus arteriosus, and interruption of the aortic arch. Developmental abnormalities are present in children with 22q11 microdeletions, even those with no cardiac abnormalities (Gerdes et al, 1999). Thus, children with cardiac defects and 22q11 microdeletions may be developmentally impaired independent of the cardiac defect and cardiac surgery. It may be difficult to separate the adverse developmental sequelae of an underlying genetic anomaly from those related to CHD and cardiac surgery.

Risk of disease or injury in response to an environmental stimulus is a complex interaction between genetic susceptibility and environmental exposures. Interindividual variation in “disease risk” and in the response to environmental factors is significant. The “risk” may be modified by age, gender, ethnicity, and the extent of exposure to environmental factors. Multiple genes are involved in determining an individual’s response to a specific environmental factor. Interindividual variation in response to environmental exposures, such as cardiac surgery, probably is due in part to genetic polymorphisms. Common

genetic variants, often due to single nucleotide substitutions, occur with a frequency of greater than 1%. For a child with CHD, environmental factors include cardiac surgery, use of DHCA, need for repeated operations, and socioeconomic status. The role of genetic polymorphisms in determining susceptibility to CNS injury in children with CHD is not known. Recent studies suggest that polymorphisms of apolipoprotein E may be predictors of adverse neurodevelopmental sequelae following infant cardiac surgery (Gaynor et al, 2003). It is likely that multiple genes modulate the CNS response to CPB, DHCA, and other environmental factors modifying the risk and pattern of injury.

**NEUROLOGIC ABNORMALITIES IN CHILDREN WITH CONGENITAL HEART DISEASE PRIOR TO SURGERY**

It has long been recognized that the neurologic status of newborns with CHD is frequently abnormal prior to open heart surgery. Gillon (1973) reported neurologic findings including tone abnormalities, abnormal posturing, weak cry, and poor coordination of suck, swallow, and breathing in many infants prior to open heart surgery. A recent

study from Montreal Children's Hospital evaluated 56 consecutive neonates referred for open heart surgery (Limperopoulos et al, 1999). Neurobehavioral and neurologic abnormalities, including hypotonia, hypertonia, jitteriness, motor asymmetries, and absence of suck reflex, were noted in more than 50% of the patients before surgery. Preoperative seizures were present in three patients, 35% were microcephalic, and 12.5% were macrocephalic. Investigators at Boston Children's Hospital evaluated neurodevelopmental outcome in infants undergoing the arterial switch operation (Newburger et al, 1993). Definite neurologic abnormalities were found before surgery in 55 of 155 patients. In addition, the preoperative electroencephalogram (EEG) was abnormal in 59 of 134 patients, with seizures in 14 patients. Mahle and colleagues (2001b) at The Children's Hospital of Philadelphia evaluated infants with MRI of the brain before cardiac surgery. Periventricular leukomalacia was present in 4 of 24 infants preoperatively; cerebral infarctions were identified in two additional infants. Congenital CNS anomalies are sometimes present in children with CHD (Glauser et al, 1990). In addition, abnormal development of the heart and great vessels may alter cerebral flow patterns during in utero development, leading to abnormal development of the brain. Kochilas and colleagues (2001) at The Children's Hospital of Philadelphia demonstrated a significant correlation between smaller diameter of the ascending aorta in patients with hypoplastic left heart syndrome (HLHS) and the occurrence of microcephaly.

Hypoxemia, low cardiac output, and cardiac arrest in patients with uncorrected CHD may result in CNS ischemia and injury. Aisenberg and associates (1982) evaluated mental and motor development with 173 infants with uncorrected CHD. Developmental delay was present in 25% and was apparent as early as 2 months of age. Congestive heart failure and hypoxemia were risk factors for developmental delay. Kurth and associates (2001) from The Children's Hospital of Philadelphia used near infrared spectroscopy (NIRS) to evaluate cerebral oxygenation in 93 infants with heart defects prior to surgery. Decreased cerebral oxygenation was present in many patients, particularly infants with TOF and those with HLHS or other single-ventricle physiology. Very low cerebral oxygen saturations (<38%) were found in 13 patients, suggesting that patients with CHD are at risk for cerebral ischemia and CNS injury in the preoperative period.

**MECHANISM OF CENTRAL NERVOUS SYSTEM INJURY DURING CARDIAC SURGERY**

Even though there is increasing evidence of congenital CNS and neurologic abnormalities as well as preoperative CNS injury in children with CHD, most studies have focused on intraoperative management as the primary mechanism of CNS injury. Multiple factors may contribute to CNS injury during surgical repair including hypoxemia, cerebral hypoperfusion, and cerebral embolism (particulate and/or air). Cerebral ischemia occurring during surgical repair of CHD has been proposed to be a primary mechanism of CNS injury. Potential contributing factors include the type of support during surgery (DHCA

or continuous CPB), use of hemodilution, the depth and rate of core cooling, and type of blood gas management. There has been particular interest in the type of support utilized during the cardiac repair. Use of CPB exposes the blood to the foreign surfaces of the bypass circuit, initiating a systemic inflammatory response characterized by neutrophil activation, complement activation, and increased circulating levels of inflammatory cytokines (du Plessis, 1999). This inflammatory response may result in increased capillary permeability, tissue edema, and organ dysfunction. When continuous CPB is utilized, perfusion to the body and brain is maintained. When DHCA is utilized, there is a period of obligate global cerebral ischemia followed by reperfusion. Use of DHCA provides a bloodless surgical field, facilitating meticulous completion of the repair, and decreases the duration of blood exposure to the bypass circuit, but at the cost of a period of global cerebral ischemia. Continuous CPB maintains perfusion to the brain and body but increases the duration of blood exposure to the bypass circuit, which may increase the severity of the inflammatory response. Use of continuous CPB avoids the period of cerebral ischemia but results in a greater increase in total body water and more severe dysfunction of other organs, such as the lungs (Skaryak et al, 1996; Wernovsky et al, 1995). Both continuous CPB and DHCA have been associated with perioperative CNS injury (Bellinger et al, 2003; Newburger et al, 1993).

### **CENTRAL NERVOUS SYSTEM INJURY IN THE POSTOPERATIVE PERIOD**

CNS injury may occur or be exacerbated in the postoperative period. Most studies have focused on the operating room as the site of CNS injury; however, events in the cardiac intensive care unit (CICU) may be as important. Cerebral ischemia can result from low cardiac output or severe hypoxemia. Postoperative hyperthermia may increase the metabolic needs of the brain, resulting in worsening CNS injury (Shum-Tim et al, 1998). In addition, postoperative cardiac arrest may result in significant CNS injury.

Especially following newborn and infant repairs, there is a predictable and reproducible fall in cardiac output (Wernovsky et al, 1995). This period of decreased oxygen delivery, usually within the first 24 hours after surgery, represents a particularly vulnerable time for the CNS, especially if associated with increased oxygen consumption (as with fever, pain, or agitation). At present, studies linking postoperative hemodynamic lability to long-term CNS outcomes are lacking. However, postoperative hypotension may lead to cerebral white matter injury characterized by periventricular leukomalacia (Galli et al, 2004).

### **NEURODEVELOPMENTAL OUTCOME FOLLOWING REPAIR OF CONGENITAL HEART DISEASE**

Only a few well-designed studies have prospectively evaluated neurologic outcome in children with CHD. A randomized trial at Boston Children's Hospital examined the incidence of acute neurologic injury, as well as late cogni-

tive outcome, following repair of transposition of the great arteries (TGA) with or without a ventricular septal defect (VSD) (Newburger et al, 1993). Although this study has the advantage of a homogeneous patient population (TGA with or without VSD, 76% male, 89% Caucasian), the results cannot necessarily be extrapolated to patients with other cardiac defects or different ethnic origins. Children were randomized to an operative strategy of either predominantly DHCA or continuous low-flow CPB. However, even those patients randomized to predominantly continuous CPB did undergo a brief period of DHCA; thus, the study does not compare use of DHCA and no DHCA. Evaluation of acute neurologic injury included EEG monitoring and neurologic examination. There was a trend toward more frequent seizures as determined by continuous EEG monitoring within the first 48 hours after surgery in children assigned to DHCA; however, the difference was not significant ( $P = .07$ ). Presence of an associated VSD was an independent risk factor for seizures. Abnormalities on neurologic examination at discharge from the hospital were common (possible, in 31% of patients; definite, in 20%); however, the incidence was not related to either treatment assignment or duration of DHCA.

Cognitive function and developmental outcomes for patients in the Boston Circulatory Arrest Study have been evaluated at 1, 4, and 8 years of age (Bellinger et al, 1995, 1999, 2003). Testing at 1 year included the Bayley Scales of Infant Development, neurologic examination, and MRI of the brain (Bellinger et al, 1995). The mean score on the Psychomotor Development Index (PDI) of the Bayley Scales for the entire cohort was  $95 \pm 15.5$  (norm  $100 \pm 15$ ). PDI scores were significantly lower among children assigned to DHCA than among those assigned to CPB, with a mean difference of 6.5 points. Longer duration of circulatory arrest also was associated with lower PDI scores. Of importance, presence of a VSD was an independent risk factor for a lower PDI score, with a similar mean difference between the two groups (6.6 points). The mean score on the Mental Development Index (MDI) of the Bayley Scales for the entire cohort was  $105.1 \pm 15$  (norm 100). MDI scores tended to be lower among children assigned to DHCA; however, the difference did not reach statistical significance ( $P = .1$ ). However, as with the PDI, presence of a VSD was an independent risk factor for a lower MDI score, with a mean difference between the groups of 8.6 points ( $P = .004$ ). Developmental outcome was also assessed by the Fagan Test of Infant Development. Scores were not related to either treatment assignment or duration of circulatory arrest; however, presence of a VSD was associated with significantly lower scores. Neurologic examination revealed no significant differences between treatment groups. Preoperative factors including a low Apgar score at 5 minutes and younger gestational age, however, were independent risk factors for abnormalities on the neurologic examination. Occurrence of an EEG-confirmed seizure in the early postoperative period was associated with a mean reduction of 11.2 points on the PDI and with a higher risk of possible or definite abnormalities on MR imaging. Thus at 1 year of age, although use of DHCA was associated with a lower PDI score, factors related to preoperative status (Apgar

scores, gestational age) and cardiac anatomy (TGA with an associated VSD) were independent predictors of adverse developmental outcomes. Because the children with an associated VSD were older at the time of surgery, it was not possible to separate the potential effects of older age at surgery and presence of a VSD. The authors noted that the “the ability to establish a safe threshold (for duration of DHCA) was limited by the modest effect of duration of circulatory arrest and by the considerable scatter in the data” (Bellinger et al, 1995).

The cohort was reevaluated at 4 years of age. Full-Scale, Verbal, and Performance IQs for the entire cohort were lower than population means; however, treatment group differences were not significant (Bellinger et al, 1999). Results were similar when the duration of DHCA replaced treatment group in the regression model. Social class and diagnosis accounted for more of the variation in IQ (24%) than did use of DHCA (3%). Presence of a VSD was an independent risk factor for lower Full-Scale IQ, Performance IQ, and Verbal IQ. Twenty-eight percent of the children had possible abnormalities on neurologic examination, and 30% had definite abnormalities. Abnormalities tended to be more common in the DHCA group, but the difference did not reach statistical significance. Assignment to DHCA was associated with significantly lower gross and fine motor function scores. Evaluation of language function revealed scores in the full cohort that were significantly below population means; however, treatment group differences were not significant for any language test. Speech evaluation demonstrated that assignment to the DHCA group was associated with a reduced ability to imitate oral movements and speech sounds. Apraxia of speech was more prevalent and more severe among children assigned to DHCA. Presence of a VSD was also significantly associated with apraxia of speech. Thus at 4 years of age cognitive, language, and motor performance for the entire cohort were significantly reduced relative to the general population. Use of a predominant strategy of DHCA was associated with worse motor function, but not with significantly worse IQ scores or worse overall neurologic status. As at the 1-year evaluation, the outcome for patients with an associated diagnosis of VSD was generally worse than that in patients with intact ventricular septum.

Results from the 8-year evaluation have recently been published. Full-Scale and Performance IQ scores for the entire cohort were slightly lower than population norms (Bellinger et al, 2003). There was no significant effect of assignment to DHCA or duration of DHCA on IQ. Scores of the entire cohort for memory, attention, and visual-spatial skills, as well as academic achievement, were lower than population means, and there was no treatment group effect. As at the 4-year evaluation, assignment to DHCA was associated with worse speech and fine motor function. Overall, there was a significant incidence of learning disabilities in both groups, and 43% received special education services. The investigators concluded that the treatment groups were similar in most aspects of neuropsychological and academic performance; however, performance was lower than in the general population. A substantial number of the patients are experiencing academic difficulties.

Cardiac diagnosis may have a significant impact on neurodevelopmental outcome and may modulate the effects of neuroprotective strategies. Presence of a VSD in patients undergoing the arterial switch procedure is a significant risk factor for poor developmental outcome (Bellinger et al, 1995, 1999; Newburger et al, 1993). At Boston Children’s Hospital, developmental and neurologic outcomes were evaluated in infants undergoing repair of a variety of cardiac defects at less than 9 months of age who were randomized to either alpha-stat or pH-stat blood gas management strategy during deep hypothermic CPB (Bellinger et al, 2001). Children with TGA with or without VSD, TOF, isolated VSD, atrioventricular canal defect, truncus arteriosus, and total anomalous pulmonary venous return were enrolled. The use of either alpha-stat or pH-stat blood gas management strategy was not consistently related to either improved or impaired neurodevelopmental outcomes. There was no effect of treatment group on the PDI score. The MDI score, however, varied significantly depending on treatment group and diagnosis. For patients with TGA and TOF, use of pH-stat resulted in a slightly higher MDI, although the difference was not statistically significant. Of interest, in the VSD subgroup, the treatment effect was opposite with use of alpha-stat management, resulting in significantly improved scores. Cardiac diagnosis had a significant effect on outcomes: PDI and MDI scores were significantly higher in the TGA group compared with those noted for the other cardiac defects. A recent study at The Children’s Hospital of Philadelphia evaluated the neuroprotective effect of allopurinol, a scavenger and inhibitor of oxygen free radical production, during infant cardiac surgery using DHCA (Clancy et al, 2001). A total of 318 infants (131 with HLHS) underwent surgery. Allopurinol provided significant neuroprotection only in patients with HLHS; no benefit was found in the non-HLHS patients. In the same cohort of patients, preoperative factors including cardiac diagnosis were evaluated as predictors of operative mortality (Clancy et al, 2000). Because of the number of different defects in these patients, they were grouped according to a classification based on anatomy and physiology: class I was defined as presence of two ventricles with no aortic arch obstruction; class II, two ventricles with aortic arch obstruction; class III, single ventricle with no arch obstruction; and class IV, single ventricle with arch obstruction. Patients with TOF, TGA, and VSD are grouped in class I, whereas patients with HLHS or variants are in class IV. This classification correlated significantly with operative mortality. Mortality rates for class I patients were 1%, compared with 10.7% for class II, and 25.5% for classes III and IV. These studies demonstrate that cardiac diagnosis has a significant impact on both operative mortality and neurodevelopmental outcome.

Previous studies have suggested that developmental outcome is worst for patients with complex cardiac defects, such as HLHS, who require multiple operations during infancy and early childhood. Rogers and colleagues at the Children’s Hospital of Buffalo evaluated 11 survivors of staged repair for HLHS at a mean age of 38 months (Rogers et al, 1995). Seven children (64%) had major developmental disabilities and were considered to be mentally retarded. Two had severe cerebral palsy. Gross

motor delays were present in five children (45%). At follow-up microcephaly was present in eight children (73%) and correlated with cognitive delay. More recent studies, however, suggest that developmental outcomes for these children have improved. Kern and associates (1998) at Columbia-Presbyterian Medical Center evaluated early neurodevelopmental outcome following stage I reconstruction for HLHS. Twelve patients who had undergone the Norwood procedure and subsequent surgery were evaluated along with a control group of children including siblings and first cousins. DHCA was utilized for the stage I reconstruction, with a mean duration of 56 minutes. The median scores for Full-Scale IQ were in the lower range of normal. Although scores for controls were generally higher than for patients, the differences between the two groups in intelligence testing did not reach statistical significance. The only statistically significant difference was in adaptive behavior, with the controls scoring higher. There was no correlation between neurologic outcome and bypass time, age at surgery, number of operations, or age at testing. Longer duration of DHCA was a risk factor for lower Full-Scale IQ. Eke and colleagues (1996) from Loma Linda evaluated the neurologic sequelae of DHCA in patients undergoing neonatal cardiac transplantation. The majority of these patients had HLHS. Developmental outcomes were evaluated using the Bayley Scales of Infant Development. There was no correlation between the duration of DHCA and neurodevelopmental outcome. Mahle and associates (2000a) at The Children's Hospital of Philadelphia evaluated neurodevelopmental outcomes in school-aged survivors of reconstructive surgery for HLHS. A majority of patients had IQ scores within the normal range; however, mean performance for the study group was lower than population norms. In a multivariable analysis, only the occurrence of a preoperative seizure predicted lower Full-Scale IQ. Duration of DHCA was not a predictor of lower IQ, although this lack of correlation may be due to the narrow spread of DHCA time in the study cohort. Scores on achievement tests (mathematics and reading) were lower than expected for the normal population. Nearly two thirds of the cohort had a clinical diagnosis of ADHD. Goldberg and colleagues (2000) evaluated neurodevelopmental outcome for children with functional single ventricle (both HLHS and non-HLHS) following completion of the Fontan procedure. Cognitive outcomes were assessed with the Wechsler Preschool and Primary Scale of Intelligence-Revised. Mean scores for the entire cohort were within the normal range for Full-Scale IQ, Verbal IQ, and Performance IQ. Scores for patients with HLHS were lower than for patients with other defects but were not significantly different from scores for the standard population. Use of DHCA was associated with lower scores. Because of the significant mortality previously associated with staged reconstructive surgery for HLHS, most of these studies evaluated relatively small numbers of young patients. In addition, these studies provide conflicting evidence concerning the significance of DHCA as a risk factor for adverse neurodevelopmental outcomes. Outcomes for these complex patients, overall, have improved in recent years, in terms of both mortality and neurodevelopmental outcome.

## Functional Status after Repair of Congenital Heart Disease

Most studies have focused on delineating cognitive impairments in children who have undergone repair of CHD; however, the impact on the child's functional status and on the child's caregivers has not been as carefully investigated. Developmental delay following cardiac surgery can impair a child's functional status, resulting in a considerable burden for family and caregiver. Limperopoulos and colleagues (2001) from Montreal Children's Hospital evaluated functional limitations and burden of care in 131 infants following surgical repair of CHD, using the WeeFIM (Functional Independence Measure), a pediatric functional assessment designed to assess and track levels of functional independence, and the Vineland Adaptive Behavior Scale. Only 21% of the patients were functioning within their appropriate age range. Moderate disability was noted in 37% and severe disability in 6%. Functional difficulties in daily living skills were documented in 40% of the patients, and greater than 50% had poor socialization skills. Factors that increased the risk of functional disabilities included microcephaly, longer duration of DHCA, longer length of stay in the intensive care unit, and maternal education.

## SUMMARY

Children with CHD constitute an at-risk population with a significant incidence of adverse developmental outcomes, particularly following surgical repair. Current techniques for developmental evaluation in neonates and infants are imprecise predictors of late outcomes. Evaluation of preschool- and school-aged children reveals a pattern of neurodevelopmental dysfunction characterized by mild cognitive impairment, motor dysfunction, impaired visual-spatial and visual-motor skills, and attention and academic difficulties. There are significant problems with expressive speech and language and a high incidence of learning disabilities. The factors resulting in CNS injury and developmental dysfunction in these children are not completely understood. Developmental dysfunction results from a complex interaction between patient-specific factors (genetic susceptibility, cardiac diagnosis) and environmental factors (preoperative events; techniques of support during surgical repair, including the use of DHCA; postoperative events; socioeconomic status). Previous studies have focused on the use of DHCA during the surgical repair as a risk factor for neurologic dysfunction. There is conflicting evidence concerning the significance of DHCA as a risk factor for adverse neurodevelopmental outcomes. However, these studies demonstrate that CPB alone (with or without use of DHCA) is associated with postoperative neurodevelopmental sequelae. Currently, reported risk factors do not adequately explain the pattern or incidence of CNS injury following cardiac surgery in infants, suggesting that other patient-specific factors may modulate the response to CHD and cardiac surgery, increasing the risk of adverse neurodevelopmental sequelae. Children with CHD are at risk for cerebral ischemia before, during, and after cardiac surgery; therefore, factors,

that impair CNS recovery following ischemia may be important determinants of long-term neurologic outcome.

# NEUROLOGIC SYSTEM

Editor: CHRISTINE A. GLEASON

## CHAPTER 61

### Developmental Physiology of the Central Nervous System

Christine A. Gleason\* and Stephen A. Back

Over the past several decades, numerous important advances have been made in neonatal cardiovascular and pulmonary medicine, which have dramatically improved survival of critically ill term and preterm infants. Attention has now turned increasingly toward improving the neurologic outcome of not only these critically ill high-risk infants but also those born with prenatal brain injuries, brain malformations, or neurodevelopmental disorders. In the first edition of this book, there was limited attention devoted to neonatal neurology. This eighth edition now features a comprehensive neurology section that, in addition to this introductory chapter, includes chapters devoted to neonatal neuroimaging; malformations and deformations of the developing brain; brain injury and neuroprotection; neuromuscular disorders; neonatal seizures and finally, risk assessment and neurodevelopmental outcomes. This introductory chapter provides an overview of central nervous system (CNS) physiology and a discussion of normal principles of regulation of cerebral blood flow (CBF) and energy metabolism. Chapter 63 discusses normal CNS developmental anatomy in the context of the associated major human brain malformations.

#### CENTRAL NERVOUS SYSTEM VASCULAR DEVELOPMENT

The earliest parts of the nervous system are essentially avascular. Blood vessels form as a meshwork in the meninges before growing into the CNS from the pial surface in a caudal-to-rostral progression. The blood-brain

barrier is essentially a function of capillary endothelial cell tight junctions and develops under the influence of astrocytes. Brain blood vessel formation and blood-brain barrier capacities are present early in the CNS, but maximal capillary sprouting occurs during the period of dendritic growth and glial cell proliferation.

The vascular development in the periventricular areas of the developing brain is particularly clinically relevant because the immature infant is susceptible to ischemic injury in the white matter around the ventricles and to hemorrhage in the germinal eminence region (part of the ventricular zone) (Takashima and Tanaka, 1978a, 1978b). The periventricular white matter may be particularly susceptible to ischemia or to reduced substrate supply because for a period of time it has a decreased density of blood vessels at the junction of penetrating vessels that extend downward from the cortex and deep white matter vessels that branch upward. This decreased density also is seen in the subcortical vessels at the depths of the sulci in the more mature infant. The conditions of periventricular leukomalacia and subcortical leukomalacia are well-known pathologic entities (Takashima and Tanaka, 1978a, 1978b).

The germinal eminence is supplied by striatal arteries through a dense capillary network that is particularly susceptible to hemorrhage in the preterm infant. The hemodynamics of this region and the biology of the maturation of its vessels are current research areas that continue to hold promise for prevention of intraventricular hemorrhage. Evidence suggests that maturation of vessels of the germinal eminence can be influenced by the postnatal environment and by agents such as indomethacin (Ment et al, 1991). Studies of the ultrastructural features of the blood-brain barrier in this region in an animal model also have suggested that postnatal endothelial basal lamina deposition occurs before tight junction formation and glial investiture and that basal lamina induction influences the latter two processes (Ment et al, 1995). In the human preterm infant less than 34 weeks of gestational age, the period of risk for germinal matrix and intraventricular hemorrhage is the first 3 to 4 postnatal days, regardless of gestational age (Ment et al, 1995). This finding suggests that postnatal induction of vascular maturation may occur at the same rate and over the same period of time in these infants.

#### REGULATION OF CEREBRAL BLOOD FLOW AND ENERGY METABOLISM

Cerebral blood flow (CBF) is regulated by many systemic and local factors, including arterial blood pressure, intracranial pressure, arterial O<sub>2</sub> content, hematocrit, and arterial

\*In writing this chapter, Dr. Gleason excerpted significant portions of the chapter titled "The Intrauterine Nervous System" by Jan Goddard-Finegold, MD, in the previous edition of this book, as well as portions of her own contribution to Arensman RM, Cornish D (eds): Extracorporeal Life Support. Boston, Blackwell Scientific Publications, 1993, pp 138-155.

CO<sub>2</sub> tension. Cerebral O<sub>2</sub> consumption (i.e., cerebral metabolic rate) (CMRO<sub>2</sub>) is an important determinant of CBF; these variables are said to be “tightly coupled.” Responsivity of the cerebral circulation to the aforementioned stimuli also is determined in part by CMRO<sub>2</sub>.

CBF normally is regulated to maintain adequate oxygen and substrate delivery to the brain. When blood flow regulatory limits and oxygen extraction capabilities of the brain are exceeded, the brain suffers hypoxic damage. When abnormally low cerebral blood flow is the primary abnormality, then the brain suffers ischemic damage. In most clinical situations, both hypoxic and ischemic types of damage occur, although one type may predominate.

### Autoregulation

Cerebral autoregulation refers to the maintenance of constant CBF despite changes in cerebral perfusion pressure (Lassen and Christensen, 1976; Paulson et al, 1990). This autoregulatory range has both upper and lower limits; above or below these limits, CBF increases or decreases passively, along with changes in perfusion pressure. Cerebral autoregulation has been demonstrated in several species and across developmental stages, but the mechanism of this important phenomenon remains elusive. Current thinking supports the notion that autoregulation is mediated by a fine balance between endothelial cell-derived constricting and relaxing factors (Volpe, 2000). In adults, CBF remains constant over an autoregulatory range of mean blood pressures from 50 to 150 mm Hg (Paulson et al, 1990). In preterm fetal lambs, the range is lower and narrower (40 to 80 mm Hg), but more important, normal blood pressure is only 5 to 10 mm Hg above the lower limit of the autoregulatory curve (Papile et al, 1985).

Autoregulation of CBF is of considerable interest to neonatologists because of the many clinical circumstances under which it may be impaired, resulting in tissue hypoxia or hemorrhage, or both. Severe asphyxia, hypoxia, head trauma, and hypercapnic acidosis, even when relatively mild, have been shown to attenuate or even abolish autoregulation (Busija and Heistad, 1984; Jones et al, 1988; Tweed et al, 1986).

The Cushing phenomenon is characterized by increasing systemic arterial pressure, enough to maintain cerebral perfusion pressure when intracranial pressure rises. Harris and colleagues et al, (1989) have shown that this response is highly developed in fetal sheep, possibly as an adaptation to the rigors of head compression during labor. If the newborn human Cushing response is similarly well developed, then the newborn brain may be better able to preserve cerebral blood pressure when intracranial pressure (ICP) rises (as with postasphyxial cerebral edema).

### Response to Hypoxia

When arterial oxygen content (CaO<sub>2</sub>) decreases, the brain responds by increasing CBF. This cerebral vasodilatory hypoxic effect is directly related to CaO<sub>2</sub> and not to arterial oxygen tension (PaO<sub>2</sub>). Increased CBF preserves cerebral oxygen delivery (CaO<sub>2</sub> × CBF) and cerebral O<sub>2</sub> consumption

[(CaO<sub>2</sub> – CvO<sub>2</sub>) × CBF]. There is a limit beyond which CBF cannot increase, and then O<sub>2</sub> delivery falls. The brain must then increase O<sub>2</sub> extraction to maintain CMRO<sub>2</sub>. There is a limit to this also (cerebral venous PO<sub>2</sub>), and when this is reached, CMRO<sub>2</sub> falls and brain tissue hypoxia results.

Jones and colleagues (1981) studied hypoxic hypoxia in neonatal sheep and found that CBF correlates best with CaO<sub>2</sub>; as CaO<sub>2</sub> decreases, CBF increases. Studies have shown similar cerebral hypoxic cerebral vasodilatory responses in fetal (Ashwal et al, 1981) and adult sheep (Koehler et al, 1984). Developmental differences have been noted, however, in the regional brain blood flow responses to hypoxia. Ashwal and associates (1981) demonstrated a hierarchy of responsivity in fetal sheep in which the brainstem is more responsive than the subcortex or cortex. Such a hierarchy has not been noted in more mature sheep. Studies in immature sheep (Gleason et al, 1990) have shown that cerebral O<sub>2</sub> delivery is not maintained during hypoxic hypoxia; therefore, fractional O<sub>2</sub> extraction must increase to maintain CMRO<sub>2</sub>. This finding suggests that important regulatory mechanisms are not fully developed in the immature brain, so that it is more vulnerable to hypoxic injury.

Anemic hypoxia produces a rise in CBF similar to hypoxic hypoxia so that oxygen delivery is maintained despite reduced CaO<sub>2</sub> (Jones et al, 1981). Arterial PaO<sub>2</sub> changes little, if at all, in anemic hypoxia, and changes in blood viscosity alone are not sufficient to account for the increase. Patchy areas of tissue hypoxia, with some areas receiving only plasma, could produce cerebral vasodilation (Jones et al, 1988).

### Polycythemia/Hyperviscosity

Arterial O<sub>2</sub> content increases when hemoglobin concentration rises, as does whole blood viscosity. An increase in CaO<sub>2</sub> alone results in decreased CBF. The independent effect of hyperviscosity on decreasing CBF in polycythemic animals has been studied by Massik and colleagues (1987). In their study in lambs, methemoglobin was used to dissociate the effects of hematocrit and CaO<sub>2</sub> as the hematocrit was raised. Approximately 50% of the decrease in CBF associated with polycythemia could be attributed to hyperviscosity and the remainder to changes in CaO<sub>2</sub>.

### Hyperoxia

Several studies have demonstrated a decrease in cerebral blood flow when PaO<sub>2</sub> is raised to relatively hyperoxic levels. Gleason and colleagues (1988) raised fetal PaO<sub>2</sub> from 20 to 73 mm Hg in fetal sheep and noted a 46% drop in CBF. Kennedy and associates (1971) showed a 20% to 30% decrease in CBF with extreme hyperoxia (PaO<sub>2</sub> of 349 mm Hg) in neonatal puppies; this CBF response disappeared by age 3 weeks. Rahilly (1980) demonstrated a 33% drop in cranial blood flow in term infants breathing 100% O<sub>2</sub>, and Leahy and colleagues (1980) showed a 15% drop in CBF in preterm infants who received similar treatment. These results are not surprising when the curve for the CBF response to hyperoxia is placed along

the inverse hyperbolic hypoxic response curve previously described by Jones and colleagues (1977) for fetal sheep. This potential decrease in CBF with increased  $O_2$  is certainly an important consideration in the decision to use extracorporeal membrane oxygenation (ECMO) in a hypoxemic neonate, during which the carotid  $PaO_2$  may be as high as 500 mm Hg, or in resuscitation of a newborn using 100% oxygen (Gleason, 1993).

### Alterations in Cerebral Oxygen Consumption

CBF normally is coupled with  $CMRO_2$ , such that when clinical conditions alter  $CMRO_2$ , CBF is adjusted appropriately (Siesjo, 1984). For example, barbiturate coma lowers  $CMRO_2$ ; therefore, CBF is comparably reduced. Donegan and associates (1985) studied CBF autoregulation and hypoxic responses during pentobarbital-induced coma in newborn lambs. The CBF response to hypoxia was attenuated during coma, but only in proportion to the decrease in  $CMRO_2$ . Chronic narcotic infusions in ventilated sick preterm infants may induce a similar response.

Cerebral  $O_2$  consumption increases during neuronal excitation such as seizures (Metzger, 1979; Plum and Duffy, 1975). Increased CBF mirrors the increased  $CMRO_2$ , but there may not be adequate  $PO_2$ . If seizure activity is sustained, the high metabolic rate and potentially maximal CBF may increase the brain's susceptibility to additional hypoxic-ischemic injury (Meldrum and Nilsson, 1976).

### Carbon Dioxide Reactivity

Changes in arterial  $PCO_2$  induce significant cerebral vascular responses in developing animals. Hypercapnia is a potent cerebral vasodilator, and hypocapnia is a potent vasoconstrictor (Reivich et al, 1971; Volpe, 2000). Hypocapnia may occur clinically secondary to overventilation or may be induced intentionally, in an attempt to decrease pulmonary vascular resistance. Numerous studies have demonstrated a 30% to 40% reduction in CBF after 15 to 30 minutes of moderately severe hypocapnia ( $PaCO_2$  of 15 to 25 mm Hg). A gradual increase in CBF during prolonged hypocapnia has been shown by Gleason and colleagues (1989) in newborn lambs, with CBF returning to baseline after 6 hours of hyperventilation. In these hyperventilated lambs and in a similar study of adult goats (Albrecht et al, 1987), significant cerebral hyperemia was noted after abrupt discontinuation of hyperventilation.

Animal studies by Delivoria-Papadopoulos and associates (1988) have suggested that severe hypocapnia ( $PaCO_2$  less than 10 mm Hg) results in tissue ischemia. Additional clinical studies have shown abnormal electroencephalograms, auditory evoked responses, and abnormal neurodevelopmental outcomes associated with significant hypocapnia.

### Brain Energy Metabolism

Oxygen and glucose are the brain's primary energy fuels. Although the requirement for oxygen is absolute, other substrates can replace or augment glucose during special

circumstances such as hypoglycemia or anoxia (Jones, 1979). When oxygen delivery to the brain is impaired and oxygen extraction capability is exceeded, tissue hypoxia occurs, and brain damage may be the result. The issue of whether or not newborns have decreased vulnerability or "resistance" to anoxic insult continues to be debated. Increased survivability after prolonged anoxia has been demonstrated in immature animals such as newborn rats, and there have been occasional anecdotal reports of this phenomenon in newborn infants, but whether or not such increased survivability reflects resistance of the *brain* to anoxia is debatable. Nevertheless, immature animals do have better survival, and this has been variously attributed to (1) lower cerebral  $O_2$  consumption, (2) predominance of anaerobic metabolism as an energy source, or (3) circulatory adaptations in immature animals, such as greater stores of cardiac glycogen that enable the heart to sustain the cerebral circulation. None of these possible mechanisms accounts for increased survival in all species, and none has been definitely proved to be important exclusively in immature animals (Jones, 1979; Gleason, 1993).

Hypoglycemia occurs quite commonly in sick newborn infants, although the associated physiologic conditions vary considerably. Poor glycogen stores, increased glucose demands, hyperinsulinism, and poor glucose intake are among the more common of these conditions. Cerebral effects of hypoglycemia may depend in part on the cerebral effects of the associated physiologic conditions. Alternative oxidative substrates are available to the brain, including ketone bodies, lactate, amino acids, and lipids. Owen and colleagues (1967) showed that cerebral ketone body consumption accounts for 50% of cerebral  $O_2$  consumption in obese adults who are starved for 5 to 6 weeks. Hypoglycemia is associated with decreased cerebral glucose consumption but no change in cerebral  $O_2$  consumption (Jones, 1979). Whether this response is adaptive or pathologic is not known.

### Metabolic Alkalosis/Acidosis

Cerebrovascular resistance is believed to be directly related to brain interstitial pH (Kontos et al, 1977). Biologic membranes are highly permeable to  $CO_2$ , so a change in  $PaCO_2$  has an almost immediate effect on interstitial pH and, consequently, on CBF. In contrast, hydrogen and bicarbonate ions do not diffuse as easily through membranes. Therefore, induction of acute metabolic acidosis or alkalosis has not been shown to change CBF or autoregulation (Hermansen et al, 1984; Harper and Bell, 1963). During hypocapnia, addition of metabolic alkalosis does not alter CBF. However, during hypercapnia, bicarbonate infusion causes a significant decrease in CBF (Arvidsson et al, 1981), suggesting that hypercapnia alters the blood-brain permeability to ions. Such alterations in blood-brain barrier may also be associated with neonatal hypoxic/ischemic brain injury.

Sodium bicarbonate may be used clinically to correct metabolic acidosis in neonates. It is used with caution because of an earlier report linking its use with hypernatremia, intracranial hemorrhage, and acute secondary changes in arterial  $PCO_2$  (Simmons et al, 1974). Such

clinical studies are difficult to interpret because bicarbonate usually is given to treat metabolic acidosis that may be secondary to perinatal asphyxia, itself a major risk factor for intracranial hemorrhage. Laptook (1985) evaluated the cerebral effects of sodium bicarbonate (2 mEq/kg given over 3 minutes) administered to paralyzed newborn piglets to correct metabolic acidosis associated with hypoxemia. This investigator noted no alterations in brain blood flow or O<sub>2</sub> delivery. Constant PaCO<sub>2</sub> was maintained by increasing the ventilator rate during the bicarbonate infusion.

### **SUGGESTED GUIDELINES FOR CEREBROVASCULAR AND METABOLIC CARE IN HIGH-RISK NEWBORNS**

Guiding principles for the cerebrovascular and metabolic care of critically ill preterm and term infants may include the following:

1. Maintain stable blood pressure. Severe hypotension is clearly detrimental, but so are rapid increases in blood pressure in a pressure-passive circulation.
2. Maintain stable acid-base balance without rapid corrections.
3. Avoid severe hypoxemia.
4. Avoid marked hyperoxemia (i.e., consider effects of resuscitating with 100% oxygen).
5. Avoid sudden changes in PaCO<sub>2</sub>.
6. Correct significant anemia or polycythemia; if chronic, correct slowly.
7. Consider cerebrovascular and metabolic effects of any new (and existing) drug therapies. Use the lowest effective dose for the shortest period of time.
8. Maintain euglycemia.

# Neonatal Neuroimaging

Richard L. Robertson and George A. Taylor

## ULTRASONOGRAPHY

### Anatomic (Gray Scale) Sonography

*Ultrasonography* (US) became a viable tool for imaging the neonatal brain in the late 1970s with the development of real-time capabilities (Pape et al, 1979). Subsequent advances in ultrasound technology have dramatically improved our ability to visualize normal structures and abnormalities in the neonatal brain. As a result, US continues to be an integral part of caring for the critically ill neonate.

Diagnostic ultrasound relies on the transmission and reflection of high-frequency sound waves into tissues. The speed and reflectivity of sound differ among various tissues, resulting in acoustic interfaces that can be used to create images of anatomic structures. By convention, tissues with high reflectance, such as clotted blood, are bright, and those with low reflectance, such as cerebrospinal fluid (CSF) or moving blood, are dark. Thick bone and air significantly interfere with the transmission of sound into deeper tissues. Consequently, cranial US requires a coupling agent (gel) between the transducer and the skin to eliminate as much intervening air as possible and most often is performed through an open fontanel.

### Doppler Sonography

Continuous wave and pulsed wave Doppler techniques have been used for decades to sample hemodynamics in specific intracranial vessels. The resistive index (RI) and mean blood flow velocity over time (time-averaged velocity) are the most commonly used spectral Doppler measures for monitoring intracranial hemodynamics. The easiest and most reproducible are measures of pulsatility, which are relatively insensitive to differences in angle of insonation and correlate well with acute changes in intracerebral perfusion pressure. However, many factors other than cerebrovascular resistance may affect the RI in an intracranial vessel, including the presence of a patent ductus arteriosus, alterations in heart rate and cardiac output, and the amount of pressure applied on the fontanel during scanning (Perlman et al, 1981; Taylor, 1992a; Taylor et al, 1989).

Although reproducible and easy to obtain, the RI is only a weak predictor of cerebrovascular resistance under most physiologic conditions. Mean blood flow velocity measures are the most informative indices of cerebral blood flow (CBF). A strong correlation has been demonstrated between mean blood flow velocity and changes in

global CBF under a variety of clinical and experimental conditions (Taylor et al, 1990).

Before 1989, the exact origin of the Doppler signal could not be determined because of the inability to resolve most intracranial vessels with gray scale sonography. The introduction of color Doppler technology made imaging and reliable hemodynamic sampling of the intracranial vasculature routinely possible in the normal newborn (Dean and Taylor, 1995; Mitchell et al, 1988, 1989; Taylor, 1992b). Standard color Doppler sonography is based on an estimate of the mean frequency shift created by the movement of red blood cells at different velocities within the tissue or blood vessel being examined. Flow is generally depicted as variations of red or blue color, depending on the degree of shift from the baseline frequency, and on the direction of the moving red cells.

## Equipment and Scanning Technique

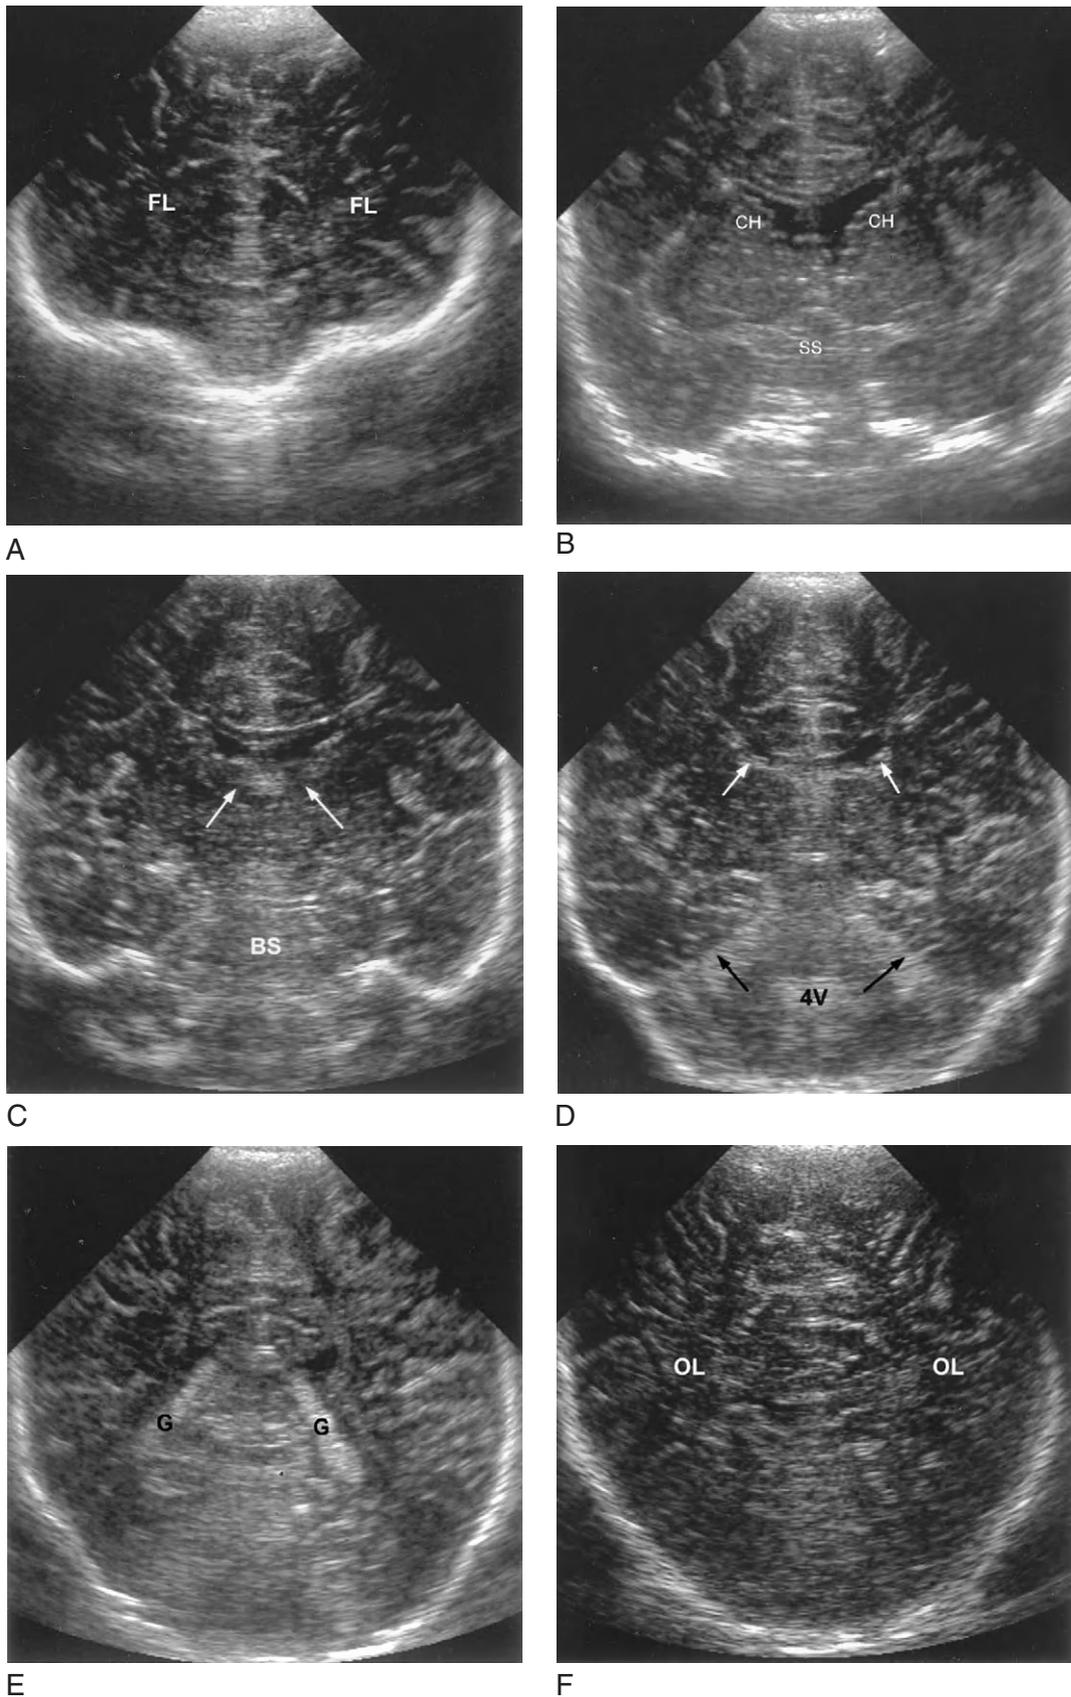

### Transducers

In the premature infant, transducers operating at a higher frequency range (7 to 10 MHz) are recommended because of their higher spatial resolution. Lower-frequency transducers (3.5 to 5 MHz) are often used in larger infants to obtain adequate sound penetration. Sector transducers with a 120-degree imaging field are most useful for imaging through the anterior and posterior fontanels.

### Scanning Technique

For sonographic examination of the neonatal brain, standardized coronal and sagittal images are obtained through the anterior fontanel. Coronal images are obtained by placing the transducer transversely across the fontanel and sweeping it in an anteroposterior direction to cover the entire brain (Fig. 62-1). The transducer should be carefully held to produce symmetrical imaging of both hemispheres.

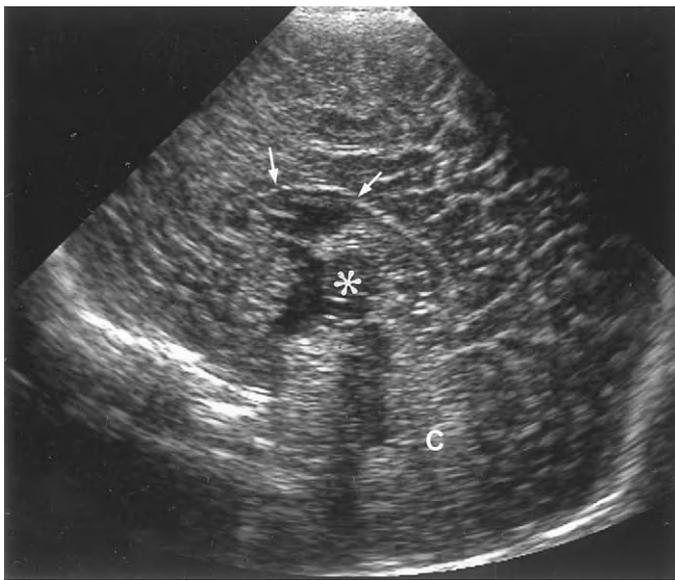

At least six angled images are obtained. The most anterior image is anterior to the frontal horns of the lateral ventricles at the level of the orbits. The frontal lobes and anterior portion of the interhemispheric fissure can be visualized. The second image is obtained through the anterior horns of the lateral ventricles at the level of the suprasellar cistern. This structure has the appearance of an echogenic five-pointed star. The hypoechoic caudate nucleus can be seen inferior and lateral to the comma-shaped lateral ventricles. The ventricles are separated from each other by the centrally positioned cavum of the septum pellucidum. Basal ganglia, frontal and temporal lobes, insula, and T-shaped sylvian fissure can be identified in this plane. The next image is obtained more posteriorly through the body of the lateral ventricles at the level of the paired foramina of Monro and brainstem. The anterior portion of the choroid plexus can be identified as three small echogenic structures along the inferomedial aspect of the lateral ventricles, and paired thalami can be seen lateral to the third ventricle. Lateral and superior to the lentiform nuclei is a region of the deep white matter called the

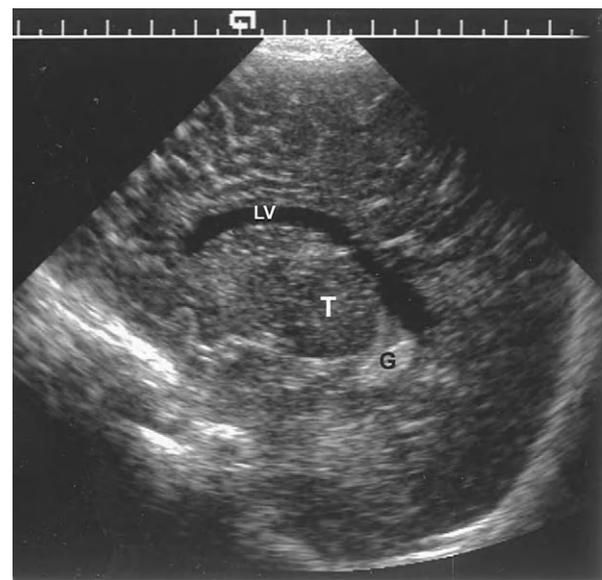

**FIGURE 62-1.** Standard coronal planes of cranial sonography performed through the anterior fontanel. **A**, Plane 1 is angled anteriorly to include the frontal lobes (FL) and orbits. **B**, Plane 2 demonstrates the caudate heads (CH) and the suprasellar cistern (SS). **C**, Plane 3 passes through the foramina of Monro (*arrows*) and the brainstem (BS). **D**, Coronal plane 4 shows the rounded echogenic choroid plexus within the body of the lateral ventricles (*white arrows*), the fourth ventricle (4V) and the tentorium (*black arrows*). **E**, Plane 5 includes the glomus (G) of the choroid plexus in the trigones of the lateral ventricles. **F**, Plane 6 is angled posteriorly to include the occipital lobes (OL).

centrum semiovale. The fourth image is obtained with the transducer angled slightly more posteriorly. At this level, the lateral ventricles have a more rounded appearance, and the choroid plexus is seen as a more prominent echogenic structure along the floor of the ventricles. The confluence of frontal, parietal, and temporal lobes can be seen as well as the echogenic tentorium cerebelli and the anterior portion of the cerebellum and fourth ventricle. The transducer sweep is continued posteriorly until the prominent paired echogenic structures of the glomus of the choroid plexus are seen in the atrium of the lateral ventricles. The parietal and posterior aspects of the temporal lobe and sylvian fissure can be visualized, along with the echogenic cerebellum inferiorly. The last coronal image is obtained posterior to the lateral ventricles. The posterior aspect of the interhemispheric fissure and the occipital lobes are seen on this view.

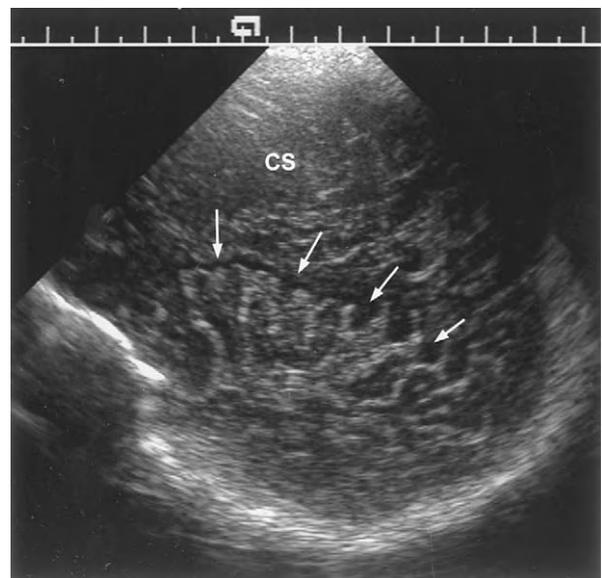

Sagittal images are obtained by placing the transducer longitudinally along the anterior fontanel (Fig. 62-2). A total of five images are usually obtained, one along the midline and two on each side by angling the transducer laterally. True midline can be established by identifying the curved corpus callosum and echogenic cerebellar vermis on the same imaging plane. The cingulate gyrus can be seen as an undulating echogenic line superior to the corpus callosum. The medial aspect of the paired thalamic nuclei, the tectum of the midbrain, and fourth ventricle can be identified on this image. The transducer is swept laterally approximately 10 degrees to show the body of the lateral ventricle. Because the lateral ventricles are not located in a straight anteroposterior line, the transducer must be slightly angled so that the posterior aspect of the probe is positioned more laterally than its anterior aspect. The echogenic choroid plexus is C-shaped and cups the

**FIGURE 62-2.** Standard sagittal planes of cranial sonography performed through the anterior fontanel. **A**, The midline sagittal image demonstrates the corpus callosum (*arrows*), interthalamic adhesion (\*), and cerebellar vermis (C). **B**, The first off-midline sagittal image is angled to illustrate the body of the lateral ventricle (LV), the glomus (G) of the choroid plexus in the trigone of the lateral ventricle, and the thalamus (T). **C**, The far-lateral sagittal image includes the sylvian fissure (*arrows*).

thalamus like a baseball in a catcher's mitt. Its superior limb extends anteriorly to the caudothalamic notch immediately posterior to the head of the caudate nucleus. Its inferior limb extends well into the temporal horn. The second angled sagittal image is obtained with the transducer angled lateral to the body of the lateral ventricle. The centrum semiovale is well shown, and the sylvian fissure can be seen separating the parietal and temporal lobes (Naidich and Yousefzadeh, 1986; Siegel, 2001).

### Clinical Indications

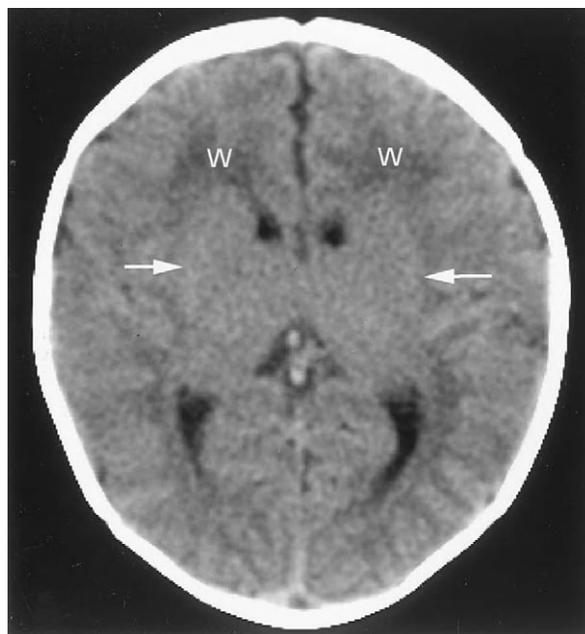

The most common indication for cranial US in the newborn is screening for suspected intracranial hemorrhage and periventricular leukomalacia (PVL) in the premature infant. Once either is detected, US is an excellent method for monitoring the progression or resolution of the pathologic process as well as for detecting the attendant complications of ventricular dilatation and progressive hydrocephalus. Sonography also is a very useful tool in the identification of focal infarction and hemorrhagic lesions in the term or near-term infant, as well as congenital midline anomalies, cystic lesions, vascular malformations, and intracranial calcifications, and in the definition of extra-axial fluid collections. The portable, noninvasive nature of cranial US allows for the cribside identification of many important lesions on an urgent basis without need for transport of the unstable or critically ill newborn. A more definitive characterization of a sonographic finding or suspected lesion can be performed subsequently with magnetic resonance imaging (MRI) or computed tomography (CT) once the infant is more stable.

### COMPUTED TOMOGRAPHY

CT uses a narrowly collimated x-ray beam in conjunction with a digital detector array to produce a cross-sectional anatomic image (Boyd, 1995) (Fig. 62–3). Although employing ionizing radiation, current-generation CT scanners effectively limit exposure to the immediate volume of interest (Raj et al, 2000). Tissue contrast in CT is dependent on differential attenuation of the x-ray beam. Tissues with high electron density, such as bone, markedly attenuate the beam, whereas brain and other soft tissues absorb fewer photons. Relative tissue densities on CT images are, by convention, measured in Hounsfield units (HU). After acquisition of the digital data, the images can be adjusted to emphasize different tissues such as bone or soft tissue.

### Techniques

CT images are typically acquired in either the axial or the coronal plane. In most systems, the patient lies supine on a specialized scan table while the x-ray tube and detector array are rotated through a 360-degree arc. The scan table is then advanced several millimeters, and the next image slice is obtained. For certain indications, the images may be acquired in a spiral (helical) or volumetric fashion with continuous rotation of the x-ray tube–detector array and uninterrupted scan table advancement.

**FIGURE 62-3.** Axial computed tomographic image in a normal term newborn. Unmyelinated white matter is characterized by low density (W), while cortex and deep gray matter (arrows) are slightly denser.

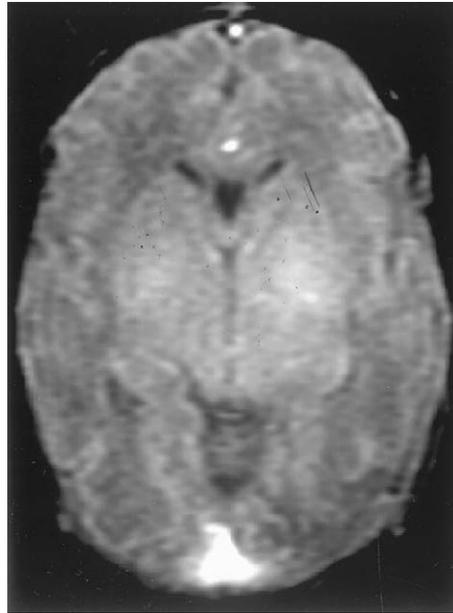

Brain CT in the newborn is usually performed without the administration of intravenous contrast. Intravenous contrast may be used in CT for the evaluation of blood-brain barrier breakdown and as a blood pool agent for vascular imaging. Most often, however, the relevant clinical questions regarding the presence of tumors, infections, vascular malformations, and vascular patency can be answered without the use of contrast or are more fully evaluated with MRI (Cowan and MacDonald, 1999; Haring et al, 1999).

### Clinical Indications

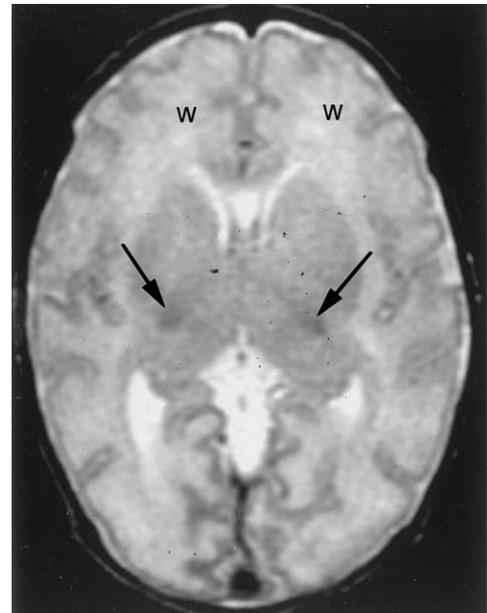

Brain CT is most often requested in the newborn to evaluate potential causes of an acute change in neurologic status. In the neonate, neurologic manifestations of intracranial abnormalities are often nonspecific and/or nonlocalizing (Rivkin, 1997; Robertson and Robson, 2001). In this setting, CT may demonstrate a variety of underlying abnormalities including intracranial hemorrhage, hypoxic-ischemic brain injury, focal infarction, posthemorrhagic hydrocephalus, vascular anomalies and malformations, infections, tumors, and certain of the phakomatoses. CT is particularly useful for the detection of acute hemorrhage, calcification or mineralization, and mass lesions.

US, because the equipment is portable and the examination can be performed at the bedside and does not utilize ionizing radiation, is the preferred method for evaluating many suspected central nervous system (CNS) disorders in the neonate. CT examination of the brain is usually obtained to clarify findings seen with US (e.g., hemorrhage versus edema) and to evaluate regions of the brain that are poorly seen with US owing to lack of an adequate acoustic

**FIGURE 62-4.** Axial images in a normal 34-week-gestation preterm neonate. **A**, Unmyelinated subcortical white matter appears hypointense (dark) on T1-weighted imaging, while the cortical and deep gray matter exhibit higher signal intensity. **B**, Unmyelinated subcortical white matter (W) appears markedly hyperintense (bright) on the T2-weighted fast spin echo image, while areas of early myelination, such as in the lateral thalamus (*arrows*), are of lower signal intensity. Loss of this focus of hypointensity is one of the earliest indicators of hypoxic-ischemic injury on T2-weighted images.

A

B

window (e.g., peripheral cortex) (Barnes and Taylor, 1998). Because the majority of CT scanners are not portable, the neonate must be transferred to the imaging suite for evaluation. Monitoring and support equipment can be brought into the imaging suite without the restrictions inherent with MRI. In recent years, however, MRI, because of its superior tissue contrast, multiplanar capabilities, available functional information, and lack of ionizing radiation, has largely supplanted CT as an adjunct to US for the evaluation of the newborn brain (Robertson et al, 2003).

## MAGNETIC RESONANCE IMAGING

MRI is an established technique based on the principles of nuclear MR. Clinical MRI uses a nonionizing radiofrequency (RF) pulse to interrogate the properties of water protons in an applied external magnetic field (Balter, 1987; Mulhern and Chung, 2000). The behavior of the protons is determined by both the applied external magnetic field and the local magnetic field produced by neighboring protons. Image signal intensity (brightness) is related to the overall water content of the tissue as well as the inherent tissue properties: T1, T2, proton flow, proton diffusion, paramagnetism, magnetic susceptibility, and chemical shift (Barnes and Taylor, 1998). MR contrast is determined by the relative emphasis (i.e., weighting) placed on these various factors during image acquisition (Figs. 62-4, 62-5, and 62-6). The manipulation of multiple tissue properties in MRI provides greater flexibility in imaging than is available with the single tissue property used in US (acoustic impedance) or CT (x-ray attenuation). MR images may be obtained in any desired anatomic plane without repositioning the patient. With few exceptions (e.g., Sturge-Weber syndrome, tumor), neonatal brain MRI does not require the use of intravenous contrast.

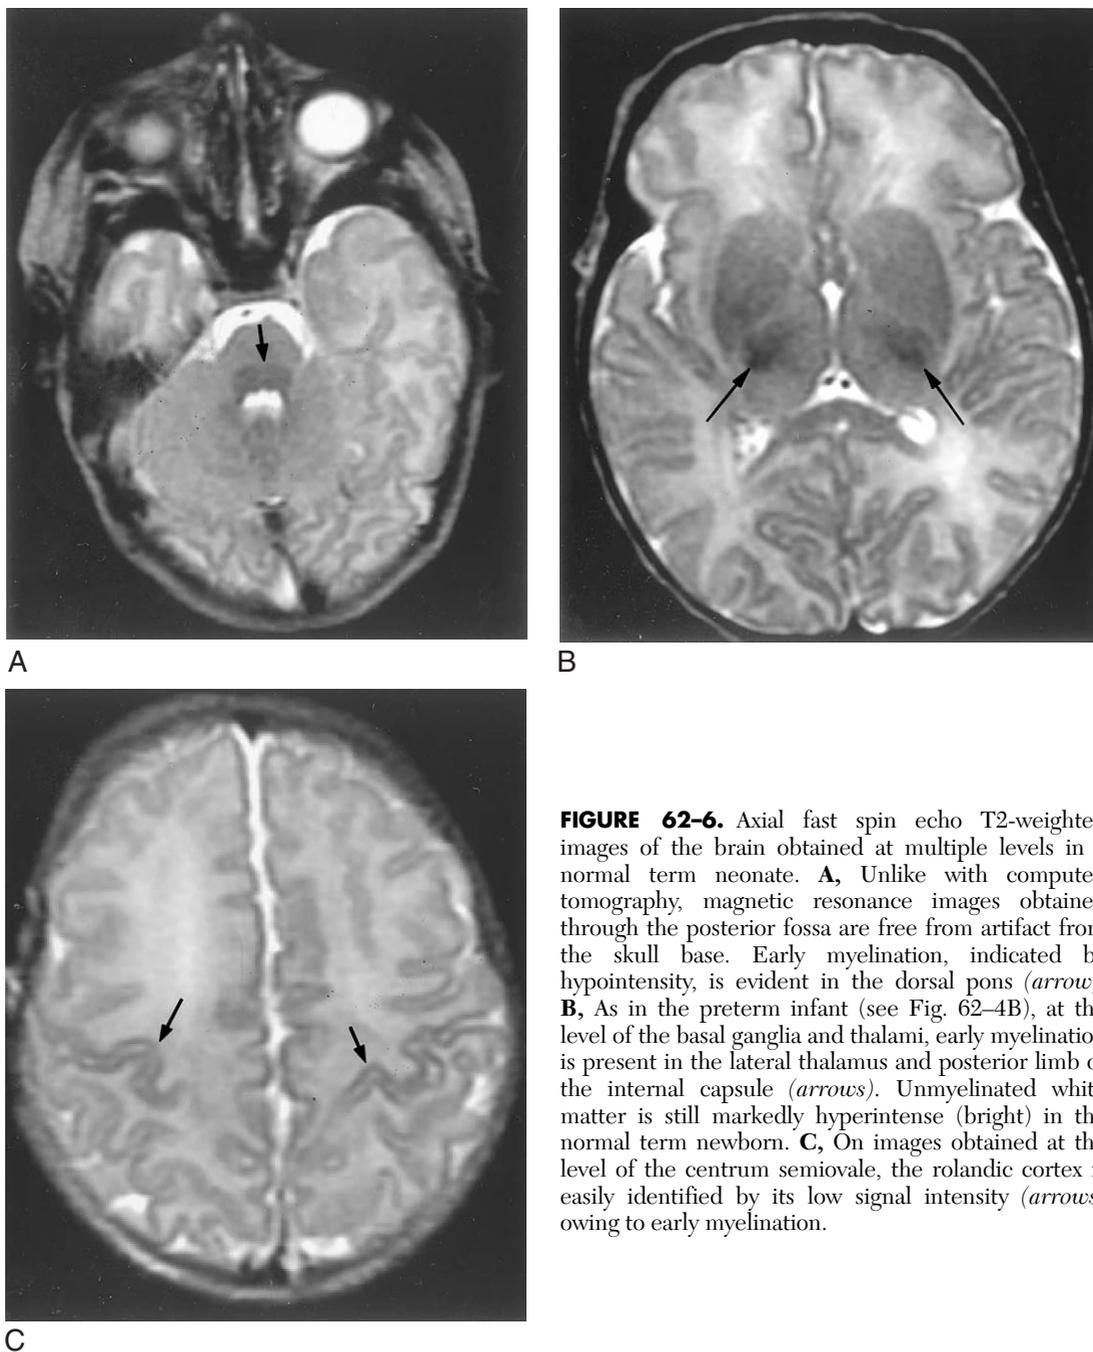

## Techniques

### Anatomic Magnetic Resonance Imaging

In general, conventional MR spin echo imaging is not as rapid as US or CT. In recent years, however, a number of fast imaging pulse sequences such as fast spin echo and fast spoiled gradient-recalled imaging have

**FIGURE 62-5.** Midline sagittal T1-weighted image from a normal term neonate. Midline structures such as the corpus callosum, brainstem, and cerebellar vermis are well seen in the newborn. Of note, the pituitary (*arrow*) is diffusely hyperintense owing to hormonal activity.

**FIGURE 62-6.** Axial fast spin echo T2-weighted images of the brain obtained at multiple levels in a normal term neonate. **A**, Unlike with computed tomography, magnetic resonance images obtained through the posterior fossa are free from artifact from the skull base. Early myelination, indicated by hypointensity, is evident in the dorsal pons (*arrow*). **B**, As in the preterm infant (see Fig. 62-4B), at the level of the basal ganglia and thalami, early myelination is present in the lateral thalamus and posterior limb of the internal capsule (*arrows*). Unmyelinated white matter is still markedly hyperintense (bright) in the normal term newborn. **C**, On images obtained at the level of the centrum semiovale, the rolandic cortex is easily identified by its low signal intensity (*arrows*) owing to early myelination.

been developed (see Figs. 62-4B and 62-6). The use of these techniques does help to minimize the examination time while preserving tissue contrast but still requires that the patient remain motionless for 2 to 3 minutes at a time. Consequently, sedation or anesthesia is often required to perform an adequate examination in the newborn.

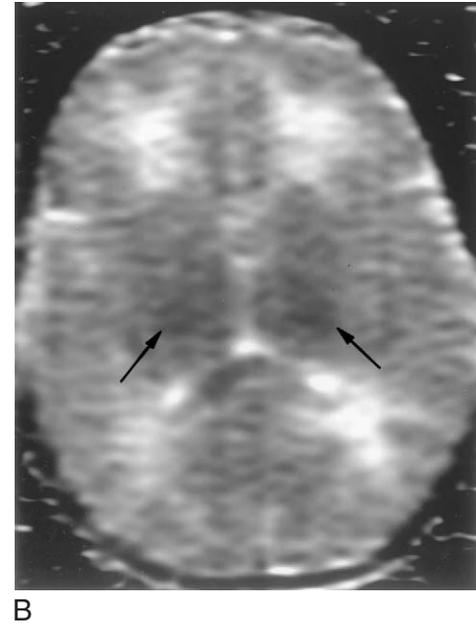

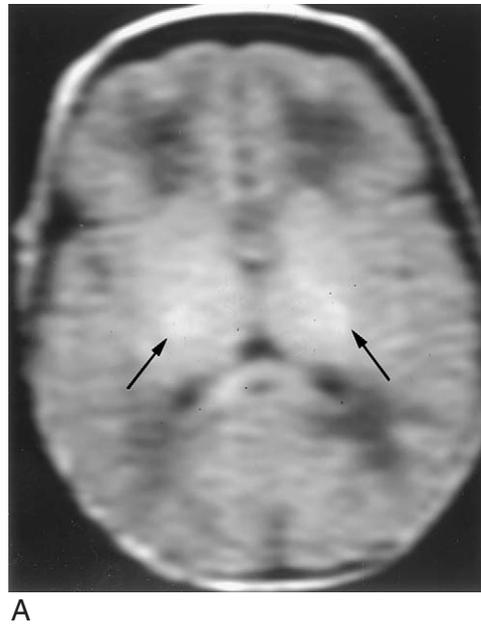

MR angiography (MRA) and MR venography (MRV) may be used to demonstrate the intracranial arteries and veins of the neonatal brain without the use of intravenous contrast. The most commonly used sequence is a gradient-echo sequence in which stationary tissues are repeatedly excited with RF pulses at short intervals. Because of the long T1 of the brain, the protons are unable to regain

longitudinal magnetization between RF pulses, and their signal is suppressed. The protons in inflowing blood have not experienced the previous RF pulses and can give back signal. This is termed the *time-of-flight (TOF) effect* and is the basis for the most commonly used MR technique for the depiction of blood flow.

### Functional Magnetic Resonance Imaging

In addition to the anatomic information available with standard MRI sequences, functional information may be obtained with newer MRI techniques such as diffusion-weighted MRI (Fig. 62-7), perfusion MRI, brain activation

**FIGURE 62-7.** Axial line scan diffusion-weighted imaging in a normal term newborn. **A**, Isotropic diffusion-weighted image at the level of the basal ganglia. Unmyelinated white matter has very low signal intensity owing to the rapid diffusion of water in these regions, while areas that have already begun to myelinate, such as the lateral thalamus and posterior limb of the internal capsule (*arrows*), have more restricted diffusion and increased signal. **B**, Corresponding processed apparent diffusion coefficient (ADC) map. These maps are produced to limit T2 effects in the images. Areas with relatively restricted molecular diffusion are, by convention, depicted as lower pixel values (*arrows*).

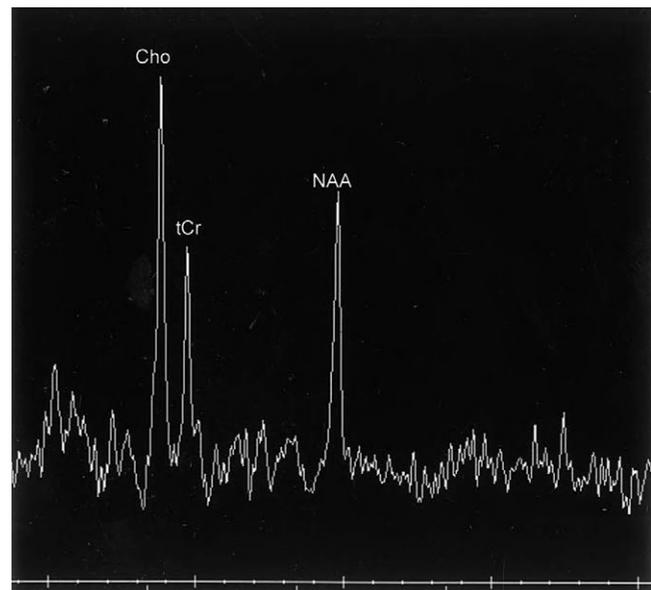

MRI, and MR spectroscopy (MRS) (Fig. 62-8) (Barkovich et al, 1999; Huppi and Inder, 2001; Robertson et al, 2000a; Warach et al, 1996). These newer sequences have been made possible in large part by the development of ultrafast imaging such as echo planar MRI and the improved uniformity of the magnetic field available with newer MR scanners. Used in adults and older children for several years, functional techniques are now being applied in the newborn.

### Diffusion Imaging

Initially popularized for its usefulness in the evaluation of acute stroke in adults, diffusion imaging (DI) is now widely utilized to evaluate the neonatal brain (Robertson et al, 1999; Rutherford et al, 1995). In newborns, DI has been used to study normal brain myelination as well as ischemic and nonischemic CNS disorders. The immature brain is characterized by a high water content and relatively rapid molecular diffusion (Robertson and Robson, 2001; Robertson et al, 1999; Sakuma et al, 1991) (see Fig 62-7). The bulk of the water in the neonatal brain is within the extracellular space (Barlow et al, 1961). As the brain matures, a gradual decline in the extracellular volume fraction occurs owing to the hydrophobic nature of myelin. Myelin also impairs the exchange of water molecules across the cell membrane. Because the movement of water within the cell is limited by its interaction with intracellular structures and the cell membrane, the apparent diffusion coefficient (ADC) of intracellular water is lower than that of extracellular water. Consequently, the ADC of myelinated white matter is lower than that of unmyelinated white matter. In addition, because of cellular structure, the direction of movement of intracellular water is preferentially along the length of the axon rather than perpendicular to it. Therefore, the relative anisotropy

(RA), a measure of the inequality of diffusibility in different directions, increases as the proportion of intracellular water increases (Takeda et al, 1997; Toft et al, 1996).

**FIGURE 62-8.** Single-voxel proton spectroscopy of the brain from a normal term neonate. The spectra were obtained with an echo time of 144 msec. Three prominent peaks are identified: At 3.2 ppm is choline (Cho). Choline compounds are involved in the metabolism of membrane lipids. At 3.0 ppm is total creatine (tCr). Creatine and phosphocreatine are involved in ATP metabolism. At 2.0 ppm is *N*-acetyl aspartate (NAA). NAA is an intracellular compound found primarily in neurons. Note that lactate, which would appear, if present, as an inverted doublet at 1.3 ppm, is not seen in the normal newborn.

### **Perfusion Imaging**

To date, performing perfusion MRI of the brain in the newborn has been relatively unsuccessful. Implementing contrast bolus tracking (Kucharczyk et al, 1993), the most common perfusion MRI technique, has been difficult because of the small volume of contrast that can be used in the newborn and the lack of adequate intravenous access to permit administration of a compact contrast bolus. The use of spin-tagging methods that do not require the administration of an exogenous contrast agent (Alsop and Detre, 1996; Kim and Tsekos, 1997) has been equally challenging.

### **Brain Activation Imaging**

MR brain activation studies have been performed successfully in the neonate, albeit in limited scope (Anderson et al, 2001; Benaron et al, 2000; Born et al, 1998). The use of MRI to indirectly demonstrate cortical activation is based on the observation that regional blood flow varies with neuronal activity. That is, in areas of the brain that are activated, there is an increase in blood flow, while the oxygen extraction fraction remains constant. Consequently, there is an increase in the local concentration of oxyhemoglobin and a decrease in the local concentration of deoxyhemoglobin (Buchbinder and Cosgrove, 1998). Deoxyhemoglobin has susceptibility effects that cause minor perturbations in the magnetic field, leading to signal loss. The increase in oxyhemoglobin that accompanies brain activation causes a local increase in signal intensity. These changes form the basis of the MRI technique called blood oxygenation level-dependent (BOLD) imaging, the MRI sequence most often used to assess brain activation. Because the signal changes associated with brain activation are quite small, a number of images can be averaged together to produce a composite view of cortical activation. Typically, therefore, BOLD imaging requires that the subject cooperate with repetitive tasks to demonstrate brain activation. Because the neonate is unable to perform such tasks, only those stimuli that produce an involuntary response, such as visual cortical activation with strobe light flashes, may be tested. Despite these limitations, the use of BOLD MRI to evaluate neonatal brain activation is an active area of research (Anderson et al, 2001; Benaron et al, 2000; Born et al, 1998).

### **Magnetic Resonance Spectroscopy**

Proton MRS exploits the minute differences in magnetic moments of hydrogen atoms reflecting differences in their local chemical environment to produce spectra characteristic of a variety of metabolites (Keevil et al, 1998) (see Fig. 62–8). Because of its ability to detect abnormal metabolites and metabolic ratios, MRS is becoming popular in the MR assessment of a number of processes affecting the newborn (Vigneron et al, 2001).

With most proton MRS techniques, the signal from water protons must be suppressed in order to demonstrate biologically interesting metabolites that are present in very small quantities. This requires a very homogeneous

magnetic field that is generally found only in newer and higher-field-strength MR systems. Because of the tiny amount of signal emanating from the metabolites of interest, relatively large voxels (1 to 2 cc) must be acquired to obtain adequate signal intensity. MRS may be performed using single voxels, which sample a small region of the brain, or multiple voxels, by which many areas may be interrogated during a single acquisition (Vigneron et al, 2001). Typically, single-voxel MRS provides higher quality spectra than those available with multiple-voxel techniques.

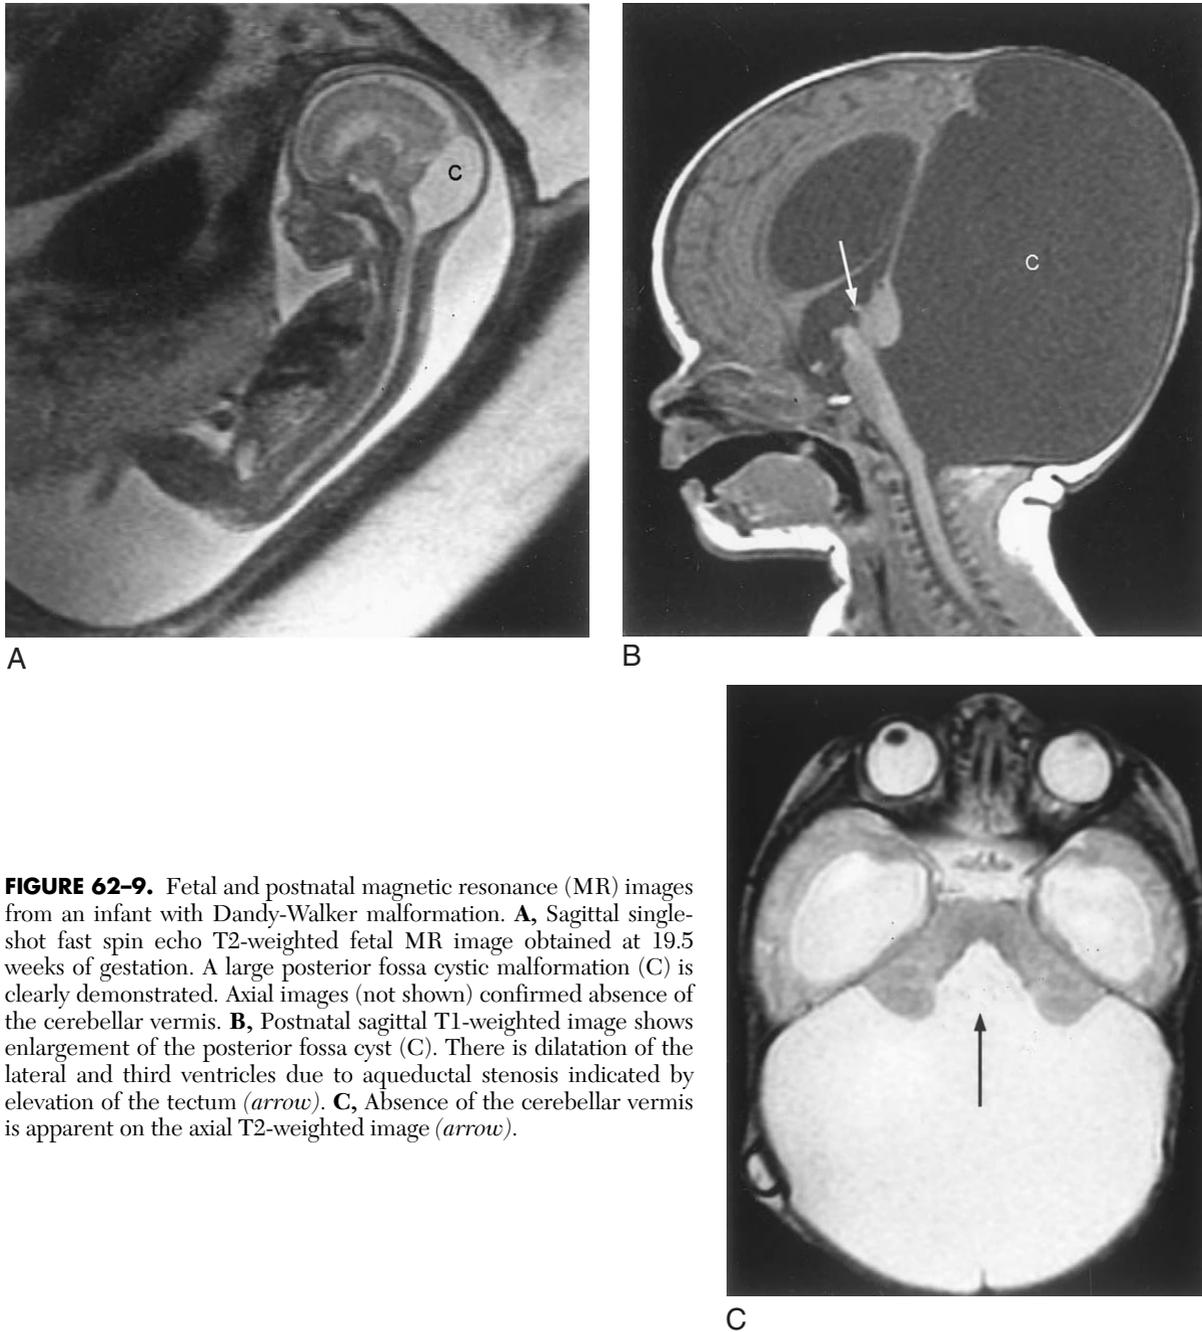

Three metabolites are most apparent in the normal neonatal brain: choline (3.2 ppm), total creatine (3.0 ppm), and *N*-acetyl aspartate (NAA) (2.0 ppm) (Heerschap and van den Berg, 1994). Choline compounds are central in the metabolism of membrane lipids and tend to be elevated in processes that result in rapid cell turnover. As a consequence of membrane development during myelination, choline tends to be relatively increased in the normal newborn brain. The creatine peak consists of creatine and phosphocreatine, which serve as a reserve for high-energy phosphates in neurons and also as an ATP/ADP buffer. Total creatine tends to remain relatively constant in most intracranial processes (Govindaraju et al, 2000). NAA is an intracellular compound found primarily in neurons, although its biologic function is largely unknown (Miller, 1991). NAA is present in smaller quantities in the neonate than in the older child or adult.

Lactate is a terminal product of glycolysis. The tissue concentration of lactate can vary from minute to minute, depending upon the status of a number of major metabolic pathways. Lactate is not demonstrated on MRS in the normal newborn brain but may be seen as a prominent doublet at 1.3 ppm in certain pathologic conditions such as infarction. Depending on the parameters chosen for imaging, the lactate peaks may project above or below the baseline.

### **Fetal Magnetic Resonance Imaging**

The recent development of ultrafast MR sequences such as single-shot fast spin echo and echo planar imaging has allowed the use of MRI to evaluate fetal abnormalities (Girard et al, 2001; Levine, 2001a, 2001b; Whitby et al, 2001) (Fig. 62–9). These studies do not require the use of sedation or anesthesia and provide reproducible and reliable images of the fetus from the late second trimester to term. To date, no known effects harmful to the developing fetus have been documented using clinical MR scanners at or below 1.5 tesla (T) (Myers et al, 1998; Baker et al, 1994). Gadolinium contrast agent is not given, as transplacental passage of the agent occurs and its toxic effects on the fetus are not fully known.

Although US remains the study of choice for screening for fetal anomalies of the CNS, MRI is becoming widely utilized to further characterize suspicious findings on prenatal US. Additionally, MRI may be useful when oligohydramnios or a difficult fetal lie (e.g., fetal head engaged in maternal pelvis) makes US examination of the fetal CNS suboptimal (Hubbard and States, 2001).

**FIGURE 62-9.** Fetal and postnatal magnetic resonance (MR) images from an infant with Dandy-Walker malformation. **A**, Sagittal single-shot fast spin echo T2-weighted fetal MR image obtained at 19.5 weeks of gestation. A large posterior fossa cystic malformation (C) is clearly demonstrated. Axial images (not shown) confirmed absence of the cerebellar vermis. **B**, Postnatal sagittal T1-weighted image shows enlargement of the posterior fossa cyst (C). There is dilatation of the lateral and third ventricles due to aqueductal stenosis indicated by elevation of the tectum (*arrow*). **C**, Absence of the cerebellar vermis is apparent on the axial T2-weighted image (*arrow*).

US and MRI are complementary imaging methods in the evaluation of high-risk pregnancy. When a CNS anomaly is suspected on US, MRI may demonstrate additional findings that can alter patient counseling (Levine et al, 1997). In a recent study, MRI demonstrated additional findings not seen on US. These findings included agenesis of the corpus callosum, cerebellar hypoplasia, cortical cleft, polymicrogyria, porencephaly, and partial agenesis of the septum pellucidum (Levine et al, 1997). Other structural anomalies such as Dandy-Walker malformation, aqueductal stenosis, hydrocephalus, Chiari malformation and vascular malformations are also readily demonstrated with MRI (Chi et al, 1977; Hubbard and States, 2001).

### Clinical Indications

MRI may be performed for clarification of known or suspected structural abnormalities or to investigate the cause of an acute change in neurologic status. Unlike US, which can be performed at the patient's bedside, MRI necessitates transporting the infant to the MRI suite. In most centers, the MRI suite is remote from the neonatal intensive care unit. Minimizing stress on the infant and ensuring patient stability during transport and MR scanning must therefore be carefully attended to. The MRI suite must be kept cool to avoid overheating of the equipment, so hypothermia in the newborn is also a concern.

Although not widely available at present, MR-compatible incubators have recently been developed and may be helpful in decreasing the stress of the MR examination for the neonate.

The requirement of a strong, homogeneous magnetic field to perform MRI places additional constraints on neonatal imaging. Supportive equipment (e.g., anesthesia ventilatory equipment, intravenous pumps, monitoring equipment) placed in the MR scanning room must be nonferromagnetic. Indwelling ferromagnetic metallic or electrical devices constitute a contraindication to MRI (Bhachu and Kanal, 2000; Ho, 2001).

## IMAGING APPLICATIONS

### Normal Preterm versus Term Infants

The most obvious difference between the preterm and the term neonatal brain is relative maturation of the sulcal/gyral architecture. As with fetal imaging, preterm infants studied at 25 weeks of gestational age equivalent will show a very smooth cortical mantle with a largely uncovered sylvian fissure and very few developed gyri. At this age, demonstration of lissencephaly and of some localized anomalies of cortical development is not possible with US and may be difficult with more advanced imaging techniques as well. Cortical maturation proceeds in a predictable fashion and should attain a fully developed secondary sulcal/gyral pattern by 40 to 44 weeks of gestational age (Chi et al, 1977). On US, gyri are depicted as linear echoes that increase in length, undulation, and branching as the infant matures.

A prominent feature of both the preterm and the term neonatal brain is the very high water content of the unmyelinated subcortical white matter. In the premature infant, there is little difference in echogenicity between gray and white matter until beyond 32 to 34 weeks of gestation. In the near-term infant, the cortical ribbon is hypoechoic in relation to the underlying white matter. Beyond 40 weeks of gestation, the overall echogenicity of white matter structures increases markedly, and visualization of deeper structures may become more difficult. On CT, unmyelinated white matter is hypodense relative to cortex and deep central gray matter. On MRI, the high water content of unmyelinated white matter produces marked prolongation of T1 and T2, causing the white matter to be hypointense to gray matter on T1-weighted imaging and hyperintense to gray matter on T2-weighted imaging. This pattern is the inverse of signal intensities of gray and white matter present in the fully myelinated brains of older children and adults (Barkovich, 2000; Barkovich et al, 1988). Because many pathologic processes result in edema, seen as low density on CT studies and resulting in T1 and T2 prolongation on MR images, these lesions are especially difficult to see in the neonatal white matter.

### Intracranial Hemorrhage

Acute intracranial hemorrhage in the neonate may be epidural, subdural, subarachnoid, or parenchymal in loca-

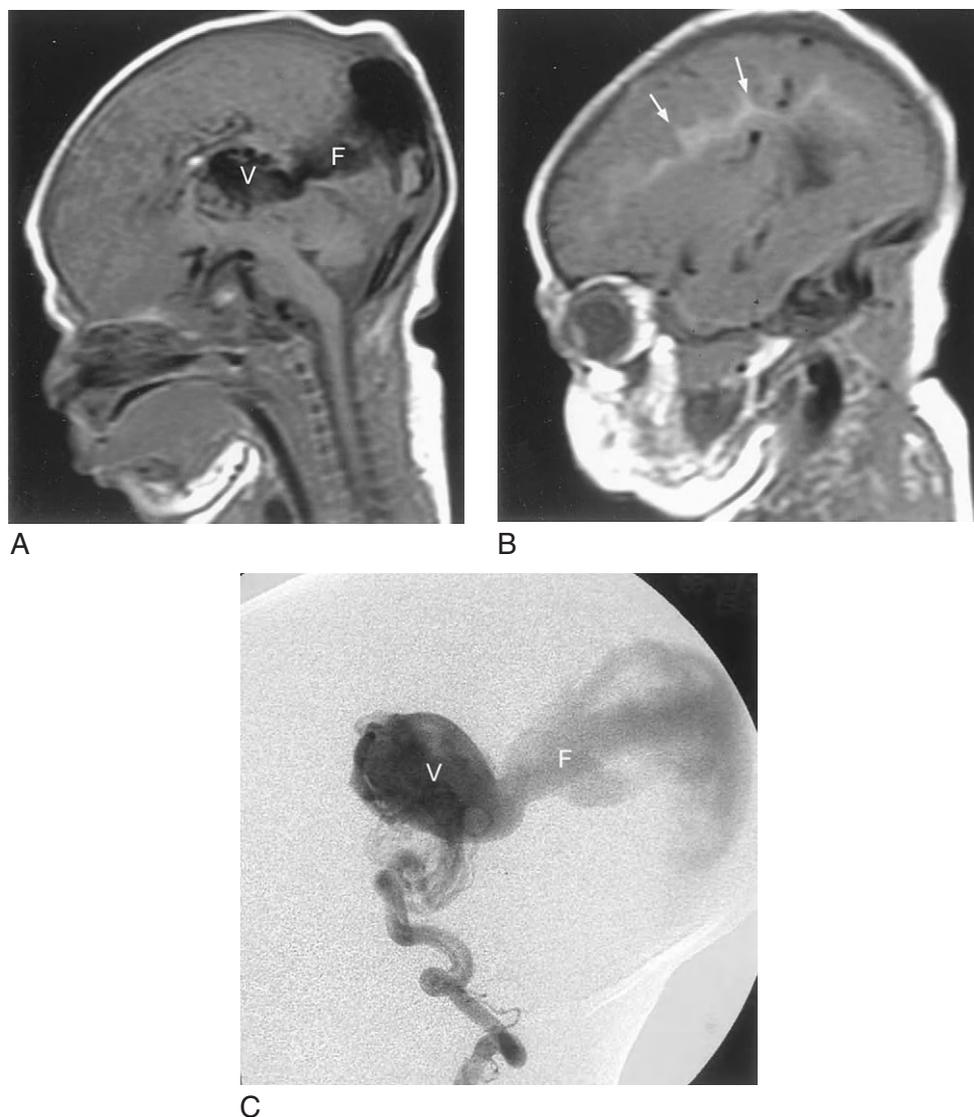

tion. Hemorrhages may be small and noted incidentally on imaging performed for other reasons or may be large and produce acute neurologic symptoms.

Small parturitional subdural hemorrhages are common even in the absence of a traumatic birth history and are often asymptomatic (Holden et al, 1999). Significant subdural hemorrhages are most frequently encountered in the setting of traumatic delivery or accidental trauma. Laceration of the falx cerebri or the tentorium cerebelli may produce large or rapidly expanding subdural hematomas. Larger subdural hematomas may be associated with acute or progressive symptoms of intracranial mass effect.

A small amount of parturitional subarachnoid bleeding is not uncommon. Subarachnoid hemorrhage with larger amounts of bleeding may occasionally occur in conjunction with vascular malformations. The most common symptomatic intracranial vascular malformation in the newborn is the Galenic malformation (Fig. 62–10). Although most newborns with Galenic malformations present with cardiopulmonary distress due to high-output cardiac failure resulting from arteriovenous shunts, massive subarachnoid bleeding may occasionally occur from either spontaneous or iatrogenic perforation of the varix or feeding arteries.

Parenchymal hemorrhage in the preterm infant occurs most often in or around the germinal matrix. Although its pathogenesis is multifactorial (Volpe, 2001), a common final pathway seems to be microscopic perivenular hemorrhage in the highly vascular germinal matrix (Ghazi-Birry et al, 1997). Rupture into the ventricular system frequently occurs. Further enlargement of the hematoma may lead to thrombosis or compression of the terminal veins in the region of residual germinal matrix at the caudothalamic groove (Fig. 62–11). Extension of the venous thrombosis can result in hemorrhagic venous infarction, which can be depicted with color Doppler techniques (Taylor, 1995, 1997).

The classification originally proposed by Papile and colleagues remains the most widely accepted method of grading the severity of intracranial hemorrhage in the preterm infant (Papile et al, 1983). Grade I consists of subependymal hemorrhage only (Fig. 62–12; see also Fig. 62–11). On US, grade I hemorrhages appear as bright echogenic foci in the subependymal area typically located in or anterior to the caudothalamic notch. Grade II is defined as subependymal and intraventricular hemorrhage without ventricular dilatation (Fig. 62–13). Grade III is the combination of subependymal and intraventricular hemorrhage with ventricular dilatation by clot (Fig. 62–14). Small choroid plexus hemorrhages may be difficult to distinguish from a normal “lumpy bumpy” choroid plexus, because both are brightly echogenic. Larger, acute intraventricular clots can be identified as echogenic irregular and asymmetrical masses. Poorly clotted blood will often result in a fluid-debris level within the ventricle that disappears when the baby is repositioned and blood is remixed with CSF. In critically ill premature infants it is important to distinguish progression of a grade II hemorrhage to grade III from the development of post-hemorrhagic hydrocephalus. Both entities are associated with intraventricular clot and dilatation of the ventricular system. However, in grade III hemorrhage, the ventricle is

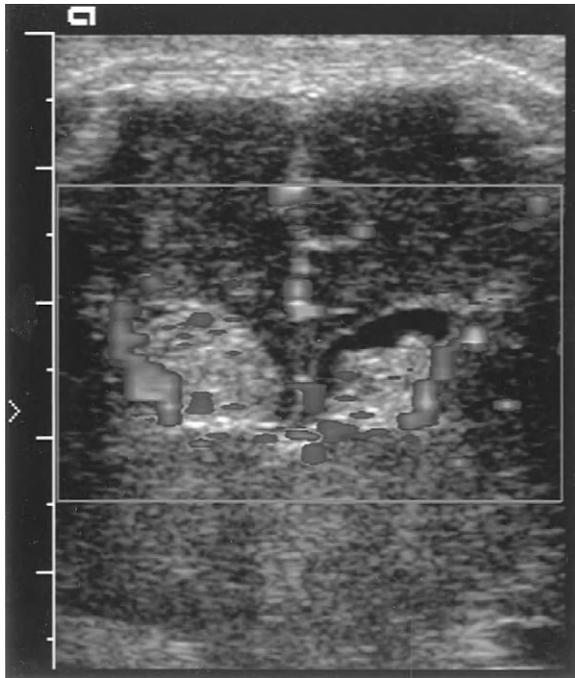

**FIGURE 62-10.** The patient was a neonate with congestive heart failure due to a Galenic arteriovenous malformation (also called vein of Galen aneurysm). **A**, Midline sagittal T1-weighted magnetic resonance (MR) image shows a signal void within the median prosencephalic vein (V), the embryologic precursor to the vein of Galen, and the persistent falcine sinus (F). **B**, Parasagittal T1-weighted MR image shows hyperintensity of the subcortical white matter (*arrows*) due to chronic ischemic injury. **C**, Selective vertebral artery conventional angiogram performed as part of a transcatheter therapeutic procedure shows flow within the varix (V) and draining sinus (F). Note that although the feeding arteries are markedly dilated owing to the massive intracranial flow that is present, all of the blood flow is diverted through the fistulas, and there are no brain parenchymal branches filling. This “steal” phenomenon produces the ischemic changes that can be demonstrated with computed tomography and MR imaging.

almost completely distended by clot, whereas the ventricle in posthemorrhagic hydrocephalus is often primarily distended with CSF. The size of the obstructing intraventricular clot may be relatively small. The distinction is important because ventricular dilatation caused by increasing hemorrhage may have therapeutic implications different from those associated with posthemorrhagic hydrocephalus. Grade IV includes all findings seen in grade III plus intraparenchymal blood. The intraparenchymal hematoma will appear brightly echogenic on US and is often associated with a mass effect on surrounding structures (Fig. 62-15A).

Within 7 to 10 days it will develop a hypoechoic center and echogenic rim. Over time, hematomas further resolve by liquefaction, resulting in cystic lesions of varying sizes (Fig. 62-15B).

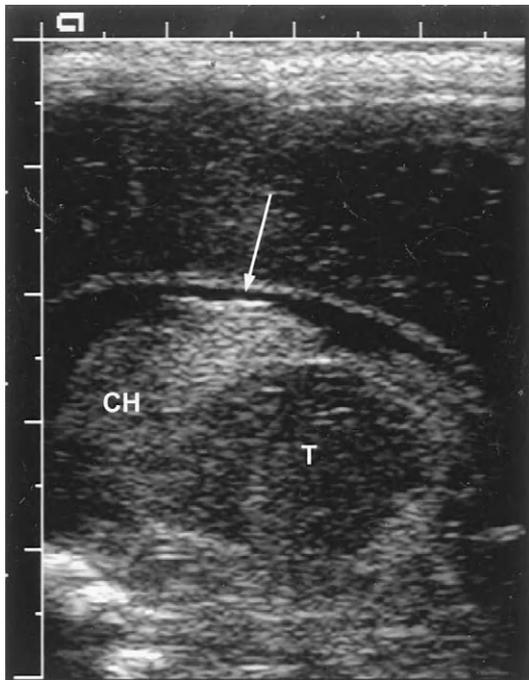

In the term infant, lobar parenchymal and subpial hemorrhages are occasionally encountered (Koenigsberger, 1999) (Fig. 62-16). These hemorrhages appear to occur spontaneously in the first few days of life in otherwise healthy babies.

Color Doppler US may be used to characterize extracerebral fluid collections as subarachnoid, subdural, or

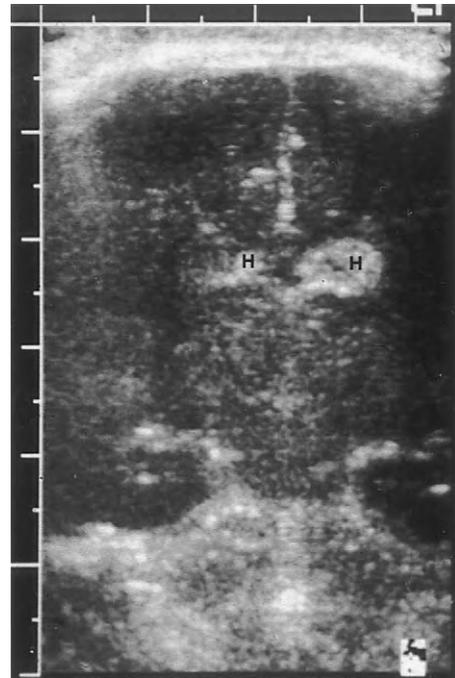

**FIGURE 62-11.** (See also Color Plate 62-11.) Coronal color Doppler image of bilateral grade I germinal matrix hemorrhages. The hemorrhages are echogenic. Although flow is confirmed within the terminal veins (*blue*), the veins are laterally displaced by the subependymal hemorrhages.

combined. Because superficial cortical blood vessels lie within the pia-arachnoid, fluid in this (subarachnoid) space lifts the cortical vessels away from the brain surface, while fluid in the subdural space approximates cortical

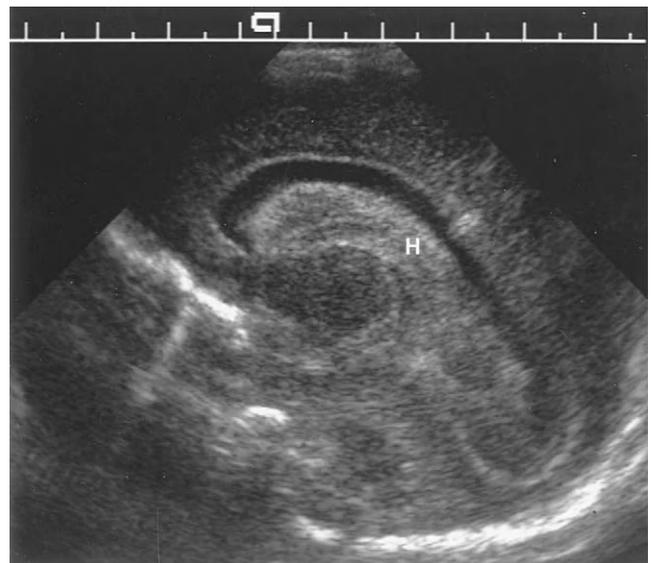

**FIGURE 62-12.** Sagittal ultrasound study of grade I germinal matrix hemorrhage. Echogenic hemorrhage (*arrow*) is seen at the caudothalamic notch situated between the caudate head (CH) anteriorly and the thalamus (T) posteriorly.

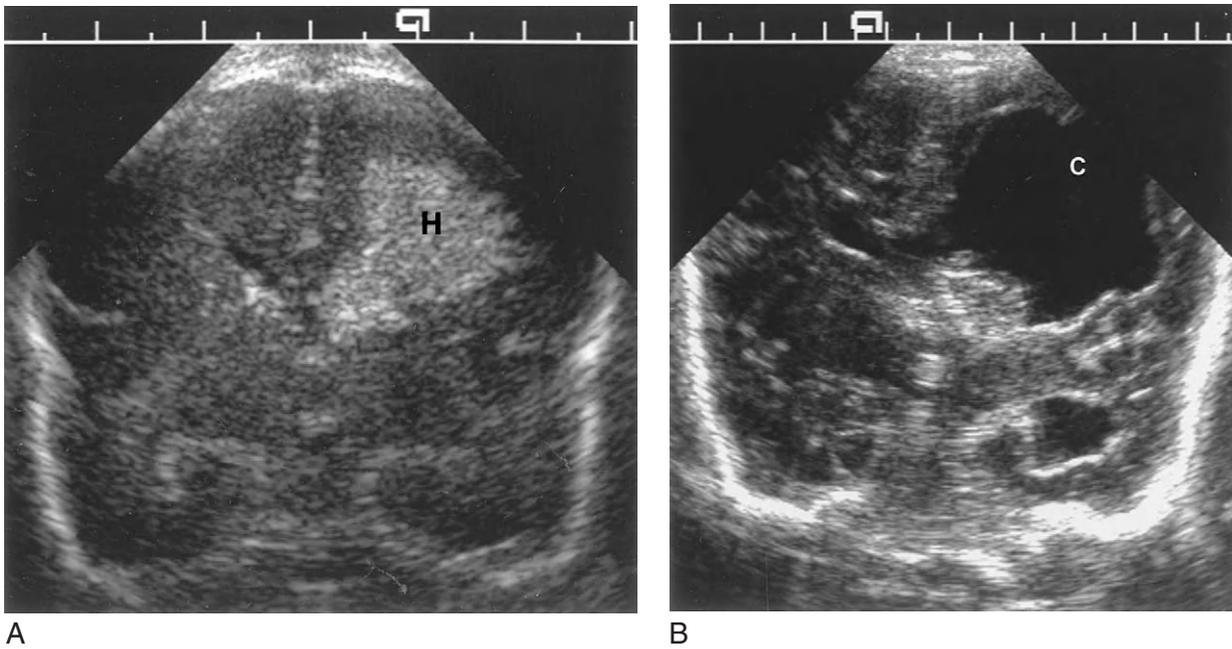

**FIGURE 62-13.** Coronal ultrasound study of bilateral grade II intracranial hemorrhage in the preterm neonate. Echogenic subependymal hemorrhages (H) are seen extending into the lateral ventricles. There is no hydrocephalus.

vessels to the brain surface and is separated from these vessels by a thin membrane (Fig. 62-17). Correlation with MRI and CT suggests that color Doppler is reliable in making this differentiation (Chen et al, 1996).

Suspected intracranial hemorrhage is one of the most common reasons to obtain a brain CT in the neonate. On CT, acute hemorrhage appears hyperdense relative to the brain parenchyma (Fig. 62-18). Of note, the dural venous sinuses and cortical veins appear relatively dense during the

**FIGURE 62-14.** Sagittal ultrasound study of grade III intracranial hemorrhage. The lateral ventricle is moderately dilated and filled with echogenic blood (H).

**FIGURE 62-15.** Coronal ultrasound study of grade IV intracranial hemorrhage. **A**, Initially the parenchymal hemorrhage (H) is echogenic. **B**, As the hematoma ages, liquefaction occurs and the hematoma becomes echolucent with the development of a porencephalic cyst (C).

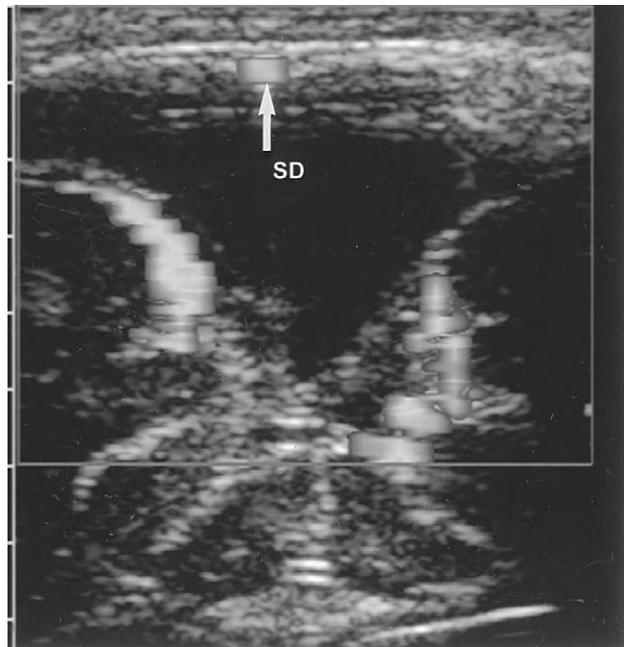

first few days of life owing to high hematocrit levels. This normal density of the venous structures should not be mistaken for subdural bleeding or dural venous sinus thrombosis on CT. As blood ages, the density of the clot will decrease. In the chronic phase, sites of extra-axial or parenchymal hemorrhage have decreased density relative to

the brain parenchyma. Parturitional subdural hemorrhages are typically completely resolved by 6 to 8 weeks of life.

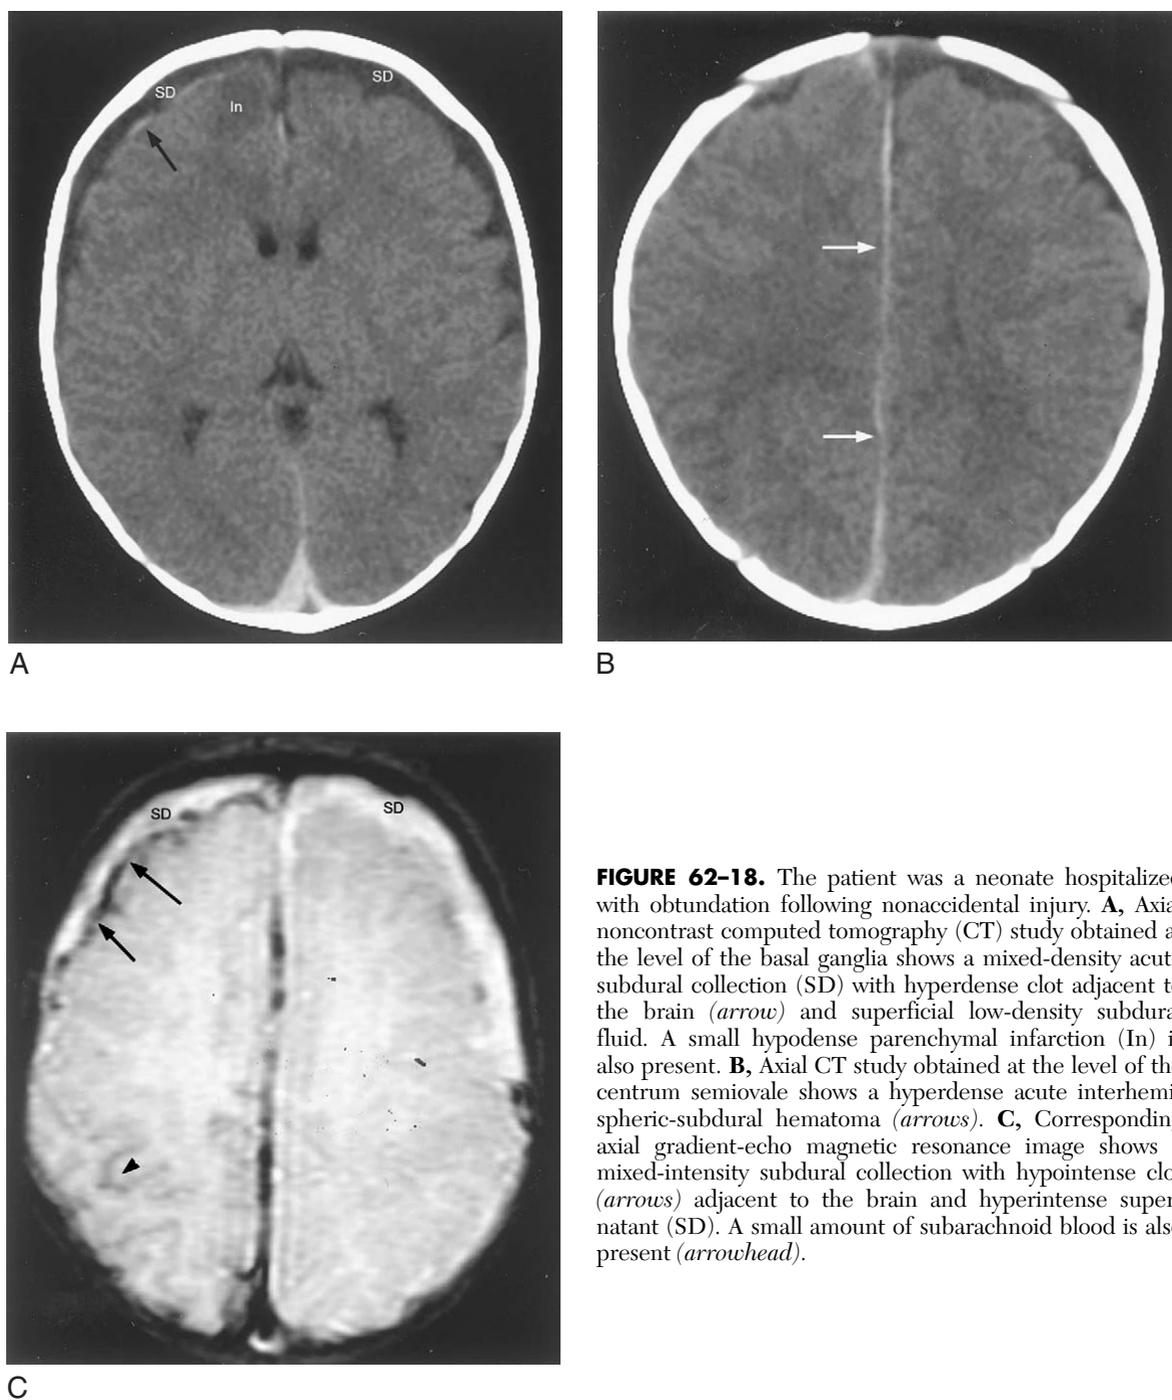

In general, MRI is considered to be less sensitive for the detection of acute intracranial hemorrhage than CT. However, in the newborn, all significant hemorrhages seen on CT are usually demonstrated by MRI (Blankenberg et al, 2000;

**FIGURE 62-16.** The patient was a term neonate with uneventful delivery who developed seizures on the third day of life. Unenhanced brain computed tomography scan shows parenchymal and subpial hemorrhage (*short arrow*) in the left temporal lobe. Surrounding low-density edema is also present (*long arrows*).

**FIGURE 62-17.** (See also Color Plate 62-17.) Coronal color Doppler ultrasound study shows that the vessels (color) are displaced toward the brain parenchyma by the subdural fluid (SD). Note flow in the superior sagittal sinus (*arrow*).

**FIGURE 62-18.** The patient was a neonate hospitalized with obtundation following nonaccidental injury. **A**, Axial noncontrast computed tomography (CT) study obtained at the level of the basal ganglia shows a mixed-density acute subdural collection (SD) with hyperdense clot adjacent to the brain (*arrow*) and superficial low-density subdural fluid. A small hypodense parenchymal infarction (In) is also present. **B**, Axial CT study obtained at the level of the centrum semiovale shows a hyperdense acute interhemispheric-subdural hematoma (*arrows*). **C**, Corresponding axial gradient-echo magnetic resonance image shows a mixed-intensity subdural collection with hypointense clot (*arrows*) adjacent to the brain and hyperintense supernatant (SD). A small amount of subarachnoid blood is also present (*arrowhead*).

Robertson et al, 2003). On MRI, the signal intensity of blood varies with age.

Although the timing for the development of the various stages of hemorrhage in the newborn may differ from that in the adult, the signal intensity changes are similar. With hyperacute hemorrhage, unclotted blood appears similar to free fluid (i.e., low signal intensity on T1-weighted images and high signal intensity on T2-weighted images). Within hours, oxyhemoglobin is converted to deoxyhemoglobin. Deoxyhemoglobin within the red blood cells causes susceptibility artifact that produces low signal intensity on T2-weighted images (see Fig. 62-18). Over

the first several days, deoxyhemoglobin is converted to methemoglobin, which results in high signal intensity on T1-weighted images and low signal intensity on T2-weighted images. Subsequently, the red blood cells lyse, and an increase in signal intensity is observed on the T2-weighted images. Chronically, hemosiderin staining occurs, which appears dark on both T1-weighted and T2-weighted images.

The administration of contrast agent is not usually required in the MR investigation of hemorrhage, except in the rare case of suspected underlying tumor. When tumor is present, it is imperative that spinal imaging also

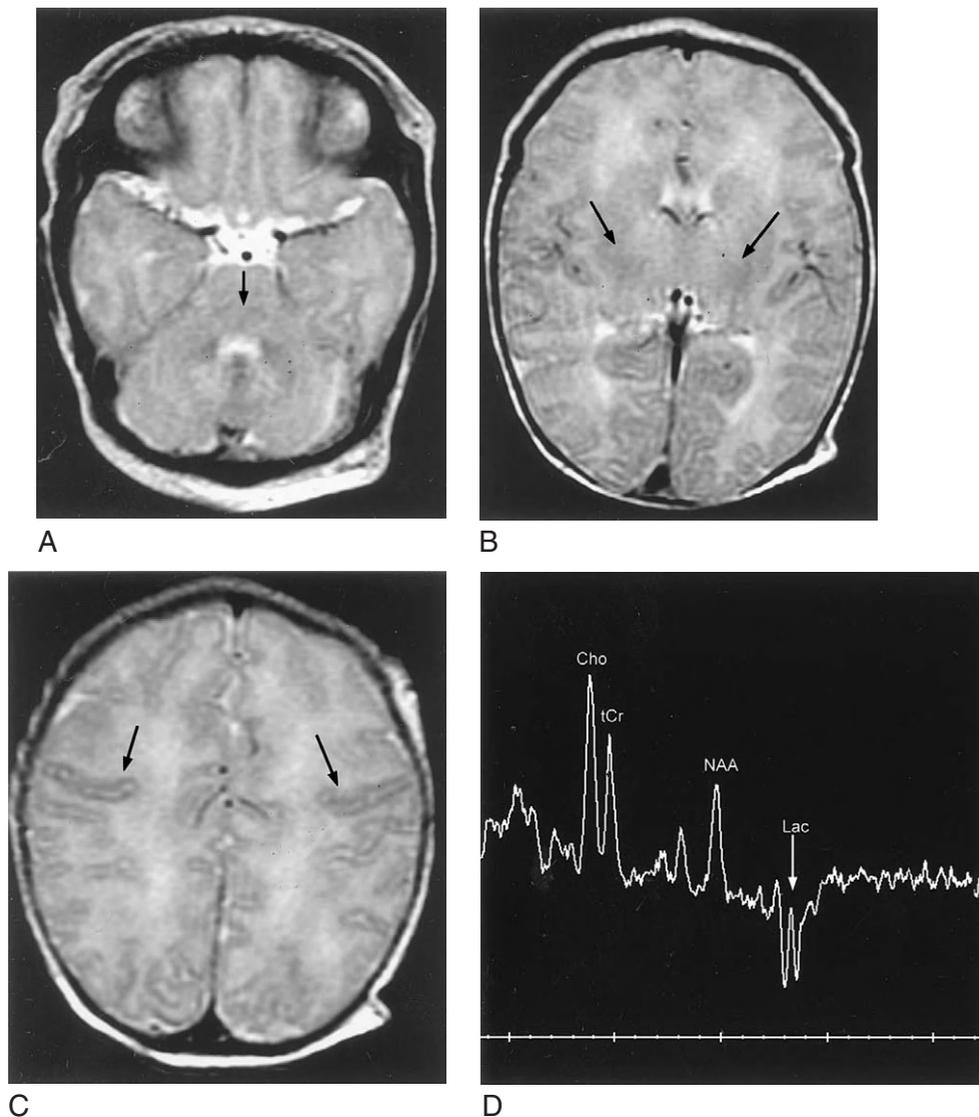

be performed because most brain tumors discovered in the newborn period have a propensity to seed the CSF.

### Neonatal Cerebral Infarction

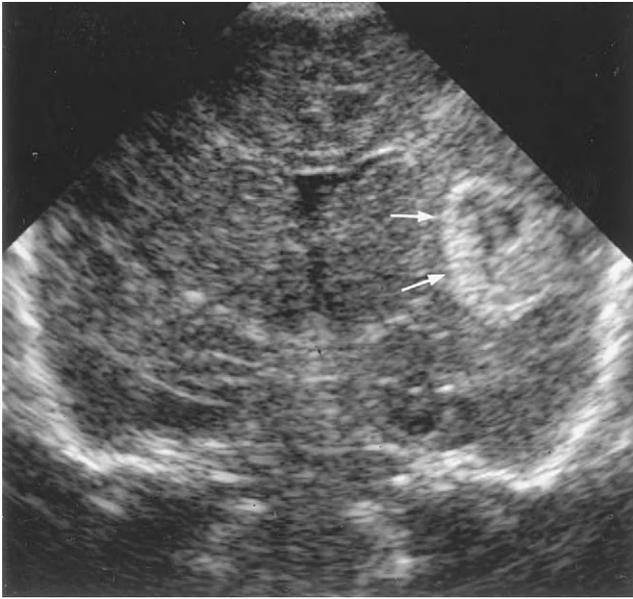

Neonatal cerebral infarction is a common cause of infant morbidity and mortality (Rivkin, 1997; Volpe, 2001). Infarctions in the newborn may be due to global transient decreases in blood flow or in oxygen delivery to the brain (hypoxic-ischemic injury) (Fig. 62–19) or to focal arterial or venous occlusions (Figs. 62–20, 62–21, and 62–22).

Hypoxia-ischemia tends to produce bilaterally symmetrical lesions, whereas arterial or venous occlusions are associated with focal or asymmetrical multifocal areas of infarction. A variety of imaging appearances of infarction may be observed at a given postnatal age, and lack of specificity in the clinical presentation may further complicate the interpretation of the imaging (Robertson and Robson, 2001).

In the term infant, the vascular border-zone territories are in a parasagittal location, anteriorly between the major branches of the anterior and middle cerebral arteries and posteriorly between the branches of the anterior, middle, and posterior cerebral arteries. In our experience,

**FIGURE 62-19.** Magnetic resonance images obtained at 24 hours of life in a neonate with profound hypoxic-ischemic brain injury. Compare with normal T2-weighted and diffusion images (see Figs. 62–6 and 62–7). **A, B, C,** T2-weighted images demonstrate edema with loss of normal hypointensity (*arrows*) in the dorsal pons (*arrow*) (**A**), the lateral thalami and internal capsule (*arrows*) (**B**), and perirolandic cortex (*arrows*) (**C**). **D,** Single-voxel spectroscopy obtained from the left basal ganglia demonstrates a prominent lactate doublet (Lac). The peaks project below the baseline because of the echo time used (TE = 144 ms). Cho, choline; NAA, N-acetyl aspartate; tCr, total creatine.

**FIGURE 62-20.** Coronal ultrasound image shows an echogenic left middle cerebral artery distribution infarction (*arrows*).

border-zone ischemic injury in the term neonate most often occurs in conjunction with deep central gray and white matter injury in cases of profound hypoxia-ischemia.

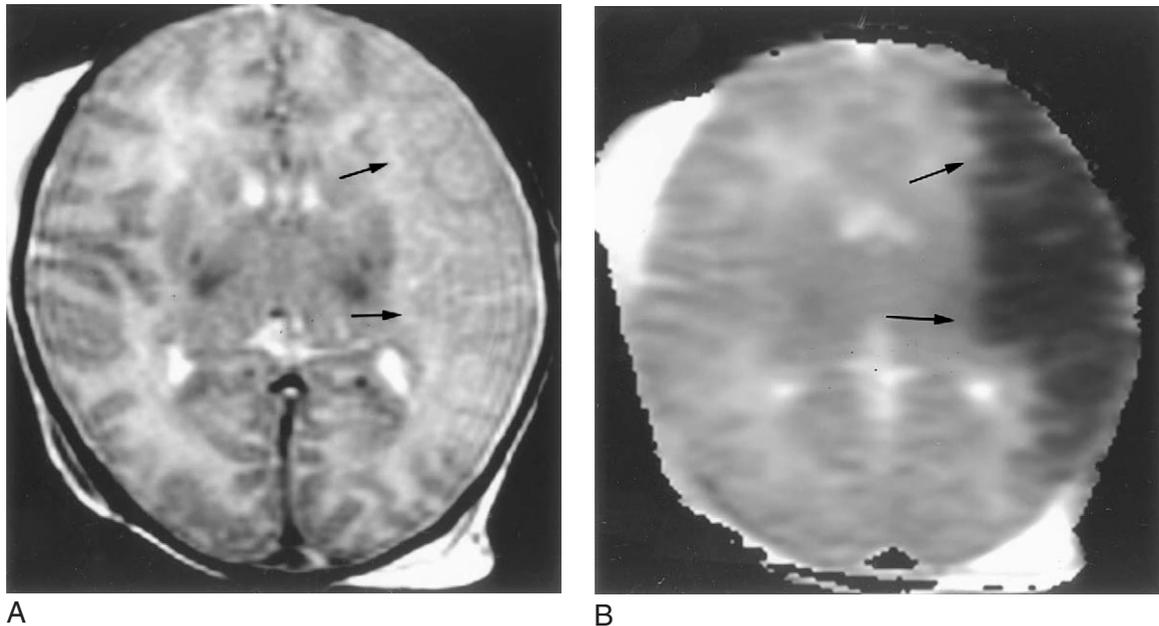

Profound hypoxia-ischemia in the preterm or term infant tends to affect those regions of the brain with the greatest metabolic requirements. These include areas with high concentrations of excitatory neurotransmitters or regions that are actively myelinating (Rivkin, 1997; Volpe, 1997). The dorsal brainstem, thalami, posterior portions of basal gan-

glia, posterior limb of internal capsule, corona radiata, and mesial temporal lobes are especially susceptible to injury (see Fig. 62-19). The medial portions of the cerebellar hemispheres and cerebellar vermis are also commonly affected. Areas of the brain with lower energy requirements, such as unmyelinated white matter and cortex tend to be relatively spared unless the ischemia is particularly severe. Following severe hypoxia-ischemia, the pattern of tissue injury is variable. In some infants, a deep central gray matter distribution of injury with relative preservation of the cortex and subcortical white matter is present (Roland et al, 1998). In other infants, there is widespread necrosis, ultimately producing a pattern of cystic encephalomalacia. The deep central pattern of injury is associated with a variable outcome, whereas widespread encephalomalacia more consistently portends a poor prognosis.

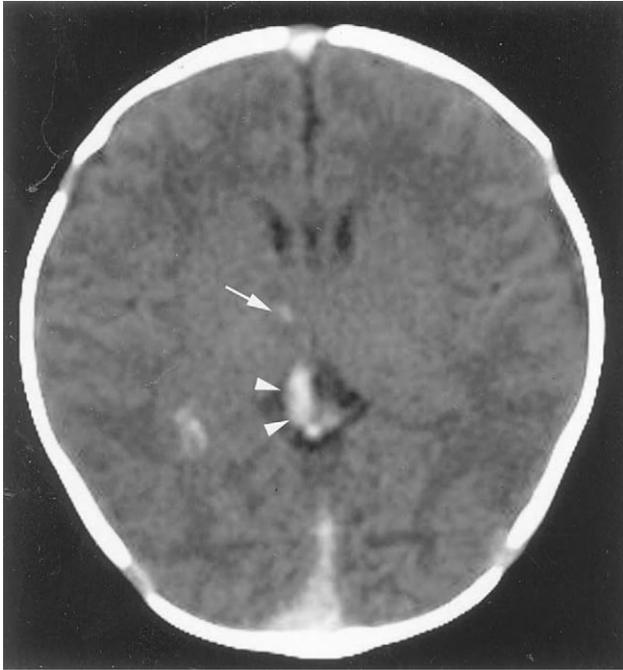

On cranial US, ischemic areas of thalamus and basal ganglia may appear focally or diffusely echogenic. US findings may be quite variable in time of onset and are insensitive to the extent of injury compared to CT or MRI.

In the first few hours following hypoxia-ischemia, brain CT findings are usually normal. Depending on the severity of the insult, changes may begin to be apparent in 24 to 48 hours. In severe hypoxia-ischemia, the thalami and basal ganglia develop low density. The cortical ribbon may become indistinct or even indistinguishable from the subcortical white matter. A subset of babies with hypoxia-ischemia will develop mineralization and hypermyelination in the deep gray matter structures, producing hyperdensity in these structures, an appearance termed *status marmoratus*.

Although there is considerable variability in the MR appearance of hypoxia-ischemia, some general trends may be observed (Johnson et al, 1999; Robertson et al, 1999; Rutherford et al, 1995; Wolf et al, 2001). By 15 to 18 hours

**FIGURE 62-21.** Magnetic resonance imaging of a focal left middle cerebral artery infarction in a 24-hour-old neonate. **A**, Axial T2-weighted image shows edema and loss of the cortical ribbon in the left middle cerebral artery territory (*arrows*). **B**, Apparent diffusion coefficient (ADC) map shows very restricted diffusion (hypointensity) in the area of infarction (*arrows*).

**FIGURE 62-22.** The patient was a newborn with sagittal sinus, straight sinus, and right internal cerebral vein thrombosis and right thalamic hemorrhagic venous infarction. An axial, non-contrast-enhanced CT scan shows high-density clot (*arrowheads*) in the right internal cerebral vein and a small hemorrhagic infarction (*arrow*) in the right thalamus.

following the ischemic event, the diffusion-weighted imaging is often normal. At this time, T1- and T2-weighted sequences typically also fail to show any abnormality. Progressively over the next 24 to 48 hours, restricted diffusion develops within the regions of the brain with the highest metabolic requirements (Robertson and Robson, 2001). During this time, the T1- and T2-weighted images also become abnormal (Barkovich et al, 1995). Toward the end of the first week, it is not uncommon to demonstrate restricted diffusion in the subcortical white matter in areas that on early examinations showed normal or even increased diffusion (Robertson et al, 1999). These white matter regions typically show hyperintensity on T2-weighted sequences in advance of the development of restricted diffusion. By 10 to 14 days, the diffusion abnormalities typically normalize, and ultimately, increased diffusion may be present. Chronically, T1-weighted and T2-weighted sequences show areas of signal abnormalities related to gliosis, mineralization, or hypermyelination associated with variable tissue loss.

MRS also has been used to evaluate neonates with hypoxia-ischemia (Barkovich et al, 1999; Cady, 2001; Groenendaal et al, 2001). The observed changes on MRS in newborns with hypoxia-ischemia include the presence of lactate, indicating energy failure, and a decrease in NAA, suggesting decreased neuronal density or activity (see Fig. 62-19). The demonstration of lactate requires the use of a long echo sequence (e.g., echo time [TE] of 135 msec or 270 msec). On the 135- msec TE acquisition, lactate is seen as a doublet peak projecting below the baseline at 1.3 ppm (lactate peaks project above the baseline at the

270-msec TE). Lactate is evident within the first few hours following onset of hypoxia-ischemia. The amount of lactate slowly diminishes over the ensuing several days. Occasionally, elevation of lactate levels will recur several weeks after the insult (Hanrahan et al, 1998). The etiology of this delayed appearance of lactate is uncertain, but it may be due to the production of lactate by macrophages moving into the area of infarction as part of the reparative process. Studies have shown that the presence of lactate within the basal ganglia or as a delayed finding is associated with an abnormal neurologic outcome at 1 year of age (Barkovich et al, 1999; Hanrahan et al, 1998).

Focal infarctions most often occur in a middle cerebral artery distribution (de Vries et al, 1997, 1999; Sreenan et al, 2000) (see Figs. 62-20 and 62-21). Focal infarcts may be small and involve the cortex only, or they may involve the subcortical white matter and basal ganglia. Infarcts that are confined to the cortex tend to carry a relatively good prognosis. Lesions also involving the internal capsule and basal ganglia are usually associated with a persistent hemiparesis (de Vries et al, 1999; Mercuri et al, 1999).

Sonographically, focal infarcts initially manifest as geographic areas of increased echogenicity, followed by progressively increased echogenicity and loss of gyral and sulcal definition (see Fig. 62-20). Mass effect and effacement of the ventricular system are often present. Initially there is diminished flow demonstrated on duplex and color Doppler US. Over time, increased flow in the surrounding tissues consistent with “luxury perfusion” can be seen on color Doppler US (Fig. 62-23) (Hernanz-Schulman et al, 1988; Taylor, 1994).

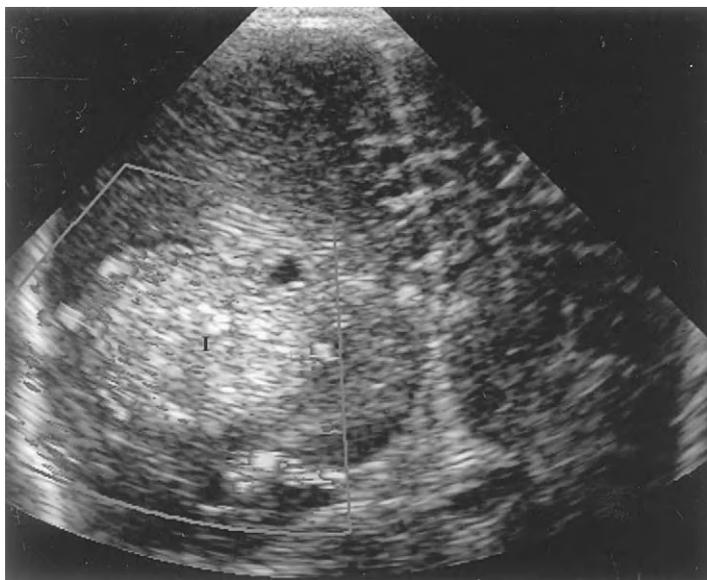

On CT, focal infarcts appear as localized regions of hypodensity with loss of the cortical ribbon. Hemorrhagic conversion of an arterial infarction in the newborn is uncommon.

On MRI, focal infarcts are seen as regions of low signal intensity on T1-weighted sequences and high signal intensity on T2-weighted sequences (see Fig. 62-21). Signal alterations occur earlier and more consistently on both diffusion and conventional MRI in focal infarctions than in hypoxia-ischemia (Robertson et al, 1999).

Unlike imaging in hypoxia-ischemia, even on the first day of life, the diffusion and the conventional imaging will typically demonstrate focal infarctions (Robertson et al, 1999). Also unlike hypoxia-ischemia, focal infarctions in the neonate do not usually show an increase in extent on follow-up imaging. The diffusion abnormality tends to normalize by 10 to 14 days. Atrophic changes are generally apparent on follow-up T1- and T2-weighted images; however, the degree of accompanying gliosis is variable. At times, chronic infarcts may appear simply as focally prominent sulci.

### Periventricular Leukomalacia

In the premature infant, periventricular leukomalacia (PVL) is the most common form of hypoxic-ischemic brain injury (Inder et al, 1999; Volpe, 1997). PVL is characterized by focal necrotic lesions in the periventricular white matter, optic radiations, and acoustic radiations and less prominent, more diffuse cerebral white matter injury.

**FIGURE 62-23.** (See also Color Plate 62-23.) The patient was a neonate with a focal right occipital infarction with surrounding “luxury perfusion.” A coronal ultrasound image obtained through the anterior fontanel shows a hyperechoic right occipital infarction (I) surrounded by increased flow on color Doppler examination.

In the premature infant, these sites have in common their location in vascular border zones, lying between the long penetrating branches of the middle, anterior, and posterior cerebral arteries that pierce the cortex from the pial surface and the basal penetrating vasculature (e.g., lenticulostriate and choroidal vessels) (Shuman and Selednik, 1980; Volpe, 2001). As the fetus or infant approaches term, there is a gradual shift in these border zone territories toward a parasagittal location. Neuropathologically, PVL is characterized in the acute phase by coagulation necrosis and neuroaxonal swelling (Volpe, 2001). A variable amount of hemorrhage may be present. In the subacute stage, cysts may form in the larger lesions. Ultimately, astrogliosis develops and the cysts become less apparent.

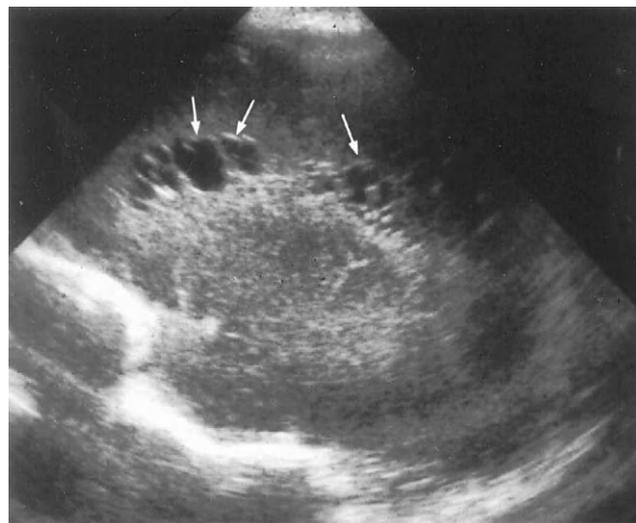

The US appearance of the brain may be normal within the first 2 weeks after the inciting ischemic event. After 10 to 14 days, the echogenicity of affected areas of deep white matter increases. These areas of abnormality may be focal or diffuse, symmetrical or asymmetrical. They are typically located along the trigones of the lateral ventricles but can involve extensive areas of white matter. The differentiation between ischemic and hemorrhagic lesions may be difficult. However, PVL is seldom associated with mass effect and displacement of surrounding structures. Cystic encephalomalacia appears in the areas of increased echogenicity within 2 to 3 weeks after the initial insult (Fig. 62-24). These are characterized by cysts ranging between 1 mm and 2 to 3 centimeters in size. They may be single or multiple and may occasionally communicate with the ventricular system. Focal or hemispheric atrophy is the final stage of PVL and is characterized by dilatation of the ipsilateral ventricle and prominence of the sulci and interhemispheric fissure (Schellinger et al, 1984).

Ischemic white matter lesions, including those due to PVL, are difficult to detect in the neonate using either CT or MRI owing to the inherent high water content of unmyelinated white matter. On CT, even relatively large cysts may be inapparent. Occasionally, the cystic areas may appear slightly more lucent (hypodense) than the surrounding parenchyma. Acute hemorrhagic lesions are

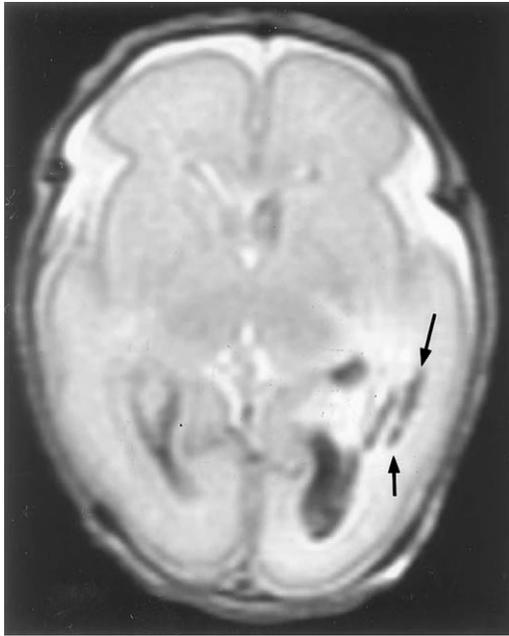

hyperdense. The cystic phase of PVL is also difficult to identify on MRI, as the cysts are characterized by long T1 (hypointensity) and long T2 (hyperintensity), similar to normal unmyelinated white matter. Hemorrhagic lesions appear as foci of hyperintensity on T1-weighted sequences and hypointensity on T2-weighted sequences (Fig. 62-25). To date, there has been little published about the DI appearance of PVL; however, PVL has been reported to show restricted diffusion in the acute phase (Inder et al, 1999).

### Congenital Malformations

Although use of cranial sonography is limited by the availability of an acoustic window, many structural anomalies

**FIGURE 62-24.** Sagittal ultrasound image of cystic periventricular leukomalacia demonstrates multiple echolucent periventricular cysts (arrows) involving the frontal, parietal, and occipital white matter.

**FIGURE 62-25.** Axial T2-weighted magnetic resonance image from a 26-week-gestation premature infant. Hemorrhagic PVL is indicated by periventricular hypointensity (*arrows*). Intraventricular hypointense hemorrhage is also present in this neonate.

of the brain can be well characterized by this portable technique, especially in the unstable neonate. However, for most congenital anomalies, MRI has become the most definitive imaging examination (Barkovich, 1988). The multiplanar capability and inherent high tissue contrast of MRI make it superior to CT for the delineation of most congenital malformations. Additionally, unlike CT, MR images are not degraded by artifact from bone. Therefore, MRI is able to provide a detailed evaluation of the regions of the supratentorial brain near the skull base and the posterior fossa.

For most congenital brain malformations, standard T1-weighted and T2-weighted images are sufficient to characterize the anomaly with MRI. Multiplanar conventional imaging is usually all that is required to characterize disorders of structural development including the holoprosencephaly spectrum, malformations of the corpus callosum, leptomeningeal malformations, and posterior fossa malformations (Dodge and Dobyns, 1995; Lena et al, 1995; Rubinstein et al, 1996; Smith et al, 1996) (see Fig. 62-9). The intracranial findings associated with the most common anomaly of neural tube closure, the Chiari II malformation, also can be documented with multiplanar T1-weighted and T2-weighted MRI using a standard head coil. Intravenous contrast is not usually required for the MR evaluation of congenital brain anomalies.

Although CT is not considered the imaging modality of choice for most congenital brain malformations, it may be used to assess bone integrity and to search for parenchymal calcifications. CT is useful in the assessment of scalp lesions and for calvarial or skull base defects in the setting of certain intracranial lesions such as cephaloceles and dermoids (Ruge et al, 1988). Sutural synostosis, although

rarely presenting in the newborn, is best assessed with three-dimensional (3D) CT. Cutis aplasia may require CT evaluation to determine the extent of underlying bone deficiency (Madsen et al, 1998).

High-resolution CT is useful for anatomic delineation of facial and temporal bone lesions (Vanzielegheem et al, 2001). Choanal atresia, especially if bilateral, may require urgent CT assessment. Nasal pits or dermoids are typically evaluated using a combination of high-resolution CT for bone detail and MRI for soft tissue extent of the lesion (Lusk and Lee, 1986). Most temporal bone anomalies do not require intervention during the neonatal period; therefore, CT studies are usually deferred until later in infancy.

### Vascular Malformations

Vascular malformations are classified on the basis of hemodynamics as high-flow or low-flow anomalies (Meyer et al, 1991). High-flow lesions include arteriovenous fistula (AVF), with direct, macroscopic connections between arteries and veins, and arteriovenous malformation (AVM), with a meshwork of dysplastic vessels termed a “nidus” interposed between the supplying artery and draining vein. Low-flow vascular malformations include cavernous malformation, developmental venous anomaly (DVA), and capillary telangiectasia. Both high- and low-flow intracranial vascular malformations may be present in the newborn; however, it is typically the high-flow lesions that are likely to be symptomatic during the neonatal period.

Many high-flow vascular malformations are now diagnosed in utero using fetal US or MRI. A majority of high-flow vascular malformations manifest in the neonate with symptoms related to high-output cardiac failure (Lasjaunias et al, 1986, 1989). CT and postnatal MRI are not typically required to diagnose the presence of the malformation but may provide useful information with respect to prognosis. In high-flow lesions, blood flow is diverted away from the brain parenchyma and through the shunt(s), so that ischemic brain injury may result (see Fig. 62-10).

The presence of encephalomalacia and parenchymal calcification on CT indicates chronic ischemic injury and is associated with a poor neurologic outcome (Brunelle, 1997). CT angiography (CTA) and CT venography (CTV) may occasionally be performed to characterize the arterial supply and size of shunts prior to intervention.

MRI is performed less frequently than CT in neonates with high-flow vascular anomalies because of the hemodynamic instability of many of the infants. MRI will show changes similar to those seen with CT including parenchymal ischemic changes (see Fig. 62-10B). MRA/MRV can be used in a similar fashion to that for CTA/CTV to characterize the vascular anomaly. However, MRA/MRV is prone to signal loss related to turbulent flow and may therefore be less reliable than CTA/CTV in high-flow lesions.

Conventional catheter angiography is usually performed as a part of a planned endovascular approach to therapy. Subselective vascular injections are used to

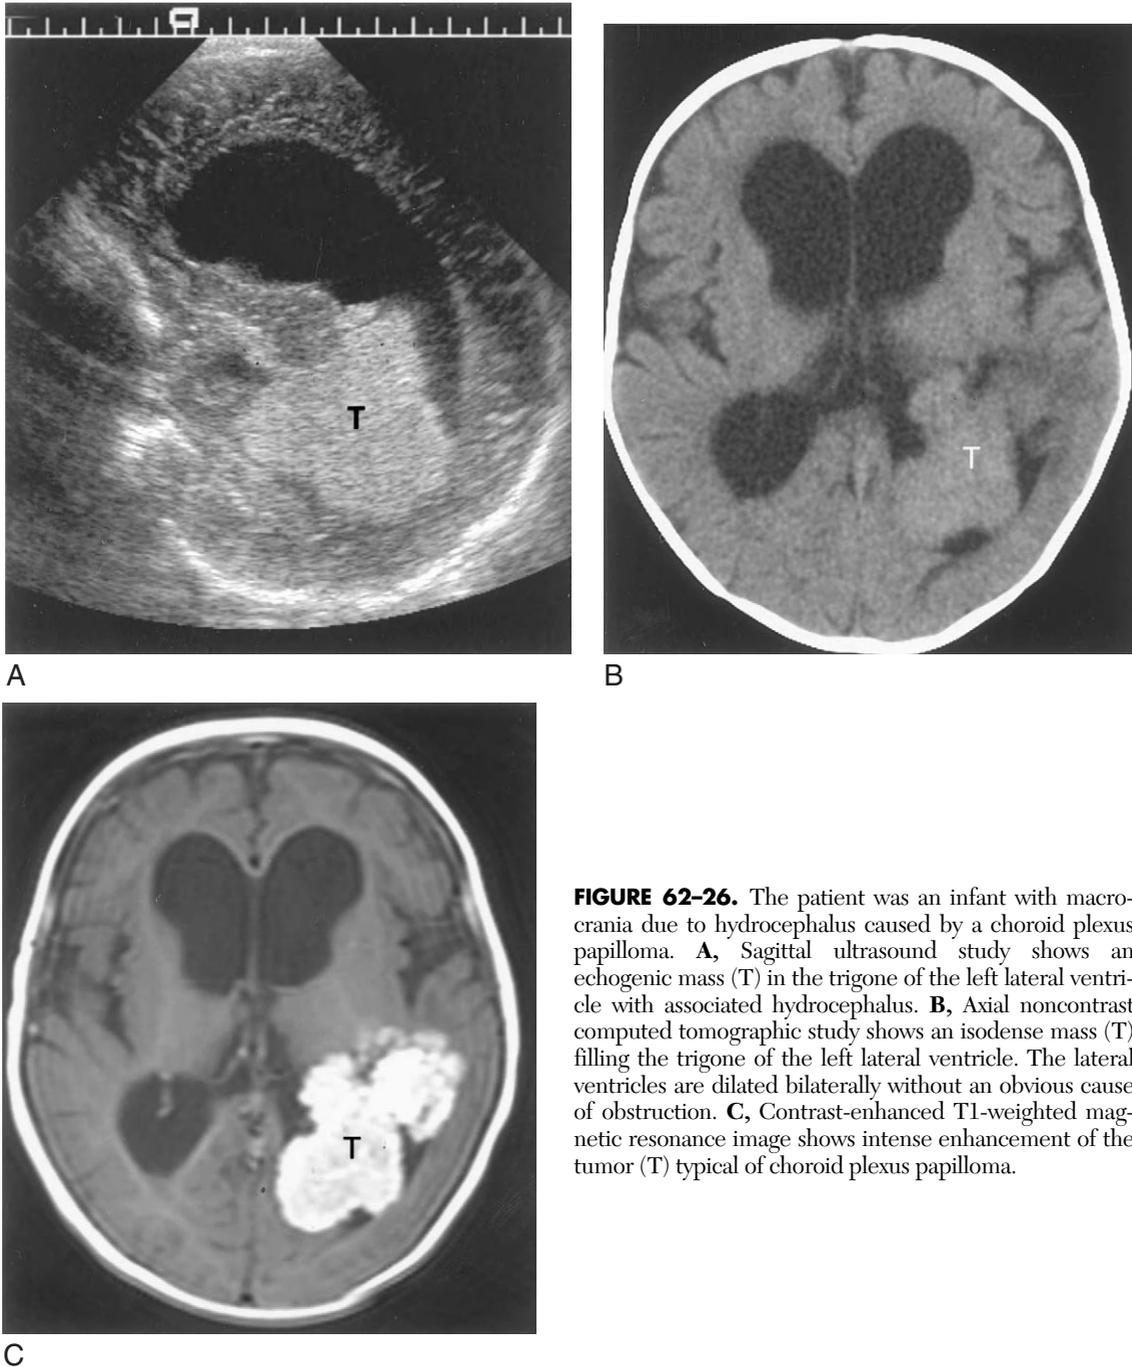

carefully define the anatomy of the arteriovenous shunts. The choice of embolic material employed depends on the nature and location of the shunts. Sonography with color and duplex Doppler techniques may be used as an adjunct to monitor changing cerebral hemodynamics and complications during endovascular procedures.

Low-flow intracranial vascular anomalies are occasionally encountered as incidental findings on brain CT and MRI in the newborn. Hemorrhage due to low-flow vascular anomalies is exceedingly rare in the neonate.

### Hydrocephalus

Hydrocephalus is one of the most common reasons to perform brain imaging in the newborn. Hydrocephalus is nearly always due to an obstruction of CSF resorption. The blockage may occur within the ventricles or in the extracerebral CSF spaces. Hydrocephalus due to the overproduction of CSF is exceedingly rare but may occasionally occur with choroid plexus papilloma (Fig. 62-26).

Hydrocephalus may be either congenital or acquired. Congenital causes of hydrocephalus include Chiari II malformation, aqueductal stenosis, encephalocele, universal

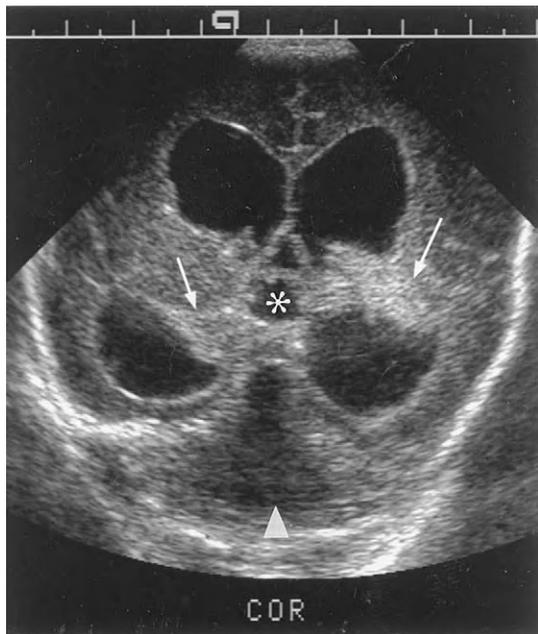

**FIGURE 62-26.** The patient was an infant with macrocrania due to hydrocephalus caused by a choroid plexus papilloma. **A**, Sagittal ultrasound study shows an echogenic mass (T) in the trigone of the left lateral ventricle with associated hydrocephalus. **B**, Axial noncontrast computed tomographic study shows an isodense mass (T) filling the trigone of the left lateral ventricle. The lateral ventricles are dilated bilaterally without an obvious cause of obstruction. **C**, Contrast-enhanced T1-weighted magnetic resonance image shows intense enhancement of the tumor (T) typical of choroid plexus papilloma.

craniosynostosis, and skull base dysplasia with jugular venous stenosis as in Crouzon syndrome (McLone and Naidich, 1992; Naidich et al, 1992; Robson et al, 2000). Acquired hydrocephalus may be due to hemorrhage, infection, mass effect from tumor, or venous hypertension (Brann et al, 1990; Hedlund and Boyer, 1999; Lasjaunias et al, 1989).

Sonography plays an important role in the evaluation of posthemorrhagic hydrocephalus (Fig. 62–27). The goals of the US examination are to determine the presence and severity of ventricular dilatation, to identify the location and cause of obstruction (ependymitis versus clot), to monitor the adequacy of treatment, and to identify potential complications of therapy. The evaluation of the ventricular system in the neonate should include standardized measurements of the lateral ventricles. Although the atria dilate early in the course of ventriculomegaly, measurements of the lateral ventricles on parasagittal images are the most variable in clinical practice (Shackleford, 1986). We use the maximal width of the frontal horns measured at the level of the foramen of Monro to follow ventricular size. This measurement was chosen because it uses reproducible landmarks that are not affected by angulation of the transducer and provide independent measures of each lateral ventricle. In our experience, it provides the most useful measurement in monitoring change in ventricular size.

In general, dilatation tends to be greatest in the ventricle just proximal to the point of obstruction to flow.

**FIGURE 62-27.** Coronal ultrasound study of posthemorrhagic hydrocephalus obtained through the anterior fontanel. Adherent, nondependent echogenic clot (*arrows*) is present within the dilated lateral ventricles. The absence of positional change in location of the echogenic material helps to differentiate blood clot from debris in ventriculitis. Note the dilated third ventricle (\*) and fourth ventricle (*arrowhead*).

For example, the normal aqueduct of Sylvius is a narrow passage and often not clearly visible on US. It typically does not become distended by clot. However, when an obstruction to CSF flow exists at the level of the fourth ventricle or beyond, the aqueduct may become markedly distended and is then easily depicted (Taylor, 2001) (Fig. 62–28). Early detection of a dilated fourth ventricle may have important therapeutic implications, especially when accompanied by clot or absence of CSF in the cisterna magna. This combination of findings strongly suggests the presence of a blockage to CSF flow into the spinal subarachnoid space (Hall et al, 1992) and the probable failure of serial lumbar punctures as a therapeutic option.

As the intracranial pressure (ICP) rises, arterial flow tends to be more affected during diastole than during systole, resulting in an elevated pulsatility of flow. Seibert and colleagues (1989) have shown that increasing resistive index (RI) on pulsed Doppler interrogation correlates well with elevation in ICP in an animal model of acute hydrocephalus. They and others also have shown a significant drop in pulsatility following ventricular tapping and shunting in infants with hydrocephalus (Bada et al, 1982). However, elevated ICP may not always be present in infants with ventricular dilatation, and the RI may be well within the normal range. Doppler examination of the anterior or middle cerebral artery during fontanel compression may be useful in the early identification of infants with abnormal intracranial compliance prior to the development of increased ICP as shown by elevated baseline RI (Taylor et al, 1994). According to the Monro-Kellie hypothesis, the volume of brain, CSF, blood, and other intracranial components is constant (Bruce et al, 1977). During graded fontanel compression in normal infants, CSF or blood can be readily displaced in order to compensate for the small

**FIGURE 62-28.** Axial ultrasound image from an infant with posthemorrhagic hydrocephalus. Due to obstructing clot at the level of the aqueduct of Sylvius (*arrow*), the lateral ventricles and upper aqueduct are distended.

increase in volume delivered by compression of the anterior fontanel, resulting in no increase in ICP. In infants with hydrocephalus however, the increase in intracranial volume with fontanel compression is translated into a transient increase in ICP and an acute increase in arterial pulsatility (Fig. 62–29). Serial examinations using this technique can also be used to follow an individual infant's ability to compensate for minor changes in intracranial volume and thus serve as a non-invasive indirect measure of intracranial compliance (Taylor and Madsen, 1996).

In our experience, transient (3 to 5 seconds) fontanel compression is a safe and well-tolerated procedure, even in critically ill premature infants. However, prolonged compression of the fontanel should be avoided. Pressure should be immediately released if heart rate significantly decreases during Doppler examination. In addition, the presence of reversed flow during diastole in a Doppler study obtained without fontanel compression is strongly suggestive of elevated ICP, and fontanel compression is not necessary or recommended in these patients.

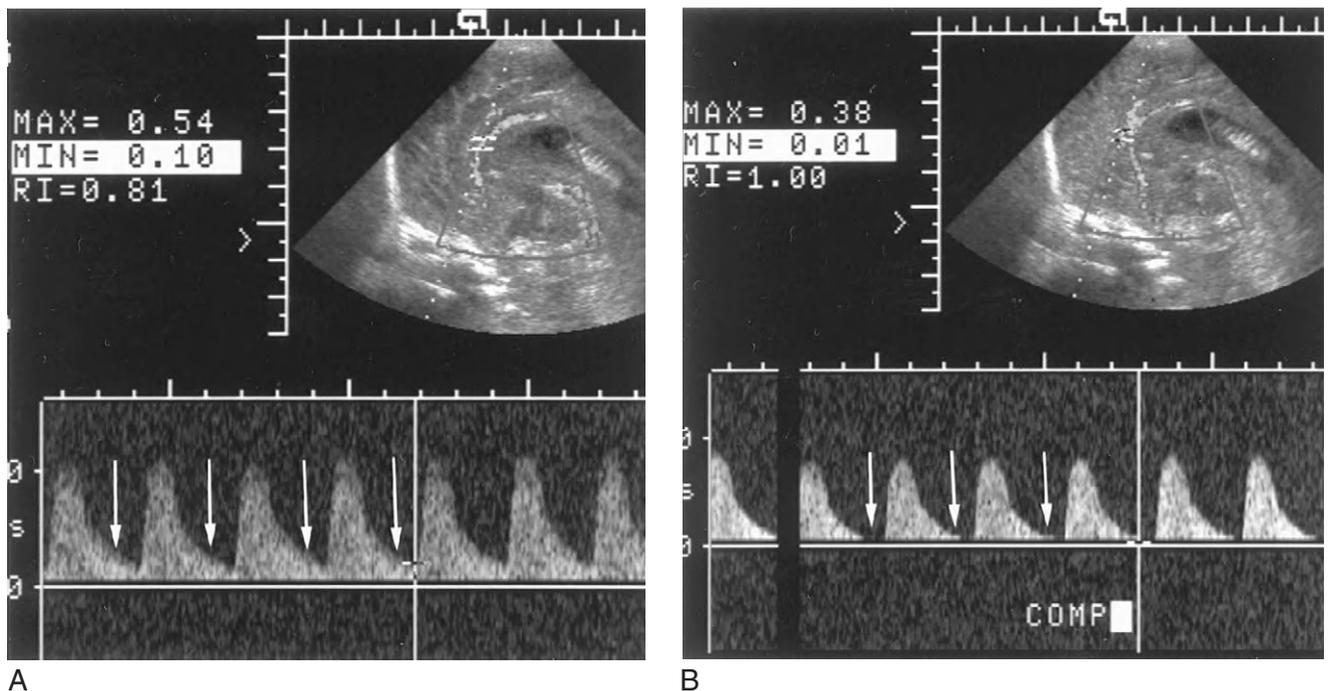

Imaging of hydrocephalus is carried out prior to shunting to determine the cause of ventricular dilatation, to identify the site of obstruction, and to differentiate hydrocephalus from other intracranial abnormalities, such as holoprosencephaly and hydranencephaly, that may mimic severe hydrocephalus. Following shunt placement, imaging is carried out to evaluate ventricular decompression and shunt position, and to assess for the presence of surgical complications and for the development of extra-axial collections.

MRI is the preferred examination for preoperative assessment of hydrocephalus. Thin-section T1- or T2-weighted images are useful in demonstrating stenosis of the aqueduct of Sylvius. On MRI, the findings in aqueductal stenosis include loss of the normal signal void within the aqueduct and elevation of the superior tectal plate (see Fig. 62–9). Occasionally, high signal intensity suggesting gliosis is seen in the periaqueductal gray matter. Tectal tumors are rarely encountered in neonates. CSF flow studies may be performed to corroborate lack of flow within the aqueduct in equivocal cases. Use of contrast media may be required to evaluate congenital tumors causing hydrocephalus and to search for leptomeningeal metastases.

### Neonatal Infection

Congenital cytomegalovirus (CMV) infection is associated with anomalies of cortical development, diminished white matter volume, delayed myelination, variably small cerebella, parenchymal calcification, and mild ventriculomegaly (Barkovich and Lindan, 1994).

Whereas both US and CT may demonstrate parenchymal calcifications, multiplanar MRI provides superior delineation of the anomalies associated with congenital CMV infection of the CNS. Conventional imaging including coronal T2-weighted images is useful in defining the anatomic abnormalities. The DI characteristics of congenital CMV affecting the brain have not been reported. We have noted increased diffusion in the regions of delayed

**FIGURE 62–29.** Positive Doppler ultrasound compression study in hydrocephalus. **A**, Baseline examination of blood flow within the anterior cerebral artery without fontanel compression shows a low resistance pattern with flow during both systole and diastole (resistive index = 0.81). **B**, Examination during transient compression of the anterior fontanel using the ultrasound transducer results in a loss of diastolic flow resulting from increased intracranial pressure (resistive index = 1.0).

myelination. DI findings have otherwise been unremarkable. Findings on high-resolution temporal bone MRI performed in infants with associated hearing loss are typically normal.

Neonatal herpes simplex virus (HSV) infection may involve any region of the brain and is typically multifocal (unlike HSV infection in adults, which has a predilection for the temporal lobes) (Schlesinger et al, 1995).

Brain CT in HSV infection usually shows multifocal low density in the cortex and subcortical white matter. Occasionally, petechial hemorrhage may occur. Conventional MRI demonstrates multiple areas of cortical and deep gray matter of low signal intensity on T1-weighted images and high signal intensity on T2-weighted images (Fig. 62–30). Hemorrhage produces shortening of T1 (hyperintensity) and T2 (hypointensity). On DI, sites of involvement typically have restricted diffusion during the acute phase of the illness. The restricted diffusion is presumably due to necrosis.

Congenital human immunodeficiency virus (HIV) infection has become a significant public health problem over the last two decades. However, despite the fact that more than 90% of all childhood HIV infections are due to in utero transmission, neurologic and imaging manifestations of HIV infection in the neonatal period are rare (Volpe, 1995). To date, we have not observed imaging abnormalities in newborns with known HIV infection.

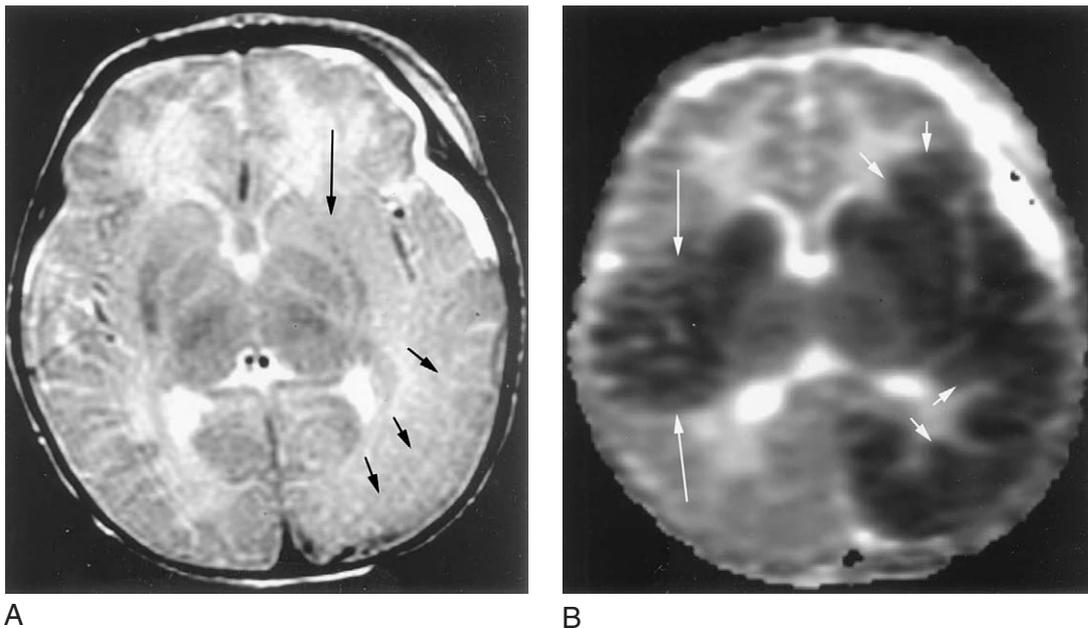

Neonatal bacterial CNS infections are rarely associated with imaging abnormalities. Some bacteria such as

*Citrobacter* species, *Serratia marcescens*, *Proteus*, *Pseudomonas aeruginosa*, and members of family Enterobacteriaceae produce parenchymal necrosis and abscess formation (Fig. 62–31). Thrombosis of cortical and subependymal veins may also occur. By both CT and MRI, leptomeningeal enhancement may be seen following the administration of intravenous contrast. If cerebritis develops, the cortex and subcortical white matter may be seen as areas of low density on CT and of increased signal intensity on T2-weighted MRI. Abscesses are demonstrated as rim-enhancing lesions on both CT and MRI. These lesions, along with the surrounding hyperemia, can also be well demonstrated by cranial US. The DI appearance of abscesses in neonates has not been reported. Widespread malacic changes may be seen on late follow-up imaging after necrotizing CNS infections.

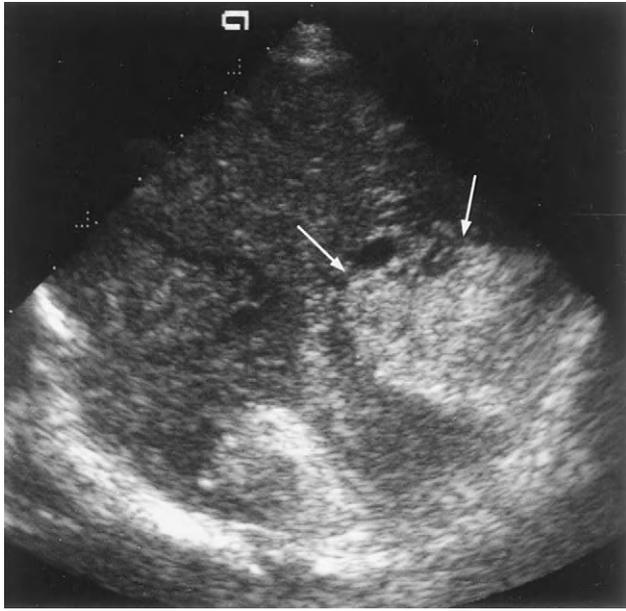

### Neonatal Brain Tumors

Brain tumors are rare in the newborn. When they occur, they are most often supratentorial, large, high-grade lesions such as primitive neuroepithelial tumors and choroid plexus carcinoma (Fig. 62–32).

The imaging appearance of brain tumors is variable depending on the cellularity of the lesion and the presence or absence of necrosis (Klisch et al, 2000) (see Fig. 62–32). Low-grade, less cellular tumors tend to have low density on CT, high signal intensity on T2-weighted

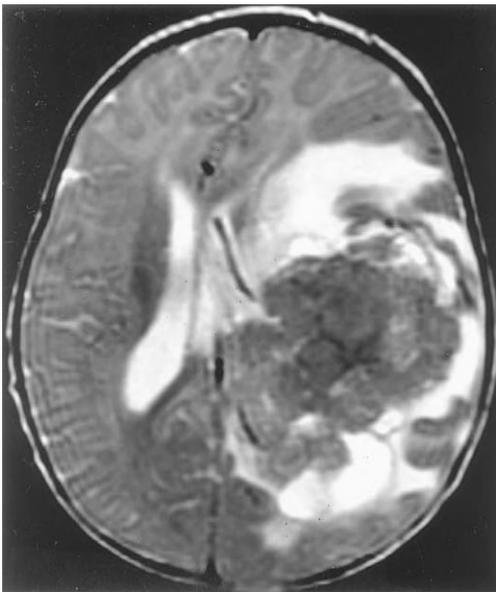

**FIGURE 62–30.** Magnetic resonance images from a term neonate with herpes simplex virus (HSV) encephalitis. **A**, Axial T2-weighted image shows high signal intensity in the left basal ganglia (*long arrow*) and loss of the cortical ribbon in the left cerebral hemisphere (*short arrows*). Unlike HSV infection in adults, neonatal herpes is not confined to the temporal and subfrontal lobes, and basal ganglia involvement is common. **B**, Apparent diffusion coefficient (ADC) map from the same examination shows extensive restricted diffusion (hypointensity) involving the areas on the left seen on the T2-weighted images (*short arrows*) and additional right hemispheric cortical (*long arrows*) and deep gray matter involvement.

**FIGURE 62-31.** Ultrasound study of abscess due to *Citrobacter* infection. A large echogenic mass/abscess (arrows) is clearly demonstrated. Abscess formation is most often associated with bacterial infections such as that due to *Citrobacter* species that cause parenchymal necrosis.

MRI, and increased diffusion relative to normal brain. High-grade, densely cellular tumors generally are hyperdense on CT and of low signal intensity on T2-weighted MRI and have decreased diffusion relative to normal brain. Enhancement of the tumors is variable but tends to increase with increasing malignancy of the tumor. Important exceptions to this general rule are pilocytic astrocytoma

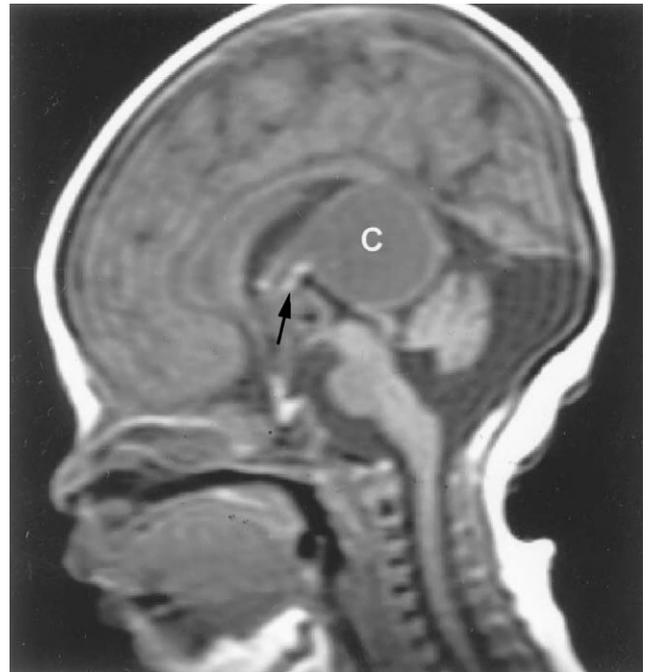

**FIGURE 62-32.** The patient was a 1-month-old infant with choroid plexus carcinoma. A large left hemispheric mass with regions hypointensity densely cellular tumor is evident on T2-weighted magnetic resonance image.

and choroid plexus papilloma (see Fig. 62-26), which, despite their low grade, tend to avidly enhance following contrast administration.

Malformative masses such as dermoid, epidermoid, and teratoma are occasionally detected in the neonate (Fig. 62-33) (Haddad et al, 1991). These lesions may be associated with other markers of cerebral dysgenesis such as anomalies of the corpus callosum or pericallosal lipoma. A dermal sinus tract is often present in association with midline cysts.

Malformative masses often have a characteristic appearance on imaging owing to the presence of fat and/or calcification within the lesion (Smirniotopoulos and Chiechi, 1995). Both dermoid and epidermoid tend to be of low density on CT. Calcification is sometimes seen within the cyst wall. Teeth formed within a teratoma will produce dense calcification on CT, whereas foci of fat have very low density, comparable to that of subcutaneous fat. CT is also used to document associated bone defects that accompany dermal sinus tracts.

On MRI, epidermoids tend to be similar to CSF in signal intensity on T1- and T2-weighted sequences. Occasionally, the cyst wall may enhance following intravenous contrast administration. Dermoid cysts containing fat have high signal intensity on T1-weighted sequences. High-resolution MRI may occasionally be required to demonstrate an associated dermal sinus tract. Teratomas may have foci of fat that produce high signal intensity on T1-weighted sequences. Calcifications appear as rounded signal voids on both T1-weighted and T2-weighted sequences.

**FIGURE 62-33.** The patient was a neonate with a pineal region teratoma. Sagittal T1-weighted image shows a large cystic lesion (C). The mass contains a small amount of high signal intensity (arrow) due to the presence of fat, which strongly suggests the diagnosis of teratoma.

### Hypoglycemia and Hyperbilirubinemia

Severe perinatal hypoglycemia may result in energy exhaustion and parenchymal infarction in the neonate. In severe hypoglycemia, diffuse cortical and subcortical white matter damage may be evident, with the parietal and occipital lobes most severely affected (Barkovich et al, 1998). Globus pallidus injury has been observed in patients with the most severe cortical injury (Barkovich et al, 1998).

Initially, on CT and MRI, cortical edema is present within the parietal and occipital regions of the cortex (Fig. 62–34). As with other causes of infarction, restricted diffusion is usually observed acutely (Barkovich et al, 1998). Chronically, tissue loss is present in the areas that earlier showed edema and restricted diffusion (Sugama et al, 2001). In newborns, severe hyperbilirubinemia and consequent kernicterus may develop. The findings on brain MRI in patients with kernicterus are characteristic. Unlike hypoxia-ischemia, which tends to primarily affect the putamen and thalamus, hyperbilirubinemia selectively affects the globus pallidus. Recently, it has been suggested that the high resting neuronal activity in the globus pallidus might make it more vulnerable to less intense, subacute oxidative stresses from mitochondrial toxins such as bilirubin (Johnston and Hoon, 2000).

The imaging findings in kernicterus are most apparent on MRI, with hyperintensity at the posterior margin or throughout the globi pallidi on T2-weighted sequences (Sugama et al, 2001).

### Neurocutaneous Disorders

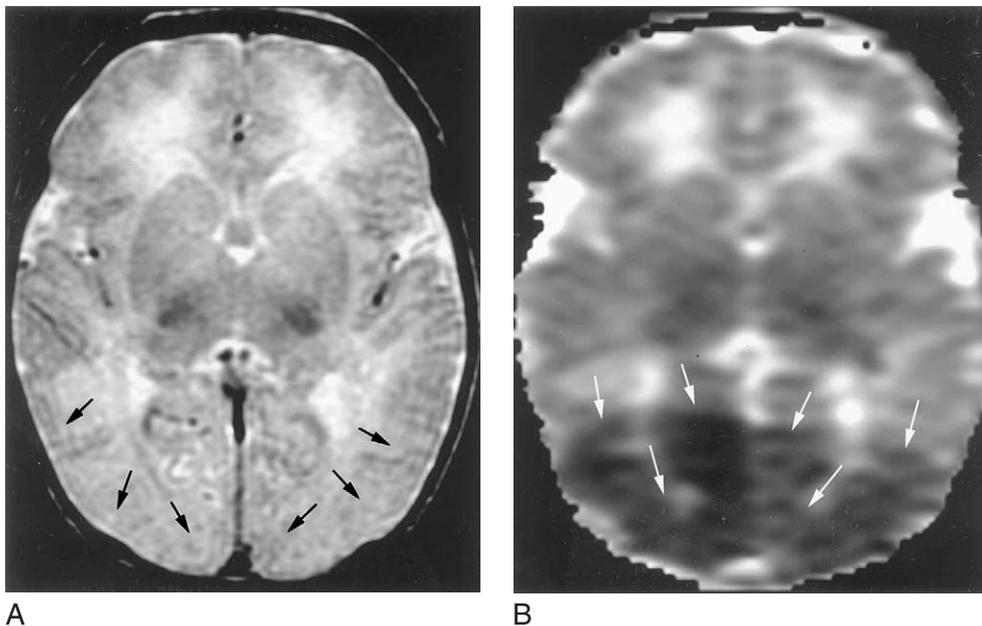

Of the phakomatoses, the two for which imaging is most commonly required in the neonate are tuberous sclerosis and Sturge-Weber syndrome. Because the outwardly apparent

clinical features of tuberous sclerosis, such as adenoma sebaceum, are not usually apparent until late childhood or adulthood, early brain imaging is most often requested when cardiac tumors are identified on prenatal US or when there is a positive family history. The intracranial manifestations of tuberous sclerosis include cortical tubers, subependymal hamatomas, subependymal giant cell tumors, and abnormal neuronal and glial cells in the white matter.

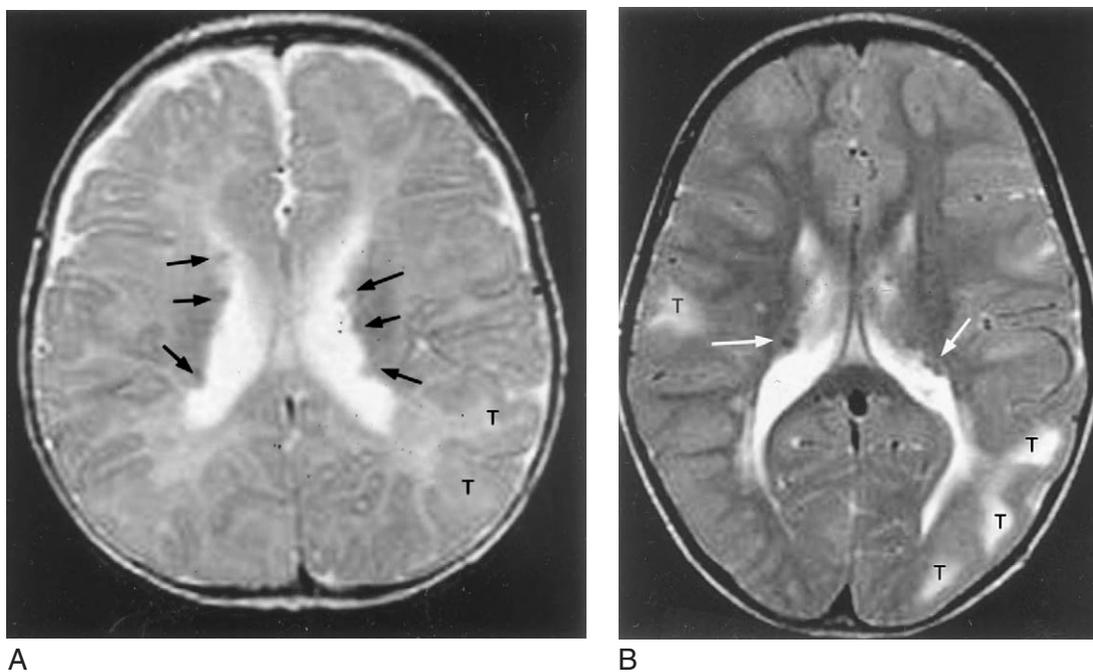

On brain CT in the neonate, there is variable calcification of subependymal nodules that appear as small nodular densities projecting into the lateral ventricles (Griffiths and Martland, 1997) (Fig. 62–35). The appearance may be similar to that of periventricular calcifications seen with congenital infections such as with CMV but can be differentiated from the latter on the basis of the projection of the lesions into the lateral ventricles and demonstration of cortical tubers. White matter abnormalities are extremely difficult to demonstrate owing to the normal low density of unmyelinated neonatal white matter. Likewise, cortical tubers, which are not usually calcified in the newborn, may be difficult to demonstrate with CT, as the affected gyri may simply appear mildly broadened.

On brain MRI in the newborn, subependymal hamatomas may be quite subtle in appearance and must be carefully searched for. The cortical lesions of tuberous sclerosis have variable signal intensity. Cortical tubers appear may appear hyperintense or hypointense to unmyelinated white matter on T1-weighted images. The cortical tubers may be difficult to identify on T2-weighted images in the neonate, as their signal intensity is often similar to that of the unmyelinated subcortical white matter (see Fig. 62–35).

Sturge-Weber syndrome (i.e., encephalotrigeminal angiomatosis) is a neurocutaneous disorder comprising a capillary malformation in the distribution of branches of the trigeminal nerve and an intracranial leptomeningeal

**FIGURE 62-34.** Term newborn with marked hypoglycemia and seizures. **A**, Bilaterally symmetric loss of the cortical ribbon is apparent in the parietal and occipital lobes on T2-weighted imaging (arrows). **B**, Decreased ADC values are present in corresponding regions of the parietal and occipital cortex (arrows).

**FIGURE 62-35.** The patient was a term neonate with cardiac rhabdomyomas. **A**, Axial T2-weighted magnetic resonance (MR) image obtained at 2 weeks of age shows subependymal nodules (*arrows*) indicative of tuberous sclerosis. Note that the cortical tubers (T) may be difficult to see in the newborn. **B**, Follow-up T2-weighted MR image in the same child at 5 years of age shows hypointense subependymal nodules (*arrows*). The cortical tubers (T) are now much more obvious.

capillary-venous malformation. Clinically, patients present with a “port-wine facial nevus” and seizures (Pascual-Castroviejo et al, 1993).

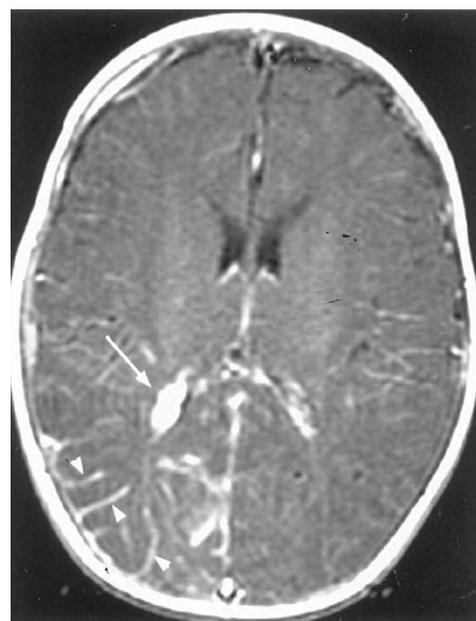

On brain CT, Sturge-Weber syndrome in the newborn may be difficult to detect. Gyral calcification, a radiographic hallmark of this disorder, may or may not be present. Even when this abnormality is present, the extent of the calcification may not reflect the entire distribution of the vascular malformation. The choroid plexus is typically enlarged on the side of the malformation, and enlarged medullary veins are seen following the administration of intravenous contrast. Hemiatrophy of the brain and overgrowth of the skull often are not apparent in the newborn.

Contrast-enhanced brain MRI is considered the imaging modality of choice for evaluation of Sturge-Weber syndrome (Elster and Chen, 1990; Pascual-Castroviejo et al, 1993). T1-weighted imaging following the administration of intravenous gadolinium provides the best depiction of the extent of the vascular anomaly (Fig. 62-36). Although gradient echo MRI may be less sensitive than CT for the demonstration of gyral calcification, it is often useful in demonstrating the presence of cortical mineralization.

## ADVANTAGES AND DISADVANTAGES OF NEUROIMAGING TECHNIQUES

### Ultrasonography

The most significant advantages of US are its portability, lack of ionizing radiation, relative availability and affordability, and ability to depict hemodynamics of blood flow in

**FIGURE 62-36.** The patient was a term neonate with seizures and facial capillary nevus. Axial T1-weighted post-gadolinium magnetic resonance image demonstrates asymmetrical leptomeningeal enhancement (*arrowheads*) in the right parietal and occipital lobes due to the presence of the leptomeningeal capillary-venous malformation that defines Sturge-Weber syndrome. The choroid plexus ipsilateral (*arrow*) to the leptomeningeal anomaly is typically enlarged. Note that the brain is not yet atrophic in the area of the malformation.

real time. The most serious disadvantages are its relative lack of spatial resolution compared with CT and MRI, the need for an acoustic window, its operator dependence, and the nonspecificity of many US findings. In addition, the differentiation between bland and hemorrhagic lesions is often difficult, and it is an insensitive tool for the diagnosis of neuronal migration disorders and diffuse neuronal injury.

### Computed Tomography

Advantages of CT include availability, compatibility with life support systems, rapid image acquisition, and relative lack of operator dependency.

Unfortunately, CT offers more limited soft tissue contrast than that provided by MRI and is prone to beam-hardening artifact from the skull base such that there is limited detail of the posterior fossa and temporal lobes. In addition, imaging can be acquired only in the axial or coronal plane. The risks associated with exposure to ionizing radiation from CT have come under increased scrutiny (Brenner et al, 2001; Huda et al, 2001). It appears that the long-term risk of malignancy due to x-ray exposure may be greatest in the newborn and gradually diminishes with age (Brenner et al, 2001). The risk associated with neonatal brain CT, however, is largely theoretical, and the decision to perform CT for neonatal brain CT should be made on a case-by-case basis, with recognition of the potentially significant medical benefit of performing the study compared with a small theoretical risk of the development of malignancy over the patient's lifetime. When appropriate, it may be prudent to consider using MRI or US, because neither employs ionizing radiation.

Although most brain CT studies in the neonate do not require the administration of intravenous contrast, occasionally, as with suspected dural venous sinus thrombosis, contrast may be of benefit. Because the primary route of contrast excretion is via the kidney, the renal status must be considered in the newborn, just as in the older child or adult. Typically, nonionic contrast is used to decrease the side effects related to the high osmolality of the ionic agents.

### Magnetic Resonance Imaging

Advantages of MRI include superior image detail compared with CT and US and the possibility of evaluating multiple tissue parameters. As with US, MRI does not carry the theoretical risks associated with the use of ionizing radiation. In addition, both anatomic and functional information may be obtained from MRI during the same examination. Moreover, MRI offers improved delineation of the posterior fossa structures without significant artifact from the skull base as occurs with CT, and without the need for an appropriate acoustic window as is essential with US.

The single biggest disadvantage of MRI is the requirement for a strong magnetic field. As a result, the MRI examination room must be magnetically shielded, and all equipment entering the room must be nonferromagnetic. For these reasons, the imaging of the ill neonate can be dif-

ficult. Additionally, because of the relatively long time of image acquisition, sedation or anesthesia is often required. However, generally, the additional information obtained with MRI over CT warrants the added inconvenience of the examination, provided that the imaging suite and personnel are equipped to handle the unique requirements of neonatal brain MRI.

## SUMMARY OF NEUROIMAGING PRACTICE GUIDELINES

A multidisciplinary group has reviewed the literature and established guidelines for neuroimaging in the neonate (Ment et al, 2002). This practice parameter is endorsed by the American Academy of Pediatrics, the American Society of Pediatric Neuroradiology, and the Society for Pediatric Radiology. The practice parameter recommendations for imaging of the preterm neonate are that routine cranial US screening be performed in all infants born at less than 30 weeks of gestational age once between days 7 and 14 of life and repeated between 36 and 40 weeks of postmenstrual age. For term infants, the recommendations are that non-contrast CT be performed to detect hemorrhagic lesions in the encephalopathic newborn with a history of birth trauma, low hematocrit, or coagulopathy. If CT is inconclusive, then MRI should be performed between days 2 and 8 of life to assess the location and extent of injury. This practice parameter reflects a review of available literature.

Of interest, the potential late untoward effects of radiation used for diagnostic CT scanning have recently been highlighted (Donnelly and Frush, 2001). The theoretical risk of malignancy related to exposure to ionizing radiation is highest in the neonate. Given that significant intracranial hemorrhage is detected by MRI as well as by CT, an argument can be made for eliminating CT for the evaluation of the encephalopathic term neonate, thereby avoiding the potential risks of ionizing radiation altogether (Robertson et al, 2003). CT is superior to MRI, and remains the study of choice, for the detection of parenchymal calcification and demonstration of bone abnormalities.

# Congenital Malformations of the Central Nervous System

Stephen A. Back

During the formation of the fetal central nervous system (CNS), developmental processes may be interrupted by deleterious intrinsic or extrinsic insults that result in CNS malformations. The origins and consequences of these disorders are best understood within the context of normal CNS development. Accordingly, for each of the major developmental processes, this chapter reviews the sequence of events and examines the associated CNS malformations that are more commonly encountered in the clinical practice of neonatal medicine. The peak timing of these events during fetal gestation is summarized in Table 63–1.

Remarkable progress in basic developmental neurobiology in the last decade has translated into rapid advances in our understanding of the molecular and genetic basis of many of these previously perplexing disorders. Although a majority of these disorders arise from adverse events that occur during the early phases of pregnancy, these new insights begin to provide a more rational basis for the assessment of prognosis, as well as for the management of future pregnancies.

A true CNS malformation may be multifactorial in origin and results when a disruption occurs in an intrinsic developmental process. Acquired defects occur when an already normally formed brain is injured by a secondary process, such as vascular compromise, hypoxia-ischemia, infection, toxic exposure, physical compression, or trauma. The nature of acquired malformations is closely related to the stage of development at which the injury occurs, as well as the duration of the insult. Although acquired lesions are usually *encephaloclastic* in nature, which means that destruction of normal brain tissue has occurred, they can resemble primary developmental lesions in some cases (Roessmann, 1995).

## PRIMARY AND SECONDARY NEURAL TUBE FORMATION (NEURULATION)

The earliest developmental stages include the one-celled embryo, the cleaving embryo, the blastocyst, the process of implantation and development of the amniotic cavity and umbilical vesicle, the formation of chorionic villi, and the formation of axial features (right and left sides, rostral and caudal ends). All of these events occur during the first 14 postconceptional days. At 16 days, the site of the future neural plate can be defined by autoradiographic means, and at about 18 days, the neural groove can be seen (England, 1988; O’Rahilly and Muller, 1994).

Neural tube formation, or neurulation, occurs through an inductive process that stimulates the dorsal aspect of the embryo to form the brain and spinal cord. Initial events involve formation of the brain and much of the spinal cord, with the exception of the sacral-coccygeal segments (primary neurulation). Later in embryogenesis, the lower sacral segments of the spinal cord are formed (secondary neurulation). Disruption of primary neurulation and of secondary neurulation results in distinctly different malformations that are considered separately.

### Primary Neural Tube Formation

The process of primary neural tube formation involves the formation of the brain and spinal cord, with the exception of the most caudal (sacral-coccygeal) segments of the spinal cord. Primary neurulation spans from 18 days of gestation to the end of the fourth gestational week. Initially, an area of thickened neuroectoderm, the neural plate, is formed after induction by the underlying notochord and chordal mesoderm (Fig. 63–1). At 20 to 21 days, the neural groove forms in the midline, with a neural fold on either side. Areas destined to become the forebrain, midbrain, and hindbrain can be identified at this early stage. By day 22, the neural folds are beginning to fuse to form the neural tube and central canal (England, 1988; O’Rahilly and Muller, 1994).

### Neural Tube Closure and Neural Crest Migration

Primary neurulation concludes with a series of critical events that result in closure of the neural tube. The neural folds fuse first in the nascent occipitocervical region. Current studies no longer support the “zipper concept” of closure of the neural tube. Rather, fusion occurs at multiple closure sites, with the closure of the cranium being the most complex. Inbred strains of mice show differences in the timing of the various closure sites and in the exact locations and sequences of closure, all of which are dependent on different, specific genes (Van Allen et al, 1993). Analysis of the locations where human anterior neural tube defects occur supports the notion that anterior neural tube closure proceeds simultaneously at multiple sites (Golden and Chernoff, 1995). Disturbances in human neural tube closure appear to occur by failure of closure at one or more sites or by defective fusion between two adjacent sites of closure.

By day 24 to 25, fusion progresses rostrally to the level of the colliculi, and fusion continues rostrally and caudally until only the anterior neuropore and the posterior neuropore are open (Fig. 63–2). By day 25, the anterior neuropore has closed; by day 26, the posterior neuropore has closed at the site corresponding to around S2 (O’Rahilly and Muller, 1994). The skull, vertebrae, and dura form through interactions between the neural tube and the adjacent mesoderm. As the rostral parts of the neural folds fuse, the neural crest is formed from ectodermal cells on both sides of the neural tube. The neural crest cells migrate shortly after neural tube closure. They give rise to sensory, sympathetic, and parasympathetic ganglia; chromaffin cells of the adrenal medulla; skin melanocytes; enteric neurons in the

TABLE 63-1

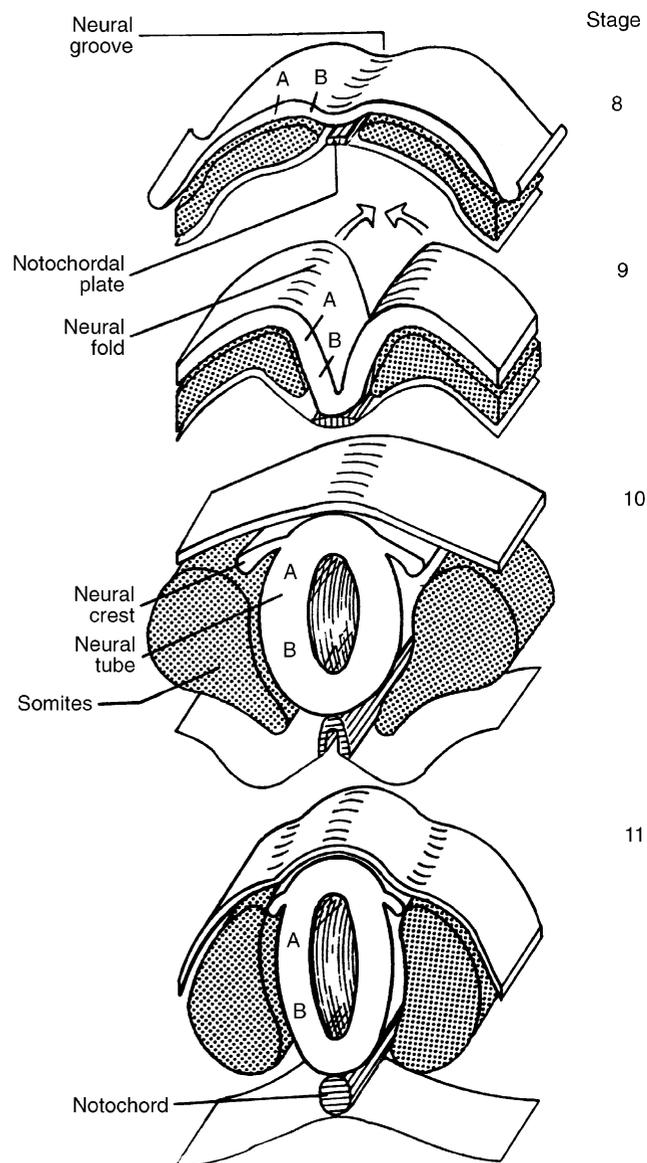

**Timing of the Major Gestational Events in Human Brain Development and Representative Examples of Significant Related Disorders**

Major Developmental Event	Window in Development
<b>Primary Neurulation</b> Craniorachischisis totalis, anencephaly, encephalocele, myeloschisis, myelomeningocele/Arnold-Chiari malformation	3-4 weeks
<b>Prosencephalic Development</b> Holoprosencephaly, agenesis of the corpus callosum, agenesis of septum pellucidum/septo-optic dysplasia	4-8 weeks
<b>Hindbrain Development</b> Dandy-Walker malformation, malformations associated with cerebellar vermis hypoplasia, malformations associated with the molar tooth sign (Joubert syndrome)	3-12+ weeks
<b>Neuronal Proliferation</b> Micrencephaly (micrencephaly vera, radial microbrain), human autosomal recessive primary micrencephaly 1-5, macrencephaly, hemimegalencephaly	8-12 weeks
<b>Neuronal Migration</b> Schizencephaly, polymicrogyria, lissencephaly/pachygyria, lissencephaly with cerebellar hypoplasia, cobblestone complex syndromes, neuronal heterotopia, cortical dysplasia	8-16 weeks

gastrointestinal tract; and facial connective tissue (O'Rahilly and Muller, 1994).

### Secondary Neural Tube Formation and Caudal Regression

The process of secondary neural tube formation occurs approximately between gestational days 30 and 50, during which vacuoles form in a caudal cell mass that surrounds the lower neural tube. The vacuoles coalesce and connect with the central canal of the already present neural tube. At post-conceptual days 41 to 51, the caudalmost part of the neural tube and central canal begins to regress as the tail of the embryo disappears. Atrophy of the caudal neural tube results in formation of a fibrous strand called the filum terminale, which is present throughout life. As the vertebral bodies grow, the end of the central canal (the conus medullaris) becomes placed higher in the vertebral column, eventually reaching the L1 to L2 level (usually by 2 weeks postnatally). This may be due to proportionately greater lengthening of the spinal vertebrae compared with the spinal cord (England, 1988; O'Rahilly and Muller, 1994).

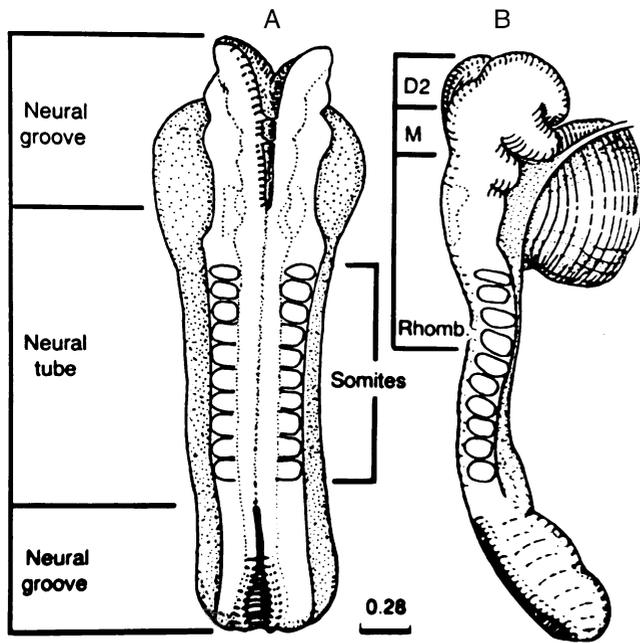

**FIGURE 63-1.** Formation of the neural tube. (From O'Rahilly R, Muller F: *The Embryonic Human Brain*. New York, Wiley-Liss, 1994, p 41.)

Disorders of secondary neurulation give rise to several clinically significant occult dysraphic states, discussed later on.

### Neural Tube Defects

Neural tube defects result from a failure of primary neural tube closure during the fourth week of human gestation (Roessmann, 1995). Most of these defects are related to some degree of failure of anterior or posterior neuropore closure. On the clinical spectrum of brain malformations associated with disrupted *anterior* neuropore closure, anencephaly represents the most profound defect, with encephaloceles of decreasing severity accounting for the remainder of such malformations. Myeloschisis and myelomeningocele with the associated Arnold-Chiari malformations are the spinal cord defects associated with failure of *posterior* neuropore closure. In addition, craniorachischisis totalis is a

**FIGURE 63-2.** Positions of anterior and posterior neuropores. (From O’Rahilly R, Muller F: *The Embryonic Human Brain*. New York, Wiley-Liss, 1994, p 45.)

severe malformation of the brain and spinal cord involving essentially *complete* failure of neural tube closure; it usually results in spontaneous abortion during embryogenesis or early fetal development. Similarly, myeloschisis commonly results in stillbirth, as a result of extensive malformation of large portions of the spinal cord. Other neural tube defects result in malformations of the CNS and the overlying axial skeleton, meninges, and skin that are associated with various degrees of viability in the newborn period.

### Epidemiology

Neural tube defects remain one of the most common congenital malformations encountered in newborns, despite a recent decline in prevalence. Because many congenital malformations occur during embryonic development, incidence data are essentially impossible to ascertain. Nevertheless, it is clear that the prevalence of neural tube defects varies widely and is particularly influenced by race, ethnicity, geographic area, and socioeconomic status (Frey and Hauser, 2003). In the United States, for example, the risk for neural tube defects is higher for Hispanics but lower for African Americans. Geographically, one of the higher prevalence rates occurs in the United Kingdom, where distinct geographic gradients also exist within this region. It should also be noted that once a woman has had a pregnancy complicated by a neural tube defect, the risk of recurrence may be disproportionately higher with each subsequent pregnancy. For unclear reasons, after the first affected pregnancy, this risk increases to become markedly higher than the baseline risk for the relevant general population. In fact, the risk may nearly triple after each subsequent pregnancy (Elwood et al, 1992).

Superimposed on these factors has been a marked decline in prevalence at birth of both anencephaly and spina bifida. In 1960, the prevalence for England and

Wales was about 6 in 1000 births; in 1990, this rate dropped to about 1 in 1000. The lower occurrence rates reflect two major interventions: in utero diagnosis with termination of affected pregnancies and maternal periconceptional folate therapy. The latter is estimated to prevent approximately 60% to 70% of neural tube defects (Castilla et al, 2003; Czeizel and Dudas, 1992; Frey and Hauser, 2003; MRC Vitamin Study Research Group, 1992; Oakley et al, 1994; Smithells et al, 1981). The mechanisms by which folate is involved in neural tube closure are currently unclear. There are approximately 150 known genes involved in folic acid metabolism and transport that are under investigation (Juriloff and Harris, 2000).

### Etiology

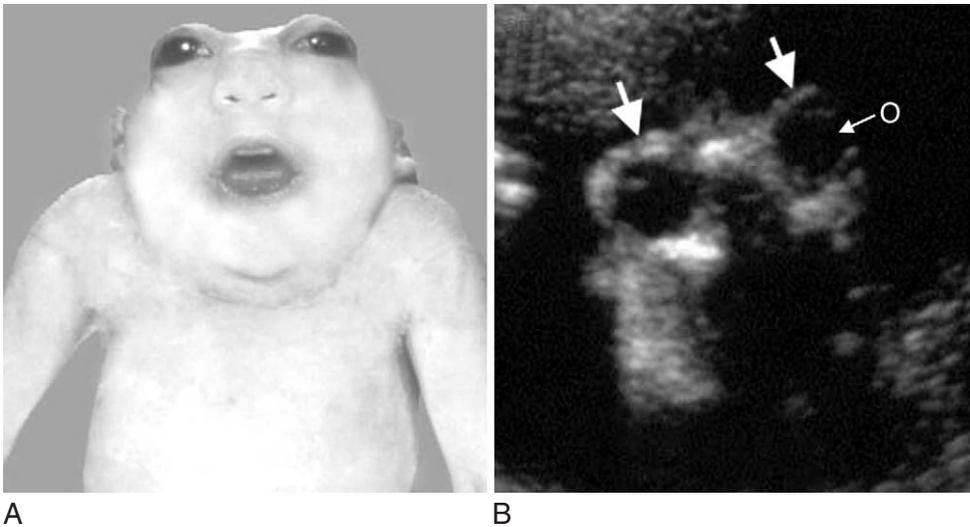

The etiology of neural tube defects is complex and clearly multifactorial. Genetic and environmental factors operate independently to determine individual and population risk. Although numerous genetic syndromes are associated with neural tube defects, affected pregnancies uncommonly come to term, and such syndromes appear to constitute a very small percentage of all cases (Hall and Solehdin, 1998). An independent role for genetic factors is supported by a particular mouse model of neural tube defects, the curly tail (*ct*) variant. The responsible *ct* gene localizes to the distal arm of chromosome 4 and has at least three modifier loci that influence the incidence of neural tube defects (Neumann et al, 1994). Among the numerous environmental risk factors that have been studied, the most prominent include maternal febrile illness, maternal heat exposure in the first trimester (e.g., sauna or hot tub use), lower socioeconomic status, dietary factors (prenatal tea but not caffeine consumption), and prenatal exposure to a number of drugs including antiepileptic medications (Frey and Hauser, 2003). Valproate and carbamazepine both are associated with an increased risk of neural tube defects (Jones et al, 1989; Yerby, 2003).

## Disorders of Primary Neurulation

### Anencephaly

Anencephaly comprises roughly more than half of all human neural tube defects. As an early neurulation defect, it occurs no later than 24 days of gestation. Anencephaly is the most severe and common of the disorders of anterior neural tube closure (Fig. 63-3). Both anencephaly and occipital encephaloceles (see later) affect girls more often than boys. A majority of infants are stillborn. Moreover, it is uniformly lethal within the first 2 months of life in the roughly 25% of cases with survival into the neonatal period (Baird and Sadovnick, 1984; Peabody et al, 1989). The duration of survival is critically related to intensive care support. Without intensive care, survival has not been reported beyond 14 days of life. Survival is related in part to persistence of rudimentary brainstem function. This finding is inconsistent with the diagnosis of brain death in the United States, which is a requirement for organ donation (AAP Committee on Bioethics, 1992; McAbee et al, 2000).

Anencephaly most commonly involves the forebrain and upper brainstem, which accounts for the devastating outcome. It is characterized by absence of the calvaria, with

**FIGURE 63-3.** **A**, An anencephalic infant. **B**, Ultrasonogram of anencephaly. Note the absence of the normal cranial structures (large arrows) superior to the orbits (O). (Courtesy of Dr. Marjorie Grafe, Department of Pathology, Oregon Health & Science University.)

replacement of the intracranial contents by vascularized, disorganized glial tissue (area cerebrovasculosa) (Menkes, 1991; Roessmann, 1995). The hypothalamus and cerebellum usually are malformed, the anterior lobe of the pituitary is present, and the internal carotid arteries are hypoplastic, which may be secondary to abnormal brain formation. Because the anencephalic fetus experiences a period of exencephaly, in which the brain tissue extrudes through the unformed calvaria and then is degraded by exposure to the amniotic fluid, some investigators have hypothesized that the primary defect is the abnormal skull formation. In some cases of anencephaly, remnants of calvarial bones are present, with normal brain under the protective bones (Roessmann, 1995).

Anencephaly can be diagnosed by fetal ultrasound examination (see Fig. 63-3B) in the second trimester of gestation (Crane, 1992; Goldstein and Filly, 1988). Polyhydramnios is frequently associated. Anencephaly also may be suggested by increased levels of alpha-fetoprotein (AFP) in maternal serum. AFP is the major serum protein in the early embryo and is fetus specific. It normally passes from the fetal serum into fetal urine and then into amniotic fluid; in the amniotic fluid, it is swallowed by the fetus and metabolized in the fetal gastrointestinal tract (Brock, 1976). In anencephaly, open spina bifida, and open encephalocele, there is leakage of fetal serum directly into the amniotic fluid, and levels of AFP as well as of maternal serum protein are elevated in the amniotic fluid. By contrast, when a neural tube defect is closed (i.e., covered by intact skin), the AFP level is not elevated. This occurs in about 5% of neural tube defects (Milunsky et al, 1980).

### Encephalocele

In contrast with anencephaly, encephalocele appears to arise from a restricted rather than diffuse failure of anterior neuropore closure around 26 days of gestation. Encephalocele typically manifests as a cranial defect through which brain tissue protrudes. Less severe defects may result with later onset. These include cranium bifidum, in which there is a failure of midline fusion of the skull, and cranial meningoceles, which contain meningeal but not neural

tissue. In up to 80% of cases, encephaloceles occur in the occipital region (Fig. 63-4), with the remainder in the parietal, frontonasal, intranasal, and nasopharyngeal regions. Although the precise pathogenetic mechanism remains unclear, geographic or ethnic-genetic factors appear to influence the location of the lesion. Frontal encephaloceles are more prevalent in Southeast Asia, for example, whereas lesions that involve the occipital lobe are more common in Western populations. A role for genetic factors is supported by the presence of encephalocele in a number of autosomal recessive syndromes (e.g., Meckel syndrome, Walker-Warburg syndrome). Overall, about one half of infants with encephaloceles have other major congenital anomalies that include microcephaly, arhinencephaly, anophthalmia, cleft lip or palate, craniosynostosis, complex congenital heart disease, and other systemic abnormalities (Brown and Sheridan-Pereira, 1992).

Encephaloceles also are associated with various other CNS defects that influence the severity of the outcome as well as the surgical management. These defects include anomalous draining veins, as well as hydrocephalus, which is observed in up to 50% of cases (Diebler and Dulac,

**FIGURE 63-4.** Newborn infant with a large occipital encephalocele. (Courtesy of Dr. Marjorie Grafe, Department of Pathology, Oregon Health & Science University.)

1987; Menkes, 1991). The occurrence of lower occipital lobe encephalocele with skull base defects and malformations of the cerebellum and lower brainstem defines Chiari type III malformations (see later discussion of Chiari type II malformations that occur in association with myelomeningocele). Partial or complete agenesis of the corpus callosum and subependymal nodular heteropias are other frequently associated CNS malformations, as discussed later.

Evaluation of the infant with an encephalocele can be aided by transillumination, skull radiography, cranial ultrasonography, computed tomography (CT) scanning, and magnetic resonance imaging (MRI). Decisions about the appropriate modality depend on the individual cases and whether other cerebral anomalies or hydrocephalus is suspected. Frontonasal encephaloceles pulse or bulge with brief bilateral jugular vein compression, indicating communication with the subarachnoid space. Nasal gliomas, dermoids, and teratomas all can occur in the same region. Intranasal encephalocele should be suspected when an intranasal mass is found in a child with a broad nasal bridge and widely spaced eyes. Some affected children may also present with recurrent meningitis (Menkes, 1991). Basal encephaloceles are not usually diagnosed until childhood and can be located in the nasopharynx, sphenoid sinus, or posterior orbit.

In a majority of patients, neurosurgical management is indicated early in life. Large lesions or other severe CNS anomalies, however, may preclude intervention. Early intervention is imperative for those infants at high risk for meningitis because their lesions externally communicate and leak cerebrospinal fluid (CSF). Survival and outcome remain difficult to predict owing to the variability of presentation and surgical selection bias. One study of a series of children with encephalocele reported an overall mortality rate of 29% (45% in infants with posterior defects; 0% in infants with anterior defects) (Brown and Sheridan-Pereira, 1992). Neurologic deficits were severe in 33% of survivors with anterior defects and in 33% of survivors with posterior defects. Mild neurologic deficits were found in 17% of survivors of anterior defects and in 50% of survivors of posterior defects.

### Myeloschisis

Myeloschisis may be regarded as being at the more severe end of the spectrum of malformations of the spinal cord that arise from failure of posterior neuropore closure no later than 24 days of gestation. Hence, myeloschisis arises from an extensive failure of posterior neuropore closure, whereas myelomeningocele (described next) arises from more restricted disturbances in posterior neuropore closure. Myeloschisis manifests as a severely malformed spinal cord that comprises an exposed primitive neural plate-like structure that lacks overlying vertebrae and skin. At the level of the malformed upper cervical cord, there often may be associated malformations of the base of the skull that result in retroflexion of the head on the cervical spine (iniencephaly). Not unexpectedly, a majority of infants with myeloschisis are stillborn.

### Myelomeningocele

Myelomeningocele and other associated malformations of the spinal cord arise from restricted failure of posterior neuropore closure probably no later than day 26 of gestation. The incidence of myelomeningocele in the United States is about 0.2 to 0.4 per 1000 live births (Yen et al, 1992). Spinal cord malformations involving the meninges include myelomeningocele and meningocele. *Myelomeningocele* is characterized by herniation of the meninges and spinal cord at the site of the defect. Myelomeningoceles are usually “exposed” lesions on the back without vertebral or dermal covering (Fig. 63–5), unless a lipoma overlies the defect (i.e., a lipomyelomeningocele) (Menkes, 1991). A *meningocele* is a restricted herniation of the meninges at the defect site, which usually is covered by skin; neurologic function is often normal. Myelomeningoceles are about four times more common than meningoceles (Friede, 1989; Menkes, 1991). These lesions most often occur in the lumbar or lumbosacral region (in 69% of cases), which supports the concept that the site of final closure of the posterior neuropore is in the lumbar region.

Myelomeningocele is rarely an isolated malformation; rather, it usually is accompanied by other clinically significant CNS abnormalities. Of major importance is hydrocephalus, which is frequently associated with the Arnold-Chiari II malformation (discussed next). Hydrocephalus is not universal, and its development in myelomeningocele correlates with the site of the lesion. Hydrocephalus develops

**FIGURE 63-5.** Newborn infant with a large thoracolumbar myelomeningocele. The infant demonstrated weakness of the distal musculature in the lower extremities. (Courtesy of Dr. Marjorie Grafe, Department of Pathology, Oregon Health & Science University.)

in 60% of patients with occipital, cervical, thoracic, or sacral lesions, whereas it develops in 90% of those with thoracolumbar, lumbar, or lumbosacral lesions (Lorber, 1961). Increased intracranial pressure is present in about 15% of newborns with myelomeningocele. In some infants, there are no signs of increased pressure because of decompression due to leakage of CSF from the myelomeningocele (Stein and Schut, 1979). In these infants, hydrocephalus and increased pressure may become evident later after surgical closure of the myelomeningocele. In most infants with hydrocephalus, an abnormal increase in head circumference occurs within a month after birth (Stein and Schut, 1979).

As in anencephaly, presence of an open myelomeningocele is suspected following detection of an elevation in alpha-fetoprotein (AFP) in maternal serum and can be confirmed by fetal ultrasound examination or MRI. Another marker, amniotic fluid acetylcholinesterase, is also used to diagnose neural tube defects in utero, along with amniotic AFP, which increases the sensitivity of the screen when the maternal serum AFP level is questionable or high (Cuckle, 1994). Other causes of a high maternal serum AFP include contamination of the amniotic fluid by fetal blood, which may occur in cases of esophageal and duodenal atresia, annular pancreas, omphalocele, gastroschisis, congenital nephrosis, polycystic kidneys, renal agenesis, or fetal demise. Elevation of maternal serum AFP also may be related to a multiple gestation pregnancy (Brock, 1976). The optimal time for determination in maternal serum is at 16 to 18 weeks of gestation and in amniotic fluid at 14 to 16 weeks of gestation.

Clinical management of the newborn with a neural tube defect must be individualized. In the past, selective aggressive treatment was instituted for infants anticipated to have a better outcome. At present, aggressive surgical therapy is advocated for most infants; to date, this approach has resulted in better outcomes as demonstrated by increased cognitive abilities, increased ambulation, a lower incidence of incontinence, and a lower mortality rate (Hunt and Holmes, 1975; McLone, 1992; Stein et al, 1975).

### Arnold-Chiari Malformation

The Arnold-Chiari malformation occurs in at least 95% of children with a myelomeningocele that includes a lumbar lesion (Fig. 63–6). This malformation results in two serious complications—hydrocephalus and brainstem dysfunction—that are a significant cause of morbidity and death in infants with a myelomeningocele. The clinical sequelae with this class of malformations are best understood in the context of the principal types of associated anatomic abnormalities. Hindbrain malformations involve both the brainstem and the cerebellum. Brainstem abnormalities include downward herniation of the medulla and the fourth ventricle through the foramen magnum into the upper cervical canal, which results in obstruction of the fourth ventricle and compression of the upper cervical cord. The resultant downward stretch of the cervical roots causes them to project cranially to their foramina rather than to follow their normal lateral or descending course. The caudal displacement of the brainstem thins and elongates the lower pons and upper medulla, which may compress brainstem nuclei as well as

**FIGURE 63–6.** Arnold-Chiari malformation seen in association with a thoracolumbar myelomeningocele. This defect is one of elongation of the lower brainstem with downward displacement of the inferior part of the vermis of the cerebellum. The tectal plate is beaked, and the massa intermedia is enlarged. Note that polymicrogyria also is present in this particular case.

compromise the roots of the cranial nerves (Blaauw, 1971; Friede, 1989; Naidich et al, 1980). The herniation of the cerebellar tonsils through the foramen magnum and flattening of the lower cerebellar hemispheres are frequently associated with the caudal displacement of the brainstem. A variety of bone malformations are observed that include enlargement of the foramen magnum, defects of the occiput, and anomalies of the cervical vertebrae. Finally, cortical neuronal migration abnormalities (cerebral cortical dysplasia or polymicrogyria) are frequently associated with Chiari malformations and may account for cognitive deficits and epilepsy seen in some patients.

It follows from this constellation of hindbrain abnormalities that hydrocephalus is commonly associated with Chiari malformations. The hydrocephalus may arise from compression of the fourth ventricle or obstruction of CSF outflow through the foramen magnum. In addition, many patients also have aqueductal stenosis or, uncommonly, aqueductal atresia (Gilbert et al, 1986; Peach, 1965; Stein and Schut, 1979). A less well-recognized but potentially fatal complication of hindbrain abnormalities is primary dysfunction of the brainstem. This deficit can manifest as apneic episodes with cyanosis, vocal cord paralysis with laryngeal stridor, or feeding disturbances that result in aspiration related to reflux. Ventilatory disturbances may be either obstructive or central and thus prominent during sleep. These disturbances may be identified by polysomnography and pulmonary function studies (Kirk et al, 1999).

### Occult Spinal Dysraphisms

Occult spinal dysraphic states are the result of defects in caudal neural tube formation (i.e., secondary neurulation). As discussed previously, development of the sacral and coccygeal segments of the spinal cord involves a process of canalization and caudal regression of the distal neural tube. In contrast with defects in primary neural tube formation, these defects thus uniformly localize to

the distal cord and are closed defects with an intact dermal covering. In some instances, these defects are truly occult, without any overlying abnormalities of the skin, and may go undetected until the affected person becomes symptomatic. In a majority of newborn infants so affected, however, a lumbosacral midline cutaneous lesion may indicate an occult spinal dysraphism (Fig. 63–7). These lesions include abnormal hair tufts, hemangiomas, pigmented spots, skin tags, aplasia cutis congenita, cutaneous dimples or tracts, and a subcutaneous mass (Albright et al, 1989; Hall et al, 1981; Scatliff et al, 1989).

The spinal cord lesions associated with occult dysraphisms include myelocystocele; diastematomyelia-diplomyelia; meningocele-lipomeningocele; lipoma, teratoma, and other tumors; dermal sinus with or without dermoid or epidermoid cyst formation; and tethered cord (Anderson, 1975; Menkes, 1991) (Fig. 63–8). More severe lesions include neurenteric cyst, anterior meningocele, and the caudal regression syndrome (dysraphia of sacrum and coccyx, atrophy of muscles and bones of the legs, fusion of spinal nerves and sensory ganglia, and/or agenesis of the distal spinal cord) (Towfighi and Housman, 1991). Infants of diabetic mothers are at increased risk for these lesions as well as for more severe neural tube defects (Becerra et al, 1990).

Regardless of the caudal neural tube malformation, an almost invariable feature is an abnormal conus with a thickened filum. The movement of the filum is commonly restricted or “tethered” by fibrous bands or masses (e.g., a lipoma or teratoma). Consequently, during growth of the lower spinal cord, progressive functional impairment can occur as the cord is stretched against the fixed filum. Neu-

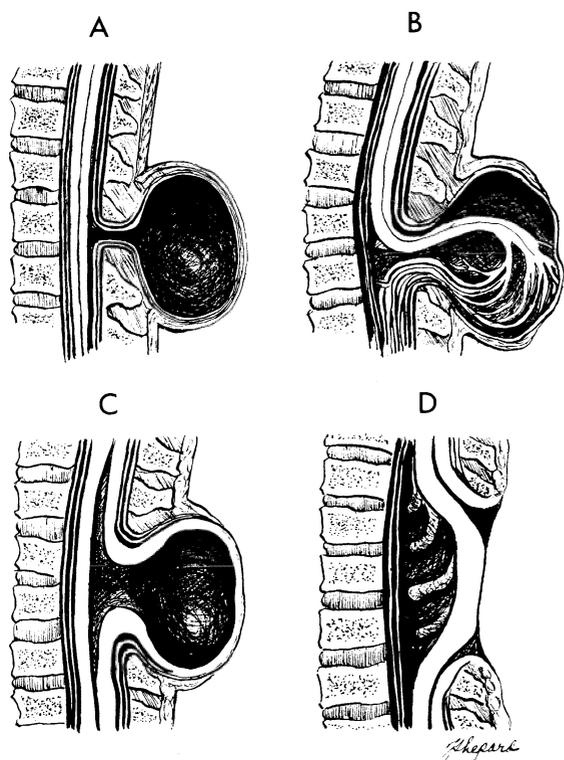

rologic impairment rarely manifests in the newborn period. Deficits related to these lesions that occur in infancy and childhood include delay in walking, disturbed sphincter control, anatomic abnormalities of the feet or legs, and pain in the back or legs. Gait and sphincter abnormalities, foot deformities, and scoliosis are more common in older patients. Recurrent meningitis and rapid loss of function are rare but serious presentations. In the newborn period, diagnostic evaluation for occult dysraphisms is indicated because early surgical intervention now carries a low risk of morbidity and can preclude sudden neurologic deterioration and the development of permanent deficits (Gower et al, 1988; Scatliff et al, 1989). Such evaluation may be facilitated by spinal radiography or CT, which may detect vertebral anomalies; spinal ultrasonography, which permits a dynamic evaluation of lower spinal cord mobility; and MRI to define structural anomalies of the cord.

### Disorders of Neural Crest Migration

As the neural tube closes during weeks 3 to 4 of gestation, the neural crest cells become isolated between the neural tube and the posterior ectoderm (Reznik and Pierard, 1995). This layer differentiates into cephalic and truncal neural crests. The cephalic neural crest forms the trigeminal neural crest, the facial-auditory neural crest, and the glossopharyngeal and vagal neural crest. These structures give rise to the cranial nerves and their sensory ganglia as well as to parts of the branchial arches (Reznik and Pierard, 1995). The truncal neural crest becomes fragmented along with the truncal somites. After the neural crest anlagen

**FIGURE 63-7.** A and B, Two examples of lipomeningocele. Each manifested in the left buttock as a firm, well-circumscribed, lobulated tumor that became tense when the infant cried. Over the surface of the lesion in B are some macular erosions and a congenital skin tag and dimple. This last feature may be a pilonidal dimple displaced by the tumor.

**FIGURE 63-8.** Diagram of meningoceles. **A**, Meningocele: Through the bone defect (spina bifida), the meninges herniate to form a cystic sac filled with cerebrospinal fluid. The spinal cord does not participate in the herniation and may or may not be abnormal. **B**, Myelomeningocele: Spina bifida with myelomeningocele; the spinal cord is herniated into the sac and ends there or may continue in an abnormal way further downward. **C**, Myelocystocele or syringomyelocele: The spinal cord shows hydromyelia; the posterior wall of the spinal cord is attached to the ectoderm and undifferentiated. **D**, Myelocele: The spinal cord is araphic; a cystic cavity is in front of the anterior wall of the spinal cord. (From Benda CE: *Developmental Disorders of Mentation and Cerebral Palsies*. New York, Grune & Stratton, 1952.)

is formed, neural crest cells migrate throughout the entire embryo. Migration is rostrocaudal, along the medial axis of the embryo (LeDouarin, 1982). After migration is accomplished, the neural crest cells are located in four areas: (1) nervous system: meningeoblasts, Schwann cells, ganglion and paraganglion cells (including enteric ganglion cells of the digestive tract); (2) endocrine system: chromaffin cells of the adrenal medulla and several types of endocrine and paraendocrine cells; (3) melanoblasts in all tissues except the retina; and (4) the skeletal system of the head, face, and neck. Abnormalities thus can arise with the migration or differentiation of the neural crest cells, or neural crest derivatives may develop tumors (Jacobson, 1991; Reznik and Pierard, 1995).

Disorders thought to arise from abnormalities of neural crest formation, migration, proliferation, or differentiation include the LEOPARD (*l*entigines, *e*lectrocardiographic abnormalities, *o*cular hypertelorism, *p*ulmonary stenosis, *a*bnormal genitalia, *r*etardation of growth, *d*eafness) syndrome; multiple lentigines syndrome; NAME (*n*evi, *a*trial myxoma, *m*yxoid neuroma, *e*phelides) syndrome; LAMB (*l*entigines, *a*trial myxoma, *m*ucocutaneous myxomas, *b*lue

nevi) syndrome; and Peutz-Jeghers-Touraine syndrome (Table 63-2).

Tumors derived from neural crest cells include those arising from Schwann cells, perineural cells, or fibrocytes; from neural sense organs; from ganglionic or neuroendocrine cells; and from melanogenic cells (Louis and von Deimling, 1995; Reznik and Pierard, 1995). Neuroblastoma is a neuroectodermal tumor that occurs mostly in children. It usually arises from the adrenal gland but can arise from sympathetic ganglia, the neuroendocrine system, or the ovary (Reznik and Pierard, 1995). It is sometimes seen in association with neurofibromatosis. Cutaneous metastases from neuroblastoma can occur as multiple skin nodules and have been seen in the newborn.

Hirschsprung disease is a disorder of neural crest stem cells that occurs in 1 in 5000 births. It is characterized by absence of hindgut intramural ganglion cells, which causes intestinal obstruction in the neonatal period. A gene associated with some cases of Hirschsprung disease has been mapped to chromosome 10 and localized to the *RET* proto-oncogene (Ederly et al, 1994; Romeo et al, 1994; Yin et al, 1994). Mutations that affect the *RET* protein also occur in patients with multiple endocrine neoplasia type 2A (Donis-Keller et al, 1993; Mulligan et al, 1993).

## PROSENCEPHALIC CLEAVAGE AND RELATED EVENTS

### Normal Prosencephalic Development

The prosencephalon refers embryologically to the telencephalon and the diencephalon, the future forebrain. The telencephalon gives rise to the cerebral hemispheres. The diencephalon gives rise to the thalamus and hypothalamus. The major period for prosencephalic development is during the second and third months of gestation. The beginning of prosencephalic development occurs shortly after the closure of the anterior neuropore. The prosencephalon essentially arises through developmental processes that induce the bifurcation of the rostral extent of the fluid-filled neural tube to form the right and left forebrain structures (Rubenstein and Beachy, 1998). This process involves the duplication of structures along the midline. It should be emphasized that the inductive processes that direct forebrain development also control craniofacial development. Hence, disruption of prosencephalic development is frequently associated with midline anomalies of both the forebrain and the face that result from a failure to cleave the neural tube.

During the fifth to sixth weeks of development, the ultimate structure of the forebrain is defined by the sequential cleavage of the forebrain along three major planes. As the anterior neuropore is closing, the first major event is formation of the optic vesicles and nasal placodes, separated along the *horizontal* plane, which will give rise to the neural and craniofacial structures of the visual and olfactory systems, respectively. Shortly thereafter, when the embryo has reached a length of about 5 mm, both neuropores have closed, thus isolating the developing ventricular system from the amniotic fluid. At this time, the retinal and lens placodes are developing. Separately, in the brainstem, the cerebellum begins to

TABLE 63-2

**Disorders of Neural Crest Formation, Migration, Proliferation, or Differentiation**

Syndrome/ Disorder	Defining Features					
LEOPARD	Multiple lentigines	Electrocardiographic defects	Ocular hypertelorism	Pulmonary stenosis	Genital abnormalities	Sensorineural deafness
Multiple lentigines	Cutaneous pigmented macules	Obstructive cardiomyopathy	Genital abnormalities	Delayed puberty	Sensorineural hearing loss	Growth retardation
NAME	Cutaneous nevi	Atrial myxoma	Myxoid neurofibromas	Ephelides		Growth retardation
LAMB	Lentigines	Atrial myxoma	Mucocutaneous myxoma	Blue nevi		
Peutz-Jeghers-Touraine	Mucocutaneous lentigines	Gastrointestinal polyposis	Schwannoma of the gut; acoustic neuromas	Increased risk of malignancies		Hypertelorism and skeletal abnormalities

form at this time, as well as some somatic and visceral efferent nuclei, the common afferent tract, and the ganglia for most of the cranial nerves.

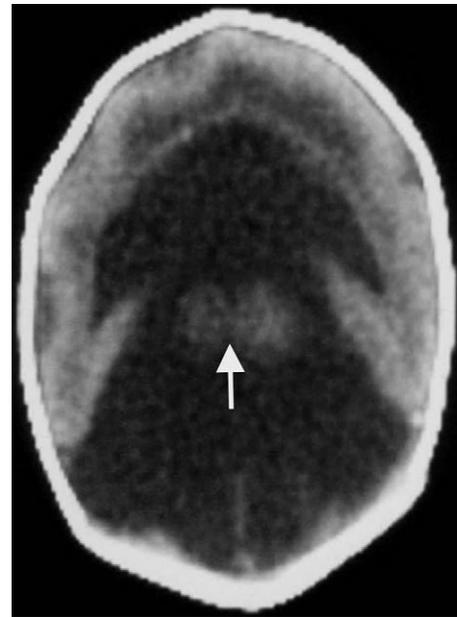

At about day 32 of gestation, when the embryo is 5 to 7 mm long, the second major event in forebrain development occurs when the forebrain is cleaved in the *sagittal* plane to give rise to the paired cerebral hemispheres, lateral ventricles, and basal ganglia. Specific areas, such as the hypothalamic, amygdaloid, hippocampal, and olfactory regions, can be defined. Shortly thereafter, the third major event in forebrain development occurs when the forebrain is cleaved in the *coronal* or *transverse* plane to separate the telencephalon from the diencephalon, thus defining the epithalamus, subthalamus, and hypothalamus.

During the remainder of the second and third months of gestation, the subsequent events in forebrain development occur along the midline to generate three major structures: the corpus callosum, the optic nerve/chiasm, and the hypothalamus. Disturbances in the formation of these midline structures, in particular, the corpus callosum and the optic chiasm, are reflected in abnormal axon “path-finding” to the midline and the failure of hemispheric and optic fibers to cross to the opposite hemisphere.

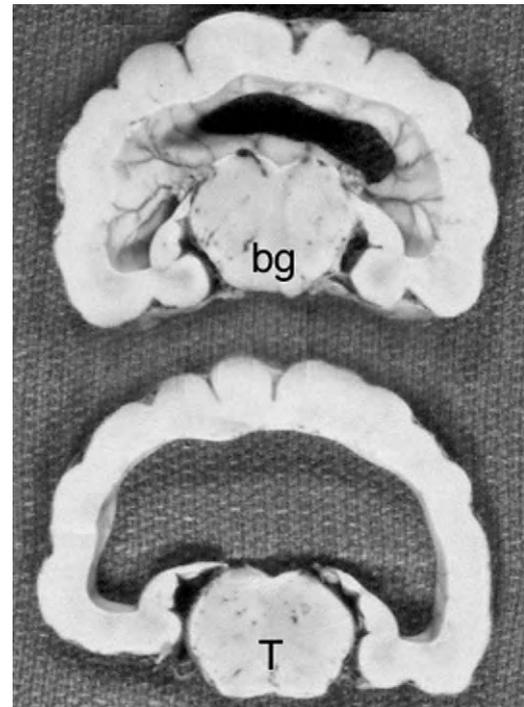

## Disorders of Structures Derived from the Prosencephalon

### Holoprosencephaly

Holoprosencephaly is the most common human brain malformation (Barr and Cohen, 1999; Norman et al, 1995a). It has a prevalence of 1/250 in the developing embryo and occurs in 1 in 10,000 to 1 in 20,000 live births. This defect involves a variable degree of incomplete cleavage of the prosencephalon along one or more of its three major planes. The spectrum includes alobar, semilobar, and lobar types. All three types have the unifying diagnostic feature of a single ventricle that is readily visualized by cranial ultrasonography, CT, or MRI (Fig. 63–9). In *alobar* holoprosencephaly (Fig. 63–10), a single anterior ventricle is contained within a holosphere (i.e., there is a complete lack of separation of the prosencephalon into two distinct hemispheres, manifesting as the absence of the interhemispheric fissure). There is agenesis of the corpus callosum, the thalami usually are fused, and the basal ganglia are a single mass. Milder presentations involve partially formed hemispheres—*semilobar* holoprosencephaly—and *lobar* forms in which the distinct hemispheres can be distinguished. Arhinencephaly, absence of the olfactory bulbs and tracts, always accompanies holoprosencephaly but can exist as an isolated lesion, in which case it usually is found incidentally at autopsy. Craniofacial anomalies range from cyclopia (a single central eye) with a nose-like structure (proboscis) above the eye, to cebocephaly (a flattened single nostril situated centrally between the eyes), to median cleft lip. Mildly affected infants may display a single central incisor or hypotelorism. Survival correlates with the severity of the brain malformations. Severely affected infants often are stillborn or rarely survive beyond the first year of life.

(Courtesy of Dr. Marjorie Grafe, Department of Pathology, Oregon Health & Science University.)

### Clinical Features

The degree of neurologic impairment is variable and directly reflects the severity of the cerebral malformation. In general, less severe pathology is associated with milder clinical deficits. These may include frequent apneic episodes that occur in association with intractable epilepsy or stimulus-sensitive tonic spasms. Autonomic dysfunction can manifest as temperature instability and hypothermia. Electrolyte dyscrasias, particularly hypernatremia or hyponatremia, occur in the setting of diabetes insipidus or inappropriate secretion of antidiuretic hormone, or both (Hasegawa et al, 1990). Failure to thrive occurs in association with impaired suck and swallow and may necessitate nasogastric or gastric tube feeding. Abnormalities of other organ systems, particularly cardiac, genitourinary, and gastrointestinal, occur commonly, even in cases without chromosomal anomalies.

Microcephaly is the norm. The spectrum of cognitive impairment correlates with the severity of the brain malformations. Less severely affected infants may display an apparently normal repertoire of behaviors, but closer examination reveals that these are often stereotypic and not stimulus-sensitive. Primitive reflexes may be persistent as well, and a social smile fails to develop.

### Etiology and Epidemiology

The etiology of holoprosencephaly clearly is multifactorial, and both genetic and environmental factors appear to contribute to the extremely variable spectrum of forebrain and craniofacial malformations (Golden, 1998; Muenke and Beachy, 2000; Norman et al, 1995a). It has been appreciated for over a century that a wide variety of environmental insults (e.g., ethanol, vitamin A toxicity related to elevated retinoic acid levels) applied experimentally can produce cyclopia during the early phase of gastrulation in vertebrate embryos. Maternal diabetes mellitus increases the risk for holoprosencephaly about 200-fold, to approximately 1% to 2% of all pregnancies.

The most common chromosomal disorders that manifest with holoprosencephaly are trisomies 13 and 18. At least 25 rare genetic syndromes are associated with holoprosencephaly and account for roughly 15% to 25% of cases. The most notable are the Smith-Lemli-Opitz, Rubenstein-Taybi, and Pallister-Hall syndromes (Muenke and Beachy, 2000), because the specific defects in these syndromes all appear to be related in part to disturbances in signaling via the Sonic hedgehog (Shh) pathway, discussed later on.

Holoprosencephaly is characterized by extreme intrafamilial variability. Asymptomatic or mildly affected family members may carry a deletion for a gene associated with holoprosencephaly, whereas in a subsequent generation, offspring with the same gene may be severely affected. One explanation for these paradoxical observations comes from recent studies supporting that the mode of inheritance for holoprosencephaly is most compatible with multigenic transmission (Ming and Muenke, 2002). Several mouse models of holoprosencephaly exist in which mutations in two distinct genes are required, whereas a mutation in only one gene results in an apparently normal phenotype. Several affected patients have been identified

in whom abnormal alleles for two separate genes were identified. Of interest, in these cases, a phenotypically normal parent carried a mutation for one gene but not the other (Nanni et al, 1999; Roessler et al, 1996). Hence, the severity of expression of the holoprosencephaly phenotype throughout a given family may be influenced by the additive contributions from multiple environmental/teratogenic and genetic factors, which may be weighted differently in each affected family member.

### Related Molecular Genetic Events

It was recognized decades ago that experimental ablation of the prechordal mesoderm, a mesodermal cell group under the ventral forebrain, disrupted the formation of the chiasmatic plate and optic vesicles and produced cyclopia. It was proposed that the prechordal plate induced the formation of ventral forebrain structures and directed the segmentation of the developing optic fields. Only recently has this complex picture begun to be clarified by the identification of eight genes expressed in the prechordal plate that directly or indirectly regulate the development of the ventral forebrain. All of these genes were identified in chromosomal regions with known deletions associated with holoprosencephaly. The complexity of the signaling pathways that regulates prosencephalic development is suggested by the fact that mutations in these eight genes account for only approximately 15% to 20% of the holoprosencephaly cases studied with normal karyotypes.

Sonic hedgehog (Shh) is a signaling molecule secreted in the prechordal mesoderm that directs early embryonic patterning of the ventral forebrain. Mutations of the gene for Shh were the first identified to cause human holoprosencephaly (Nanni et al, 1999; Roessler et al, 1996). *SHH* mutations appear to occur more frequently than do mutations of other genes and have been identified in both sporadic and familial cases. Subsequently, mutations in other genes in the Shh signaling pathway also were identified, underscoring the importance of defects in Shh signaling in the pathogenesis of holoprosencephaly (Muenke and Beachy, 2000). These include mutations in the receptor for Shh (Patched) and in the Gli family of zinc finger transcription factor that mediate Shh signaling downstream of the Patched receptor. Mutations in *GLI3* are associated with human disease.

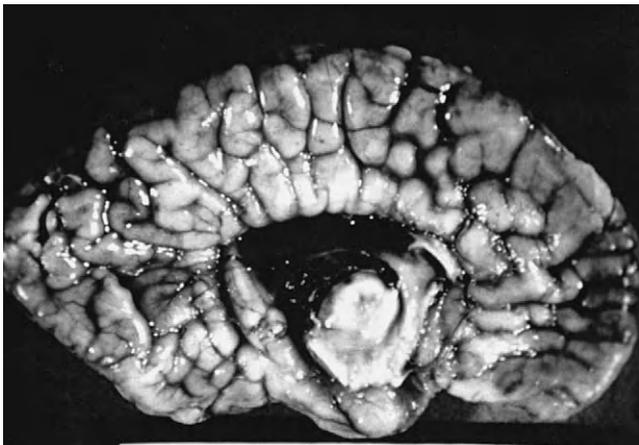

The signaling activity of Shh is regulated both by initial enzymatic processing of a precursor protein and by lipid modifications that involve the coupling of cholesterol and palmitate to Shh. The role of these lipid modifications is unclear, but they may serve to limit the diffusion of Shh, thereby controlling the sites in the embryonic ventral forebrain where Shh biologic actions occur. The importance of these lipid modifications is suggested by an apparent association between holoprosencephaly and some cases of Smith-Lemli-Opitz syndrome, which arises from a defect in the terminal step in cholesterol biosynthesis (7-dehydrocholesterol reductase); approximately 5% of cases of this syndrome manifest with cerebral malformations in the spectrum of holoprosencephaly. Of interest, two plant alkaloids—cyclopamine and jervine—have been identified that caused epidemics of cyclopia in sheep that ingested plants rich in these compounds. Both compounds alter Shh signaling pathway by inhibition of

cholesterol biosynthesis. Such findings support that the interactions of multiple environmental/teratogenic and genetic variables are likely to account for the considerable heterogeneity in the phenotypic expression of holoprosencephaly within families and populations.

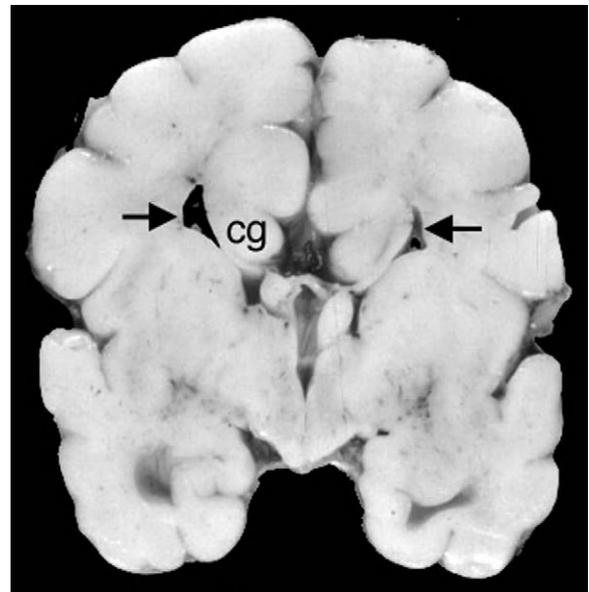

### Agenesis of the Corpus Callosum

Although sometimes found at autopsy as an incidental finding in otherwise asymptomatic persons, agenesis of the corpus callosum is not a discrete entity (Fig. 63–11). Rather, it is a nonspecific feature of at least 70 conditions and is associated with a wide variety of CNS malformations (Norman et al, 1995a). The corpus callosum is absent, for example, in alobar holoprosencephaly. Agenesis of the corpus callosum frequently is found in association with abnormalities of chromosomes 8, 11, 13 to 15, and 18 (Jeret et al, 1987). Agenesis of the corpus callosum also is variably found in fetal alcohol syndrome, Dandy-Walker syndrome, and Leigh disease and in association with the Arnold-Chiari type II malformation. Other CNS lesions are common in patients with agenesis of the corpus callosum (occurring in 29% to 80% of such patients) (Jeret et al, 1987; Parrish et al, 1979).

Agenesis of the corpus callosum may be difficult to distinguish from conditions in which dysgenesis, hypoplasia, or destructive lesions have occurred. The anatomic features of true agenesis of the corpus callosum include abnormal gyration of the medial portion of each hemisphere, eversion of the cingulate gyri, and sulcation that is perpendicular to the long axis of the hemisphere (Barkovich and Norman, 1988). The external angles of the lateral ventricle are oriented parallel and upward, toward the vertex, and the fornices are widely separated (Fig. 63–12). When present, a useful distinguishing feature is Probst's bundles, which are fiber bundles that run parallel to the ventricle and carry callosal fibers in an anterior-to-posterior direction. Agenesis of the corpus callosum can be total or partial; when it is partial, the splenium is involved, and the genu remains intact (Roessmann, 1995; Schaefer, 1991). Other, less frequently associated pathologic findings are neuronal migration abnormalities (neuronal

**FIGURE 63–11.** Agenesis of the corpus callosum. (Courtesy of Dr. Dawna L. Armstrong, Department of Pathology, Texas Children's Hospital.)

**FIGURE 63–12.** Agenesis of the corpus callosum. Note the eversion of both of the cingulate gyri (cg). The lateral ventricles are oriented parallel and pointed upward toward the vertex (arrows). Probst's bundles are not apparent in this immature brain. (Courtesy of Dr. Marjorie Grafé, Department of Pathology, Oregon Health & Science University.)

heterotopias, lissencephaly, pachygyria, and schizencephaly), hydrocephalus related to ventricular obstruction by a midline dorsal cyst of the third ventricle (Jeret et al, 1987) and tumors (Tagawa et al, 1989).

Four syndromes are characterized by agenesis of the corpus callosum: Aicardi, acrocallosal, Andermann, and Shapiro syndromes (Jeret et al, 1987). The Aicardi syndrome is notable for the association of complete or partial agenesis of the corpus callosum with severe epilepsy, mental retardation, and ocular lesions (optic coloboma, microphthalmia, chorioretinal lacunae) in girls (Aicardi et al, 1965). The inheritance pattern is proposed as X-linked dominant, with lethality in males. Nonrandom X-inactivation in lymphocytes has been noted to correlate with the severity of the neurologic symptoms (Neidich et al, 1990). The prominence of intractable seizure types, particularly infantile spasms, is related to neuronal migration abnormalities. These are primarily periventricular nodular heterotopias and polymicrogyria.

### Agenesis of the Septum Pellucidum and Septo-optic Dysplasia

Agenesis of the septum pellucidum frequently accompanies optic nerve hypoplasia and agenesis or thinning of the corpus callosum (Mott et al, 1992; Williams et al, 1993). This triad, known as *septo-optic dysplasia*, is clinically associated with pituitary dwarfism and other forms of hypothalamic-pituitary dysfunction. Although agenesis of the septum pellucidum is never an isolated finding, optic nerve hypoplasia can occur unilaterally or bilaterally without other associated lesions (Barkovich and Norman, 1989; Ouvrier and Billson, 1986; Zeki et al, 1992). Frequently,

other cerebral abnormalities are present, including schizencephaly and absence of the pituitary infundibulum. Children with septo-optic dysplasia are blind or have reduced vision and nystagmus. Their neurodevelopmental prognosis has been controversial. In earlier studies, cerebral palsy was found in 57%, mental retardation in 71%, epilepsy in 37%, and behavior problems in 20% of children with septo-optic dysplasia (Acers, 1981; Margalith et al, 1984). A more recent neurodevelopmental study of seven children with unilateral or bilateral optic nerve hypoplasia, whose only other documentable CNS abnormality was absence of the septum pellucidum, found normal cognitive development, intact neurologic status, normal language development, and age-appropriate behavior in six of the seven (Williams et al, 1993). Thus, the abnormalities found in many patients with septo-optic dysplasia are probably due to other associated brain lesions.

The cavum septi pellucidi is an opening formed by the separation of the lamellae of the septum pellucidum; the lamellae fuse as the fetal brain matures. The cavum septi pellucidi may persist into extrauterine life, especially in preterm infants. Mott and associates (1992) have documented the presence of a cavum septi pellucidi in all infants born at less than 36 weeks of gestation routinely studied by cranial sonographic examination. A cavum septi pellucidi was present in 36% of term newborns in the series reported by these investigators.

## DEVELOPMENT OF POSTERIOR FOSSA STRUCTURES

### Normal Hindbrain Development

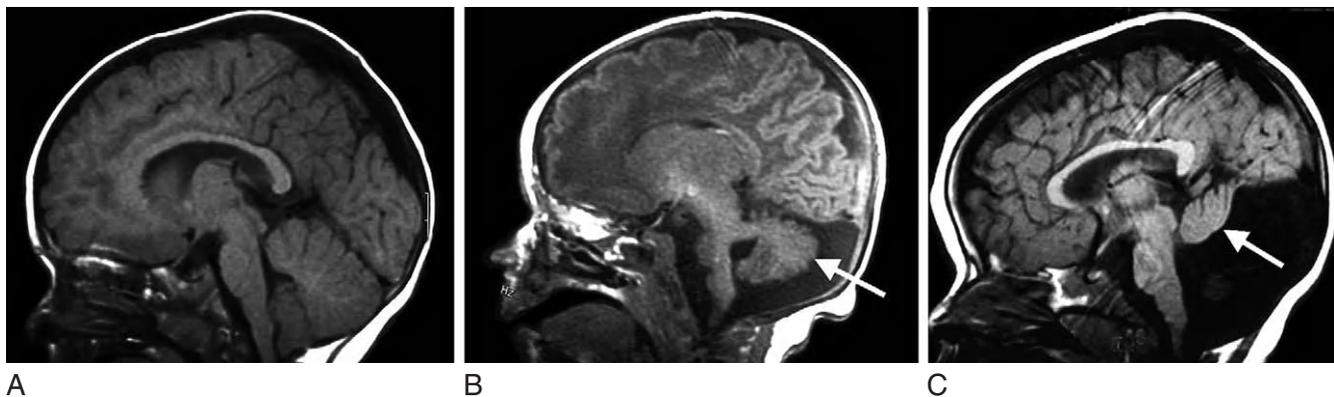

Malformations of the posterior fossa constitute an embryologically diverse group of disorders. Because these disorders frequently are associated with compromise to vital functions of the brainstem, clinical management may focus on concerns for apnea and hydrocephalus, for example. Controversies will undoubtedly persist regarding the appropriate classification of these disorders until such time as the molecular genetic basis is further resolved.

The onset of development of posterior fossa structures occurs shortly after closure of the neural tube and coincides with the onset of prosencephalic development. At this time, the primary brain vesicles of the primitive hindbrain (rhombencephalon) emerge distal to the prosencephalon along an anterior-posterior axis. The midbrain derives from the mesencephalon and is embryologically distinct from the rhombencephalon, from which the major hindbrain structures derive (cerebellum, pons [metencephalon], and medulla [myelencephalon]). At 3 to 5 weeks of gestation, the rhombencephalon can be identified between the cranial and cervical flexures of the neural tube. Eight distinct rhombomeres have been defined in the rhombencephalon. Rhombomere 1 gives rise to the cerebellum, and rhombomeres 2 to 8 give rise to the pons, medulla, and cranial nerves V to X.

## Malformations with Major Cerebellar Involvement

### Dandy-Walker Malformation

Of the cerebellar malformations associated with significant posterior fossa CSF collections, the prototype is the Dandy-Walker malformation (DWM). A number of other posterior fossa malformations share similar embryologic derivatives or similar anatomic features with DWM (Fig. 63–13). These include several syndromes of cerebellar vermis hypoplasia and dysplasia, syndromes that involve diffuse cerebellar hypoplasia, and syndromes with normal cerebellar size and architecture but with a large posterior fossa fluid collection that does not communicate with the fourth ventricle (e.g., mega cisterna magna, arachnoid cyst) (Altman et al, 1992; Niesen, 2002; Parisi and Dobyns, 2003; Patel and Barkovich, 2002). Moreover, numerous chromosomal anomalies, such as trisomies 9, 13 and 18, manifest with DWM. This malformation also has been described in association with a variety of genetic syndromes. One such is the Walker-Warburg syndrome,

**FIGURE 63-13.** Dandy-Walker malformation (DWM). Sagittal magnetic resonance images (MRI) from a normal brain (**A**), a child with Joubert syndrome (**B**), and a child with DWM (**C**) illustrate that features of the hindbrain malformations seen in DWM overlap with those of other disorders. Note the presence of cerebellar vermis hypoplasia (*arrow*) in both **B** and **C**. By contrast, the patient with Joubert syndrome (**B**) has only a slightly enlarged fourth ventricle, whereas in DWM (**C**) the fourth ventricle is massively dilated. (Courtesy of Dr. Joseph G. Gleason, Department of Neurology, University of California, San Diego, School of Medicine; and Dr. William B. Dobyns, The University of Chicago School of Medicine.)

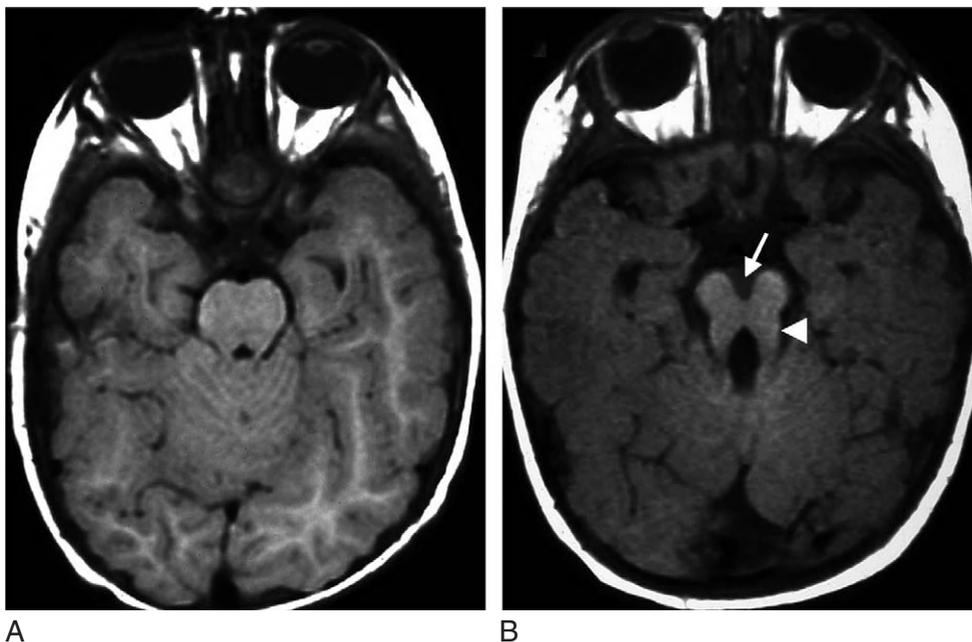

which is characterized by not only extensive brainstem and cerebellar hypoplasia but also ocular anomalies, congenital muscular dystrophy, cortical migration abnormalities, and encephalocele. These associations have led to a variety of attempts for unifying classification schemes under the rubric of “DWM and its variants.” Because the molecular mechanisms that underlie these malformations are mostly unknown, there is currently no basis for linking them as a spectrum. It should be emphasized that a more unfavorable outcome is related to the extent of other posterior fossa and CNS malformations. Hence, when “DWM” is diagnosed, the prenatal and postnatal management and prognosis depends on precise definition of the particular anatomic abnormalities present. High-resolution MRI is particularly valuable for definition of associated CNS malformations. The most clinically significant defects are agenesis of the corpus callosum and cerebral neuronal migration disturbances (polymicrogyria and heterotopias).

Precise estimates of the incidence of DWM are clearly affected by the lack of agreement regarding the definition of DWM. Nevertheless, DWM appears to occur in at least 1 in 5000 live born infants (Parisi and Dobyns, 2003). The invariant features of DWM are aplasia or hypoplasia of the vermis of the cerebellum, cystic dilation of the fourth ventricle, and enlargement of the posterior fossa with upward displacement of the lateral sinuses, tentorium, and torcular (Benda, 1954; D’Agostino, 1963; Friede, 1989; Hart et al, 1972). The enlargement of the posterior fossa and displacement of its contents are related to communication of the fourth ventricle with a retrocerebellar cyst, which may be of considerable size. Communicating hydrocephalus with dilated lateral ventricles also is a common feature and may manifest in the neonatal period with macrocephaly. In fact, a majority of cases of DWM manifest with symptoms related to hydrocephalus (Costa and Hauw, 1995; Hart et al, 1972). There is no general agreement regarding the optimal management of hydrocephalus in DWM, which usu-

ally involves some combination of ventricular or posterior fossa shunt placement. Other prominent pathoneurologic features include ataxia, nystagmus, apnea, cranial neuropathies, and developmental delay.

### Syndromes Associated with the Molar Tooth Sign

Abnormalities of the cerebellum also are found in Joubert syndrome, which is the most extensively studied of several uncommon autosomal recessive cerebello-oculorenal syndromes associated with the molar tooth sign (MTS) (Parisi and Dobyns, 2002). The cerebellar lesion usually involves complete or partial agenesis of the vermis (see Fig. 63-13B), but there may also be dysplasia of the dentate nucleus, cerebellar heterotopias, anomalies of brainstem nuclei, and absence of decussation of the pyramidal tracts (Curatolo et al, 1980). The lesion responsible for the MTS is defined as the triad of cerebellar vermis hypoplasia and two mid-hind brain malformations (an abnormally deep interpeduncular fossa and elongated cerebellar peduncles). When viewed on axial MRI studies (Fig. 63-14), the brainstem malformations have the distinctive appearance of a molar tooth. The most prominent clinical features of Joubert syndrome are hypotonia, abnormal eye movements (horizontal nystagmus and oculomotor apraxia), ataxia, abnormal breathing patterns (periods of hyperpnea alternating with apnea), and cognitive delays/mental retardation (Joubert et al, 1969). Variable features of Joubert syndrome include occipital encephalocele, microcephaly, low-set ears, polydactyly, and pigmentary retinopathy (Egger et al, 1982; Friede and Boltshauser, 1978). Renal disease in Joubert syndrome includes cystic dysplasia of the kidneys and juvenile nephronophthisis. The latter is a form of medullary cystic renal disease that progresses to chronic renal failure (Satran et al, 1999).

**FIGURE 63-14.** Molar tooth sign (MTS). Compare the axial magnetic resonance image of a normal brain (**A**) with that of the brain of a child with Joubert syndrome (**B**). Note two key features of the MTS: a deepened interpeduncular fossa (*arrow*) and the elongated superior cerebellar peduncles (*arrowhead*). The third feature, cerebellar vermis hypoplasia, is seen in Figure 63-13B. (Courtesy of Dr. Joseph G. Gleason, Department of Neurology, University of California, San Diego, School of Medicine.)

## CENTRAL NERVOUS SYSTEM DEVELOPMENT IN THE POSTEMBRYONIC PERIOD

### Normal Development of the Cortical Plate

#### *Proliferative Events*

Four transient tangential layers form during the process of cerebral cortical development. From the ventricle to the brain surface, these layers are the ventricular, subventricular, intermediate, and marginal zones. Initially, the nascent cortical plate derives from the *ventricular zone* (VZ). The VZ is the site of earliest proliferation of neuronal and radial glial progenitor cells in the wall of the neural tube. As the cerebral wall expands, the *subventricular zone* becomes a secondary site of later neuronal and glial proliferation. These proliferative events occur roughly between 4 and 16 weeks of gestation. Peak cell proliferation occurs around 8 to 16 weeks. This coincides with the appearance and expansion of the cortical plate, which appears when the embryo is about 22 to 24 mm long, at about 52 days.

The initial cycles of neural progenitor proliferation in the VZ result in the symmetrical expansion of the stem cell pool such that each mitotic event results in the generation of two additional stem cells (Caviness et al, 1995; Rakic, 1995). This process determines the total pool of stem cells, or so-called proliferative units, from which the cortical plate will form. Once the generation of this stem cell pool stabilizes, a second phase of proliferation begins during which individual stem cell clones begin to divide asymmetrically. During this phase of clonal expansion, each mitotic division generates an additional stem cell and another neuronal cell that withdraws from the cell cycle. The latter postmitotic neuron then begins migration from the VZ to the outer wall of the neural tube. Hence, this second phase of asymmetrical cell division results in the expansion of each individual stem cell clone or proliferative unit. Eventually, this phase results in a proportionately larger number of postmitotic cells that all derive from the same proliferative unit.

#### *Migrational Events*

Rakic (1998) first proposed that the postmitotic neurons that derive from an individual clonal population in the VZ migrate together along the same radial glial fiber to generate individual columns of cells within the cortical plate. The radial glial processes extend from the VZ to the outer wall of the neural tube and serve as a scaffold to guide the migration of individual clones of postmitotic neurons to form the preplate. Migration of neurons from the VZ occurs in an “outside-in” fashion, such that the neurons farthest from the ventricle migrate first and those closest to the ventricle migrate last.

As neuronal migration proceeds, the preplate is split by the arrival of subsequent populations of neuronal progenitors that will form the cortical plate. The cortical plate ultimately gives rise to cortical layers IIB to IV. The splitting of the preplate results in the formation of the *marginal zone* (future cortical layer I) and the subplate, which resides between the *intermediate zone* (the future cerebral white matter) and the bottom of the cortical plate (Marin-Padilla, 1988, 1998). The Cajal-Retzius

neurons of the marginal zone and the subplate neurons play critical roles in neuronal migrations, as discussed later.

As neuronal migration progresses, each subsequent group of neurons migrates past the neurons that migrated earlier. Hence, the earliest neurons to migrate eventually reside in the deepest cortical layer. Because the last neurons to migrate are closest to layer 1, the cortical layers are thereby formed in an “inside-out” sequence. The major events involved in formation of the cortical layers are occurring between approximately 7 and 11 weeks.

#### *Subplate Neurons and Establishment of Thalamocortical Connections*

As emphasized previously, the cortical plate develops from within the preplate. The preplate consists of the earliest-generated neurons and a plexus of nerve fibers. With subsequent waves of neuronal migration, the preplate is split into the marginal zone (i.e., a superplate) and a subplate. Hence, the cells in these layers are among the earliest-generated neurons. In the second trimester, two subcortical afferent systems are present in the subplate (Allendoerfer and Shatz, 1994): thalamocortical fibers and basal forebrain fibers, which remain in the subcortical region for a period of time before their fibers penetrate the cortical plate. The neurons of layer IV in the cortex receive their predominant ascending inputs from the thalamus. Of interest, however, the thalamic axons are present in the cortex long before the layer IV neurons have reached the cortical plate. These axons reside in the subplate for a period of weeks in proximity to postmitotic neurons in the subplate. Most of these early-maturing subplate neurons undergo programmed cell death after the thalamic axons have grown into the cortical plate (Chun et al, 1987).

Hence, subplate neurons transiently appear during a critical window in development, and few are present in the adult neocortex. In humans, the subplate achieves its peak size by 24 weeks of gestational age and declines thereafter (Kostovic and Rakic, 1990). The hypothesis that these subplate neurons play a critical role in thalamocortical development by guiding thalamic axons into the cortical plate has been substantiated by studies showing that deletion of the early subplate neurons prevents the thalamic axons from innervating the cortex. Thus, the transient subplate neurons play an important role in establishing both thalamocortical and corticocortical connections (Ghosh et al, 1990; Kanold et al, 2003).

## Disorders of Neuronal Proliferation

### Micrencephaly

*Micrencephaly* is a disorder in which the primary defect is a marked reduction in the size of the brain or of the cerebral hemispheres. *Microcephaly* denotes a small cranial vault (less than 2 standard deviations below normative curves for age) that is associated with either micrencephaly or acquired brain atrophy (e.g., multicystic encephalopathy, hydranencephaly, diffuse cortical atrophy). Until recently, micrencephaly was considered to be an isolated defect of either decreased neuronal proliferation or increased apoptosis (programmed cell death). Representative examples

are radial microbrain and “microencephaly vera,” discussed next (Evrard et al, 1989; Rakic, 1988). However, MRI studies have begun to define greater heterogeneity in the types of malformations that are associated with micrencephaly (Barkovich et al, 2001). Associated malformations include simplified gyral patterns, microlissencephaly with thickened cortical gray matter, and polymicrogyria (Barkovich et al, 1998; Peiffer et al, 1999; Sztriha et al, 1998). The association of micrencephaly with features of cortical neuronal migration abnormalities suggests overlap in the mechanisms that direct neuronal proliferation and migration in humans.

Two subgroups of isolated micrencephaly, *radial microbrain* and “*micrencephaly vera*,” provide insight into mechanisms of isolated disturbances of neuronal proliferation. Radial microbrain appears to be related to a reduced number of proliferative units. By contrast, “microencephaly vera” appears to be related to a reduced size of proliferative units (Evrard et al, 1989; Rakic, 1988). Radial microbrain is a rare familial condition characterized by a normal gyral and cortical lamination pattern but an abnormal number of cortical neuronal columns. Because the number of cells per column is normal, this implies that the defect resides in early neural stem cell division with an impact on the ultimate number of “proliferative units” available to generate the cortical columns.

“Micrencephaly vera” describes a variety of conditions with small brain size in which the underlying etiology may be related to a disturbance in neuronal proliferation. Cases of autosomal recessive “micrencephaly vera” demonstrate a simplified gyral pattern. The number of cortical neuronal columns is normal, but the cell number in each column is reduced (Evrard et al, 1989). This constellation of findings is most likely to occur between 6 and 18 weeks of gestation, when later proliferative events occur.

The etiology of micrencephaly includes diverse factors. Irradiation before 18 weeks of gestation is a well-known teratogenic factor that can produce micrencephaly. Exposure to alcohol and cocaine during this time also can result in micrencephaly (Gieron-Korthals et al, 1994; Peiffer et al, 1979). Maternal hyperphenylalaninemia also has been associated with these defects in nonphenylketonuric offspring (Lenke and Levy, 1980; Waisbren and Levy, 1990). Autosomal dominant, autosomal recessive, and X-linked recessive inheritance patterns have been described (Robain and Lyon, 1972; Warkany et al, 1981).

Recently, at least five genetic loci for human autosomal recessive primary micrencephaly (MCPH) have been mapped (Mochida and Walsh, 2001). All result in a small but structurally normal-appearing brain and a similar degree of mental retardation without other neurologically distinguishing features. The most prevalent is MCPH5, for which the defect was recently shown to involve protein-truncating mutations in the *ASPM* gene. *ASPM* (abnormal, spindle-like, microcephaly-associated) encodes a human microtubule-associated protein required for normal mitotic spindle function in embryonic neuronal stem cells (Bond et al, 2003). Of interest, some deletions that were sufficient to cause MCPH5 mapped to a region of *ASPM* that contains a series of repeated calmodulin-binding “IQ” (intelligence quotient) domains (Bond et al, 2002). The number of these “IQ” repeats varies between species and

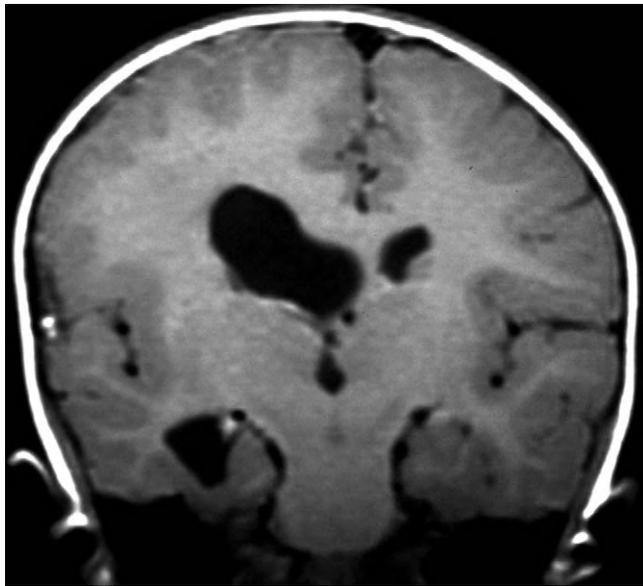

is directly proportional to the ultimate size of the protein. Whereas the *Drosophila* homologue contains only 24 “IQ” repeats, the mouse has 61 and the human *ASPM* gene contained the highest number, 74. Although the function of the large insertion encoded by these IQ repeats is unknown, a direct correlation was established between the size of the IQ domain and brain size during evolution. The distribution and timing of appearance of *Aspm* in proliferative regions of the developing murine CNS before and after birth indicate that it is required for normal neurogenesis and determination of brain size.

## Macrencephaly

Macrencephaly refers to a diverse group of conditions characterized by a large brain. Although it has been hypothesized that macrencephaly is related to an aberrant increase in neuronal proliferation, quantitative neuropathologic studies are lacking. Macrencephaly manifests most commonly as an isolated finding in familial (autosomal dominant or autosomal recessive) and sporadic cases. Among the other diverse conditions that are associated with macrencephaly are chromosomal disorders (fragile X syndrome and Klinefelter syndrome) and neuroendocrine disorders related to a generalized disturbance in growth (Beckwith-Wiedemann syndrome, cerebral gigantism, and achondroplasia) (DeMyer, 1972; Dodge et al, 1983).

At birth, the head circumference in about half of the cases is greater than that for the 90th percentile. The diagnosis of autosomal dominant macrencephaly is greatly favored by the finding of a large head circumference (macrocephaly) in either parent. Autosomal dominant inheritance generally is associated with a more favorable outcome, whereas the rare cases of autosomal recessive inheritance commonly are associated with mental retardation and epilepsy. One generally benign form of autosomal dominant macrencephaly is accompanied by extracerebral fluid collections that enlarge the subarachnoid spaces (Alvarez et al, 1986). Erroneously referred to as “external hydrocephalus,” this condition rarely constitutes an indication for placement of a shunt to drain the fluid. Rather, the initial acceleration in head circumference generally arrests spontaneously by around the first year of life; thereafter, the fluid collections decrease in amount. These fluid collections appear to be related to an imbalance in CSF generation at birth related to developmental immaturity of the subarachnoid granulations that resorb this fluid (Barlow, 1984; Neveling and Truex, 1983).

Hemimegalencephaly (Fig. 63–15) refers to a rare malformation consisting of unilateral macrencephaly related to enlargement of some portion of one cerebral hemisphere and accompanied by increased cortical thickness and abnormal cortical gyration (Robain et al, 1972). The primary defect is unknown. The pathologic features include apparent disturbances in astroglia proliferation and morphology as well as neuronal heterotopias in subcortical white matter (DeRosa et al, 1992). The usual onset for intractable epilepsy is in the neonatal period (Ohtsuka et al, 1999). A markedly improved outcome may be achieved in selected patients after hemispherectomy performed as early as the neonatal period (Battaglia et al, 1999).

**FIGURE 63-15.** Hemimegalencephaly: Magnetic resonance image. Note the marked asymmetry of the two cerebral hemispheres, with the pronounced enlargement on the left. (Courtesy of Dr. Martin Salinsky, Department of Neurology, Oregon Health & Science University.)

### Disorders of Neuronal Migration

Neuronal migration disorders are characterized anatomically by defects in the lamination of the cerebral cortex. Most of these defects are related to some degree of failure of neurons to migrate to their appropriate target positions within the normal six layers of the developing cerebral cortex. The clinical spectrum of brain malformations associated with disrupted neuronal migration ranges from complete focal agenesis of an entire region of the cerebral cortex in schizencephaly to more subtle abnormalities in which heterotopic clusters of neurons are retained in abnormal locations within the subcortical white matter (see Table 63-1). In many disorders, there are prominent disturbances in the formation of the cortical surface that manifest as gyral abnormalities. At one end of the spectrum of these abnormalities is complete absence of gyri, with a smooth cortical surface (lissencephaly); at the other end is an excess of small gyral convolutions (polymicrogyria). The fact that these gyral abnormalities often are accompanied by other malformations, such as hypoplasia or agenesis of the corpus callosum, points to a complex interplay between the mechanisms that determine neuronal migration and axon path-finding. This is consistent with the fact that the timing of neuronal migration and that of midline prosencephalic development overlap. Hence, disturbances in neuronal migration would be anticipated to have a deleterious impact on the axonotropic signaling required for establishment of interhemispheric and intrahemispheric cortical connections.

### Schizencephaly

Schizencephaly (“split brain”) is characterized by severe focal malformations of the cerebral cortex that result in complete agenesis of all layers of the cortical wall. The

resultant defect is a cleft in the cerebral cortex in one or both hemispheres, which thus connects the lateral ventricle with the extracerebral space (Fig. 63-16). When the defect is wide (separated-lip schizencephaly), the malformation may be confused with a lesion due to a severe destructive process. However, a feature of schizencephaly that differentiates it from an encephaloclastic lesion (e.g., hydrancephaly, porencephaly) is that on histologic examination, the cleft has features of a migrational disturbance, such as large neuronal heterotopias bordered by adjacent polymicrogyria. When the defect is narrow (closed-lip schizencephaly), it has the appearance of a narrow groove in the cortical mantle. The morphologic features of schizencephalic clefts by neuroimaging are best delineated by MRI, which has demonstrated the common occurrence of subependymal heterotopias and polymicrogyria and the universal finding of diminished volume of the cerebral white matter (Hayashi et al, 2002a). In addition, a wide range of anomalies related to disturbances of prosencephalic development may occur in association with schizencephaly.

A

B

**FIGURE 63-16.** Bilateral open-lip schizencephaly: Magnetic resonance images. **A**, Axial T1-weighted image. Note that the bilateral clefts (arrows) extend to the lateral ventricles. **B**, Coronal T1-weighted image. Note that the clefts (arrows) are lined with gray matter (\*). (Courtesy of Dr. A. James Barkovich, Department of Radiology, University of California, San Francisco, School of Medicine.)

These include holoprosencephaly, agenesis of the corpus callosum, and agenesis of the septum pellucidum.

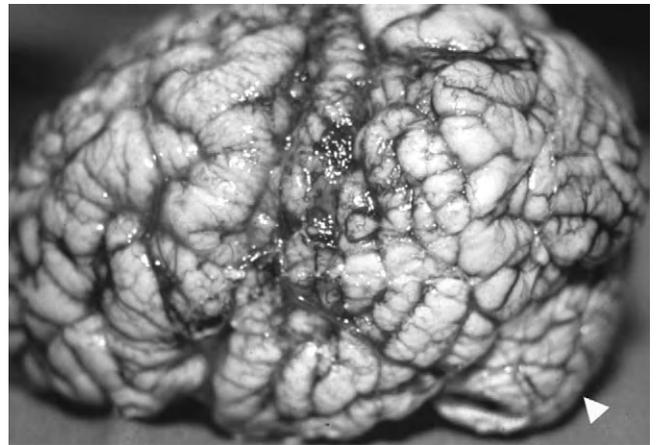

Schizencephaly occurs with a wide range of clinical severity that is related to the size and distribution of the cerebral clefts and the extent of associated malformations (Barkovich and Kjos, 1992; Packard et al, 1997). Significant cognitive impairment is almost universal with bilateral anomalies but occurs in a minority of cases with unilateral lesions. Motor disturbances are common with both unilateral and bilateral lesions; this finding may be related in part to the predilection for frontal lesions. A wide variety of seizure types, including partial epilepsies, are common (Guerrini and Carrozzo, 2001). Hydrocephalus is seen almost exclusively with separated-lip lesions.

Of interest, in one large series, schizencephaly involved predominantly the regions of the rolandic and sylvian fissures in the frontal cortex (Barkovich and Kjos, 1992). The basis for this predilection is suggested by rare familial cases of severe separated-lip schizencephaly associated with mutations in the human homeobox gene *EMX2* (Granata et al, 1997). In mice, *Emx2* and the *Pax6* homeobox genes are expressed in opposing anterior-to-posterior gradients in the cortical ventricular zone. Multiple studies support that these *Emx2* and *Pax6* countergradients intrinsically specify the size of anterior and posterior cortical areas (Monuki and Walsh, 2001). Mutations in *Emx2* result in disturbances in neuronal migration via radial glial fibers and cause shifts in the regionalization of cerebral cortex such that anterior lateral cortical areas are expanded, whereas posteromedial areas are reduced in size (Bishop et al, 2000; Mallamaci et al, 2000). Other potential etiologic factors in schizencephaly are suggested by both experimental and clinical findings in schizencephaly following fetal viral infection of the CNS (Iannetti et al, 1998; Takano et al, 1999).

### Polymicrogyria

Polymicrogyria constitutes a heterogeneous group of malformations with multiple potential etiologic factors. The unifying feature is an excess number of small convolutions on the cortical surface (Fig. 63–17). The cortical mantle is thin and excessively folded and may contain multiple fused gyri. Histopathologic studies have defined two major types of polymicrogyria, layered and unlayered, each characterized by an abnormal cortical lamination pattern. In contrast with the normal six-layered cerebral cortex, *layered polymicrogyria* comprises four distinct cortical layers. This “classic” form is not associated with other migrational abnormalities but often is more diffusely localized adjacent to regions of encephalomalacia related to infection (e.g., toxoplasmosis, cytomegalovirus infection) or ischemia with cortical laminar necrosis.

*Unlayered polymicrogyria* is characterized by a markedly disorganized cortex that lacks distinct cortical layers. The timing of appearance of this form appears to be no later than 4 to 5 months of gestation. Unlayered polymicrogyria is associated with other migrational disturbances, particularly subcortical nodular heterotopias, lissencephaly, and schizencephaly. A genetic basis is suggested by syndrome associations (e.g., Zellweger syndrome, Miller-Dieker syndrome),

**FIGURE 63–17.** Polymicrogyria. Much of the cerebral cortex in this photograph shows the irregular, “cobblestone” appearance of polymicrogyria. More normal gyri are present at the frontal pole (*lower left*). The cerebellum is indicated at lower right (*arrowhead*). (Courtesy of Dr. Marjorie Grafe, Department of Pathology, Oregon Health & Science University.)

familial transmission, and sporadic cases with X-linked, autosomal recessive and autosomal dominant inheritance patterns (Barkovich et al, 1999; Ross and Walsh, 2001). Several syndromes of bilateral polymicrogyria have been mapped to specific genetic loci (Chang et al, 2003; Villard et al, 2002).

Delineation of the spectrum of CNS malformations associated with polymicrogyria has been greatly advanced by MRI. Of importance, if thick sections (thicker than 4 mm) are imaged, these anomalies may resemble focal pachygyria owing to signal averaging from the microgyri. Four subtypes have been identified by high-resolution MRI with thin sections: isolated polymicrogyria, an association with localized megalencephaly, subcortical heterotopias, or schizencephaly (Hayashi et al, 2002b). Polymicrogyria shows a strong predilection for the sylvian fissure and adjacent regions of frontal and parietal cortex, whereas the cingulate cortex, striate cortex, gyrus rectus, and hippocampus are spared. A further defining feature is often a decrease in cerebral white matter volume adjacent to the regions of dysplastic cortex.

The clinical features of patients with polymicrogyria are variable and relate in part to the distribution of cortical dysplasia. Several familial syndromes of bilateral polymicrogyria encompass much of the spectrum of clinical findings (Barkovich et al, 1999). Epilepsy, notably partial complex seizures and multiple generalized seizure types, is common but may be delayed in onset beyond the neonatal period. In bilateral frontoparietal polymicrogyria, consistent findings include global developmental delay, dysconjugate gaze/esotropia, and bilateral pyramidal and cerebellar motor signs (Chang et al, 2003). The perisylvian cortex is devoted to control of the mouth and the motor programs of language. Dysarthria, language delay, abnormal tongue movements, dysphagia, and severe seizures are features of familial syndromes with bilateral polymicrogyria of the perisylvian cortex. Discoordination of suck and swallow is common in the neonate (Guerriero et al, 2000).

### Lissencephaly and Pachygyria

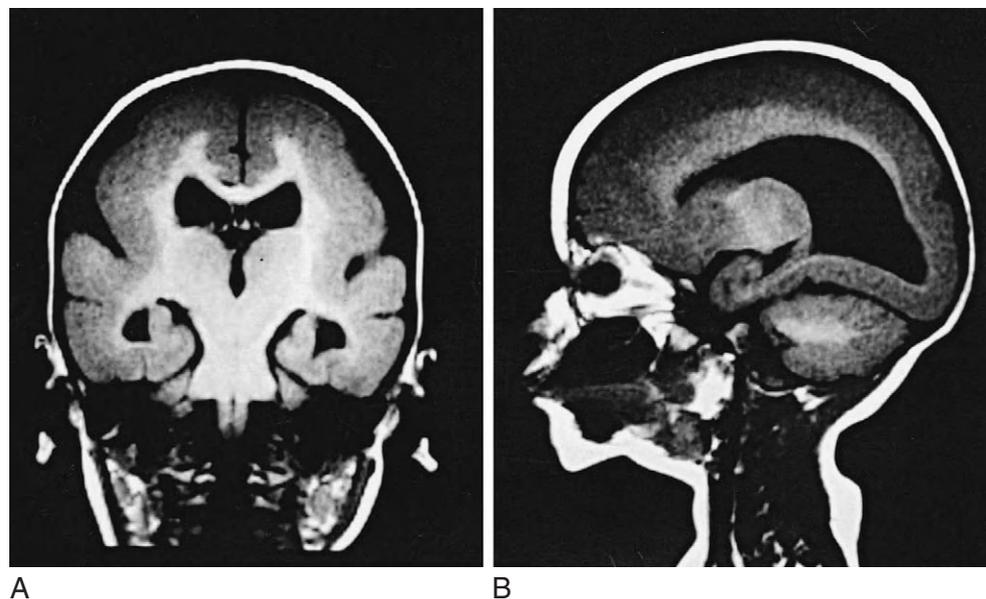

The lissencephalies are a class of neuronal migrational disorders characterized by a paucity or absence of gyri (*agyria*), which gives the cortical surface a smooth or nearly smooth appearance (Kato and Dobyns, 2003). In most patients, lissencephaly is characterized by an abnormally thick cortex and disturbances in the organization of the cortical layers that may be accompanied by diffuse neuronal heterotopias (Fig. 63–18). The spectrum of gyral malformations includes *pachygyria*, characterized by regions of cortex with a reduced number of coarse, broadened gyri, and *subcortical band heterotopia* (“double cortex”), in which a circumferential band of heterotopic neurons resides within the subcortical white matter directly beneath a relatively normal cortex.

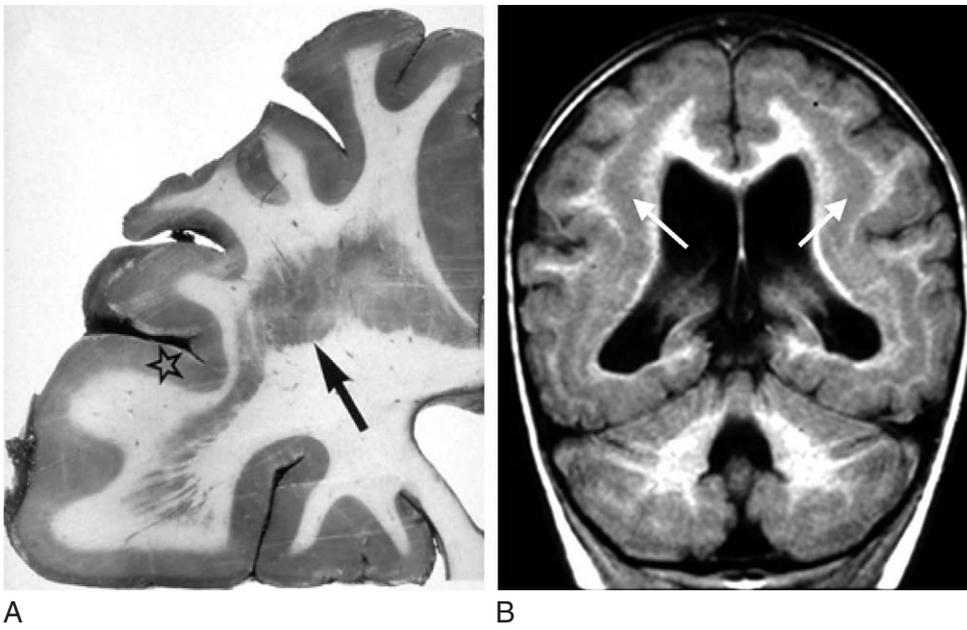

The classification of the lissencephalies has undergone major revision to reflect the rapidly evolving understanding of the molecular basis of these disorders (Barkovich et al, 2001). A majority of cases are subsumed under the *classic lissencephaly/subcortical band heterotopia spectrum* (previously type 1). At present, five genes are known to cause or contribute to lissencephaly in humans (Kato and Dobyns, 2003). Two of these genes, *LIS1* and *DCX*, account for a majority of cases of classic lissencephaly. Mutations of the *LIS1* gene were first detected in the Miller-Dieker syndrome (severe lissencephaly and distinct craniofacial abnormalities) after identification of chromosome 17p13.3 deletions in greater than 90% of these patients (Ledbetter et al, 1992). This syndrome is always associated with a more severe lissencephaly phenotype, which appears to reflect the fact that the 17p deletion also contains the 14–3–3 $\epsilon$  gene, which also is implicated in neuronal migration. Subsequent studies determined that sporadic cases of isolated lissencephaly were caused by *LIS1* mutations as well. *LIS1* encodes a noncatalytic subunit of a ubiquitously expressed enzyme, platelet-activating factor acetylhydrolase. The mechanisms by which *LIS1* mutations disrupt neuronal migration relate in part to its roles in cell motility as well as mitosis (neurogenesis).

The *DCX* gene was first demonstrated to cause X-linked lissencephaly and subcortical band heterotopia. *DCX* encodes the doublecortin protein, which is a neuron-specific protein that functions in part in microtubule polymerization and may interact with LIS-1 (des Portes et al, 1998; Gleeson et al, 1998). Mutations in the *ARX* gene result in another form of X-linked lissencephaly with abnormal genitalia, further characterized by abnormal basal ganglia, often with small cysts, immature white matter, and agenesis of the corpus callosum (Kitamura et al, 2002). *ARX* is a homeobox gene specifically expressed in forebrain interneurons and the male gonads, where it directs differentiation of the testes. *ARX* functions in proliferation of neuronal progenitors and in differentiation and migration of interneurons.

LIS-1, doublecortin, and other genes implicated in neuronal migration encode proteins that appear to interact via functionally complex signaling mechanisms to modulate alterations in cell shape at the level of the actin and microtubule-based cytoskeleton (Ross and Walsh, 2001). It is thus not surprising that LIS-1 and DCX mutations are associated with considerable variation in the phenotypic expression of classic lissencephaly. Six distinct grades of morphologic severity have been defined that overlap among agyria, pachygyria, and subcortical band heterotopia (Kato and Dobyns, 2003). The most severe form (grade 1) usually is associated with either the Miller-Dieker syndrome or a severe mutation of *DCX*. Moreover, the gyral malformations associated with *LIS1* mutations are more pronounced posteriorly than anteriorly, whereas the gradient of injury is reversed (more pronounced anteriorly than posteriorly) with *DCX* mutations. The picture is further complicated in X-linked dominant lissencephaly insofar as males and females typically display different phenotypes related to *DCX* mutations. Owing to hemizygoty for *DCX* on the X chromosome, males often display severe lissencephaly resembling that seen in *LIS1* mutations. Because of lyonization (random X-inactivation), females typically display the subcortical band heterotopia phenotype (Fig. 63–19). However, when mosaicism for the aberrant

**FIGURE 63–18.** T1-weighted magnetic resonance images of the brain of a child with classic lissencephaly. **A**, Coronal view. **B**, Sagittal view. Elizabeth Ross, Department of Neurology, University of Minnesota; Christopher A. Walsh, Department of Neurology, Harvard Medical School.)

*DCX* allele predominates, some *DCX* females can display severe lissencephaly.

Although predictions of genotype are not readily feasible on the basis of the pattern of malformations present, clinical features more consistently correlate with the lesions present. Superior definition of malformations is achieved by MRI. In the newborn, the typical presentation of isolated lissencephaly is pronounced hypotonia accompanied by a lack of motor activity. Only later in the first year may spasticity develop. Depending on the nature of the *LIS1* mutation on chromosome 17, craniofacial anomalies can be subtle (bitemporal hollowing and a small jaw) or may entail the full expression of the Miller-Dieker syndrome (Dobyns et al, 1984). Head circumference is typically normal at birth, but progressive microcephaly evolves during the first year of life. Although neonatal seizures may occur, severe myoclonic epilepsy typically develops in the latter half of the first year (e.g., infantile spasms, Lennox-Gastaut syndrome) (Gerrini and Carrozzo, 2002). Isolated lissencephaly carries poor long-term prognosis dominated by mental retardation, spastic quadriplegia, and epilepsy. The severity of clinical deficits is typically less for infants with focal pachygyria. Patients with subcortical band heteropia are much less affected than those with isolated lissencephaly. Although potential sequelae include development of seizures and cognitive impairment, roughly 25% of patients have normal or near-normal intelligence. Neurologic deficits roughly correlate with the thickness and extent of the subcortical band (Dobyns et al, 1996).

### Lissencephaly with Cerebellar Hypoplasia

Lissencephaly with cerebellar hypoplasia (LCH) encompasses six broad classes (designated a to f) of malformations that have in common a lissencephaly spectrum of agyria-pachygyria plus some degree of cerebellar hypoplasia (Barkovich et al, 2001; Kato and Dobyns, 2003; Ross et al, 2001). Individual classes are defined on the basis of

additional malformations (e.g., brainstem hypoplasia, agenesis of the corpus callosum). The prototype for these disorders is LCHb, in which lissencephaly is accompanied by severe global cerebellar hypoplasia and a very malformed hippocampus. The lissencephaly is characterized by a moderately thick cortex with an anterior-to-posterior decreasing gradient of severity. Several patients with LCHb have proven mutations in the *RELN* gene, which encodes reelin, a large extracellular matrix protein (Hong et al, 2000; Ross and Walsh, 2001). This is a notable finding, because the mouse homologue of the *RELN* gene has been shown to account for the phenotype of the reeler mouse, a severely ataxic mutant mouse strain in which the cerebral cortex and cerebellar cortex display an inversion of the normal mammalian “inside-out” laminar organization pattern (Rakic and Caviness, 1995). A role for reelin in neuronal migration is supported by the observation that it is secreted by the Cajal-Retzius cells of the embryonic preplate as well as cerebellar external granule cell layer neurons and pioneering cells of the hippocampus. The distribution pattern of reelin is thus consistent with the pattern of malformations seen in LCHb. Functionally, reelin activates a signal transduction pathway via two distinct membrane-associated lipoproteins, the apolipoprotein E<sub>2</sub> and the very-low-density lipoprotein receptors. These receptors direct the phosphorylation of mDab1, which on activation participates in actin polymerization, an integral event in cell migration. Of interest, abnormalities very similar to those in the reeler mouse are observed in mutant mouse strains with disruptions of mDab1 or both lipoprotein receptors.

### Cobblestone Complex Syndromes

The cobblestone complex syndromes are included here because they all involve abnormal neuronal migration and were previously classified with type II lissencephaly (Barkovich et al, 2001). Three congenital muscular dystrophy syndromes are represented: Walker-Warburg syndrome,

muscle-eye-brain disease, and Fukuyama congenital muscular dystrophy. The isolated cobblestone complex malformation without retinal or muscle involvement is rare. The neuronal migration anomaly in the cobblestone complex arises as a result of failure of early migrating neurons to arrest at the marginal zone (the future layer I of the cerebral cortex). Rather, these heterotopic neurons migrate further through a defective glia-limiting membrane into the leptomeninges, which thicken and adhere to the cortical surface—hence the term *cobblestone lissencephaly*. These collections of leptomeningeal neurons can be sufficiently large to obliterate the subarachnoid spaces, with resultant communicating hydrocephalus related to disruption of CSF resorption. The organization of the cerebral cortex is markedly more abnormal than in classic lissencephaly and is characterized by large ectopic clusters of neurons with no discernible lamination pattern.

*Walker-Warburg syndrome* is the most severe of the three cobblestone complex congenital muscular dystrophy syndromes (Warburg, 1987). Several clinical features distinguish this entity from classic lissencephaly. Macrocephaly commonly is present at birth or develops in the first year of life. The macrocephaly typically is related to communicating hydrocephalus, as well as dilation of the third and fourth ventricles when a retrocerebellar cyst is present (see later). In addition to lissencephaly, cerebellar/hindbrain and oculoretinal malformations and congenital muscular dystrophy also are universal and required for the diagnosis. Cerebellar malformations are discussed earlier, in the context of DWM, and include midline cerebellar hypoplasia and retrocerebellar cyst. Protrusions of the retrocerebellar cyst through a skull defect can result in a posterior encephalocele. Ocular anomalies include retinal detachment, optic nerve hypoplasia, microphthalmia, and colobomas. The muscular weakness is typically severe and is associated with elevated serum creatine kinase. The prognosis for survival beyond the first year is poor. This complex constellation of features may be recalled by the eponym CHARM + E (*cerebellar hydrocephalus, agyria, retinal, muscle, encephalocele*) (Volpe, 2000).

The spectrum of brain malformations in *muscle-eye-brain disease* is generally less severe than in Walker-Warburg syndrome. These include milder lissencephaly with frontal pachgyria and less severe occipital gyral dysplasia. Midline cerebellar hypoplasia is more variable, and the retrocerebellar cyst and encephalocele are not seen. Ocular abnormalities include retinal and optic nerve hypoplasia, cataracts, and glaucoma.

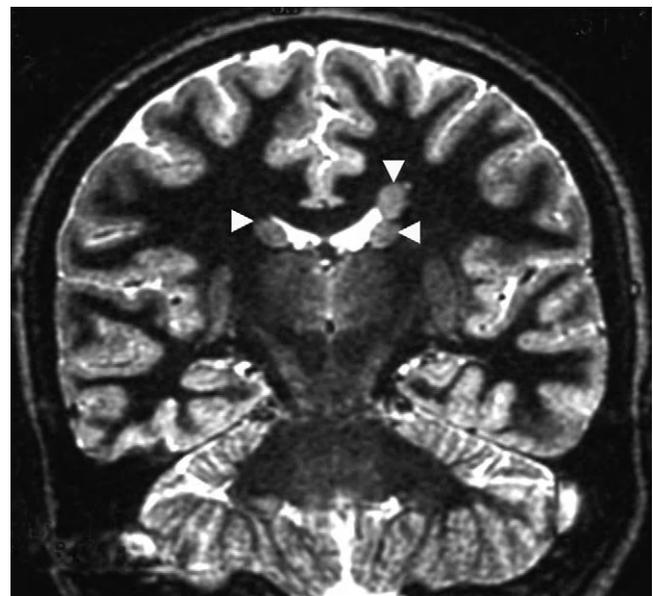

The cobblestone complex malformations are generally the least severe in *Fukuyama congenital muscular dystrophy* (FCMD), and the eye abnormalities are minor or do not occur (Fukuyama et al, 1984). The cortical dysplasia in FCMD, however, is sufficiently severe to produce severe mental retardation in at least half of the patients. Hence, it can be difficult clinically to distinguish between patients with severe FCMD and those with mild Walker-Warburg syndrome.

Despite overlap in their clinical features, current data indicate that the cobblestone complex muscular dystrophy syndromes are genetically distinct autosomal recessive disorders (Cormand et al, 2001). Emerging evidence suggests that these disorders belong to a new class of

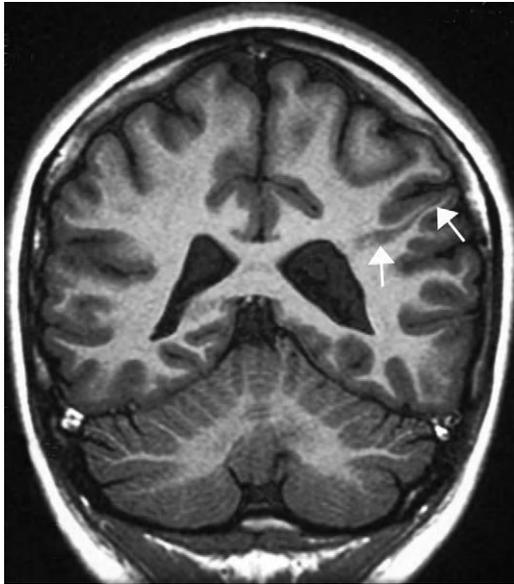

glycosylation-deficient muscular dystrophies that are related to mutations in enzymes that catalyze the post-translational *O*-glycosylation of a small number of mammalian glycoproteins (Grewal and Hewitt, 2003). Point mutations in POMT1, a putative *O*-mannosyltransferase, account for approximately 20% of cases of Walker-Warburg syndrome (Beltran-Valero de Barnabe et al, 2002). The defect in muscle-eye-brain disease is in *POMGnT1*, the gene for a definitive mannosyltransferase, *O*-linked mannose  $\beta$ 1,2-*N*-acetylglucosaminyltransferase-1 (Taniguchi et al, 2003). The defect in FCMD resides in the protein fukutin (Kobayashi et al, 2000), a putative phospholigand transferase that shares homology with microbial proteins involved in mannosyl phosphorylation. Hence, the preponderance of data suggests that the overlapping clinical phenotypes for the three cobblestone complex muscular dystrophies are related to defects in a common glycosylation pathway that involves *O*-mannosylation of proteins.

### Neuronal Heterotopia

Heterotopia are displaced collections of neurons that have failed to complete their normal migration from the ventricular zone. They are most commonly observed in periventricular white matter, where they are nodular collections of cells (“periventricular nodular heterotopia”) (Fig. 63–20), or in the subcortical white matter, where they may be nodular or diffuse (Fig. 63–21). Heterotopia are in fact a feature of virtually all of the migrational disorders. In addition, they are often the primary migrational disturbance associated with a wide range of disorders. These include metabolic disorders, fetal toxic exposures,

**FIGURE 63-20.** Magnetic resonance imaging scan of brain in periventricular nodular heterotopia. Three discrete periventricular nodular masses (*arrowheads*) are visualized adjacent to the lateral ventricles in this T2-weighted coronal image. Note the otherwise normal convoluted pattern of the cerebral cortex. (Courtesy of Dr. Martin Salinsky, Department of Neurology, Oregon Health & Science University.)

**FIGURE 63-21.** Subcortical white matter heterotopia: Magnetic resonance imaging scan. This T1-weighted coronal image shows a diffuse stream of heterotopic gray matter (*arrows*) that spans from near the ventricular surface to the cerebral cortex. The appearance of this focal disturbance of neuronal migration suggests that the neurons were “hung up” in their migration from the ventricular surface to the cerebral cortex. (Courtesy of Dr. Martin Salinsky, Department of Neurology, Oregon Health & Science University.)

and neurocutaneous, multiple congenital, and chromosomal syndromes (Volpe, 2000). Hence, the clinical significance of heterotopic neurons in these conditions may be as an overt sign of a more serious underlying neurologic condition.

As isolated disorders, the heterotopias are clinically and pathologically less severe than the subcortical band heterotopias, separate disorders that are variously expressed in the spectrum of classic lissencephaly, discussed earlier. The isolated heterotopias are classified with regard to a primary periventricular (subependymal), subcortical white matter, or marginal (superficial cortical/leptomeningeal) site of pathology (Barkovich et al, 2001). Typically, superficial cortical neuronal heterotopias are incidental finding at autopsy. However, glial-neuronal heterotopias that infiltrate the leptomeninges occur in association with fetal exposure to teratogens such as methylmercury (Choi et al, 1978) or as seen in the fetal alcohol syndrome (Norman et al, 1995b).

The most well-characterized isolated heterotopia syndrome is the bilateral periventricular nodular heterotopia (BPNH) syndrome (Ross and Walsh, 2001). The BPNH syndrome is inherited as an X-linked dominant disorder that therefore occurs in females and usually is embryonic lethal in males. A familial syndrome exists in which the typical presentation is one of epilepsy associated with normal intelligence. The milder phenotype in females relates to apparent X-inactivation, in which silencing of the normal allele has occurred in the heterotopic neurons. The gene defect in BPNH involves filamin 1 (FLN-1), an actin cross-linking phosphoprotein that appears to function in

the actin remodeling required for cell migration out of the ventricular zone (Fox et al, 1998).

Focal cortical dysplasias are commonly associated with subcortical neuronal heterotopias. They are characterized by focal gyral abnormalities in which a normal cortical lamination pattern is lacking. These lesions may have the appearance of focal polymicrogyria or pachygyria. Although the origin of these lesions is unclear, they are composed mostly of ectopic neurons that express glutamatergic markers (Crino et al, 2001). This finding has led to the speculation that cortical dysplasias derive from single clones of ventricular zone progenitors that normally are destined to generate a cortical column of glutamatergic projection neurons (Monuki and Walsh, 2001).

The development of high-resolution MRI has greatly advanced the detection of neuronal heterotopias and cortical dysplasias. Such studies, together with autopsy findings, support the notion that subtle migrational dysplasias are not uncommon and may be present in virtually all of us. The application of positron emission tomography has also greatly facilitated the detection of heterotopias and other cortical dysplasias that may be undetected by MRI (Juhasz et al, 2003). Such imaging studies have demonstrated the role of these lesions in the pathogenesis of a variety of medication-resistant seizure disorders that may be controlled by surgical resection (Guerrini and Carrozzo, 2002; Russo et al, 2003).

It is clear that the evolutionary pressures that led to the enormous expansion of the human cerebral cortex required more elaborate genetic programs, at times unique to human development (Gupta et al, 2002). Remarkably, the study of human brain malformations has now become a critical interface between developmental molecular neurobiology and neonatal medicine that is unraveling the intricate mechanisms that determine the development of the human brain.

## Central Nervous System Injury and Neuroprotection

Ashima Madan, Shannon E. G. Hamrick, and Donna M. Ferriero

### INJURY AND PROTECTION IN THE DEVELOPING NERVOUS SYSTEM

Injury in the developing brain from ischemia results in a variety of pathologic patterns based on age at the time of insult, severity of the insult, mechanism of the insult, and the selective vulnerability of populations of cells undergoing active metabolic change. The most common type of injury in the preterm brain is intraventricular hemorrhage (IVH) from germinal matrix bleeding. IVH is a common injury in the premature brain due to perturbations of circulatory factors affecting the venous system. Hypoxic-ischemic injury results in periventricular leukomalacia (PVL) in the premature brain, whereas in the term brain, the deep gray matter is more likely to be affected. A variety of patterns of cortical and subcortical parenchymal injuries can be seen, depending on how the arterial supply is disrupted. Stroke from arterial or venous (sinovenous thrombosis) causes can occur at any time in the perinatal period. A number of traumatic injuries also can occur in the neonatal period, including damage to the calvaria, cranial nerves, spinal cord, and peripheral nerves. The ability to protect against these varied types of ischemic injuries will depend on accurate diagnosis, careful early management, and the development of age-appropriate therapies.

#### Intraventricular and Periventricular Hemorrhage in the Preterm Infant

##### Pathogenesis

IVH originates in the subependymal germinal matrix. Cortical neuronal and glial cell precursors develop from the germinal matrix and adjacent ventricular germinal zone during the late second and early third trimesters. The subependymal germinal matrix is a highly vascularized region whose arterial supply is derived from the anterior and middle cerebral arteries as well as the anterior choroidal artery. These arteries feed an elaborate capillary network of thin-walled vessels that is continuous with a deep venous system that terminates in the vein of Galen. The terminal, choroidal, and thalamostriate veins course anteriorly to form the internal cerebral vein, which courses posteriorly to join the vein of Galen, thus leading to a U-shaped turn

in the direction of blood flow. Involution of the germinal matrix occurs with advancing gestation.

The predisposition of the premature infant to IVH probably is due to several factors. A pressure-passive state exists due to the lack of autoregulation of cerebral blood flow in the cerebral arterioles in the premature brain. In the presence of a highly vascularized subependymal germinal matrix, the lack of a supporting basement membrane in the blood vessels of the germinal matrix and an increased amount of fibrinolytic activity in the germinal matrix region also predispose to the development of IVH. Extravascular tissue pressure decreases in the first few days of extrauterine life, and in the setting of elevation of venous pressure or an increase in fluctuations in cerebral blood flow velocity from a variety of factors (respiratory distress, pneumothorax, asphyxia, myocardial failure, patent ductus arteriosus, hypotension, hypothermia, hyperosmolarity), IVH may occur (Ment and Schneider, 1993).

IVH has been produced experimentally after hypotension followed by reperfusion (Goddard-Finegold et al, 1982; Ment et al, 1982), and infants with IVH are more likely to have had an early period of prolonged hypotension followed by an increase in blood pressure (Miall-Allen and Whitelaw, 1987; Miall-Allen et al, 1987). Hypertension associated with seizures, attempts at intubation, and suctioning also can lead to IVH. Even gavage feeding can lead to changes in cerebral hemodynamics as measured by near-infrared spectroscopy (NIRS) (Mischel et al, 1997). Disturbances in coagulation from various causes can lead to IVH. In rare cases, hemorrhage can result from a congenital arteriovenous malformation, a ruptured aneurysm, or small hemangiomas or papillomas of the choroid plexus (Schum et al, 1979). Table 64–1 lists the different factors that may interact in an individual case to produce IVH.

Cellular injury in infants with grade III or IV IVH may occur from ischemic injury that may precede IVH, from a decrease in cerebral blood flow to the region of the intraparenchymal bleed, or from increased intracranial pressure, as well as vasospasm and from post-hemorrhagic hydrocephalus. These conditions are associated with periventricular white matter injury and pontine neuronal necrosis (Volpe, 2001b). In this setting, venous infarction leads to neuronal as well as oligodendroglial cell death (Craig et al, 2003).

##### Site, Incidence, and Timing of Hemorrhage

In preterm infants, germinal matrix hemorrhage is most commonly seen at the junction of the terminal, choroidal, and thalamostriate veins in the germinal matrix over the body of the caudate nucleus at the level of the foramen of Monro. Parenchymal hemorrhage occurs most commonly in the frontoparietal region, in approximately 15% of cases, and is thought to be not an extension of the IVH but rather a separate process, a hemorrhagic infarction. The hemorrhage is more often unilateral or, in less than 30% of cases, asymmetrically bilateral.

The incidence and severity of IVH increase with decreasing gestation. It occurs in approximately 4.6% of term newborns and was previously reported to occur in

**TABLE 64-1****Pathogenetic Factors Leading to Intraventricular Hemorrhage**

Increase in cerebral venous pressure
Endothelial injury
Vulnerable germinal matrix capillaries
Coagulation disturbances
Increased fibrinolysis

40% to 60% of very low-birth-weight (VLBW) infants (less than 1500 g). An overall reduction of IVH in this population to 15% to 20% has been observed in the past decade (Paneth et al, 1993; Vohr et al, 2000). Although there has been a gradual decline in the incidence of all grades of IVH, the increased survival of VLBW infants has resulted in an increase in the absolute number of infants with IVH. The risk period for the occurrence of IVH is highest in the first 3 or 4 days of life. Hemorrhage is rarely seen at birth, although it has been reported as early as within the first hour of age (Ment et al, 1984). Antenatal hemorrhages can occur, especially in the setting of neonatal alloimmune thrombocytopenia. Twenty-five percent of hemorrhages occur by the sixth hour and 50% of hemorrhages occur during the first 24 hours of life. Less than 5% of infants develop IVH after the fourth or fifth day of life (Ment and Schneider, 1993). Extension of the hemorrhage may occur over the first few days secondary to events leading to alteration in cerebral blood flow.

**Clinical Presentation**

The clinical presentation of IVH in the newborn depends on the extent of the hemorrhage and may vary from asymptomatic to a sudden and catastrophic deterioration that manifests with neurologic signs such as stupor or coma, fixed pupils, seizures, decerebrate posturing, or apnea. A full fontanel along with drops in hematocrit, hyperglycemia, hyperkalemia, hypotension, and bradycardia herald an IVH. Inappropriate secretion of antidiuretic hormone may also be present. The more common presentation, however, is that of a gradual clinical deterioration with an altered level of consciousness, hypotonia, abnormal extremity or eye movements. In 25% to 50% of cases, clinical correlation is lacking (Dubowitz et al, 1998).

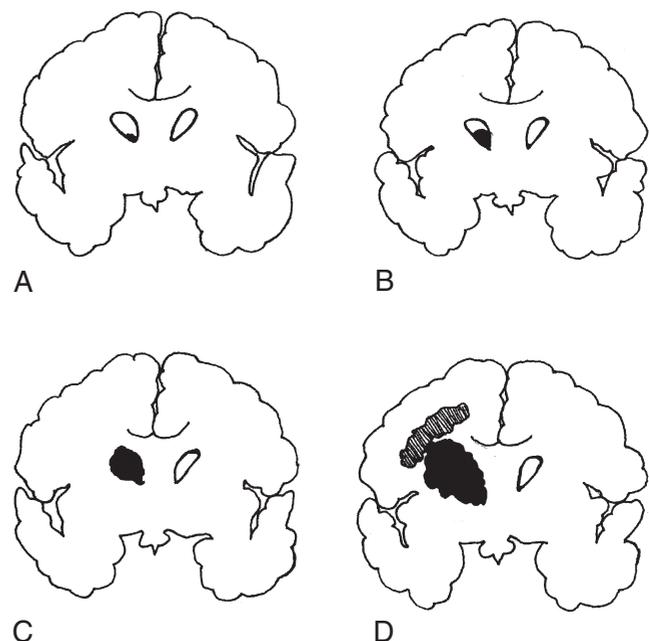

**Screening for Intraventricular Hemorrhage**

A practice parameter published jointly by the American Academy of Pediatrics, the American Society of Pediatric Neuroradiology and the Society for Pediatric Radiology recommends routine screening with cranial ultrasonography for all infants of less than 30 weeks of gestation between 7 and 14 days of age. A repeat ultrasound examination is recommended between 36 and 40 weeks of postmenstrual age (Ment et al, 2002). Insufficient evidence

exists at present to recommend routine magnetic resonance imaging (MRI) screening of all LBW infants with abnormal findings on head ultrasound examination (Ment et al, 2002). However, considerable advances in the field of MRI in premature infants have been made recently (Miller et al, 2002a). Several studies have focused on determining the spectrum of white matter injury detected by MRI and its effect on neurodevelopment (Groenendaal et al, 1997; Huppi et al, 1998; Inder et al, 1999; Maalouf et al, 1999, 2001; Ment et al, 2002; van Wezel-Meijler et al, 1998). It is now becoming clear that lesions that affect developmental outcome and that are not present on cranial ultrasound images can be detected by MRI. Therefore, we recommend that an MRI study be considered in all extremely low-birth-weight (ELBW) infants at 36 to 40 weeks of postmenstrual age if clinical suspicion for parenchymal brain injury exists.

**Grading of Intraventricular Hemorrhage**

Ultrasound examination is a reliable and sensitive technique for evaluating the severity of IVH in the newborn nursery (Pape et al, 1979, 1983). Papile and associates (1978) adapted the standard grading system originally applied to computed tomographic images of IVH to ultrasound images and classified IVH into four different grades of severity depending on the location and extent of the bleed (Fig. 64-1; Table 64-2). Outcome studies performed over the past decade use this system for classification. In

**FIGURE 64-1.** Illustration of intraventricular hemorrhage (IVH) grades as determined by degree of hemorrhage (see Table 64-2). **A**, Grade I hemorrhage involves less than 10% of the ventricular volume in the lateral ventricles; **B**, grade II hemorrhage involves 10% to 50%; **C**, grade III involves greater than 50% of the ventricular volume and is often associated with some ventricular dilatation; and **D**, grade IV (Papile et al, 1978) or unclassified (Volpe, 2001) is associated with parenchymal echodensities on head ultrasound study, indicating parenchymal infarction.

TABLE 64-2

**Grading of Intraventricular Hemorrhage (IVH) by Cranial Ultrasound Findings**

Papile	Grading System	Volpe	Grading System*
I	Subependymal hemorrhage with minimal or no intraventricular hemorrhage	I	Germinal matrix hemorrhage <10% IVH
II	Definite intraventricular hemorrhage without distention of the ventricles	II	IVH 10%-50%
III	Enlargement of the ventricles secondary to distention with blood	III	IVH >50%, usually with distention of lateral ventricle
IV	Extension of the hemorrhage into the parenchyma along with intraventricular hemorrhage and enlargement	Separate notation	Periventricular echodensity signifying parenchymal lesion

\*By cranial ultrasound

IVH, intraventricular hemorrhage

the preferred grading system used by Volpe (2001b), the presence of intracerebral hemorrhage or parenchymal lesions is mentioned separately and not designated as grade IV. This system relies on the head ultrasound examination as the diagnostic measure and more accurately defines IVH based on the extent of the ventricular hemorrhage. Because parenchymal involvement is a distinct process, it is not included in the continuous grading (see Table 64-2).

### Outcome and Prognosis

Grade I hemorrhage and grade II hemorrhage generally are followed by resolution. Grade III hemorrhage evolves over a period of 1 to 3 weeks and in some cases produces a fibrotic reaction that obliterates the subarachnoid space and leads to ventricular dilatation and hydrocephalus. Traditional clinical criteria of increasing ventricular dilatation such as rapid head growth, full anterior fontanel, and separated cranial sutures often appear days or even weeks after the dilatation begins. This delayed appearance is due to the presence of a large subarachnoid space as well as the paucity of myelin in premature infants. In 15% of cases of IVH, areas of periventricular hemorrhagic involvement are noted (Volpe, 2001b). This finding is believed to be due to an independent venous infarct of the periventricular white matter and not a direct extension of the IVH into the parenchyma (Volpe, 2001b). Intraparenchymal hemorrhage is followed in 1 to 8 weeks by tissue destruction and formation of a porencephalic cyst. Outcomes vary between studies, but in general, mortality rates are not significantly increased in infants with a grade I or II hemorrhage. Grades III and IV are associated with increased mortality, with mortality rates in neonates suffering hemorrhagic infarction approaching 50% (Vohr et al, 2000; Whitelaw, 2001).

Several studies have focused on the relationship between IVH and subsequent neurologic dysfunction. Again, grade I IVH and grade II IVH are not associated with significant morbidity. However, grade III is associated with neurologic sequelae in 35% of infants, and grade IV is associated with sequelae in as many as 90% of affected infants (Whitelaw, 2001). The severity of neurologic sequ-

lae such as seizures, severe motor handicap, and severe hearing and vision impairment increases in infants with grade III or IV hemorrhage in whom persistent ventriculomegaly develops. The presence of hydrocephalus with or without shunting at term increases the odds of a poor neurodevelopmental outcome. Vohr and colleagues (2000), in a longitudinal study of 90 preterm infants with birth weights of less than 1750 g, reported that by 2 years of age, only infants with grade III and grade IV differed in neurologic examination findings from the term control infants. Unlike motor function, cognitive function as assessed by the Bayley scores deteriorates in the first 18 months of life. Infants with grade I and grade II IVH have lower scores than those infants with no IVH or normal term infants. Follow-up studies have shown that the degree of IVH at birth and the presence of ventriculomegaly are predictors of neurologic status at 5 years (Lowe and Papile, 1990; Ment et al, 1999; Vohr et al, 1992, 1999). Data suggest that even infants with lesser degrees of hemorrhage are at risk for cognitive difficulties possibly related to under-recognized white and gray matter injury (Inder, 1999).

### Prevention

Prevention of preterm birth is the most effective method of eliminating IVH. In the event of preterm labor it is advisable that the infant be born at a center specializing in high-risk deliveries. The risk of IVH is higher in infants who are transported after birth. Adequate management of labor and delivery is essential. Appropriate resuscitation of the preterm infant and vigilance in avoiding hyperventilation and low PCO<sub>2</sub> or hypoxia, maintaining adequate mean arterial pressure, and avoiding elevations in cerebral blood flow by excessive handling or tracheal suctioning are vital. Prevention of pneumothorax and acidosis and avoidance of rapid infusions of sodium bicarbonate or volume expanders also are critical. Due to the increased risk of neurodevelopmental sequelae in infants with IVH, several clinical trials have studied the effects of different pharmacologic interventions to reduce the incidence of IVH. Muscle paralysis causes a decrease in the fluctuations of cerebral blood flow velocity, and a controlled prospective

study of short-term paralysis showed reduction in IVH in the paralyzed group (Perlman et al, 1985). Several clinical trials have been done to evaluate the role of prolonged neuromuscular paralysis in preterm infants. A meta-analysis of five trials concluded that although neuromuscular paralysis with pancuronium may help decrease IVH and pneumothorax in asynchronously breathing infants, its routine use cannot be recommended because of concerns about safety and long-term pulmonary and neurologic effects. (Cools and Offringa, 2000).

A low mean arterial blood pressure (MAP) and an increase in fluctuation of blood pressure have been associated with an increased risk of IVH. Close monitoring of the MAP is recommended; however, there is no evidence suggesting that pharmacologic manipulation of the MAP (e.g., with pressors, steroids, or volume expanders) to achieve a set goal (e.g., MAP >30 mm Hg) alters the incidence of IVH or improves neonatal outcome. Antenatal phenobarbital administration was shown in early studies to be beneficial by preventing fluctuations in blood pressure (Donn et al, 1981). Subsequently, the results of a large multicenter trial testing the effect of antenatal administration of phenobarbital (10 mg/kg) to 610 women on the frequency of IVH in infants between 24 and 33 weeks of age showed no decrease in IVH in infants born to mothers treated with phenobarbital (Kaempf et al, 1990). Although additional studies showed some benefit for higher grades of hemorrhage, there was no significant difference in neurologic outcome in the treated population (Shankaran et al, 1996). Postnatal administration of phenobarbital has also not been shown to be effective (Kuban et al, 1986).

Pharmacologic doses of vitamin E, an antioxidant, were associated with a reduction in the incidence of IVH in LBW infants when given intramuscularly (Speer et al, 1984). However, following reports of the association of such large doses of vitamin E with sepsis and necrotizing enterocolitis, its use for prevention of IVH was curtailed (Finer et al, 1984; Johnson et al, 1985).

Indomethacin, a prostaglandin synthetase inhibitor, had originally been shown to decrease the incidence of IVH in infants weighing less than 1250 g (Ment et al, 1985). In a subsequent study of 431 infants, low-dose indomethacin (0.1 mg/kg) given intravenously (IV) at 6 to 12 hours of age and every 24 hours for a total of three doses decreased the incidence and severity of IVH (Ment et al, 1994). Follow-up studies at 4.5 years of age showed no adverse effect of indomethacin on neurodevelopmental function (Ment et al, 2000). However, indomethacin is not without short-term serious side effects. A meta-analysis of 16 studies demonstrated an increase in renal complications and necrotizing enterocolitis to achieve only a slight reduction in grade III or IV IVH (Fowlie, 1996). A more recent study on the long-term effects of indomethacin prophylaxis in extremely LBW infants showed no improvement in the rate of survival without neurosensory impairment at 18 months, despite the reduction in severe IVH (Schmidt et al, 2001).

Ethamsylate, an inhibitor of prostacyclin synthesis used to reduce capillary bleeding in surgery, has been shown in a multicenter randomized controlled trial to reduce the severity and overall incidence of IVH (Benson et al, 1986). Use of antenatal steroids (Canterino et al, 2001; Elimian et al, 2000; Smith et al, 2000) and surfactant replacement

therapy have been shown to decrease the incidence of IVH as well as neonatal mortality in LBW infants (Soll and Dargaville, 2000). The increase in IVH reported with surfactant administration may occur as a result of the mode of instillation (Cowan et al, 1991; Hellstrom-Westas et al, 1991, 1992). A significant drop in MAP and cerebral blood flow volume can occur during surfactant administration; attention should be paid to the speed and volume of instillation.

Several studies have been done to evaluate the early use of high-frequency oscillatory ventilation (HFOV) versus conventional ventilation for infants with respiratory distress syndrome. Some of these studies have shown an increased incidence of IVH with HFOV (HIFI Study Group, 1989; Castro et al, 2000; Moriette et al, 2001). Other studies did not find an increase in IVH (Keszler et al, 1997).

It is important to avoid both hypocarbia ( $PCO_2 < 30$  mm Hg) or hypercarbia ( $PCO_2 > 55$  mm Hg) because of effects on cerebral blood flow. Hypocarbia is associated with hypotension as well as an acute decrease in cerebral blood flow. Avoiding low  $PCO_2$  has been shown to be neuroprotective in animal studies (Sola et al, 1983; Vannucci et al, 1995). Although the effect of low  $PCO_2$  levels has not been systematically studied in preterm infants, low levels have been shown to be deleterious in term infants with pulmonary hypertension (Ferrara et al, 1984). Hypercarbia leads to increases in cerebral blood flow, which in the presence of other therapies aimed at increasing blood pressure, may be damaging to the central nervous system (CNS).

Free radicals and iron have been shown to be damaging to oligodendrocytes in both cell culture and animal studies (Back et al, 1998; Dommergues et al, 1998). Also, iron-chelating agents such as deferoxamine have been shown to be neuroprotective (Sarco et al, 2000). It may be wise to prevent iron overload during the period of critical cortical development (Gressens et al, 2002). Similarly, avoiding hyperoxia is important to prevent free radical injury.

Several of the medications that are used frequently in LBW infants may have effects on neurodevelopment. The long-term neurodevelopmental effects of theophylline and caffeine, which are frequently used to prevent apnea in preterm infants, have not been studied. Postnatal steroid use in preterm infants has been found to be associated with an increased risk of PVL and poor neurodevelopment (Merz et al, 1999; Murphy et al, 2001). Pain medications such as morphine, fentanyl, and midazolam are often used for analgesia in ventilated preterm infants. However, there is increasing concern regarding the potential detrimental effects of this practice on the developing brain. Recently, Simons and colleagues (2003) found that routine morphine infusion in ventilated preterm newborns had no measurable analgesic effect and no beneficial effect on neurodevelopment. More controlled studies are needed comparing the efficacy and safety of different analgesic practices in the preterm population.

## Management

Infants with birth weights of less than 1500 g or gestational age of less than 32 weeks should have a screening ultrasound performed to detect IVH. A scan on the fourth

postnatal day detects 90% of lesions. Because extension of the bleed sometimes occurs over the next few days, a repeat ultrasound examination after 5 days is necessary to establish the extent of the bleed.

The decision to continue intensive care support depends on the severity of the bleed as assessed by head ultrasound examination as well as the infant's gestational age and clinical condition. Parents should be informed regarding the presence of IVH and the prognosis of the infant.

The acute management is mainly supportive and requires control of ventilation, maintenance of a normal metabolic status and optimal nutritional state, and avoidance of seizures. Systemic blood pressure should be maintained with cautious attention to the rate of administration of fluid. Consideration of the aforementioned risk factors is important to prevent ischemic infarction.

Of the infants in whom enlargement of the ventricles occurs, approximately 50% develop rapidly progressive ventricular dilatation over the next 4 to 8 weeks. Regular measurement of head circumference and examination of the fontanel and clinical status are recommended in the first 4 weeks in cases of slowly progressive hydrocephalus. Serial lumbar puncture or use of carbonic anhydrase inhibitors has been recommended by some clinicians. A recent randomized controlled trial of the combined use of furosemide and acetazolamide in 177 infants with post-hemorrhagic hydrocephalus concluded that this treatment is ineffective in decreasing the need for shunt placement and is associated with increased risk of a poor neurologic outcome (Kennedy et al, 2001). Use of streptokinase immediately after an IVH with development of post-hemorrhagic hydrocephalus has been advocated by some to be beneficial. However, the studies to date have been too small to allow reasonable conclusions (Haines and Lapointe, 1999; Luciano et al, 1998; Whitelaw, 2001).

In infants with rapidly progressive hydrocephalus that does not respond to serial lumbar punctures, placement of an external ventriculostomy is necessary as a temporizing measure. Placement of a ventriculoperitoneal shunt that diverts cerebrospinal fluid (CSF) from the lateral ventricles to the peritoneal cavity in a premature infant is problematic due to the risk of skin breakdown, shunt obstruction, and/or infection. However, some centers are placing subgaleal shunts as a temporizing measure in these infants; these shunts may be associated with significantly fewer complications (Fulmer et al, 2000).

### **Hypoxic-Ischemic Reperfusion Injury in the Newborn**

Perinatal hypoxic-ischemic reperfusion (HI-R) injury may result in neonatal hypoxic-ischemic encephalopathy (HIE), which is a significant cause of neonatal morbidity and mortality and can lead to severe long-term neurologic deficits. The incidence of HIE is approximately 6 in 1000 term infants, with the incidence of death or severe neurologic deficit being 1 in 1000 (Levene and Evans, 1985). Much of our understanding concerning the effects of hypoxic-ischemic injury in the newborn brain has been derived from studies done in experimental models in animals.

### **Etiology**

Hypoxia-ischemia results when the decrease in cerebral perfusion is severe enough to overcome the ability of tissue to extract oxygen from the blood, thereby leading to a mismatch between cerebral blood flow and oxidative metabolism. Although the final pathways leading to cerebral brain death are remarkably similar regardless of the instigating event, the extent, location, and evolution of cell death probably are determined by the nature of the insult. The etiology of HIE is multifactorial. In a study of risk factors for neonatal encephalopathy, antepartum risk factors such as maternal hypotension, infertility treatment, and thyroid disease were present in 69% of the cases; both antepartum and intrapartum risk factors were present in 24%; and a history of an intrapartum event such as maternal fever, difficult forceps delivery, breech extraction, cord prolapse, or abruptio placentae was present in 5% of the cases (Badawi et al, 1998). Postnatal events such as severe respiratory distress or congenital heart disease, sepsis, and shock are responsible for fewer than 10% of cases of HIE.

### **Clinical Signs and Symptoms**

The clinical signs and symptoms depend on the severity, timing, and duration of the insult. The infant's gestational age needs to be taken into consideration in the evaluation. Symptoms usually evolve over a period of 72 hours (Sarnat and Sarnat, 1976) (Table 64-3).

During the first 12 hours after birth, the signs and symptoms are secondary to cerebral hemisphere depression, although signs of brainstem involvement may be present. During this period the infant is not easily arousable. This alteration in consciousness is attributed to the involvement of the cerebral hemispheres, the reticular activating system, or the thalamus. Periodic breathing with apnea or bradycardia is usually present. The infant has intact pupillary responses and may have spontaneous eye movements, depending on involvement of cranial nuclei 3, 4, and 6. Cerebral cortical or cerebellar cortical involvement may manifest as hypotonia with decreased movement or as jitteriness or seizure activity, which is seen in 50% of severely affected infants by 6 to 12 hours after birth. The Moro, grasp, and suck and swallow reflexes may be absent or depressed. In cases of severe asphyxia, seizures may be seen within 2 to 3 hours following the insult. Seizure activity in a term infant can be multifocal or focal in nature. Subtle seizures may also manifest as ocular movements such as tonic horizontal deviation of the eyes or sustained eye opening or blinking; orolingual movements such as tongue or lip smacking or sucking, or rowing or bicycling movements of the extremities, or as recurrent apnea (Mizrahi and Kellaway, 1987).

During the 12- to 24-hour period after the injury, there is an apparent increase in the level of alertness, but this is not associated with other signs of improvement in neurologic function. This period is accompanied by seizures in 15% to 20% of infants, apneic episodes in 50%, and jitteriness as well as weakness in the proximal limbs in 35% to 50%. The Moro reflex is exaggerated, the infant's cry is shrill and monotonous, and the deep tendon reflexes are exaggerated.

TABLE 64-3

**Clinical Staging of Hypoxic-Ischemic Encephalopathy**

Factor	Stage 1	Stage 2	Stage 3
Level of consciousness	Alert	Lethargy	Coma
Muscle tone	Normal	Hypotonia	Flaccidity
Tendon reflexes	Normal/increased	Increased	Depressed/absent
Myoclonus	Present	Present	Absent
Complex reflexes			
Sucking	Active	Weak	Absent
Moro	Exaggerated	Incomplete	Absent
Grasping	Normal/exaggerated	Exaggerated	Absent
Oculocephalic (doll's eyes)	Normal	Overreactive	Reduced/absent

Data from Sarnat NB, Sarnat MS: Neonatal encephalopathy following distress. *Arch Neurol* 33:696-705, 1976.

After 24 to 72 hours the infant's level of consciousness deteriorates. This is followed by respiratory arrest and signs of brainstem dysfunction such as loss of responsiveness to the doll's eyes maneuver, fixed and dilated pupils, and sometimes death. Infants who survive until 72 hours continue in stupor with disturbed suck, swallow, and gag reflexes; hypotonia; and weakness of the proximal limbs and especially facial and bulbar musculature.

### Diagnosis

The diagnosis of HIE is made through a careful history, laboratory studies, and neurologic examination. Metabolic abnormalities, cerebral dysgenesis, and infection all can mimic HIE. There is sometimes a history of intrauterine distress, as evidenced by abnormalities on the fetal heart tracing, passage of meconium, or a history of difficult labor or delivery with a decrease in placental or fetal blood flow. A history of a difficult resuscitation that includes the use of cardiopulmonary resuscitation, medications in the delivery room, and intubation and assisted ventilation at birth and low extended Apgar scores after 5 minutes of age are associated with HIE. Presence of jitteriness, seizures, apneic episodes, or abnormal cry is suggestive of injury.

The neurologic examination provides important information for prognosis. Laboratory tests can be helpful in diagnosing HIE. Metabolic complications such as hypoglycemia, hypocalcemia, hyponatremia, hypoxemia, and acidosis are frequently seen. The nucleated red blood cell count may be elevated on review of the complete blood count. Several other metabolic parameters such as serum brain-specific creatine kinase (BB fraction), serum hypoxanthine, and serum lactate also are elevated. Lumbar puncture should be performed if the history is not consistent with perinatal distress, to rule out conditions that may mimic HIE. Lumbar puncture should be used to measure cell count, protein and glucose levels, and ratio of lactate to pyruvate, as well as brain-specific creatine kinase. A CSF protein level above 150 mg/dL is considered abnormal. Urinary lactate-to-creatine ratios have been shown to be elevated in asphyxiated infants (Huang et al, 1999).

Changes on the electroencephalogram (EEG) can be helpful in determining the severity of the insult. The initial change is a suppression of amplitude and frequency. This is followed after 24 hours by a periodic pattern that consists of periods of greater voltage suppression interspersed with bursts of sharp and slow waves. Subsequently, a "burst suppression" pattern with fewer bursts and more severe voltage depression is seen, followed by an isoelectric tracing. The EEG is helpful in supporting the diagnosis of HIE, and amplitude-integrated electroencephalography has been used in both animal and human studies as an aid to identify newborns moderately to severely compromised by hypoxic-ischemic injury (al Naqeeb et al, 1999; Toet et al, 1999). Obtaining an EEG is critically important after phenobarbital administration because this drug causes electroclinical dissociation (Biagioni et al, 1998).

Neuroimaging has become increasingly useful for the accurate diagnosis of HIE. Computed tomography (CT) often is not helpful in making a diagnosis because it is insensitive to changes in water content. Also, especially in the posterior fossa, injury can be obscured by bone artifact. CT is best used to determine the extent of bleeding in an emergency situation when MRI is not available.

MRI has proved to be a sensitive technique to determine injury in both the premature and term brain. In the term infant, absence of signal in the posterior limb of the internal capsule (PLIC) is strongly associated with poor neurologic outcome (Rutherford et al, 1995). Newer techniques such as diffusion tensor imaging (DTI) have been shown to be helpful in defining areas of the brain at risk for damage (Barkovich et al, 2001; Huppi et al, 2001). DTI can also be used to monitor normal development of pathways using the apparent diffusion coefficient (ADC) and anisotropy in certain regions (Miller et al, 2002c). In a comparison of head ultrasound examination with MRI, MRI was more sensitive in identifying PVL (Rijn et al, 2001).

Ultrasonography is extremely useful for imaging the unstable patient if performed with high-resolution transducers (de Vries et al, 1997). Injury to the basal ganglia, periventricular echodensities, and presence of focal or multifocal ischemic parenchymal lesions suggest neurologic deficits.

Ultrasound is insensitive to cortical damage; therefore, in term infants, ultrasound findings may under-represent the extent of the lesion.

Proton magnetic resonance spectroscopy (MRS) also has been useful for depicting age-dependent changes in preterm infants and can be a powerful tool for diagnosing early damage in both preterm and term infants (Vigneron et al, 2001). MRS provides a quantitative in vivo measure of brain biochemistry. At long echo times, it can measure resonance intensities for *N*-acetyl aspartate (NAA), creatine (Cr), and phosphocreatine, choline (Cho), and lactate. The measure of NAA in reference to baseline Cr or Cho has provided a sensitive indicator of neuronal integrity, whereas lactate has indicated the presence of oxidative stress or ongoing injury. MRS is now being used more extensively to identify areas at risk in perinatal HIE (Holshouser et al, 2000).

NIRS is a noninvasive technique that holds promise in the future. It can be used at the bedside to provide information regarding cerebral oxygen delivery. However, this modality is not quantitative and is not available at many centers.

### Patterns of Injury and Pathology

The mechanism of injury can be one of several types. Different patterns of injury may result, depending on the duration and severity of the insult.

#### Global Ischemia

Global hypoxia-ischemia develops when the oxygen requirements for cerebral metabolism are unable to be met by cerebral perfusion pressure, as is seen with a decrease in cerebral arterial pressure or an increase in cerebral venous pressure. Although the injury may be transient, it sets into motion a cascade of events that ultimately lead to neuronal death. The duration of the insult necessary to produce brain injury is inversely proportional to the gestational age of the fetus. The extent and location of the injury can be patchy bilaterally or diffuse involving the entire cortex. The latent period to neuronal cell death produced by a global insult can range from hours to days and is determined by a complex interaction among various vascular, cellular, and metabolic factors (see later). A detailed understanding of these mechanisms is necessary for determination of appropriate timing for therapeutic intervention.

#### Focal or Partial Ischemia

Focal ischemia occurs when the artery or venous supply to a region is compromised. The degree of injury is dependent on the collateral blood supply to this region. The injured region typically consists of a central dense region of ischemia that undergoes rapid cell death—the *core*—surrounded by a region of evolving cell injury—the *penumbra*. The cells in the penumbral region initially are sustained by anaerobic glycolysis. However, within hours the injury becomes irreversible, thus bringing the penumbra

into the gradually enlarging area of infarction. This period of delay in cell death provides an opportunity for therapeutic intervention and prevention of further cell damage. Partial asphyxia without acidosis, as occurs in response to impairment of placental gas exchange by uterine contractions, maternal hypotension, or impairment in maternal placental circulation, can produce either a widespread cerebral cortical necrosis or a more focal injury to the posterior parietal parasagittal regions. Partial asphyxia with acidosis has been shown to cause white matter injury.

Cerebral blood flow is closely autoregulated over a wide range of systemic blood pressure by either vasoconstriction or dilatation of cerebral arterioles. However, this mechanism is imperfect in the newborn. Therefore, rapid changes in cerebral perfusion pressure can occur in response to changes in systemic blood pressure, as well as changes in cerebral PaO<sub>2</sub> and PaCO<sub>2</sub>. Injury typically tends to occur in the watershed regions, which in the term newborn are located in the parasagittal regions of the cerebral cortex. The periventricular white matter is the most vulnerable region in preterm newborns.

Certain portions of the brain such as the basal ganglia, the thalamus, and the brainstem nuclei are more prone to injury by virtue of either increased myelination or metabolism or the presence of glutamate-responsive receptors and increased glutaminergic synapses. The major patterns of neuropathologic injury are as follows: selective neuronal necrosis, parasagittal lesions, status marmoratus of the basal ganglia and thalamus, focal or multifocal necrosis, pontosubicular necrosis, spinal cord ischemic infarction, and periventricular leukomalacia.

*Selective neuronal necrosis* can involve specific regions of the cortex, thalamus, brainstem, cerebellum, or hippocampus. An acute global injury such as is seen with uterine rupture or cord prolapse causes injury to the basal ganglia, thalamus, and brainstem, whereas a prolonged partial injury affects mainly the cortex and subcortical white matter. Damage is more extensive in the posterior parietal-occipital region than in the anterior cortical areas. Clinical signs in the infant relate to the site of injury. Seizures are a feature of cortical injury, whereas irritability, posturing, and brainstem dysfunction are seen with infarcts affecting the basal ganglia and thalamus. Long-term sequelae of such an injury include cerebral atrophy and multicystic encephalomalacia.

Clinical features of *parasagittal injury* include hypotonia and weakness, especially in the upper trunk. Cortical infarcts usually occur in the watershed region supplied by the most peripheral branches of the anterior, middle, and posterior cerebral arteries.

*Status marmoratus* refers to the marbled appearance of the basal ganglia, thalamus, and cerebral cortex in response to the injury. This appearance results from gross shrinkage of the striatum and defects in myelination. It may relate to the type of insult or the density of glutaminergic receptors in the basal ganglia (Johnston, 1995). Although the clinical correlate of this condition in the newborn is not well defined, it is seen in children with choreoathetoid cerebral palsy.

*Focal and multifocal cerebral necroses* occur secondary to an embolus or thrombus (see “Perinatal Stroke”). There are often underlying problems such as thrombophilias,

maternal idiopathic thrombocytopenic purpura (ITP), vascular maldevelopment, or history of maternal cocaine use. Infants may present with unilateral, focal seizures or display asymmetrical motor function, or they may be asymptomatic. In some circumstances, lesions may involve the brain stem (*pontosubicular necrosis*) or the cerebellum. Babies with pontosubicular necrosis have impairment of the cranial nerve nuclei and will exhibit ptosis and facial diparesis.

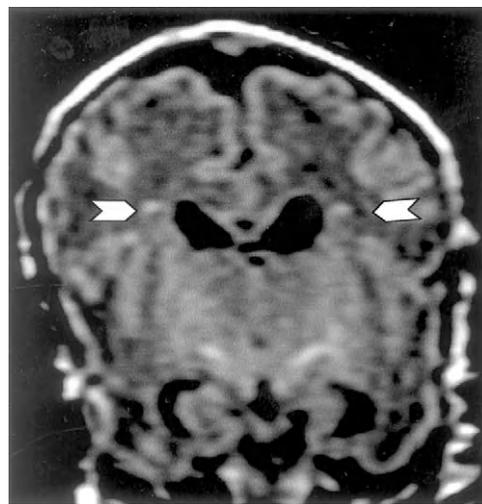

*Spinal cord ischemia* is not uncommon following HI-R injury. In patients with hyporeflexia or areflexia, spinal cord pathology should be considered. Ischemic necrosis occurs in spinal cord gray matter. (Clancy et al, 1989).

*Periventricular leukomalacia* (PVL) is a form of white matter injury that occurs at the arterial end zones in premature infants. The pathologic features of PVL consist of a focal, deep component that is characterized by localized necrosis and cyst formation, as well as a less severe diffuse injury to the oligodendroglial cell precursors that is much more difficult to visualize on cranial ultrasound examination. The focal component of PVL occurs mainly in the regions that are in the end zones of the long penetrating arteries, whereas the diffuse component occurs mainly in the regions bordering the areas between the long penetrating arteries. Together with periventricular hemorrhagic infarction, a complication of IVH, and focal periventricular white matter injury (Miller et al, 2002c), these conditions result in severe spastic motor deficits and other developmental and cognitive disabilities in up to 50% of affected children (Volpe, 1997). Asphyxia, sepsis, recurrent episodes of apnea, seizures, and prolonged ventilation all are conditions that may predispose the premature infant to develop PVL. Hypotension frequently accompanies all of these conditions. It is hypothesized that oxidative stress is the major cause of PVL in the setting of ischemia (Volpe, 2001b). Newer theories of the pathogenesis of white matter injury implicate several other mechanisms besides hypoxic-ischemic events (Nelson and Ellenberg, 1986). Prenatal or perinatal factors such as thyroid hormone deficiency, growth factor deficiency, genetic factors, maternal infections, and free radicals may lead to an increase in cytokine production (Gressens et al, 2002). Studies in animal models have shown that cytokine exposure followed by an insult can produce white matter damage, whereas cytokine exposure alone does not cause injury; this finding suggests a “two-hit mechanism” in which injurious factors after birth could exacerbate the damaging events that originated in utero (Dammann et al, 2002; Dommergues et al, 1998).

The cellular target in white matter injury is unknown. It has been suggested that late oligodendrocyte progenitors that populate human cerebral white matter during the high-risk period for PVL are the major target of ischemic, free radical, or cytokine injury (Back and Volpe, 1997; Back et al, 2001, 2002). In addition, recent data suggest vulnerability of the subplate neurons as well (McQuillen et al, 2003). Tissue damage is associated with proliferation of astrocytes and microglial cells in areas of subcortical degeneration. PVL may be associated with hemorrhage into the lesion in some cases and may be unilateral or asymmetrical. This condition is often confused with the hemorrhage observed after IVH. The severity of injury in PVL can range from small areas of focal necrosis to diffuse involvement leading to cavitations over a period of

A

B

**FIGURE 64-2.** **A**, Head ultrasound image with no evidence of periventricular leukomalacia. **B**, Abnormalities are well seen on T1-weighted magnetic resonance image (*arrows*) in the same patient.

2 to 4 weeks (cystic leukomalacia). The head ultrasound study sometimes misses the lesions seen on MRI (Fig. 64-2). Clinical features in the premature infant may involve impairment of gaze and hearing, weakness, or altered muscle tone. Long-term problems may include spastic diplegia and visual and auditory impairment.

Maintenance of cerebral perfusion is key for prevention of PVL. Also important is avoidance of factors that lead to cerebral ischemia such as marked hypocapnia or hypotension. In the future, use of free radical scavengers, anti-apoptotic agents, or amino-3-hydroxy-5-methyl-4-isoxazole-propionic acid (AMPA) antagonists, or combinations of therapies, may be effective at preventing PVL (Volpe, 2001a).

### Pathogenesis

Studies in animal models of asphyxia have shown that although the newborn can survive an asphyxial insult better than the mature animal, the brain is still injured. The

immature brain is more susceptible to hypoxic ischemic injury for several reasons, including immaturity of vascular regulation, along with maturational differences in metabolic oxidative function between the newborn and adult brain (Ferriero, 2001).

Asphyxia leads to a redistribution of cardiac output, with a 30% to 175% increase in cerebral blood flow. Because cerebral vasoautoregulation is compromised, the cerebral arterioles are unable to respond appropriately in response to the alteration in blood flow or hypercapnia. Continued asphyxia leads ultimately to a fall in cardiac output, hypotension, and thus a fall in cerebral perfusion. Cerebral edema can further compromise cerebral blood flow and set into motion a cascade of events that leads to necrosis.

Although overall cerebral  $O_2$  demands are lower in the infant than in the adult, cerebral oxidative metabolism is considerably increased in areas of active neural development that are associated with either synapse formation or activation of enzymes required for ion homeostasis. Glucose is the primary source of energy in cerebral metabolism and although the newborn brain is capable of utilizing alternative energy substrates such as ketones, lactate, and free fatty acids, glucose uptake mechanisms are relatively underdeveloped (Cremer et al, 1979; Gregoire et al, 1978). Absence of energy stores makes the brain dependent on sustained perfusion. Animal studies have shown that this impaired uptake of glucose can impair cerebral metabolism even prior to oxygen depletion (Yager et al, 1996).

Vasoautoregulation in response to increased cerebral blood pressure or flow is relatively underdeveloped in the newborn, thus rendering the infant more vulnerable to ischemic events. The gradual increase in vascularity of the developing brain leads to the creation of “watershed areas” (i.e., areas not well vascularized). These regions are more vulnerable to global ischemic events. These global events lead to patterns of focal injury that are dependent on maturational processes. The similarities between processes essential for brain development and those mediating cellular injury make the immature brain particularly vulnerable to ischemic insult. These similarities include an increased density of glutamate receptors, an increase in glutaminergic synapses in particular regions of the immature brain, and enhanced accumulation of cytosolic calcium after activation of the glutamate receptor. It has been shown that there are proportionately more glutamate receptors in the immature rat brain than in the mature rat brain and that the developing rat brain is much more sensitive to injury than the newborn or adult brain (Yager et al, 1996). HI-R injury triggers a complex series of cellular events that evolve rapidly through amplifying cascades, eventually leading to severe cerebral damage. A gradual or sudden decrease in cerebral oxygen and energy substrates initially leads to synaptic inactivation, which is a reversible and adaptive response to HI-R injury. Decreased cerebral energy stores lead to membrane pump failure and the subsequent inability to maintain normal ion gradients (Fig. 64–3). This is followed by neuronal membrane depolarization and release of neurotransmitters such as glutamate, which increase cytosolic calcium and induce destructive enzymes and free radicals. Reoxygenation after the ischemic episode plays a significant role in cellular injury. The pathogenesis of HI-R injury can be

divided arbitrarily into four phases (Table 64–4; see also Fig. 64–1):

1. A decrease in cerebral energy and membrane depolarization
2. A phase of increased release of neurotransmitters and neuronal damage
3. A period of reperfusion
4. A final phase of irreversible cell death

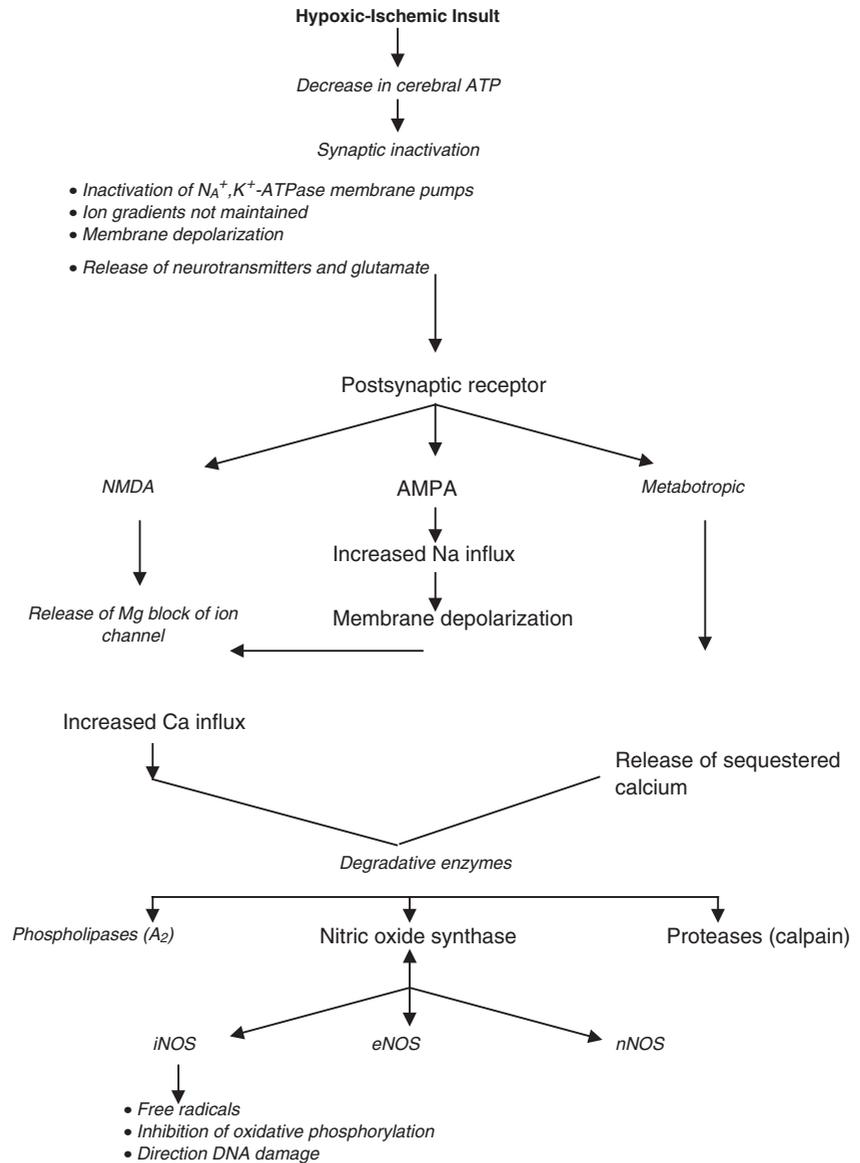

**Decrease in Cerebral Energy and Membrane Depolarization.** HI-R injury is followed by a depression of brain function that probably is a protective mechanism to preserve energy. In the normal state, glucose and oxygen are the main requirements for brain energy production, which occurs by oxidative phosphorylation. Glucose is taken up by a carrier-mediated diffusion process and phosphorylated to glucose-6-phosphate, the major portion of which enters the glycolytic pathway to form pyruvate. Pyruvate enters the mitochondria and is converted to acetyl coenzyme A (acetyl CoA); acetyl CoA enters the citric acid cycle and undergoes oxidation to  $CO_2$ . The electrons generated get transported through several carrier proteins such as (reduced) nicotinamide adenine dinucleotide (NADH) within the mitochondria. NADH couples to molecular oxygen and forms ATP through phosphorylation of ADP by adenine kinase. Phosphocreatine also can serve as a store of energy that can transfer phosphorus to generate ATP. HI-R injury is followed by a decrease in brain glucose and ATP. Anaerobic glycolysis is much less efficient at ATP production. Aerobic glycolysis generates 38 moles of ATP per mole of glucose, compared with 2 moles of ATP produced by anaerobic glycolysis.

A decrease in ATP affects the  $Na^+, K^+$ -ATPase pump that helps to maintain the state of polarization of the neuronal membrane. A failure of the pump leads to an influx of sodium into the cell and potassium outside the cell. Associated glial uptake of sodium and water leads to astrocytic swelling that in turn decreases diffusion of oxygen and glucose to the neurons.

Accumulation of lactate secondary to anaerobic glycolysis leads to tissue acidosis, which inhibits both vascular autoregulation and phosphofructokinase, the rate-limiting enzyme in glycolysis. In immature animals hypoglycemia has been shown to be damaging; pretreating animals with glucose decreases the impact of the injury when given prior to, but not during, the injury (Sheldon et al, 1992; Vannucci and Vannucci, 2000). This is in contrast to the effect of glucose administration in mature animals.

**Increased Release of Neurotransmitters and Neuronal Damage.** There is sufficient evidence that excitatory neurotransmitters play a major role in HI-R injury. Under normal conditions there is a balance between excitatory neurotransmitters such as acetylcholine, dopamine, serotonin, glutamate, and aspartate and inhibitory agents such as glycine and gamma-aminobutyric acid (GABA). Neuronal injury is initiated by release of glutamate and other excitatory neurotransmitters from the presynaptic neurons. Initially the decrease in energy supply decreases ATP-dependent exocytosis of glutamate and decreases activity of glutamate synthetase, the enzyme responsible

**FIGURE 64-3.** Flow diagram of events occurring after hypoxic-ischemic/reperfusion injury leading to energy depletion, membrane polarization, neurotransmitter release, calcium influx, and intracellular enzymatic activation leading to cell death.

Cytotoxic edema leading to delayed seizures

for converting glutamate to nontoxic glutamine. Subsequently, glutamate release occurs by both a reversal of normal glutamate uptake mechanisms by the nerve terminals and glia and membrane leakage. A secondary increase in glutamate occurs during the phase of reoxygenation.

Glutamate receptors are of three subtypes: the N-methyl-D-aspartate receptor (NMDA), the AMPA receptor, and the G protein-associated metabotropic receptor. The NMDA receptor is a postsynaptic receptor that is activated by glutamate and has been shown to play an important role in normal brain development including neuronal survival, differentiation, arborization of dendrites, growth of axons, and development of synapses. The expression of NMDA receptor subtypes as well as the subunit composition of the glutamate receptors changes with maturation (Johnston, 1995; MacDonald and Nowak, 1990). The density of receptors is higher in regions of active development,

and the different subtypes vary in different regions of the brain at different gestational ages. Several features in the subunit composition of the immature NMDA receptor result in enhanced opening and influx of calcium into the ion channels (Andersen et al, 1995; Ben-Ari et al, 1988; Morrisett et al, 1990). Thus, neuroprotective interventions that act at the level of the glutamatergic receptors may disturb normal brain development.

Activation of any of the three subtypes of glutamate-activated postsynaptic neuron receptors leads to an influx of calcium into the postsynaptic neurons. Activation of the NMDA receptor releases the magnesium block within the ion channel and leads to the entry of calcium into the ion channel. Activation of the AMPA receptor mediates fast excitatory neurotransmission by triggering an influx of sodium. The resulting membrane depolarization opens calcium channels and releases the magnesium block of the NMDA channel, thereby leading to cytosolic accumulation of calcium. Activation of the metabotropic receptor results in the generation of inositol triphosphate, which triggers release of sequestered calcium.

The increase in intracellular calcium sets into motion an irreversible cascade of events that leads to cell injury. Calcium activates several degradative enzymes such as phospholipases, proteases, and endonucleases. Activated phospholipases such as phospholipase A<sub>2</sub> hydrolyze membrane phospholipid, thereby releasing free fatty acids such as arachidonic acid. Arachidonic acid can mediate injury by several mechanisms, including increased release of glutamate, uncoupling of oxidative phosphorylation, and inactivation of membrane Na<sup>+</sup>,K<sup>+</sup>-ATPase. Proteases degrade cytoskeletal and other proteins. Cyclooxygenase stimulates production of arachidonic acid and prostaglandins. Enzyme activation as well as activation of xanthine and prostaglandins generate free radicals that perpetuate the injury by lipid membrane peroxidation. Hypoxic-ischemic injury also leads to a change in iron homeostasis. Iron is usually maintained in a nontoxic “ferric” state but is reduced into the injurious “ferrous” form, which can react with oxygen-reactive species to propagate further injury.

Nitric oxide synthase (NOS), one of the enzymes that are released during HI-R injury, has been identified as a mediator of cellular injury. It has multiple and complex biologic functions and converts L-arginine to nitric oxide (NO). Several lines of evidence support the role of NO in hypoxic-ischemic injury. Studies in transgenic mice that are deficient for the *nNOS* gene showed that these mice had a decreased propensity for brain injury compared with that in their wild-type littermates (Ferriero et al, 1996). Also, expression of *nNOS* protein in the developing brain correlates with regions of vulnerability to hypoxic injury (Black et al, 1995). NOS exists in three different isoforms—eNOS (endothelial), iNOS (inducible), and nNOS (neuronal). The increase in NOS in HI-R injury occurs in two phases. The initial decrease in cerebral perfusion leads initially to a rapid increase in the eNOS and nNOS isoforms, followed by a sustained increase in NO. A subsequent increase in the iNOS isoform occurs several hours after the injury in response to inflammatory mediators such as lipopolysaccharides and cytokines. It is hypothesized that NO generated by different isoforms of NOS either can be beneficial by causing vasodilatation and inhibition of leukocyte and

platelet activation or can mediate injury. NO causes cellular injury by various mechanisms: combining with superoxide to form a peroxynitrite radical that causes lipid peroxidation, generating of free radicals by stimulation of cyclooxygenase activity, direct DNA damage, and participating in the neurotransmitter response by reentering the presynaptic neuron and further increasing release of glutamate.

Membrane peroxidation and ATP breakdown lead to the accumulation of free fatty acids, adenine nucleotides, and hypoxanthine in endothelial cells as well.

**Phase of Reperfusion.** During the immediate period of return of cerebral circulation and reoxygenation, there is a resolution of the acute cellular hypoxic depolarization and cellular edema, with a restoration of cellular energy metabolism over the next 30 minutes. This is followed by a latent phase with near-normal oxidative cerebral energy metabolism as seen by MRS. However, EEG activity is blunted and cerebral blood flow is decreased during this period. The phase of delayed cerebral energy depletion follows subsequently, with clinical deterioration, delayed seizures, and cytotoxic edema as well as a release of excitatory neurotransmitters. This phase may last for 6 to 15 hours prior to neuronal death and therefore offers a therapeutic window. These delayed forms of neuronal injury have clinical correlates in the seizure activity that is seen after a latent period of 6 to 12 hours in HIE as well as the secondary deterioration seen after 24 hours in asphyxiated newborns. The exact mechanism responsible for the delayed injury is the subject of intense research. The overall effect of post-HI-R injury changes is to cause an augmentation of calcium influx and perpetuation of the injury.

NO may mediate both the initial reperfusion by vasodilatation and the later mitochondrial enzyme inhibition. During the initial period of reperfusion there is a clearance of glutamate (Takahashi et al, 1997). Several mechanisms that have been proposed to explain the ultimate increase in calcium influx and perpetuation of injury have been the subject of recent reviews (Inder and Volpe, 2000; White et al, 2000). Some of the mechanisms proposed include a long-term potentiation of NMDA receptors to low levels of extracellular glutamate, which can then lead to an exaggerated calcium influx, an impairment of the Na<sup>+</sup>, K<sup>+</sup>-ATPase pump from delayed energy failure (Obrenovitch and Urenjak, 1997), and enhanced release of glutamate by NO. Generation of free radicals during this phase occurs by two methods: free fatty acids enter the cyclooxygenase pathway and generate arachidonic acid and prostaglandins, and xanthine oxidase converts hypoxanthine to uric acid. Free radicals activate adhesion molecules in platelets and leukocytes, which increases occlusion of the microvasculature, thereby perpetuating injury.

**Phase of Irreversible Cell Death.** HIE results in two major forms of cell death: necrosis and apoptosis. *Apoptosis* refers to programmed cell death, a mechanism that is ongoing during the process of brain maturation. Apoptotic cells are characterized by nuclear shrinkage, chromatin condensation, and DNA fragmentation. Necrotic cells are characterized by cellular swelling, fracture of cell membranes, and an inflammatory cellular reaction. It is hypothesized that a severe insult leads to necrosis, as is

seen in the central area of injury, whereas a longer duration of a less severe injury may lead to apoptosis, as seen in the penumbra. In the immature brain, a third pathologic form of injury has been described: the apoptotic-necrotic continuum (Portera-Cailliau et al, 1997). This particular pattern may represent the predominant form of injury (Northington et al, 2001a, 2001b). It has recently been shown in animal models that there is a prolonged period of delayed cell death due to apoptosis (Nakajima et al, 2000; Northington et al, 2001a, 2001b). This exciting finding suggests that there is a prolonged window of opportunity for interventional strategies.

Apoptotic cell death is a highly regulated process that in most cases requires activation of caspases, a superfamily of cysteine aspartyl-specific proteases (Kumar, 1995). Several of the 14 known mammalian caspases are involved in initiation of the apoptotic cascades; other caspases are responsible for the execution of apoptosis. Caspase-3, an executional caspase, appears to play a central role in apoptosis in a wide variety of cells (Marks and Berg, 1999). Activation of caspase-3 occurs through at least two distinct caspase cascades and requires cleavage of its proenzyme. The level of inactive caspase-3 in normal forebrain tissue gradually declines from a high level in P7 rat pups to a very low level in adult rats (Hu et al, 2000). The involvement of caspase-3 in cell death after hypoxia-ischemia also diminishes on brain maturation (Hu et al, 2000).

### Management

The immediate management of HIE requires securing an appropriate airway and maintaining adequate circulation. Cerebral edema resulting from hypoxia-ischemia is maximal between 36 and 96 hours and can impair cerebral blood flow secondary to increased vascular pressure. There is no consensus regarding the need to treat cerebral edema aggressively, as its role in producing neurologic sequelae is debatable. Although steroids have been shown to be beneficial in vasogenic cerebral edema, most investigators agree that corticosteroids are not beneficial for cerebral edema arising from hypoxic-ischemic injury. Attempts to decrease intracranial pressure by controlled hyperventilation (PaCO<sub>2</sub> of 20 to 25 mm Hg) as well as the use of furosemide or mannitol may actually be harmful (Collins et al, 2001). Seizure activity should be controlled to limit further compromise of neurologic status, and electroencephalography should be used to monitor for subclinical seizures. Multiorgan function must be monitored carefully. Maintenance of adequate cerebral perfusion is necessary and inotropic agents need to be used in cases of myocardial dysfunction. It is important to avoid both systemic hypotension and hypertension. Infants with hypoxic-ischemic injury can develop hyponatremia from syndrome of inappropriate secretion of antidiuretic hormone (SIADH). Hypoglycemia in an immature animal model during the evolution of HIE has been found to aggravate the insult (Sheldon et al, 1996). Therefore, fluid overload should be avoided, and serum glucose and electrolytes should be monitored closely.

### Prognosis

Predicting the neurodevelopmental outcome for the asphyxiated newborn is extremely difficult. Explanations for the lack of predictive success include functional and anatomic plasticity, interindividual variability for the same insult, differences in provision of services, and differences in socioeconomic status (Shevell et al, 1989). Outcome of HIE depends on the severity of the injury and the degree of brain damage. Some investigators have suggested that there is a threshold of injury beyond which the brain is damaged. Several factors such as maturity of the infant, placental-fetal blood flow, energy reserves, or presence of cerebral anomalies can affect the final outcome. It is often difficult to determine the duration of the insult because the vast majority of insults occurs in utero and because adequate fetal surveillance is difficult. Certain clinical factors as well as the results of brain imaging studies can help identify infants with a poor prognosis (Barkovich et al, 1995; Biagioni et al, 2001).

### Clinical Factors

The Apgar score is not a good predictor of outcome. This measure is affected by the use of maternal drugs or anesthesia, and by the vagal-induced respiratory depression that occurs from the use of suction catheters or from oropharyngeal secretions. There is also considerable variation among personnel in assigning the Apgar score, and all of the five different parameters that compose the Apgar score are not equally weighted for neurologic outcome. Although the Apgar score at 1 minute is not predictive of a poor outcome, the predictive ability does increase with a continued depressed score with increasing age of the infant. It has been shown that infants with Apgar scores of less than 6 at 5 minutes are three times more likely to have abnormalities on neurologic examination than are infants with scores greater than 6 (Levene et al, 1986). However, if the infant shows no neurologic symptoms in the perinatal period, the outcome is often normal. Ekert and colleagues (1997) built a model to predict severe adverse outcome within 4 hours of birth in neonates with HIE and found that delayed onset of breathing, need for chest compressions, and seizures had a sensitivity of 85% and specificity of 68%. In a population-based case-control study using these and expanded criteria in 84 children with spastic cerebral palsy, only 18 had 5-minute Apgar scores of less than 6, 20 required ventilation in the delivery room, and only 5 had initial pH of less than 7.00. Only 3 children had all three signs, and these 3 had neonatal seizures (Nelson and Grether, 1999).

The severity of the neurologic symptoms is helpful in assessment of the prognosis. The incidence of long-term problems is low in infants with mild HIE (Robertson and Finer, 1985). Infants with moderate encephalopathy have an abnormal outcome in 20% to 40% of cases, whereas infants with severe encephalopathy either die in the first 3 days of life or have severe deficits. Sarnat scores are a commonly used indicator of HIE and show similar predictive ability for which infants are at risk for sequelae (Volpe, 2001b). Hypotonia with depressed primitive reflexes or episodes of recurrent apnea indicate a poor outcome. The

presence of seizures is perhaps the best clinical indicator of adverse outcome, especially if seizure activity occurs in the first 12 hours of life or if they are difficult to control (see Miller et al, 2002d).

The duration of the neurologic abnormalities is usually helpful in predicting long-term neurologic disability. In two separate studies, normal examination findings at 1 week of age and at 2 weeks of age correlated with a good outcome (Robertson and Finer, 1985; Sarnat and Sarnat, 1976). Other clinical tools used include the presence of impairment of other organ systems and the Score for Neonatal Acute Physiology-Perinatal Extension (SNAP-PE) score, a physiologic assessment done within the first 24 hours of life (Newton et al, 2001). As with other clinical measures, neither of these tools is able to prognosticate outcome in the moderately asphyxiated newborn.

### Brain Imaging Findings

**Electroencephalography.** The rate of recovery of the EEG to normal baseline activity and the severity of neonatal encephalopathy can be helpful in establishing the neurologic prognosis (Biagioni et al, 2001).

**Evoked Potentials.** Ideally, evoked potentials would be done for pathways selectively vulnerable to HIE. A substantial HI-R event that results in the absence of visual or auditory waveforms is strongly predictive of significant abnormalities (McCulloch et al, 1991; Taylor and McCulloch, 1992).

**Magnetic Resonance Imaging.** MRI has been shown in a variety of studies to be useful in predicting outcome in neonates with HIE (Barkovich et al, 1998; Biagioni et al, 2001; Ment et al, 2002; Rutherford et al, 1994). In particular, absence of the signal in the posterior limb of the internal capsule has been associated with poor neurodevelopmental outcome. A joint statement from the American Academy of Pediatrics, the American Society of Pediatric Neuroradiology, and the Society for Pediatric Radiology recommends that a noncontrast CT study be performed to detect hemorrhagic lesions in term infants with encephalopathy and a birth history of trauma, coagulopathy, or low hematocrit. If the CT findings are inconclusive, MRI is recommended between days 2 and 8 to assess location and extent of injury (Ment et al, 2002). Because the CT scan does not compare favorably with MRI for confirming the diagnosis of hypoxic-ischemic injury or for providing prognostic information, Miller and colleagues (2002a) recommend that an MRI study be performed in the first week of life for establishing the diagnosis in an encephalopathic newborn (Fig. 64-4A).

**Magnetic Resonance Spectroscopy.** MRS has been shown to correlate with neurologic outcome and may be more sensitive in identifying injury and metabolic disturbances from seizures than standard imaging (Miller et al, 2002b) (see Fig. 64-4B). Abnormalities seen on MRS have been highly significantly associated with both neurologic and cognitive outcomes. Both high lactate and low NAA

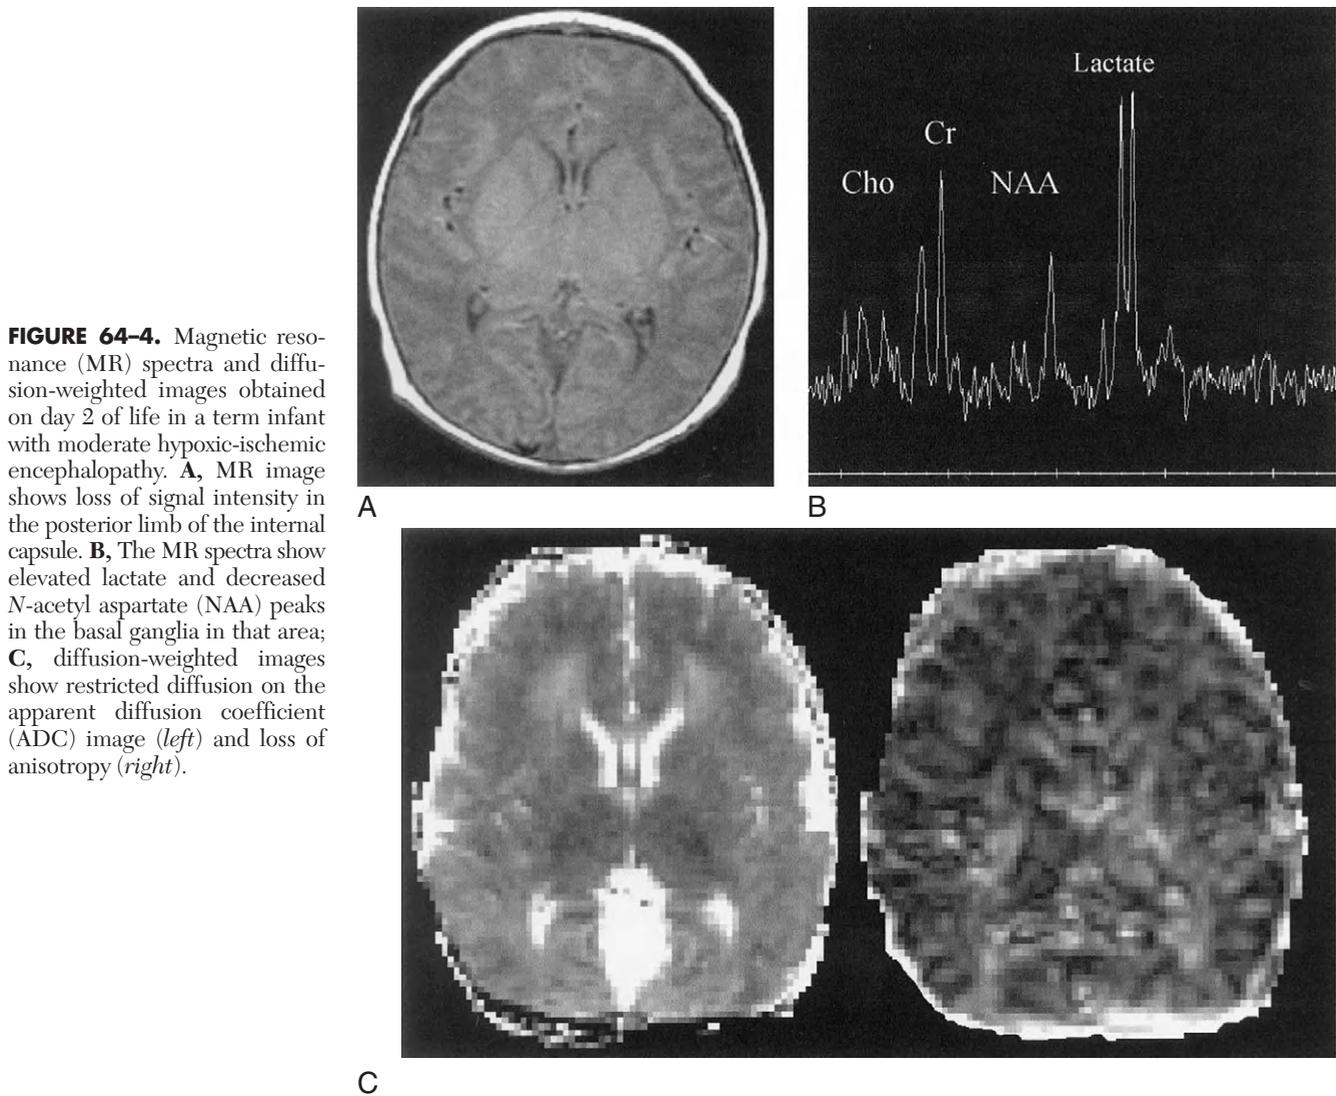

levels have been associated with persistent injury (Barkovich et al, 2001; Miller et al, 2002d). Study results have varied in accordance with the timing of the scan in relation to the injury. It has been reported that the lactate level of the injured brain increases within the first 24 hours and remains elevated thereafter, presumably due to energy failure and the necessity to metabolize glucose anaerobically (Hanrahan et al, 1996; Penrice et al, 1996). However, the NAA level does not diminish significantly until sometime beyond 48 hours (Penrice et al, 1997). The precise time at which NAA begins to diminish in asphyxiated neonates is not precisely known.

### Outcome

The outcome for ischemic injury differs substantially for the preterm infant and the term infant. Although more preterm infants survive the insult than term infants, preterm survivors are affected with more neurodevelopmental disabilities. In a recent study of extremely preterm children, 49% had disabilities, with 23% meeting criteria for severe disabilities (Wood et al, 2000). In term babies with neonatal encephalopathy, the presence of seizures and the severity and duration of encephalopathic state are predictors of poor outcome (Robertson et al, 1989; Thornberg et al, 1995). Infants with mild neonatal encephalopathy syndromes have no deficits, whereas those with severe encephalopathy die or are severely impaired with spastic quadriplegia, cortical visual impairment, and seizure disorders. Those with moderate degrees of encephalopathy can be normal to severely abnormal, depending on the pattern of injury seen on MRI and MRS and the persistence of EEG abnormalities (Barkovich et al, 2001; Biagioni et al, 2001). The neurologic examination at 3 months may be a good prognostic indicator (Hajnal et al, 1999).

### Perinatal Stroke

Perinatal strokes are arterial in nature (Fig. 64-5), but this section also includes venous infarction and sinovenous thrombosis in the term infant. Perinatal stroke is defined as an ischemic event that occurs between 28 weeks of gestation and 7 days of age and includes in utero strokes. The term *neonatal stroke* is reserved for events occurring between birth and the end of the first month of life. It is difficult to establish the exact prevalence of perinatal stroke. Using studies of children with neonatal seizures, prevalence has been estimated to be roughly 12% of neonates of greater than 31 weeks of gestation with seizures (Lynch et al, 2002). This rate translates to a prevalence of perinatal stroke of 24.7/100,000 per year in infants of greater than 31 weeks of gestation and is similar to the estimated prevalence of 28.6/100,000 live births reported by Perlman (1994). On the basis of these estimates, perinatal stroke is recognized in approximately 1/4000 live births. However, there is a subgroup of neonates who do not present with evidence of injury until late infancy because the neurologic examination findings are normal in the newborn period. These infants present later with pathologic early hand preference and/or seizures (Golomb et al, 2001). Stroke in the newborn has a male predominance,

and there is a tendency toward left-sided lesions (Golomb et al, 2001; Trauner et al, 1993). It is unclear why there is a gender difference.

The United States infant mortality rate for years 1995 to 1998 due to stroke (ICD-9 CM 430-437) is 5.33/100,000 per year, perinatal mortality is 2.21/100,000, and neonatal mortality is 3.49/100,000 live births per year (Lynch and Nelson, 2001). The National Hospital Discharge Survey, from 1980 through 1998, determined that for infants younger than 30 days of age, the in-hospital mortality rate for neonatal stroke was 10.1%, or 2.67/100,000 live births (Lynch and Nelson, 2001; Lynch et al, 2002).

### Cerebral Venous Thrombosis

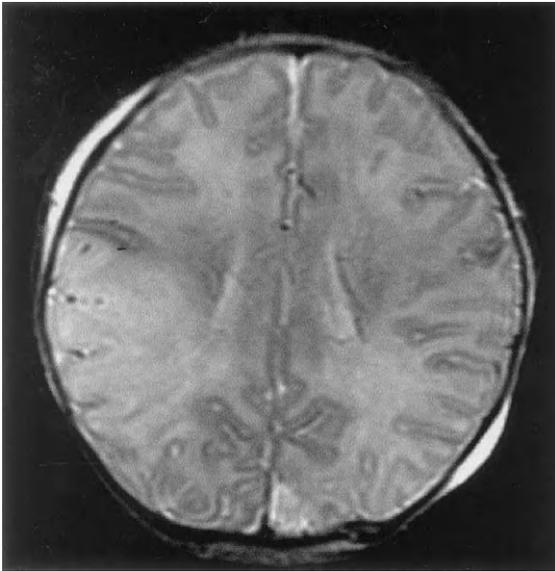

Sinovenous thrombosis (SVT) is an important cause of stroke in the neonate. It is being increasingly diagnosed in recent years, probably reflecting the use of more sensitive neuroimaging techniques. In a retrospective series of children with abnormal imaging studies suggestive of SVT,

61% were neonates (Carvalho et al, 2001). The Canadian Pediatric Ischemic Stroke Registry (CPISR) identified 0.67 cases per 100,000 per year, with neonates the most commonly affected (43%) (deVeber and Andrew, 2001). Risk factors are similar to those for ischemic stroke, with thrombophilias, asphyxial stress, dehydration, and infection being more common in the neonate. Often, more than one risk factor is present (Wu et al, 2003).

Neonates present with seizures as the most common sign. The head ultrasound examination often reveals an intraventricular hemorrhage. Further neuroimaging with MRI and MR venography will reveal the site of the venous thrombosis and may also show other parenchymal abnormalities, such as thalamic hemorrhage (Wu et al, 2003) (Fig. 64-6).

### Risk Factors

A number of different types of studies of infants with perinatal stroke has found an association with cardiac disorders, blood disorders, infection, trauma, drugs,

**FIGURE 64-5.** Brain magnetic resonance T2-weighted image in term neonate who suffered ischemic arterial stroke. Increased signal intensity is seen in the right parietal and frontal areas and the left posterior parietal region.

maternal and placental disorders, and perinatal asphyxia. In some studies, the occurrence of multiple risk factors has been noted, especially blood disorders and asphyxial stress (Golomb et al, 2001; Wood et al, 2000).

### Outcome

A review of the literature for case reports, series, and case-control studies of perinatal or neonatal stroke, which included 572 infants with perinatal stroke, revealed that 40% of infants with perinatal stroke were neurologically normal, 56% were abnormal (having neurologic or cognitive abnormalities), and 3.0% had died by the outcome evaluation period (Lynch et al, 2002). A similar review concluded that more than 50% of children with neonatal stroke appear normal by 12 to 18 months of age (de Vries et al, 1997). In the CPISR, the recurrence rate among children with neonatal stroke was 3% to 5%, and among survivors, outcome was normal in 33% (deVeber and Andrew, 2001). In one case series of 24 infants with MRI-confirmed cerebral infarction, 64% of the neonates had neurodevelopmental sequelae. The presence of prothrombotic disorders, especially presence of factor V Leiden, was associated with poor outcome in term infants (Mercuri, 2001).

The neurodevelopmental outcome of neonates with SVT is reported to be normal in 77% to 82%. Presence of venous infarction and refractory seizures has been associated with neurologic sequelae. (Carvalho et al, 2001; deVeber and Andrew, 2001; Shevell et al, 1989; Wu et al, 2003).

### Management

The use of anticoagulation therapy for the newborn is undetermined. It is difficult to extrapolate from adult or even non-neonatal pediatric studies. However, the CPISR

data suggest that anticoagulant therapy is not associated with serious hemorrhage in selected patients. Its use in neonates awaits further evaluation.

### Perinatal Trauma

Injuries of the cranial structures and the brain can occur secondary to trauma during the process of birth. Perinatal trauma can result from various causes in utero, during labor, and postnatally. The nature of the trauma can be either mechanical or vascular. Embolism and thrombosis can result from placental infarcts or absorption of material from a macerated twin fetus, or with disorders of coagulation or sepsis. Mechanical trauma can cause injury to both cranial and extracranial structures as well as the spinal cord and peripheral nerve structures.

### Mechanical Trauma

Mechanical trauma can result in damage to either extracranial structures, cranial structures, intracranial structures, spinal cord, or peripheral nerves. Extracranial injury can present as molding of the head and caput succedaneum, subgaleal hemorrhage, or cephalohematoma.

### Scalp Electrode Injury

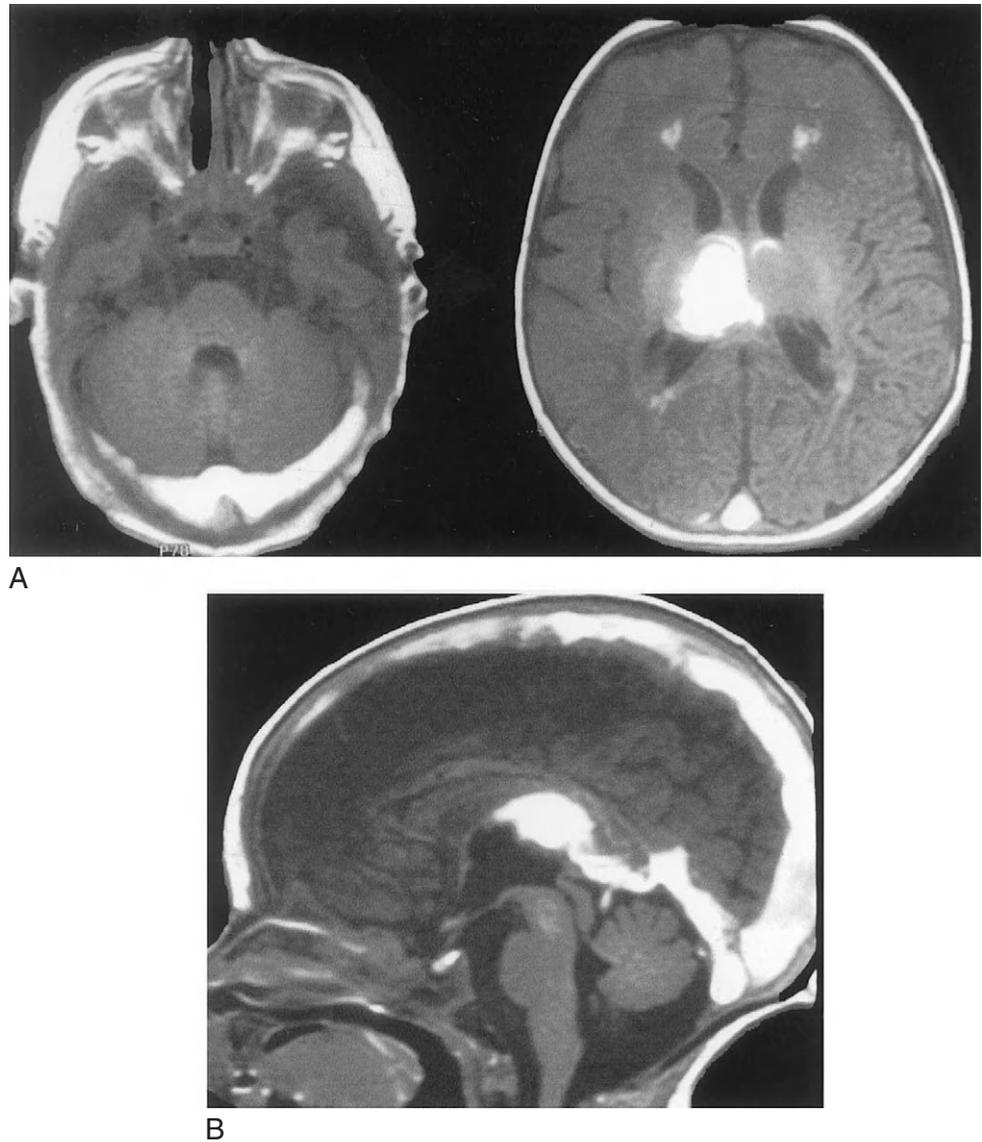

Use of scalp electrodes for fetal monitoring has increased, along with fetal blood sampling for blood gas measurement. The site of insertion can become a site of infection or bleeding. Although generally benign, such lesions are associated with infection in 1% of cases, and in rare cases (usually in premature infants) they can cause severe bleeding leading to hypotension.

### Molding of the Head and Caput Succedaneum

Molding of the head is frequently seen in the newborn delivered either vaginally or by cesarean section. It refers to the asymmetrical shape of the head that results from mechanical pressure exerted during passage through the birth canal or during extraction by cesarean section. *Caput succedaneum* refers to the edematous soft tissue swelling that is often associated with bruising over the molded region. Although this condition is generally benign and resolves with time, abrasions over the area can become infected, and hyperbilirubinemia may develop with resolution of bruising (Fig. 64-7).

### Subgaleal Hemorrhage

In certain cases the trauma may be severe enough to cause a subgaleal hemorrhage, which consists of extension of the bleeding beneath the scalp aponeurosis to the nape of the neck. This condition needs to be recognized immediately because it can lead to severe blood loss and shock. The coagulation status should be evaluated, as subgaleal hemorrhage may be a presenting sign of hemophilia, hemorrhagic disease of the newborn, or other coagulation disorders. A CT scan or MRI is indicated, especially in

**FIGURE 64-6.** Brain magnetic resonance images of sinovenous thrombosis with thalamic infarction in a term neonate. **A**, Right thalamic infarction and hemorrhage seen on axial T1-weighted MR image; **B**, thrombosis of entire venous system seen on sagittal T1-weighted MR image.

conditions associated with an enlarging swelling, altered mental status, or decreasing hematocrit. Maintenance of the circulatory status of the infant is critical and may require use of packed cells or plasma to correct hypovolemia and any coagulopathy. Occasionally, severe trauma can lead to tearing of either the tentorium or the falx cerebri. A subdural hematoma may occur in cases with venous lacerations.

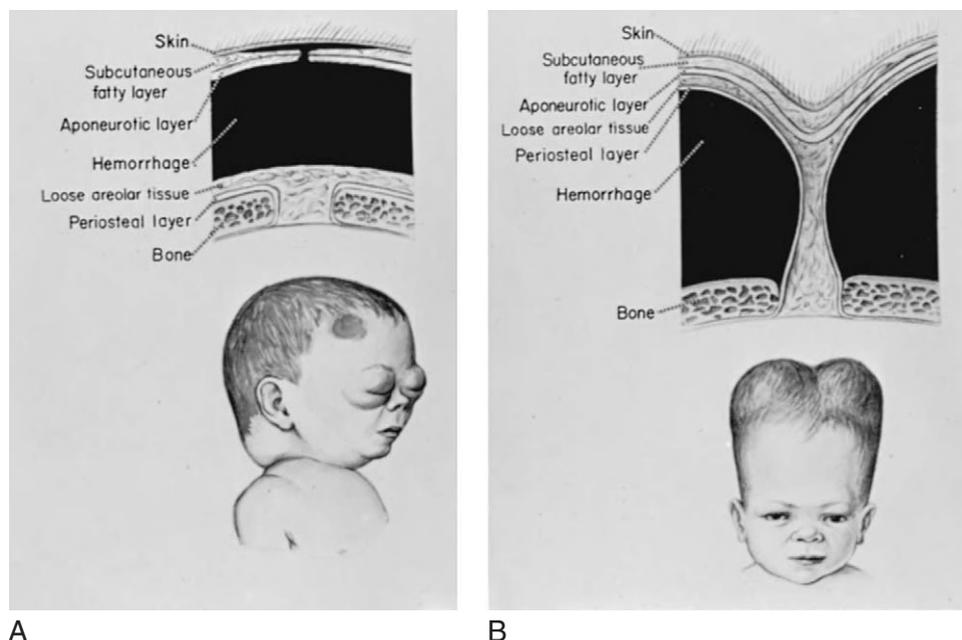

### ***Cephalohematoma***

Hemorrhage beneath the subperiosteum of the scalp leading to an elevation in usually the parietal region of the skull is called a *cephalohematoma*. It is distinguished from a caput as follows: it does not cross suture lines, it manifests as a firmer swelling that does not transilluminate, and it has a well-defined edge. Rarely, it is seen in the occipital region as a soft swelling that needs to be distinguished from an encephalocele. The incidence of cephalohematoma

is estimated to be 1.5% to 2.5% of all deliveries. It is seen twice as frequently in male infants and presents bilaterally in 15% of patients. Linear fractures are seen in 5% of unilateral lesions and in 18% of bilateral lesions.

A cephalohematoma generally resolves over a period of 2 to 8 weeks. It often leaves behind a sharp palpable ridge due to calcium deposition. Resorption of the extravasated blood can lead to hyperbilirubinemia, and infants should be observed for jaundice. A severe bleed can lead to anemia. Infection of the mass with formation of an abscess and associated osteomyelitis can occur in rare cases. It should be suspected in the event of an enlarging mass manifesting with fever and laboratory results suggestive of an infection. Needle aspiration may be necessary to establish a diagnosis, although this should not be performed in all cases of cephalohematoma due to the risk of introducing an infection.

A skull radiograph or a CT scan is indicated in cases in which a fracture is suspected. Hyperostosis and thickening of the parietal region, calcium deposition, or cystic defects within the hematoma may be seen on neuroimaging studies.

**FIGURE 64-7.** **A,** Location of edema and hemorrhage seen with a caput succedaneum. **B,** Location of hemorrhage seen with a cephalohematoma.

### Skull Fractures

Several features of the skull of the newborn make it less likely to sustain fractures, even in the presence of considerable pressure during the process of birth. The presence of unossified sutures and decreased mineralization make the neonatal skull less rigid and more amenable to temporary distortion. However, fractures do occur in deliveries, especially those associated with forceps or blunt abdominal trauma to the mother. Fractures can also occur simply from pressure of the head against the sacral promontory during delivery from forceful uterine contractions.

Fractures may be linear or depressed and usually occur in the frontal or parietal region. Linear fractures are more common and if nondisplaced usually do not pose a problem and do not need treatment. They are seen as a linear region of decreased density on a skull radiograph.

Depressed skull fractures associated with application of pressure over the parietal region are seen on the anteroposterior skull radiograph as a linear region of increased density. These may not be visualized on the lateral film. A depressed fracture can serve as a focus for seizure activity, and it is therefore recommended that the region be elevated by a surgical procedure.

### Subdural Hemorrhage

The dura mater, the outer meningeal layer, lies immediately below the bony layer of the skull and contains several blood vessels. It also encloses the major sinuses between its two layers. Severe compression and stretching can lead to tears of the falx cerebri or the tentorium cerebelli, especially at the site at which the falx meets the tentorium. Risk factors include macrosomia, cephalopelvic disproportion, shoulder dystocia, forceps delivery, and premature delivery. Hemorrhage can occur by injury to

the dural sinuses, the major cerebral veins, or the vein of Galen. Injury of the superficial cerebral veins leads to hemorrhage over the cerebrum. Injury to the straight sinus or the vein of Galen can cause extension of a subdural hemorrhage from the base of the brain into the posterior fossa. Damage to the sagittal sinus from overriding parietal bones, and damage to the occipital sinus in conditions leading to separation of the squamous from the lateral parts of the occipital bone, can be seen with breech presentation.

A subdural hemorrhage should be suspected in cases in which there is a history of trauma or a difficult delivery with development of focal cerebral signs such as unequal pupils, deviation of the eyes, or hemiparesis. Symptoms may present over a period of a few hours to days. Often the infant presents with nonspecific signs such as pallor, lethargy, irritability, and a decreased Moro response. A bulging anterior fontanel may be the sign of an acute bleed. Posterior fossa hemorrhages, which can be accompanied by cerebellar hemorrhages or IVH, may manifest later with ophtisotonos, apnea and bradycardia, altered mental status, and seizures. Pressure on the fourth ventricle can lead to signs of increased intracranial pressure and apnea.

Ultrasonography is inadequate for demonstrating the presence of a subdural bleed. Either CT or MRI is a more appropriate imaging study for this purpose and should be undertaken immediately once the diagnosis is suspected.

No surgical treatment is recommended in asymptomatic cases. Evacuation of a posterior fossa bleed can sometimes be lifesaving, although surgical evacuation is not effective in the case of a large subdural hemorrhage. Close monitoring is necessary to detect signs of deterioration in neurologic status. Presence of increased intracranial pressure may require a subdural tap or placement of a subdural shunt.

### **Subarachnoid Hemorrhage**

Subarachnoid hemorrhage occurs as a result of damage to veins traversing the subarachnoid space. This type of injury is fairly common and may manifest as seizures. Diagnosis is suspected when frank blood or blood-tinged fluid is obtained on lumbar puncture. No treatment is needed, as the condition usually resolves spontaneously.

### **Spinal Cord Injury**

Spinal cord injury was first described in the 1800s and is a relatively rare event now because of improved obstetric practices. In a review of studies of cerebral palsy, spinal cord injury was noted to account for just 0.6% of injuries. It is most commonly associated with breech delivery and occurs secondary to either a lateral or longitudinal stretching force or torsion of the neck during delivery. It can also be seen in premature infants as a result of extension of an intracranial hemorrhage. Damage occurs to the cord, the covering meninges, nerve roots, and blood vessels.

The pathologic findings may include laceration of the cord, epidural hemorrhage, laceration of the dura with a subdural hemorrhage, and tears of the nerve roots, as well as focal hemorrhages within the cord.

Most patients with a severe spinal cord injury do not survive. The cervical and upper thoracic segments of the spine are most commonly affected. The condition should be suspected in any infant with a breech presentation who has poor muscle tone and flaccid weakness of the extremities. The presentation in many cases is that of spastic paraparesis with respiratory depression and hypotonia. There is often involvement of both the motor and the sensory systems. Urinary retention and abdominal distention with paradoxical respirations may be present. The neurologic examination is significant for an absence of sensation below the level of the injury. This can manifest as reduced skin temperature and decreased tendon reflexes in the acute phase, followed by the appearance of triple-flexion withdrawal movements.

The differential diagnosis includes neuromuscular disorders such as spinal muscular atrophy, congenital myasthenia gravis, and a tumor of the cervical or lumbar region of the cord. Spinal muscular atrophy is usually not associated with loss of sensation or bladder control. A tumor of the spinal cord is usually associated with midline skin abnormalities such as dimpling, hemangioma, or tufts of hair.

Treatment is usually supportive and may require intubation for respiratory support. No specific treatment is available. Most cases are severe and irreversible, although milder degrees of injury are potentially reversible.

### **Cranial Nerve Injury**

#### **Facial Nerve Injury**

Facial nerve injury is the most common cranial nerve injury seen secondary to birth trauma. Contrary to common belief, forceps application is not associated with an increased incidence of facial nerve palsy. The site of injury and the precise timing of injury are controversial. The nerve is most commonly injured at the point where it

emerges from the stylomastoid foramen, and the lesion is therefore similar to a lower motor neuron lesion. The signs and symptoms include difficulty in closing the eyelid on the affected side, loss of the normal nasolabial fold, and an asymmetrical crying facies. The forehead is spared, as it is innervated by the opposite facial nerve. The injury occurs as a result of compression of the nerve against the sacral promontory especially in cases in which presentation of the fetal head leads to compression of the mandible and the neck against the shoulder. Usually, compression of the nerve occurs after it has exited the mastoid canal, although occasionally the portion within the mastoid can also be affected.

Nerve excitability or conduction tests are not usually recommended unless there is no improvement over 3 to 4 days. Most lesions begin to resolve after 1 week. Nerve excitability tests are usually helpful in distinguishing partial from complete denervation. In the case of partial injury, nerve stimulation can lead to some muscular contraction. However, the lack of response to nerve stimulation does not necessarily predict a poor outcome. A neurology consultation should be obtained in cases that do not show resolution within a few weeks. Methyl cellulose eye drops should be used on the affected side to prevent irritation from dryness of the conjunctiva. In severe cases, surgery may be necessary to repair a severed nerve.

### ***Congenital Hypoplasia of the Depressor Anguli Oris Muscle***

Congenital hypoplasia of the depressor anguli oris muscle is not due to perinatal trauma but is included here for differential diagnosis purposes. In affected infants, unilateral congenital absence of the depressor anguli oris muscle leads to an inability of contraction and eversion of the lower lip on the same side during crying episodes. The infant thus appears to have an asymmetrical face while crying. The condition becomes less prominent with age, as episodes of crying are reduced in the older child. This condition can occur as an isolated anomaly or be associated with other anomalies. In a review of 41 infants with the condition, 27 had associated genitourinary, respiratory, or cardiovascular abnormalities (Pape and Pickering, 1972). Congenital heart disease, especially ventricular septal disease, is the most common associated anomaly.

### ***Injury to Other Cranial Nerves***

Injury of other cranial nerves secondary to birth injury is rare. Transient ptosis may be seen as a result of damage to the oculomotor nerve. Unilateral as well as bilateral optic nerve atrophy has been reported to occur from orbital fracture.

### **Peripheral Nerve Injury**

#### ***Brachial Plexus Injury***

Injury to the brachial plexus usually results from the prolonged delivery of a macrosomic infant. Traction of the shoulder in a breech presentation as well as turning away

of the head in a difficult vertex presentation leads to stretching of the plexus. In the mildest cases, nerves C5 and C6 are affected, followed by additional nerves in more severe cases. The nerve is compressed within the nerve sheath from hemorrhage and edema. In severe cases there may be avulsion of the nerve from the spinal cord. Improvement in obstetric care has resulted in a decrease in incidence of this condition.

In most cases, the condition is unilateral; it is located on the right twice as often as on the left. *Erb-Duchenne paralysis* refers to the paralysis of the upper brachial plexus involving nerves C5 and C6. Weakness of the deltoid, biceps, brachioradialis, and supinator muscles leads to the classic clinical picture in which the infant holds the affected arm in a position of tight adduction and internal rotation of the shoulder along with extension and pronation of the elbow. Involvement of C7 can lead to a weakness of the extensors and exaggerated flexion of the wrist. The Moro reflex is asymmetrical and absent on the affected side, and the biceps reflex is weak or absent. The grasp reflex is usually present. The injury may be associated with a fracture of the clavicle or humerus, displacement of the radial head, or shoulder dislocation. Injury of C4 can lead to phrenic nerve paralysis, which manifests with rapid, shallow breathing and decreased movement of the diaphragm on the affected side.

*Klumpke paralysis* results from injury to the lower brachial plexus and accounts for 2.5% of cases of brachial plexus injury. It is associated with weakness of the flexor muscles of the wrist as well as the intrinsic muscles of the hand. The grasp reflex is absent, and there may be loss of sensation over the hand. Involvement of the cervical sympathetic nerves can lead to unilateral miosis (Horner syndrome). Complete paralysis of the arm is seen in cases in which the entire brachial plexus is damaged.

The diagnosis can be made on the basis of the history of difficult delivery, posture of the affected arm, and the loss of voluntary and reflex movements. Radiographic examination performed with fluoroscopy or ultrasonography can help make the diagnosis of phrenic nerve injury. Radiographic studies can also detect any associated fractures or dislocations. Use of somatosensory evoked potentials may help to distinguish completed avulsion at the spinal cord from a more distal lesion. MRI also can be used to demonstrate root avulsion. The extent of denervation can be demonstrated by performing an EEG 2 to 3 weeks after the injury.

The treatment is mainly supportive and consists of physical therapy to avoid the development of contractures. The arm should be positioned in a natural position and not be overimmobilized. Passive exercises should be started 1 week after birth. The timing of recovery is dependent on the extent of the lesion. In mild partial plexus injury and Erb-Duchenne injury, improvement is seen by 1 or 2 weeks after birth, and recovery is complete by 1 to 18 months. Prognosis is poorer in Klumpke paralysis and in cases of complete plexus damage. Recovery is rarely complete in these infants, and sequelae may include muscle atrophy and contractures. Return of neuromuscular function is not always associated with return of normal movements of the extremities due to early deprivation of sensorimotor function.

### Sciatic Nerve Palsy

Sciatic nerve palsy is usually iatrogenic from injection of medications into the umbilical artery or from an inappropriate injection into the gluteal muscle. Direct injury to the sciatic nerve may result, or more commonly, ischemic sciatic neuropathy can result from spasm or occlusion of the inferior gluteal artery. The weakness may be mild, affecting only dorsiflexion of the foot, or may be severe enough to result in extensive weakness and atrophy of the muscles of the thigh and below the knee. Ischemic neuropathy is sometimes associated with signs of vascular insufficiency in the regions of the buttocks and the lower limb.

Prompt recognition of this condition is important for institution of physical therapy and measures to avoid joint contractures. Surgical resection of the affected nerve segment may be necessary in cases without any improvement over a period of 6 months. Permanent sequelae such as weakness and atrophy are common in cases of sciatic nerve injury.

## STRATEGIES FOR NEUROPROTECTION IN CENTRAL NERVOUS SYSTEM INJURY

Considerable advances have been made in recent years in elucidating the cellular and vascular mechanisms of hypoxic-ischemic brain injury. Anticipation and prevention of conditions that cause HIE constitute the best neuroprotective strategy. However, until such time as appropriate techniques to detect imminent fetal hypoxia become available, the best method is to target post injury sequelae. Several agents are currently being explored. Many of these potential strategies have been studied in animal or adult models of disease. Extrapolating the effects of these studies to the human newborn is difficult because the mechanism of injury in experimental animal models is not necessarily similar to that in infants, and several features of the newborn developing brain make it uniquely more susceptible to injury than the adult brain. Therefore, these therapies must be tested in the neonatal population (Table 64-5).

Because infants with mild HIE usually do not suffer long-term neurologic consequences and because severe injury leads to a devastating outcome, most therapies should be directed at infants with moderate- to severe-intensity insults. Early identification of infants with a moderately severe insult is necessary in order to initiate appropriate therapy within the narrow therapeutic window. The lack of sophistication of the current technology compromises our ability to make an early diagnosis and intervene earlier in cases of HI-R injury (Nelson and Grether, 1999).

In addition to our lack of ability to select neonates for neuroprotective therapies, interruption of the injurious events by neuroprotective agents may also simultaneously affect normal developmental processes. Another important issue relates to the route and timing of intervention. Administration of medications to the mother at the time of identification of fetal distress may adversely affect the mother and the process of labor. Asphyxia in neonates is often associated with multiorgan dysfunction, which can

TABLE 64-5

**Possible Neuroprotective Strategies**

Hypothermia
Adenosine
Glutamate receptor antagonists
NMDA receptor antagonists
Glutamate-binding site
Glycine, phencyclidine, magnesium-binding sites
AMPA receptor antagonists
Erythropoietin
GABA antagonists
Calcium channel blockers
Nitric oxide synthase inhibitors
Other free radical inhibitors
Allopurinol
Vitamin E
Lazaroids
Metalloporphyrins
Desferoxamine
Growth factors
Caspase inhibitors

AMPA, amino-3-hydroxy-5-methyl-4-isoxazole propionic acid; GABA, gamma-aminobutyric acid; NMDA, *N*-methyl-D-aspartate.

affect the pharmacokinetics of drug therapies. Side effects of these agents can include hypotension and cardiac depression, exacerbating the initial injury by reducing cerebral perfusion pressure.

Given the complexity of cellular events triggered by HI-R injury, it is most likely that a multi-tiered approach will be more effective than a single drug in achieving neuroprotection. However, such an approach will need to take several factors into consideration. An ideal neuroprotective agent can cross the blood-brain barrier and accumulate in sufficient quantities at the site of action, has minimal side effects so as not to further extend the injury, does not inhibit the normal processes of maturation, and preferably has a long therapeutic window of action with no drug interactions.

Several strategies for neuroprotection exert their effects at different stages of the cascade of events that is initiated after injury. These strategies include methods to reduce depletion of ATP stores, both in cases in which hypoxic-ischemic insult is predictable and in the early postinsult phase, to reduce membrane depolarization, to inhibit glutamate release, to inhibit accumulation of intracellular calcium, to block glutamate-responsive NMDA and AMPA receptors, to prevent release of degradative enzymes, to sequester free radicals, to use thrombolytic agents, and to prevent the reperfusion injury by inhibition of xanthine oxidase. The following discussion examines some of these methods in more detail.

**Maintaining Energy Stores**

Prevention of depletion of cerebral energy stores is a strategy that can be utilized in cases in which injury is anticipated (e.g., cardiac surgery requiring placement of the infant on cardiopulmonary bypass). It is recommended that seizures and conditions that exacerbate energy deple-

tion, such as hyperthermia, be avoided in cases of HI-R injury.

**Hypothermia**

Mild sustained hypothermia is one of the most exciting and viable neuroprotective strategies for limiting neonatal HI-R injury to emerge from the laboratory in recent years. Cerebral metabolism after the initial phase of energy failure during asphyxia may recover in a latent phase but then deteriorate in a secondary phase of brain injury 6 to 15 hours later. In studies in cell culture and in vivo models of focal and global cerebral ischemias in both adults and immature animals, hypothermia has been shown to have a neuroprotective effect (Coimbra and Wieloch, 1994; Colbourne and Corbett, 1994; Sirimanne et al, 1996). Experimental studies in animal models have shown that moderate hypothermia established within 30 minutes after the HI-R injury is neuroprotective (Edwards et al, 1995; Haaland et al, 1997; Thoresen et al, 1995, 1996). These and other studies have shown that hypothermia inhibits early events as well as later events such as secondary energy failure and apoptosis. Studies in fetal sheep have shown that prolonged cerebral cooling starting 5.5 hours but not 8.5 hours after cerebral ischemia may still be associated with neuronal rescue (Gunn et al, 1997).

The possible mechanisms by which hypothermia helps in neuroprotection are inhibition of glutamate release, decreased metabolism and energy conservation, decreased metabolic acidosis, decreased free radical generation, prevention of energy failure and apoptosis, and inhibition of effects of adhesion molecules at the microvascular level, thereby inhibiting the breakdown of the blood-brain barrier and reducing brain edema. Some studies indicate that hypothermia delays but does not prevent the cellular or vascular outcome of HIE. However, even delaying onset of damage can be helpful in prolonging the therapeutic window for other therapies to take effect.

Hypothermia was first reported in the therapy of infants after perinatal asphyxia in 1959, but these experiments did not have a group of control infants (Westin et al, 1959). The adverse consequences of hypothermia and the importance of maintaining infants in a normothermic environment are well known. Metabolic, cardiovascular, pulmonary, coagulation, and immunologic disturbances all have been reported with hypothermia. A prospective randomized trial conducted to identify the adverse effects of hypothermia showed that selective head cooling was safe, with minimal systemic toxicity (Gunn et al, 1998). Mild hypothermia in this study was induced by application of a water-cooled coil to the infant's head, thereby lowering the cranial temperature to 34.5° C for 72 hours within 2 to 5 hours after the injury. Rectal temperature was maintained up to 35.7° C. The results of this and other studies led to the initiation of a multicenter clinical trial for neuroprotective efficacy. Although hypothermia holds much promise as a treatment modality for HI-R, several details regarding detection of early injury, timing and duration of the treatment, technique of head cooling, combination with other therapies, and whole-body cooling versus head

cooling will need to be determined before it can be used routinely in infants.

### Pharmacologic Adenosine

Adenosine is an inhibitory agent that is endogenously produced. It acts on the presynaptic and postsynaptic A<sub>1</sub> receptors that colocalize with the NMDA receptors, inhibiting release of glutamate and glycine and delaying the onset of depolarization (de Mendonca et al, 2000). Although adenosine and its analogues may mediate neuroprotective actions at a number of cellular or vascular sites, side effects associated with its use such as hypotension and generation of free radicals may limit its application in HI-R.

### Inhibition of Glutamate Release

Prevention of glutamate release can occur by blocking presynaptic voltage-dependent sodium channels and stimulating presynaptic adenosine receptors. Prevention of sodium accumulation inhibits the reversal of the glutamate uptake carrier mechanism that is induced by ischemia. The Na<sup>+</sup>,K<sup>+</sup>-ATPase pump that maintains ionic gradients uses considerable energy. Inhibition of sodium influx also helps to decrease energy consumption. Agents that have been found to be beneficial in adults include phenytoin and lamotrigine. Phenytoin has been shown in some studies to be protective only when used prior to the injury; other studies have described protection when the drug is given soon after the injury (Hayakawa et al, 1994; Stanton and Moskal, 1991; Vartanian et al, 1996). Although it is able to cross the fetal blood-brain barrier, its role as a neuroprotective agent in neonates with HI-R is unclear.

### Glutamate Receptor Antagonists

Glutamate receptor antagonists can be broadly divided into two types: agents that block the NMDA receptor and those that block the AMPA receptor. Antagonists of the NMDA receptor act either by competitive antagonism at the glutamate-binding site or by noncompetitive antagonism at the glycine-, phencyclidine (PCP)-, and magnesium-binding sites. Competitive antagonists such as CGS-19755 have been shown to have limited clinical utility because of poor penetration of the blood-brain barrier.

Noncompetitive antagonists acting at the NMDA receptor have been shown to be effective in adult models of focal ischemia, with a therapeutic window as long as 3 hours. However, these are not as effective in global ischemia. Dizocilpine (MK-801), the most widely used NMDA blocker in experimental models, was shown to be protective in the newborn beagle puppy model (Ment et al, 1989). It also has been shown to be protective in the rat but not the piglet model (LeBlanc et al, 1993). In the rat model it reduced the infarct volume by 50% to 70%, with a post-therapeutic window of 2 hours. However, it has a low therapeutic index and steep dose-response curve. There are no published data on the use of this agent in humans. A more recent report described apoptosis in

the immature P7 rat brain after injection of the antagonist even in the absence of injury (Ikonomidou et al, 1999).

Dextromethorphan is a widely used antitussive agent and a competitive NMDA receptor blocker that is able to cross the blood-brain barrier. It has several side effects, however, and is unlikely to be useful in neonates.

Magnesium, which has been used for several years to treat preeclampsia and whose effects on the fetus and newborn are well known, has shown mixed results in regard to neuroprotection (Galvin and Oorschot, 1998; MacDonald and Nowak, 1990). It is hypothesized to work by blockade of the immature NMDA ion channel as well as inhibition of neurotransmitter release and induction of NOS. In a study evaluating two different doses of magnesium sulfate in a group of full-term infants with Apgar scores of less than 6 at 10 minutes within 12 hours after delivery, even the lower dose of 250 mg/kg resulted in respiratory depression and hypotension (Levene et al, 1995). Maternal MgSO<sub>4</sub> does not reduce the risk of neonatal white matter damage, IVH, or ventriculomegaly (Leviton et al, 1997), and MgSO<sub>4</sub> during labor does not reduce the risk of cerebral palsy in infants with birth weights of less than 2000 g (Paneth et al, 1997).

In contrast to NMDA antagonists, AMPA receptor antagonists protect against global ischemic insults in adult models of ischemia, with a therapeutic window of as long as 12 hours (Li and Buchan, 1993). AMPA receptors are activated in the postischemic phase of injury. Antagonists to these receptors decrease glucose metabolism and increase brain-derived neurotrophic factor (BDNF), thereby promoting neuronal protection.

Erythropoietin has been shown in cell culture experiments to reduce neuronal cell death from oxygen-glucose deprivation and to attenuate the neurotoxic effect of AMPA. It has been used extensively in premature infants to treat anemia and has not been shown to have any major side effects (Ohls, 2000).

### Calcium Entry Blockade by Gamma-Aminobutyric Acid

Activation of the postsynaptic GABA receptor, an inhibitory receptor, stimulates entry of chloride and hyperpolarization of the neuronal cell membrane. Stimulation of these receptors by agents during the ischemic phase can prevent entry of calcium into the postsynaptic neuron. Stimulation during the postischemic phase can reduce the energy expended by the Na<sup>+</sup>,K<sup>+</sup>-ATPase pump and thus stabilize the cell membrane. Agents in this group include benzodiazepines, GABA uptake inhibitors (tiagabine), and inhibitors of GABA transaminase (vigabatrin). These drugs have shown mixed results in animal studies, and it is unclear if they will be of any use in the neonate because the inhibitory systems in the newborn brain are underdeveloped (Sternau et al, 1989).

### Calcium Channel Blockers

Calcium channel blockers exert their effects at both their neuronal and vascular targets by inhibition of calcium influx into the cell. Large clinical trials in adults as well as

a meta-analysis of nimodipine use have not been successful due to a narrow therapeutic window (Di Mascio et al, 1994). Nicardipine was tested in four full-term newborns but was found to be associated with severe hypotension (Levene et al, 1990). Flunarizine pretreatment has been shown to decrease dopamine release during hypoxia and to reduce infarct size in the Rice-Vannucci rat model (Gunn et al, 1989; Silverstein et al, 1986). Nonselective agents such as dihydropyridines also can cause hypotension. Newer neuron-specific calcium channel blockers seem more promising.

### Enzyme Inhibition

Inhibition of activation of enzymes such as calpain, a proteolytic agent that affects membrane proteins, as well as cyclooxygenase, xanthine oxidase, and NOS, is a potential therapeutic strategy.

NOS inhibitors have been studied in animal models of global and focal ischemia. Inhibition of NOS is complicated by the presence of three different isoforms, with differences in the timing of NOS inhibition, duration of treatment, and degree of effective binding to NOS. Increased understanding of the actions of the different isoforms, the stimuli that induce them, and their duration of action will help in designing newer and more focused treatment methods using these agents. In a study in the neonatal rat, *N*<sup>G</sup>-nitro-L-arginine (NO-Arg) showed efficacy if the drug was administered prior to the insult, but not afterward (Hamada et al, 1994). Similar results were obtained by Trifiletti (1992), who showed that documented inhibition of NOS with NO-Arg 15 hours before the onset of the hypoxic-ischemic insult provided almost complete protection against neuronal damage. In a post-treatment study in fetal sheep, Marks and colleagues (1996) showed that a continuous infusion of NO-Arg at a dose of 50 mg/kg instituted 2 hours after a 30-minute in utero ischemic insult delayed the increase in cerebral blood volume but did not decrease the extent of cerebral injury. Better protection has been achieved with the use of more selective neuronal NOS inhibitors, but the timing of administration is critical for protection (Groenendaal et al, 1999; Hamada et al, 1994; Muramatsu et al, 2000).

At present, no NOS inhibitors have been approved for use in humans.

### Inhibition of Other Free Radicals

Free radicals can be produced by different mechanisms. Endogenously occurring enzymes such as superoxide dismutase (SOD), catalase, and glutathione help in decreasing production of free radicals. In a murine model, transgenic mice that overexpress SOD showed less injury than wild-type mice in adult animals but more injury in immature animals (Ditelberg et al, 1996). Exogenous SOD has been of limited effectiveness due to its inability to penetrate lipid membranes and its short half-life. Lazaroids are a new class of lipophilic steroids that inhibit lipid peroxidation selectively without any effect on glucose metabolism. However, a randomized trial in adults treated within 6 hours of

a stroke with tirilazad, a lazaroid medication that had been shown in animal models of focal ischemia to help decrease the size of the infarct, failed to show any improvement (RANTTAS investigators, 1996).

Metalloporphyrins have been shown in *in vitro* experiments with hippocampal cells to be neuroprotective via direct neural effects (Panizzon et al, 1996).

Allopurinol has been shown to be neuroprotective in some animal studies, but when this drug was administered to severely asphyxiated neonates, there was no significant improvement in outcome despite documented decrease in oxidative stress (Van Bel et al, 1998; Veen et al, 1999). It acts primarily by inhibiting xanthine oxidase and by decreasing synthesis of uric acid. However, the mechanism of action is not completely clear, because the doses needed are higher than those required to block xanthine oxidase. Allopurinol may act by preventing the release of lysosomal enzymes, by chelating iron or copper, or by scavenging hydroxyl radicals. Allopurinol did not further improve outcome when used in combination with other scavengers such as deferoxamine (DFO) or indomethacin in animal models (Shadid et al, 1998).

### Hypoxic Preconditioning and Deferoxamine

Hypoxic preconditioning has been shown in both hippocampal cells and in the Rice-Vannucci neonatal rat model to activate protective mechanisms, possibly by triggering expression of gene products or deoxygenation of a heme moiety. Levels of a hypoxia-inducible transcription factor (HIF-1) are elevated in the penumbra in neonatal rats treated with hypoxia preconditioning (Bergeron et al, 2000). Pretreatment of animals with either cobalt chloride or DFO before injury was found to provide a 75% or 56% degree of protection, respectively. Other studies in the ischemic gerbil model (Patt et al, 1990), as well as in the neonatal rat, mouse, and lamb models, have shown decreased injury with use of DFO (Groenendaal et al, 2000; Kompala et al, 1986; Palmer et al, 1994; Sarco et al, 2000). DFO may act by iron chelation or by inducing HIF-1, or by other mechanisms. Although it has not been tested in human trials, it is a good candidate for clinical trials in neonates, as it has been studied extensively in clinical situations requiring iron chelation.

### Growth Factors

Genes up-regulated by stress, such as those that induce growth and differentiation including brain-derived neurotrophic factor (BDNF) and insulin-like growth factor (IGF), have been shown to be neuroprotective in animal models (Han and Holtzman, 2000). IGF-1 administered shortly after an injury is neuroprotective in the modified Levine adult rat model (Guan et al, 2000; Sizonenko et al, 2001).

### Caspase Inhibitors

Use of relatively specific inhibitors of apoptosis—caspase inhibitors—in immature animals significantly decreases brain injury, with the neuroprotective effect being dependent

on the drug used (Cheng et al, 1998). Evidence suggests that although some of the cell death in the adult brain following ischemia is apoptotic and caspase dependent, apoptotic-like death is particularly prominent in the neonatal brain after hypoxic and ischemic insults including hypoxia-ischemia (Cheng et al, 1997; Ferrer et al, 1997). This finding, coupled with the prolonged evolution of cell death after HI-R injury, provides new opportunities for intervention.

### Combination Regimens

Due to the complexity of the pathways involved in cell death, it is likely that more than one method or agent will be needed to stop the cascade of deleterious events. Modalities that reduce cellular metabolic demands (hypothermia) coupled with agents that reduce oxidative stress (scavengers) and inhibit cell death (caspase inhibitors) might provide the best results.

### SUMMARY

The past decade has seen an explosion of information regarding the pathophysiology of ischemic and traumatic injuries to the developing nervous system. The realization that the immature brain has different pathogenetic mechanisms in response to these insults has led investigators to think differently about designing therapies for the immature brain. With the continued investigations regarding the mechanisms of cell death in the immature brain, the development of age-appropriate neuroprotective strategies is not far behind.

## Neonatal Neuromuscular Disorders

Harvey B. Sarnat and Laura Flores-Sarnat

Many primary myopathies and neuropathies are already expressed in the neonatal period, whereas others, even if not yet clinically evident, may be diagnosed by proper testing if suspected because of an affected sibling or other family history of genetic disease. It is not necessary to defer investigations to an older age when the disease becomes more obvious clinically, if early diagnosis is desired for prognosis, management, and genetic counseling.

### ONTOGENY OF STRIATED MUSCLE

Interpretation of the neonatal muscle biopsy and of the clinical presentation of myopathies, in both preterm and term neonates, requires an understanding of the embryonic and fetal development of muscle. These features are detailed elsewhere (Sarnat, 1998) but are here briefly summarized.

All skeletal muscles of the extremities develop from two sources: The myocytes themselves are derived from the segmental myotomes, whereas all other tissues of the muscle—the connective tissue, blood vessel walls, nerve sheaths, tendons, and fascia—are derived from the superficial of the two sheets of lateral mesoderm. The medial mesoderm is the somites that contain the myotomes and dermatomes; the intermediate mesoderm gives rise to the kidneys; the deeper sheet of lateral mesoderm becomes the omenta and peritoneum.

*Myoblasts* differ from undifferentiated mesenchymal cells by their formation of filaments of actin and myosin, a process that begins at 5 to 8 weeks of gestation. The *myotubular stage* of muscle development in the human encompasses weeks 8 to 15 of gestation. Myotubes are formed by the fusion of myoblasts and by the organization of their interdigitating filaments to form parallel arrays in bundles (myofibrils) and periodic Z-bands and M-bands that create the repeating sarcomeres of mature muscle. Myotubes still differ from mature muscle in other ways. The nuclei and mitochondria are concentrated in rows in the centers of the fiber, surrounded by the “tube” of myofibrils. Myotubes also have many ribosomes, unlike more mature muscle, which has few.

Between 15 and 20 weeks of gestation, the central nuclei of myotubes “migrate” to the peripheral, subsarcolemmal position of mature muscle. The mitochondria become redistributed from the central core between nuclei to the internyofibrillar sarcoplasm throughout the myofiber and to the subsarcolemmal region. A regression of vimentin intermediate

filaments allows this cytoarchitectural reorganization by no longer holding the nuclei and mitochondria in the central core of the myofiber (Sarnat, 1990). The period of 20 to 28 weeks of gestation is the histochemical stage of development, when myofibers differentiate their slow- or fast-twitch characteristics that correspond in histochemical stains of the muscle biopsy to type I or type II fibers. Early in this period, nearly all fibers closely resemble type II. By 24 weeks, about 10% of the fibers are larger than the rest; these fibers are uniformly scattered without grouping and stain as type I fibers. Subsequently, more small type II fibers become converted to type I until the ratio is about equal in most muscles by 28 weeks. The population of type II fibers also grows in size so that the two types are no longer distinguished by size. The differentiation of fiber types depends on innervation and not independent genetic programming.

At 30 weeks, the transverse tubules and terminal cisternae of the sarcoplasmic reticulum (triads) change their orientation from parallel to perpendicular to the long axis of the myofiber. The alignment of Z-bands of adjacent myofibrils also is a late development, at about 30 weeks. The mean myofibril diameter in full-term neonatal muscle is 15  $\mu\text{m}$ ; the adult diameter of 65  $\mu\text{m}$  is not achieved until about 13 years of age.

The sarcolemmal and basement and nuclear membrane proteins of striated muscle fibers, including those defective in various muscular dystrophies, are demonstrated at 9 to 11 weeks of gestation. During this same period, innervation of the muscle from axons of motor neurons takes place. Initially, myofibers are innervated by several axons, but later, only one persists in the center of the fiber, and all others retract. The postsynaptic membrane of the neuromuscular junction continues to acquire more complexity of folding and specialization of the membrane throughout gestation and in the postnatal period.

The most important intermediate-filament proteins of muscle during development are vimentin and desmin. They are in highest concentration in myotubes and then diminish until vimentin disappears completely by 36 weeks of gestation, whereas desmin persists in very low concentration even in adult muscle. Desmin forms links between the Z-bands of adjacent myofibrils so that they are aligned. One or both of these intermediate-filament proteins retain high fetal concentrations after birth in several congenital myopathies.

Four principal genes are essential to myodifferentiation, each having a basic helix-loop-helix transcription factor. The earliest-expressed gene to signal myoblast differentiation is *myoblast factor 5* (*MYF5*), on chromosome 12; *myogenin*, on chromosome 1, promotes the fusion of myoblasts to form myotubes; *herculin* (*MRF4/6*), essential for myotube conversion to myofibers, is on chromosome 12; *MyoD1* is so potent a gene of myoblast differentiation that, in cell culture, it can cause the transformation of partially differentiated nonmuscular cells of mesodermal lineage, such as fibroblasts and chondroblasts, into muscle. It is localized on chromosome 11, very near to the domain for rhabdomyosarcoma. *Pax-3* is redundant with *MYF5* and, in the absence of *MYF5*, can activate *MyoD1*. Up-regulation of *Pax-3* results in precocious differentiation of

muscle. Another gene, called *myostatin*, is expressed after the myogenic genes and functions as a negative regulator of muscle differentiation, by inhibiting the shift from proliferation to differentiation of myoblasts, but does not affect mitosis or cause apoptotic cell death.

Regenerating muscle recapitulates the stages of embryonic and fetal myogenesis.

### ONTOGENY OF PERIPHERAL NERVE

The embryology of peripheral nerve begins with the migration of the neural crest cells, which include precursors of Schwann cells, and lateral mesodermal components that contribute connective tissue portions of the nerve in preparation for the arrival of the growing axon of motor neurons or dendrite of sensory neurons. The ontogeny of nerve in the fetal period was demonstrated and reviewed by Hasan and associates (1993) and Teixeira and colleagues (1999). Immature unmyelinated axons and early myelinating axons contain more microtubules than neurofilaments, but this ratio becomes reversed with maturation so that neurofilaments predominate in mature axons. Cross-linkages between neurofilaments begin to form before midgestation and progressively increase with phosphorylation throughout the remainder of fetal life. Growth in axonal diameter, as well as in length, continues in the postnatal period.

Initially, all axons of peripheral nerve are unmyelinated and variable in diameter, and as many as 25 may be enclosed by a single Schwann cell. The mean axonal diameter increases in inverse relation to the decreasing ratio of axons per Schwann cell as the nerve matures. Myelination occurs only in Schwann cells that enclose a single axon, although occasionally two axons may be myelinated by one Schwann cell. Axonal diameter is inversely related to the number of axons per Schwann cell. Myelin sheaths initially are thin, and the number of whorls of Schwann cell cytoplasm increases. Nodes of Ranvier (gaps between myelin formed by adjacent Schwann cells that are important for saltatory conduction of depolarization or action potentials) and Schmidt-Lanterman clefts (normal discontinuities in the myelin) are formed from the onset of myelination. The number of myelinated axons increases, and the emergence of two distinct populations of large and small myelinated axons is a relatively late event, this bimodal distribution occurring at about 37 to 38 weeks of gestation. Fibers that persist as unmyelinated axons at maturity also decrease in their ratio to enclosing Schwann cells, so that at birth no more than four unmyelinated axons per Schwann cell are found, as in the adult.

As with muscle, the development of nerve is highly genetically programmed, and several genes are recognized that are essential to normal development. *Desert hedgehog (DHH)* is key to the differentiation of Schwann cells. *EGR2* (human homologue of *Krox-20* in the mouse) is necessary for the maintenance of myelin, but *peripheral myelin protein-22 (PMP22)* is the regulator of the initiation of myelin, and *myelin protein zero (MPZ)* is the major determinant of myelin structure including periodicity of the concentric whorls. *EGR3* is needed for the maintenance of axoplasm. *PMP22* and *MPZ* are mutated

in most of the hereditary sensory-motor neuropathies, whereas *EGR2* is deficient in at least one form of congenital insensitivity to pain.

### MUSCULAR DYSTROPHIES

The *muscular dystrophies* are a group of unrelated diseases that may be defined and distinguished from all other neuromuscular diseases by four obligatory criteria: (1) primary myopathy, (2) genetic determination, (3) progressive course, and (4) degeneration of myofibers noted at some stage in the disease, although not always demonstrated in the neonatal muscle biopsy. Several distinct diseases are known, and the molecular genetic basis, as well as the pattern of inheritance, is now known for a majority of them. Table 65-1 summarizes the genetic data for the most frequent disorders that may present in the neonatal period.

#### Duchenne Muscular Dystrophy

Duchenne muscular dystrophy is inherited as an X-linked recessive trait and is the most frequent muscular dystrophy, with an incidence of 1:3000 liveborn male infants, affecting all racial and ethnic groups throughout the world. The defective gene at the Xp21.2 locus is the largest known gene, and it programs a sarcolemmal protein known as *dystrophin*. Clinical myopathic features often are not yet expressed at birth, but some infants may already show generalized weakness and hypotonia. Calf pseudohypertrophy is not yet present in neonates. Cardiomyopathy is rare in early infancy but common at older ages. The serum creatine kinase (CK) level is always extremely elevated in Duchenne dystrophy at all ages. Therefore, if the diagnosis is suspected in an asymptomatic male infant because of an affected brother or male maternal cousin, determination of the serum CK (after 5 days of age to allow for the transient rise due to birth trauma) may be performed as a screening test; in affected infants, serum CK is already in the range of several thousand IU/L. The diagnosis is confirmed by polymerase chain reaction (PCR) genetic blood testing, but false-negative results are obtained in one third of boys with Duchenne muscular dystrophy. In those cases, the muscle biopsy is definitively diagnostic, even in presymptomatic stages in the neonatal period. The dystrophin abnormality may be demonstrated in myofibers by immunocytochemical studies or immunofluorescence of biopsy tissue, and different portions of the protein may be studied individually (C-terminus, N-terminus, and rod domain). Fetal muscle biopsy before midgestation was briefly advocated, shortly before the genetic defect was demonstrated (Kuller et al, 1992), but prenatal diagnosis using chorionic villi is now available, so that fetal muscle biopsy in this disease is now of historical interest only.

Male infants with Becker muscular dystrophy are not symptomatic in the neonatal period and have normal findings on neuromuscular examination, but if the diagnosis is suspected because of a previously affected brother, it may be confirmed by high serum CK after 5 days of age, by the PCR marker in blood, or by neonatal muscle biopsy showing defective dystrophin in myofibers.

TABLE 65-1

## Genetic Myopathies Symptomatic in the Newborn

Disease	Transmission	Locus	Gene	Transcription Product
<b>Muscular Dystrophies</b>				
Muscle-eye-brain	AR	1p3	<i>MEB</i>	OMGnT
Duchenne (neonatal)	XR	Xp21.2	(Dystrophin)	Dystrophin
Facioscapulohumeral	AD	4q35	<i>FSHD</i>	
Myotonic, neonatal form	AD (M)	19q13	<i>DMPK</i>	Myotonin protein kinase
<b>Congenital Myopathies</b>				
Congenital fiber-type disproportion	AR, sporadic	?	?	None known
Nemaline rod	AD	1q21-q23	<i>NEM1 (TPM3)</i>	$\alpha$ -Tropomyosin
	AR	2q21.2-q22	<i>NEM2</i>	Nebulin
	AD, AR	1q42.1	<i>NEM3 (ACTA1)</i>	$\alpha$ -Actin
	AD	9p13	<i>NEM4 (TPM2)</i>	Tropomyosin
	AR	19q13	<i>NEM5 (TNNT1)</i>	Troponin-T
Infantile myofibrillar	AR, AD	?	?	?
X-linked myotubular	XR	Xq28	<i>MTMX</i>	Myotubularin
Central core	AD	19q13.1	<i>RYR1</i>	Ryanodine receptor
Myotonia congenita: Thomsen disease, Becker disease	AD, AR	7q35	<i>CLC1</i>	Muscle chloride channel protein
<b>Glycogenoses with Myopathy</b>				
Glycogen storage disease type II (Pompe disease)	AR	17q23	<i>GAA</i>	$\alpha$ -Glucosidase (acid maltase)
Glycogen storage disease type V (McArdle disease, neonatal form)	AR	11q13	<i>PYGM</i>	Myophosphorylase
<b>Spinal Muscular Atrophy</b> (motor neuron disease, not a myopathy)				
Type I: Werdnig-Hoffmann	AR	5q11-q13	<i>SMN/NAIP</i>	Neuronal apoptosis inhibitory protein

AD, autosomal dominant; AR, autosomal recessive; M, maternal; XR, X-linked recessive.

### Emery-Dreifuss Muscular Dystrophy

Emery-Dreifuss muscular dystrophy is not usually symptomatic in the neonatal period, but the severe cardiomyopathy and cardiac conduction defects sometimes appear surprisingly early in infancy or even in the first days of life, before the generalized myopathy is evident. The X-linked recessive form of this disease is due to a defective protein called *emerin*. An autosomal dominant form of the disease is due to another defective protein, *lamin*, of which three varieties have been distinguished. Both *emerin* and *lamin* are proteins of the nuclear, rather than the sarcolemmal, membrane, and both may be demonstrated by immunocytochemical studies on muscle biopsy tissue.

### Congenital Muscular Dystrophy

*Congenital muscular dystrophy* refers to a group of disorders that usually manifest in the neonatal period with variable congenital contractures, generalized hypotonia and weakness, often facial weakness, and sometimes dysphagia

and respiratory insufficiency. The muscle biopsy specimen is characteristic and shows extensive endomysial connective tissue proliferation but only minimal cytoarchitectural changes in myofibers or fiber necrosis. *Merosin* (the  $\alpha 2$  chain of laminin that connects the sarcolemma to the basal lamina or basement membrane) is not expressed on immunocytochemistry studies in half of the cases, and electron microscopy demonstrates absence of the basal lamina, but there is little clinical correlation of the severity of the myopathy with the presence or absence of *merosin*. Many cases of congenital muscular dystrophy are associated with cerebral malformations, usually pachygyria, and imaging of the brain is indicated if this diagnosis is established from the muscle biopsy. Some genetic diseases that regularly include congenital muscular dystrophy and cerebral dysgenesis are Fukuyama muscular dystrophy (the second most common muscular dystrophy in Japan after Duchenne dystrophy, but rare in other populations), Walker-Warburg syndrome of type 2 lissencephaly, and muscle-eye-brain disease of Santavuori (Fukuyama et al, 1997; Muntoni, 2002).

### Myotonic Muscular Dystrophy, Neonatal Form

The neonatal form of myotonic muscular dystrophy differs from the adult form both clinically and pathologically. Findings in the neonatal period include generalized weakness, hypotonia, often contractures ranging from clubfoot to more extensive arthrogyposis involving the cervical spine, characteristic facial weakness associated with a high-arched palate, inverted V-shaped upper lip, dolichocephaly, dysphagia, and respiratory insufficiency (Sarnat et al, 1976). Myotonia is not expressed in neonates. Smooth muscle also is involved, and affected infants have poor peristalsis, inability to expel meconium or later stool, and often abdominal distention due to gas in the stomach and intestines that impinges on the diaphragm from below, further compromising respiratory effort. Congenital cataracts are found in a minority. Cardiac conduction defects may occur. On pathologic examination, the muscle shows either congenital muscle fiber-type disproportion (Agrov et al, 1980) or arrest of maturation in various stages of development, with myoblasts, myotubes, histochemically undifferentiated myofibers and mature neonatal myofibers all mixed in the same fascicles (Iannaccone et al, 1986; Sahgel et al, 1983; Sarnat and Silbert, 1976). Immature features are confirmed ultrastructurally. Muscle spindles also are abnormal in myotonic dystrophy, unlike in most other myopathies.

Although myotonic dystrophy is an autosomal dominant trait, the mother is the transmitting parent in 94% of cases (Harper, 1992). The reason for the maternal predominance is not due to hormonal factors but is genetic. The triplet expansion (CTG codon) of the myotonic dystrophy gene that encodes a serine-threonine kinase (*DMPK*) on chromosome 19q13 is many times greater in affected neonates than in the usual childhood or adult presentation of the disease, sometimes with as many as 2000 repeats (normal allele shows 5 to 37 repeats, with the usual adult form of myotonic dystrophy typically showing 50 to 500 repeats) (Hofman-Padvanyi et al, 1993). The female locus is more unstable than the male locus—hence the predominance of maternal transmission (Mulley et al, 1993). There is no gender predominance among affected neonates, however. The genetic anticipation phenomenon may be seen in myotonic dystrophy (Harper, 1992).

In pregnancy, myotonic mothers often show worsening of their disease and have a high rate of fetal loss or premature birth. Prolonged labor is not frequent, but contractions may be ineffective, and intrapartum asphyxia of the fetus is an additional risk (Sarnat et al, 1976).

In suspected neonatal myotonic dystrophy, the investigation should begin with examination of the mother and then proceed in the infant to include assay for the molecular genetic marker in blood, electrocardiography (ECG), slit-lamp examination of the lens of the eye, and muscle biopsy if the blood marker assay is inconclusive. Electromyography (EMG) is of very limited value. Serum CK is normal or only mildly elevated.

### Facioscapulohumeral Muscular Dystrophy

Facioscapulohumeral muscular dystrophy is inherited as an autosomal dominant trait. The disease usually becomes symptomatic in childhood or adolescence but shows a

propensity for the genetic phenomenon of *anticipation*, and neonates may sometimes be symptomatic or even severely affected. Facial muscles and sometimes extraocular muscles are affected. The atrophy or hypoplasia of the orbicularis oris muscle gives the mouth an unusual shape, with protruding and turned-out lips exposing mucosal surfaces; this is unlike the inverted V-shaped mouth of neonatal myotonic dystrophy and nemaline rod disease. Shoulder girdle and parascapular muscles are thin and weak. Dysphagia may be a feature. Assay for a molecular marker in blood to demonstrate the defective *FSHD* gene at the 4q35 locus is available. Findings on neonatal EMG are nonspecifically myopathic, and the muscle biopsy shows endomysial connective tissue proliferation, hypertrophic type II fibers as well as atrophic fibers of both types, little or no myofiber necrosis, and, in many cases, lymphocytic infiltrates in perivascular and interstitial spaces that may be confused with an inflammatory autoimmune myopathy. Steroid treatment is ineffective, despite the presence of lymphocytic “inflammation.”

### Limb-Girdle Muscular Dystrophies

Limb-girdle muscular dystrophies, a mixed group of diseases with a variety of genetic defects often due to sarcoglycanopathies, dysferlinopathies, or caveolin-3 deficiency, rarely produce clinical manifestations in infancy and are not evident in the neonatal period.

### CONGENITAL MYOPATHIES

*Congenital myopathy* is a generic term that refers to any of a group of mainly nonprogressive, non-necrotizing myopathies, most of which are genetically determined and others of which are sporadic. Most are characterized by structural alterations in myofibers, such as rod-like inclusions or internal sarcolemmal nuclei; additional findings include abnormalities in relative growth, differentiation, and ratio of fiber types within the muscle. The diagnosis is usually established by muscle biopsy. More genetic markers in blood are becoming available for some, however, and clinical features including phenotype may be suggestive of a diagnosis, to justify muscle biopsy. Congenital myopathies may be thought of as “developmental disorders” of striated muscle.

*Amyoplasia*, a term that technically denotes absence of muscle, is sometimes misused in reference to disappearance of muscle as a result of chronic neurogenic atrophy, as in severe spinal muscular atrophy (SMA) or the *Pena-Shokeir syndrome* with motor neuron involvement, but this usage is incorrect. The lack of differentiation of muscle does occur on a genetically programmed basis and may be divided into *segmental amyoplasia*, *generalized amyoplasia*, and *focal amyoplasia* of specific muscles.

The prototype of segmental amyoplasia is sacral agenesis, which most often occurs in infants of diabetic mothers. Not only do the bony and cartilaginous elements of the lower spine (sacrum and often lumbar and even lower thoracic vertebrae) fail to form, but the associated somites including the myotomes are incomplete or totally aplastic, resulting in absence of muscle formation in those segments, particularly muscles of the lower legs innervated by sacral roots. The spinal cord also is severely dysplastic

at the sacral levels due to failure of induction by the defective or absent notochord, so that the *Sonic hedgehog* gene needed for motor neuron differentiation is not expressed. Despite the absence of myofibers in muscles such as the peroneus longus, gastrocnemius, and soleus, the connective tissue components and blood vessels, which are derived from lateral mesoderm, are present, and adipose tissue replaces the myofibers (Sarnat, 1992).

The selective agenesis of individual muscles may also be classified under the rubric of segmental amyoplasia, but these abnormalities are not field effects as with sacral agenesis. An example is the absence of the pectoralis major in the Poland anomaly. Another example is the isolated agenesis of the depressor angularis oris muscle on one side only, which gives the neonate an asymmetrical mouth when crying and may be confused with facial nerve palsy. Yet another example, of no clinical importance, is the congenital absence of the flexor palmaris longus muscle of the forearm, which is absent in one third of all normal persons; in this case, other flexors of the wrist easily compensate for the lack of function.

Generalized amyoplasia, which involves the diaphragm and other muscles of respiration and of deglutition as well as those of the spine and extremities, is incompatible with life and usually results in spontaneous fetal death at the end of the first trimester of gestation. The cause is probably a deletion of or mutation in one of the essential myogenic genes (see earlier), although this hypothesis is not yet proved. *Pax-3* and *Myf-5* are redundant together; in the chick and rat, mutations in *Pax-3* with lack of expression result in severe amyoplasia, whereas underexpression of *Myf-5* results only in hypoplasia with some muscular development. At autopsy, the affected human fetus with generalized amyoplasia shows arthrogryposis and only rudimentary striated muscle formation throughout the body, although cardiac and smooth muscles are developed. The *fetal akinesia sequence* may be a form of generalized amyoplasia.

### **Congenital Muscle Fiber-Type Disproportion**

Congenital muscle fiber-type disproportion (CMFTD) is both an isolated congenital myopathy and also a syndrome associated with a variety of unrelated other congenital myopathies, with systemic metabolic diseases, or with central nervous system (CNS) malformations. CMFTD is a muscle biopsy diagnosis that refers to disproportion in (1) the ratio and (2) the size of the two principal histochemical types of myofibers. Type I fibers are uniformly smaller than type II fibers and more numerous, with a predominance of 80% or more (Brooke, 1973; Iannaccone et al, 1983; Sarnat, 1994). Degenerative changes are rare, but some cases show myofibrillar lysis (Barth et al, 1998).

When CMFTD occurs as an *isolated congenital myopathy*, affected patients already have a characteristic phenotype at birth, and the muscle biopsy also is diagnostic in the neonatal period. The appearance of these infants is nearly identical to those with nemaline rod disease and also resembles the neonatal form of myotonic dystrophy. Craniofacial anomalies include a dolichocephalic head shape, high-arched palate, and facial weakness (Baccetti et al, 1997); generalized hypotonia, weakness, and thin muscle bulk in the trunk and extremities are other features.

Congenital contractures such as clubfoot occur in a few patients, and some have congenital subluxation of the hip, but most do not have contractures, and arthrogryposis multiplex congenita is rare. Affected infants may have dysphagia and require feeding by gavage. Mild ptosis is sometimes seen, but extraocular movements usually are not impaired, although a few infants with ophthalmoplegia have been reported (Owen et al, 1981). Cardiac involvement or anomalies are found in a minority of cases (Barth et al, 1998). Respiratory failure is exceptional (Mizuno and Komiyama, 1990). Severe insulin-resistant diabetes mellitus occurs rarely (Vestergaard et al, 1995).

Both genders are affected equally; presence of the disorder in siblings (Barth et al, 1998; Eisler and Wilson 1978; Fardeau et al, 1975; Gerdes et al, 1994; Jaffe et al, 1988; Marolda, 1992) and identical twins (Curless and Nelson 1977) suggests an autosomal recessive inheritance, but other affected families appear to have an autosomal dominant trait (Kim et al, 2000). No defective genes are yet demonstrated; thus, no genetic markers in blood are available, although a chromosomal translocation was discovered in one family (Gerdes et al, 1994). The serum CK is normal, and the EMG and nerve conduction velocity (NCV) studies also show no specific alterations. The clinical course is that of a nonprogressive congenital myopathy, with persistent hypotonia, weakness, and developmental delay for gross motor skills in particular.

CMFTD also occurs in the context of other congenital neuromuscular diseases that also are evident in the neonate. *Nemaline rod myopathy*, both the autosomal dominant and recessive forms, shows CMFTD as an associated finding in the muscle biopsy (see later). In globoid cell leukodystrophy (Krabbe disease, severe infantile form), CMFTD is seen in muscle biopsy tissue earlier than the neurogenic atrophy of progressive neuropathy is expressed (Dehkharghani et al, 1978; Marjanoic et al, 1996; Martin et al, 1976). CMFTD also is a feature of some cases of the severe neonatal form of myotonic muscular dystrophy (see earlier). It is reported rarely in infants with Emery-Dreifuss muscular dystrophy, but whether it appears in neonates with this myopathy is unknown. CMFTD is a feature of the *rigid spine syndrome* (Goebel et al, 1977; Seay et al, 1977), associated with a mutation of the *SEPN1* gene at 1p3 (Muntoni, 2002); this disorder may also involve interneurons in the ventral horns of the spinal cord.

CMFTD occurs inconstantly, in the neonatal period, in many systemic metabolic diseases including glycogenosis II (Pompe disease), III (Cori-Forbes disease), and X (phosphorylase-B kinase deficiency); multiple sulfatase deficiency; phosphoglyceromutase deficiency; mitochondrial cytopathies; and congenital hypothyroidism. It also is found in some cases of fetal alcohol syndrome (Martin et al, 1976) and in oculocerebrorenal disease of Lowe (Kohyama et al, 1989). In these disorders, CMFTD often is incomplete and does not involve all fascicles, or the type I predominance is not as massive as in the pure congenital myopathy.

CMFTD also is found in some infants with diffuse hypotonia due to cerebellar hypoplasia or other posterior fossa malformations, as a suprasegmental effect on the motor neurons during fetal life (Nakagawa et al, 1996; Sarnat, 1985, 1986). A magnetic resonance imaging (MRI) study of the brain should be considered in the clinical investigation of CMFTD.

If the diagnosis of CMFTD is made on the basis of neonatal muscle biopsy findings, therefore, the clinician should not accept this as a definitive diagnosis but should recognize the need to look further for an associated condition responsible for this unique developmental pattern.

### Nemaline Rod Myopathy

The phenotype of nemaline rod myopathy is virtually identical to that described for CMFTD but is often more severe, particularly in terms of respiratory insufficiency and dysphagia. Other children with nemaline myopathy have little or no problem with respiration or swallowing in the neonatal period, but all show diffuse muscular hypotonia and weakness. Nemaline rods are seen in muscle biopsy tissue as rod-shaped structures within the myofibrils that represent excessive Z-band material and that have the same ultrastructural periodicity as that of the Z-band. The diagnosis can be established by muscle biopsy in the neonatal period (Shimomura et al, 1989). CMFTD is an integral part of the histopathologic pattern in infancy, and myofiber degeneration does not occur. Both autosomal dominant and autosomal recessive mendelian patterns are well documented, and five genes are now identified in various cases. Loci for autosomal dominant forms are at 1q21-q23 and 9p13, which both encode  $\alpha$ -tropomyosin (Laing et al, 1995), and 1q42.1, which encodes  $\alpha$ -actin (Nowak et al, 1999). The locus in the most frequent autosomal recessive form is 2q21.2-q22, encoding *nebulin*, a very large molecule of the Z-band of muscle (Pelin et al, 1999; Wallgren-Pettersson et al, 1995), 19q13 that encodes troponin-T<sub>1</sub> and another autosomal recessive form is at the same  $\alpha$ -actin locus as that of the autosomal dominant gene encoding this protein, 1q42.1.

### X-Linked Recessive Myotubular Myopathy

Male infants with X-linked recessive myotubular myopathy exhibit severe involvement at birth, often with respiratory failure and dysphagia in addition to generalized hypotonia, weakness, and undescended testes; the condition often progresses to neonatal death (Barth et al, 1975; Sarnat, 1990, 1994). They do not, however, have the craniofacial characteristics of CMFTD, nemaline rod myopathy, and myotonic dystrophy. Cardiac involvement is exceptional but is reported. The defective gene (*MTMX*), at the Xq28 locus, produces a defective form of a protein called *myotubularin* (Laporte et al, 1997). A genetic blood test is available, and the muscle biopsy also is diagnostic. Internal nuclei, a central core location of mitochondria, and persistently high concentrations of desmin and vimentin are suggestive of fetal myotubes, but these fibers are not true arrested myotubes and show histochemical differentiation and ultrastructural features of much more mature myofibers.

### Other Centronuclear Myopathies

Some nonprogressive congenital myopathies presenting in the neonatal period, as well as some that do not become symptomatic until later, are characterized histopathologi-

cally by rows of central nuclei in myofibers resembling those of X-linked myotubular myopathy, but genetic tests prove that that are not due to a defective *MTMX* gene. The inheritance of these disorders may be autosomal recessive or autosomal dominant, or they may be sporadic. Some are associated with CMFTD, and it is uncertain whether the central nucleation of the CMFTD is the primary or most important feature; the clinical manifestations are usually more severe than in isolated CMFTD (Sarnat, 1994). These diseases are not as well understood as some of the other congenital myopathies, but in general hypotonia, developmental delay, weakness and thin muscle mass are the characteristic features, with or without facial involvement and dysphagia.

### Central Core Disease

Central core disease is a myopathy with the same genetic mutation at 19q13.1 as in malignant hyperthermia, with both autosomal dominant and autosomal recessive forms determined at this same locus. The gene encodes a tetramer “ryanodine” receptor to a calcium channel of the sarcoplasmic reticulum within the myofiber. The central cores are longitudinal columns of disorganized myofibrils in the centers of myofibers, seen in muscle biopsy tissue by both light and electron microscopy. Histochemically, these patients have a massive type I myofiber predominance, or almost no type II fibers are differentiated. Most infants are not symptomatic in the neonatal period, or the manifestations are nonspecific myopathic features of hypotonia and weakness. Some, however, have congenital contractures and dislocations of the hips and knees, kyphoscoliosis, and pes cavus. Malignant hyperthermia is precipitated by exposure to anesthetic drugs and may be prevented by pretreatment with dantrolene sodium.

A morphologically similar but unrelated disorder, *multicore* or *minicore myopathy*, manifests shortly after birth with generalized hypotonia and weakness (Panegyres and Kakulas, 1991). The diagnosis rests on muscle biopsy.

### Infantile Myofibrillar Myopathy

Infantile myofibrillar myopathy is a congenital myopathy characterized pathologically by sarcomeres of disorganized myofilaments and fragmented Z-bands within myofibrils in which other sarcomeres show normal structure. Some infants exhibit severe involvement at birth and have respiratory failure and dysphagia in addition to generalized weakness and hypotonia. Autosomal recessive transmission is suspected, but the chromosomal locus and gene are not yet identified. The diagnosis is established by muscle biopsy. Serum CK is normal, and genetic markers are not available.

### Proteus Syndrome Myopathy

The Proteus syndrome is a sporadic disorder of cellular growth involving many tissues of the body and often producing grotesque, asymmetrical malformations. The muscle in Proteus syndrome shows features of a “muscular dysgenesis” with abnormal structure of sarcomeres that do not

correspond to normal anatomic boundaries, but it is not a neoplastic condition (Sarnat et al, 1993).

### Myotonia Congenita

Myotonia congenita is a nonprogressive myopathy. Both the autosomal dominant form (Thomsen disease) and the autosomal recessive form (Becker disease) of this disorder are due to a genetic (*CLC1* gene) abnormality in the same chloride channel in muscle, both at the 7q35 locus. Generalized muscular pseudohypertrophy is an important clinical characteristic and sometimes can be seen even in the neonate, although myotonia is not expressed in infancy and the weakness may be subtle. This disease is unrelated to myotonic muscular dystrophy or to Becker muscular dystrophy.

### INFLAMMATORY AND AUTOIMMUNE MYOPATHIES

Autoimmune diseases causing myositis are extremely rare at birth, in large part because of the immaturity of the immune system and lack of time for autoantibodies to develop. Inflammation in the neonatal muscle biopsy probably is a form of facioscapulohumeral muscular dystrophy, but a few cases have been reported as neonatal myositis and not genetic dystrophy.

### EXTRAMEDULLARY HEMATOPOIESIS IN MUSCLE

Extramedullary hematopoiesis may occur in the muscles of normal, as well as abnormal, neonates, similar to hematopoiesis in the liver. This is a benign, transitory, asymptomatic condition that is occasionally seen as an incidental finding in neonatal muscle biopsy specimens. It must be distinguished from inflammation and not treated with steroids.

### METABOLIC AND ENDOCRINE MYOPATHIES

Congenital hypothyroidism (cretinism) is associated with diffuse muscular hypotonia and weakness and often an enlarged tongue. In one form, *Kocher-Debré-Sémélaigne syndrome*, generalized muscular hypertrophy and weakness are seen. Muscle biopsy is not needed for diagnosis if the condition is recognized clinically, but if performed before the diagnosis is established, it shows a variety of abnormalities including, at times, CMFTD (Mastaglia et al, 1989). Myopathy also may accompany adrenocortical insufficiency in the neonate. Vitamin E ( $\alpha$ -tocopherol) deficiency can cause myopathy, and neonates on prolonged total parenteral nutrition (TPN) suffered this complication before vitamin E was regularly added to the TPN composition. Infants with *Prader-Willi syndrome* have diffuse and severe hypotonia. They do not require muscle biopsy for diagnosis if the deletion at 15q11-q13 is confirmed by fluorescence in situ hybridization (FISH) analysis of blood, but the muscle histopathologic findings are abnormal and include excessive perimysial fat, a feature shared with infants of diabetic mothers, patients with congenital hypothyroidism, spinal muscular

atrophy, and occasionally, infants on chronic parenteral nutrition.

Mitochondrial cytopathies are now recognized as an important category of systemic metabolic disease that affects striated muscle and the nervous system. The muscle biopsy specimen is an excellent source of tissue for mitochondrial study because of the large number of mitochondria and their large size in muscle. Some of the classical histopathologic features in older children and adults, such as ragged red fibers and paracrystalline inclusion-like structures in mitochondria seen by electron microscopy, are not formed in neonates, but many other abnormalities are present at birth. These include the absence of cytochrome-*c* oxidase from scattered myofibers, ultrastructural alterations in cristae, and deficiencies in respiratory chain enzymatic activities and point mutations in mitochondrial DNA. One limitation of biochemical analysis of muscle for mitochondrial studies in the newborn is the small volume of tissue that can be taken in a neonatal muscle biopsy. Nevertheless, at times it may be useful to study neonatal muscle if the diagnosis cannot be provided from markers in blood. It is useful in the diagnosis of Leigh encephalopathy, the most frequent mitochondrial cytopathy of early infancy.

### SPINAL MUSCULAR ATROPHY

Spinal muscular atrophy (SMA) is a progressive degenerative disease of spinal and brainstem motor neurons that begins in fetal life and continues postnatally. The etiology is a pathologic continuation of a process of programmed cell death that is normal in embryonic life. A surplus of motor neuroblasts and other neurons is generated from primitive neuroectoderm, but only about half survive and mature to become neurons; the excess cells have a limited life cycle and degenerate. If the process that arrests physiologic cell death fails to intervene by a certain stage, neuronal death may continue. The *survivor motor neuron (SMN)* gene arrests apoptosis (programmed cell death) of motor neuroblasts (Roy et al, 1995). Unlike most genes that are highly conserved in evolution, *SMN* is a unique mammalian gene not identified in other animals.

SMA is clinically divided into three forms by presentation: type 1 is *Werdnig-Hoffmann disease*, a severe disorder expressed at birth and associated with death by age 2 years in 75% of affected children; type 2 is a milder form that also may show diffuse hypotonia, weakness, and areflexia in the neonatal period or early infancy, associated with a less rapidly progressive course and longer survival into childhood; and type 3 is *Kugelberg-Welander disease*, having the slowest course and compatible with survival well into adult life and not symptomatic in infancy. The cardinal clinical features of SMA type 1 in the neonatal period are severe generalized hypotonia and weakness, a thin muscle mass, absence of tendon stretch reflexes, and involvement of the tongue, face, and jaw muscles with selective sparing of extraocular muscles and sphincters. Infants who are symptomatic at birth may have respiratory distress and are unable to feed. Congenital contractures, ranging from simple clubfoot to generalized arthrogyposis, are present

in about 10% of severely involved neonates. Infants lie flaccid with little movement and are unable to overcome gravity. They lack head control. Fasciculations are a specific clinical sign of denervation of muscle. They are best observed in the tongue, where almost no subcutaneous connective tissue separates the muscular layer from the epithelium. If the intrinsic lingual muscles are contracted, such as in crying or when the tongue protrudes, fasciculations are more difficult to see than when the tongue is relaxed. The heart is not involved in SMA. Neonates and infants with SMA are alert and show normal social responses, unlike infants with encephalopathy at birth, and there are no signs of CNS disease except for motor neuron involvement.

The simplest, most definitive diagnostic test is a molecular genetic marker in blood for the *SMN* gene. The serum CK level may be normal but more commonly is mildly elevated in the hundreds. Results of motor nerve conduction studies are normal, at times an important feature distinguishing SMA from congenital peripheral neuropathies. EMG shows fibrillation potentials and other signs of denervation of muscle, but findings are often nonspecific in neonates. Muscle biopsy tissue in SMA reveals a characteristic pattern of perinatal denervation that is unlike that of mature muscle. Groups of giant type I fibers are mixed with fascicles of severely atrophic fibers of both histochemical types. Scattered immature myofibers resembling myotubes also are demonstrated. The muscle biopsy does not distinguish between type 1 and type 2 SMA. Sural nerve biopsy is not required, but often shows giant unmyelinated axons and other changes. At autopsy, mild degenerative changes are seen in sensory neurons of dorsal root ganglia and in somatosensory nuclei of the thalamus, but these alterations are not detected by clinical or electrophysiologic examination.

Molecular genetic diagnosis by DNA probes in blood samples or in muscle biopsy or chorionic villi tissues are available not only for diagnosis in suspected cases but also for prenatal diagnosis. Most cases are inherited as an autosomal recessive trait. The incidence of SMA is 10 to 15 cases in 100,000 live births; it affects all ethnic groups and is the second most common neuromuscular disease following Duchenne muscular dystrophy. The incidence of heterozygosity for autosomal recessive SMA is 1:50. The genetic locus for all three of the common forms of SMA is on chromosome 5, a deletion at the 5q11-q13 locus, indicating that they are variants of the same disease rather than different diseases. The affected gene is called *survival motor neuron (SMN)* and contains 8 exons that span 20 kilobases, with telomeric and centromeric exons that differ only by 5 base pairs and produce a transcript encoding 294 amino acids. Another gene, the *neuronal apoptosis inhibitory gene (NAIP)*, is located next to the *SMN* gene, and in many cases there is an inverted duplication with two copies, telomeric and centromeric, of both genes; isolated mutations or deletions of *NAIP* do not produce clinical SMA. Infrequent families with autosomal dominant inheritance are described, and a rare X-linked recessive form is reported. Carrier testing by dosage analysis is available.

## NON-SPINAL MUSCULAR ATROPHY MOTOR NEURON DISEASES

Motor neuron diseases that are not hereditary SMAs are rare in neonates. The Pena-Shokeir sequence has two forms. One is associated with arthrogryposis and a progressive motor neuron degeneration closely resembling SMA but with normal *SMN* gene expression; this disorder often can be recognized clinically by the associated pulmonary hypoplasia (Hageman et al, 1987). The Marden-Walker syndrome is another arthrogryptic disorder involving progressive motor neuron degeneration beginning before birth, but with anomalies of several organ systems. *Pontocerebellar hypoplasias* are progressive degenerative diseases of the CNS, transmitted as autosomal recessive traits, that begin in fetal life; one form also involves motor neuron degeneration resembling an SMA, but the *SMN* gene on chromosome 5 is normal (Barth, 1993).

Involvement of motor neurons is a feature of several metabolic diseases of the nervous system, such as gangliosidosis (Tay-Sachs disease), ceroid lipofuscinosis (Batten disease), and glycogen storage disease type II (Pompe disease), but the signs of denervation may be minor or obscured by the more prominent involvement of other parts of the CNS or of muscle.

Enteroviral infections may specifically target motor neurons and include *poliovirus*, *echovirus*, and *coxsackievirus* infections; maternal infections with these viruses affect the fetus and neonate rarely. The clinical picture is that of diffuse flaccid paralysis and may include dysphagia, but symptoms of diffuse meningoencephalitis also may be present, distinguishing it from spinal muscular atrophy. Specific PCR tests and viral cultures of cerebrospinal fluid are diagnostic. West Nile virus involves motor neurons, but this infection has not been reported in neonates.

## CONGENITAL HEREDITARY NEUROPATHIES

Some hereditary motor-sensory neuropathies (HMSNs) manifest at birth. Congenital insensitivity to pain may be due to a congenital hypomyelinating neuropathy, for example. Neuropathies symptomatic at birth often have a component of autonomic dysfunction, such as with familial dysautonomia type 3 (Riley-Day syndrome, localized to 9q31). The majority of HMSNs have a known genetic basis, largely related to mutations in genes that program peripheral nerve development (see "Ontogeny of Peripheral Nerve," earlier), but the genetic relations in these diseases are complex. Molecular genetic diagnosis from blood is confirmatory in most cases, but if not, sural nerve biopsy often can determine the nature of the neuropathy. Prenatal testing also is available. Most HMSNs are not clinically symptomatic in the neonatal period.

## ARTHROGRYPOSIS MULTIPLEX CONGENITA

*Arthrogryposis multiplex congenita* is a descriptive term that implies multiple congenital contractures and is not a diagnosis. The specific etiologic disorder may vary from motor neuron diseases such as SMA to congenital myopathies and muscular dystrophies and, rarely, congenital

myasthenia gravis. Arthrogyposis also may be secondary to CNS malformations, bone dysplasias, and even mechanical factors such as immobilization of the fetus in utero secondary to oligohydramnios or bicornuate uterus. A form of arthrogyposis occurs without evident neuromuscular, neurologic, or systemic disease. Simple clubfoot deformities are not arthrogyposis.

### TORTICOLLIS

Isolated contracture of the sternocleidomastoid muscle (SCM) with obligate head turning to one side may be due to a lesion of one SCM, as with a hematoma in the muscle due to traumatic birth injury or with anomalous absence of one SCM, or may be due to a lesion of the spinal accessory nerve (cranial nerve XI) to one SCM muscle. This nerve is unique in passing through the belly of the clavicular head to innervate the sternal head of the muscle (Sarnat and Morrissey, 1981). Torticollis also may be due to CNS lesions. Occasionally, it appears to simply be the functional result of an unusual position in utero; in such cases it responds well to gentle physiotherapy.

### CONGENITAL, NEONATAL, AND FAMILIAL MYASTHENIA GRAVIS

Infants born to myasthenic mothers may have respiratory insufficiency, inability to suck or swallow, and generalized hypotonia and weakness. They may show little spontaneous motor activity for several days to weeks. Some require ventilatory support and feeding by gavage during this period. After the abnormal antibodies disappear, the infants have normal strength and are not at increased risk for developing myasthenia gravis in later childhood. The syndrome of *transient neonatal myasthenia gravis* is to be distinguished from a rare, and often hereditary, *congenital myasthenia gravis* not related to maternal myasthenia that is nearly always a permanent disorder without spontaneous remission (Engel et al, 2000). Apnea and hypoventilation in sleep may be serious complications (Iannaccone et al, 2000). Three *presynaptic* congenital myasthenic syndromes are recognized, all inherited as autosomal recessive traits, but their molecular genetic basis remains undeciphered (Walls et al, 1993). An additional *synaptic* form is caused by absence of marked deficiency of acetylcholinesterase (AChE) in the synaptic basal lamina. *Postsynaptic* forms of congenital myasthenia are due to mutations in acetylcholine receptor (AChR) subunit genes that alter the synaptic response to ACh. An abnormality of the AChR channels appearing as high conductance and excessively fast closure may be due to a point mutation in a subunit of the receptor affecting a single amino acid residue. Neonates with congenital myasthenia gravis do not experience myasthenic crises or exhibit elevations of anti-ACh antibodies in plasma.

Infantile botulism is an important consideration in the differential diagnosis if signs and symptoms suggestive of congenital myasthenia gravis manifest in early infancy (Schreiner et al, 1991). This diagnosis would be most likely if the delivery had been performed at home or under less than sterile conditions, or if the neonate had

been given contaminated honey on a pacifier or in a bottle of formula.

### Laboratory Findings and Diagnosis

Myasthenia gravis is one of the few neuromuscular diseases in which EMG is more specifically diagnostic than a muscle biopsy. A decremental response is seen in response to repetitive nerve stimulation; the muscle potentials diminish rapidly in amplitude until the muscle becomes refractory to further stimulation. Motor NCV remains normal. This unique EMG pattern is the electrophysiologic correlate of the fatigable weakness observed clinically and is reversed after a cholinesterase inhibitor is administered. A myasthenic decrement may be absent or difficult to demonstrate in muscles that are not involved clinically. This feature may be confusing in early cases or in patients showing only weakness of extraocular muscles.

*Anti-ACh receptor antibodies* should be assayed in the plasma but are inconsistently demonstrated. About one third of adolescents show elevations, but anti-ACh receptor antibodies are only occasionally demonstrated in the plasma of prepubertal children. Other serologic markers of autoimmune disease, such as antinuclear antibodies and abnormal immune complexes, should also be sought. If assays for these markers are positive, more extensive autoimmune disease involving vasculitis or tissues other than muscle is likely. A thyroid profile should always be examined. The serum CK level is normal in myasthenia gravis. An enlarged thymus is not seen in neonates. Muscle biopsy is not indicated.

Edrophonium should not be given to young infants because cardiac arrhythmias may result. An alternative agent with fewer cardiogenic side effects is intramuscular neostigmine. If the initial test dose of 0.04 mg/kg produces negative results, the infant may be retested 4 hours later with 0.08 mg/kg. A maximal effect occurs in 20 to 40 minutes. Because of muscarinic side effects, 0.01 mg/kg of atropine may be given just before the prostigmine.

Recommendations on the use of cholinesterase inhibitors as a diagnostic test for myasthenia gravis in neonates include the following:

1. Ideally, the test should measure a specific fatigable weakness, such as ptosis of the eyelids, dysphagia, or inability of cervical muscles to support the head; in nonspecific generalized weakness without cranial nerve motor deficits, results are more difficult to assess, but generalized weakness may be a criterion at times.
2. An intravenous infusion should be started as a rapid route for medications in the event of an adverse effect of the test medication.
3. ECG monitoring is recommended during testing.
4. Pretreatment with *atropine sulfate* to block the muscarinic effects (abdominal distention, diarrhea, profuse tracheal secretions) of the test medication may be given, although this is not essential, but this drug should be available at the bedside in a prepared syringe. If needed, it should be administered intravenously in a dose of 0.1 mg/kg.
5. *Edrophonium is not recommended for use in infants;* its effect is too brief for objective assessment, and an

increased incidence of acute cardiac arrhythmias is reported in infants, especially neonates.

6. *Prostigmine methylsulfate* (Neostigmine) is administered *intramuscularly* in a dose of 0.04 mg/kg; if the result is negative or equivocal, another dose of 0.04 mg/kg may be administered 4 hours after the first dose. The peak effect is seen in 20 to 40 minutes. Intravenous administration is not recommended because of the risk of arrhythmia.

### INVESTIGATION OF NEUROMUSCULAR DISEASES IN THE NEONATE

Investigation of myopathies and neuropathies in the neonatal period is generally as reliable as at older ages, although in some diseases, EMG or muscle biopsy features may not develop until the pathologic process has progressed further.

#### Genetic Markers

Assays for genetic markers in blood are available for many of the muscular dystrophies, SMA, and many hereditary neuropathies and are already diagnostic at birth. A positive result may confirm a diagnosis without the need for more invasive procedures such as muscle biopsy. These tests are expensive, however, and many health insurance plans in the United States do not include them; this may be a limiting economic factor.

#### Serum Creatine Kinase

Serum CK (formerly creatine phosphokinase [CPK]) is not a general screening test for neuromuscular diseases and is normal in most congenital myopathies and neuropathies and normal or only mildly elevated in SMA. It is greatly elevated to levels of several thousand IU/L even at birth in all male infants affected with Duchenne muscular dystrophy, even if they are clinically asymptomatic at this stage; thus, it is a reliable and inexpensive screen for this disease if the family history suggests an increased risk. In other muscular dystrophies, including congenital muscular dystrophy and neonatal myotonic dystrophy, the CK is normal or only mildly to moderately increased in neonates. The serum CK of normal infants is less than 160 IU/L and often is elevated to as much as five times normal soon after birth, as a result of the normal trauma of delivery with stretch and compression of muscles, and returns to normal within 5 days. An elevated CK in infants younger than 5 days of age should be interpreted with great caution, and the test should be repeated in a few days.

#### Blood Studies of Metabolic Products and Endocrine Function

Blood studies of metabolic products and endocrine function may be indicated in some cases. Examples are lactate and pyruvate in mitochondrial cytopathies, thyroid-stimulating hormone and thyroxine ( $T_4$ ) for suspected hypothyroid myopathy, and serum amino acids if a systemic metabolic

disease that may also produce muscular hypotonia and weakness is suspected.

#### Nerve Conduction Velocities

The conduction velocity of motor and sensory nerves, such as the peroneal, ulnar, and median nerves, is about half the velocity of adults at birth (average 24 m/sec in the term neonate versus 48 m/sec in the adult, the adult velocity being achieved at about 2 years of age). The results of NCV studies are inherently not as precise as in the adult because the distance over which the conduction is measured (e.g., ankle to hip) is very short in neonates. Nevertheless, if a neonatal polyneuropathy is suspected, this test is both feasible and confirmatory even at birth. More than 80% of the largest conducting axons must be impaired before a reduction in conduction velocity is shown electrophysiologically; thus, a normal result does not exclude neuropathy.

#### Electromyography

EMG is generally not very useful in early infancy, both because of technical limitations and because of difficulty in interpretation. Some diagnostic features, such as myotonia, are not yet expressed at this age. If a myopathic or a neurogenic pattern is shown, it does not specify the type of myopathy or neuropathy and usually does not preclude the need for other tests, including the muscle biopsy, which provides the same information and much more. EMG should not be ordered routinely for all infants with suspected neuromuscular disease. Myasthenic decremental responses to repetitive nerve stimulation, as a specialized EMG technique that is not routinely done, may sometimes be demonstrated.

#### Muscle Biopsy

Muscle biopsy is the most specific diagnostic test for most neuromuscular diseases, with a few exceptions such as myasthenia gravis and some endocrine myopathies. If molecular genetic analysis of blood does not provide confirmation of a suspected hereditary disease, muscle biopsy often is more specific (e.g., one third of assays for genetic PCR blood markers for Duchenne dystrophy are falsely negative, but the demonstration of deficient dystrophin in the muscle biopsy is 100% reliable). It was shown in 1978 that the muscle biopsy is as diagnostic in the neonatal period as in older children; therefore, definitive diagnosis should not be deferred (Sarnat, 1978). A quarter-century later, this is even more true, because in addition to the traditional histochemical stains used in 1978, many immunohistochemical markers for proteins of the sarcolemma region and nuclear membranes are now available to precisely diagnose the type of muscular dystrophy, as well as studies of muscle tissue to diagnose mitochondrial cytopathies that have been developed only in the past decade.

The muscle biopsy requires a highly specialized and complex pathological preparation that includes frozen sections for histochemistry, fixation for possible electron

microscopy, and separate frozen tissue for biochemical analysis as needed, and also a pathologist who is experienced and skilled with interpretation of neonatal muscle biopsies and normal maturation patterns. If the tissue cannot be properly processed and interpreted at the hospital where the infant is admitted, arrangements should be made for transfer of the infant or for having the tissue properly fixed or frozen and sent to another medical center with this specialized type of laboratory.

The vastus lateralis (quadriceps femoris) muscle is generally the best muscle to biopsy because it is a proximal large muscle that shows all of the features of generalized myopathies and neuropathies and is not traversed by major blood vessels or nerves that could become damaged. The laboratory should be given advance notice to prepare to receive the specimen. The biopsy itself is a simple surgical procedure that can be done at the bedside or in an isolette with the use of local anesthesia and femoral nerve block (regional anesthesia); a general anesthetic is almost never required.

### Sural Nerve Biopsy

Sural nerve biopsy may be diagnostic of hereditary neuropathies even in the neonate, but patients should be selected carefully. As with muscle biopsy, considerable specialized tissue preparation and interpretation are required. The sural nerve is a pure sensory nerve, and biopsy specimens usually are taken from behind the lateral malleolus of the ankle, where the nerve is superficial, easy to find, and functions only to innervate a small sensory cutaneous zone on the lateral side of the foot. If the surgery is performed carefully so that internal scarring is minimal, the nerve often regenerates at this distal site. Care should be taken to not stretch or crush the nerve during biopsy, as the tissue is delicate and artifacts are more easily introduced by trauma to nerve than to muscle.

### Cardiac Evaluation

Cardiac evaluation, including ECG and echocardiography, sometimes is indicated in diseases in which cardiac muscle or conduction may be involved, such as Duchenne and myotonic muscular dystrophies, even if the infant is clinically asymptomatic for cardiovascular disease. Pediatric cardiology consultation may be useful in selected cases.

### Central Nervous System Evaluation

CNS evaluation, including imaging studies and EEG, may be indicated in some cases, particularly in congenital muscular dystrophy, which often is associated with cerebral malformations such as pachygyria, or in CMFTD that may be secondary to cerebellar hypoplasia.

## Neonatal Seizures

Mark S. Scher

Neonatal seizures are one of the few neonatal neurologic conditions that require immediate medical attention. Although prompt diagnostic and therapeutic interventions are needed, multiple challenges impede the physician's evaluation of the newborn with suspected seizures (Table 66-1) (Scher, 1989, 1997a, 2001b, 2002). Clinical and electroencephalographic manifestations of neonatal seizures vary dramatically from those in older children, and seizure recognition remains the foremost challenge to overcome. This dilemma is underscored by the brevity and subtlety of the clinical repertoire of the neonatal neurologic examination. Environmental restrictions in an intensive care setting—the sick infant may be confined to an isolette, intubated, and attached to multiple catheters—limit accessibility by caregivers. Medications alter arousal and muscle tone and limit the clinician's ability to detect clinical neurologic signs reflective of the underlying disease state. Brain injury from antepartum factors may precipitate neonatal seizures as part of an encephalopathic clinical picture during the intrapartum and neonatal periods (Scher, 1994), well beyond when brain injury occurred. Overlapping medical conditions from fetal through neonatal periods must be factored into the most appropriate etiologic algorithm that explains seizure expression before application of the most accurate prognosis. Medication options that effectively treat seizures remain elusive and may need to be designed and utilized on the basis of the underlying diagnosis (Scher, 2001a). This chapter presents issues regarding recognition, differential diagnosis, prognosis, and treatment of neonatal seizures, in the context of current neurobiologic and pathophysiologic explanations or causes for neonatal seizures and consequential brain injury.

### DIAGNOSTIC DILEMMAS: CLINICAL VERSUS ELECTROENCEPHALOGRAPHIC CRITERIA

Because neonatal seizures are generally brief and subtle in clinical appearance, unusual behaviors may be difficult to recognize and classify. The most common practice in many neonatal intensive care units (NICUs) is to rely on clinical behaviors to identify seizures, without confirmation by electroencephalogram (EEG). Motor or autonomic behaviors, however, may represent normal gestational age- and state-specific behaviors in healthy infants or, alternatively, nonepileptic paroxysmal conditions in encephalopathic infants. Medical personnel also vary significantly in their ability to recognize suspicious behaviors; this variability will contribute to overdiagnosis or underdiagnosis. There-

fore, confirmation of suspicious clinical events as seizures using coincident electroencephalographic recordings is now strongly recommended. Using either routine electroencephalographic studies (Glauser, 1992) or continuous synchronized video-EEG-polygraphic recordings (Mizrahi and Kellaway, 1998), more reliable start and end points of electrographically confirmed seizures can be established before decisions are made regarding treatment intervention. Rigorous physiologic monitoring of non-central nervous system (CNS) measures also assists in the recognition and management of seizures.

### Clinical Seizure Criteria

The International League Against Epilepsy's classification adopted by the World Health Organization still considers neonatal seizures within an unclassified category (Commission, 1981). A more recent classification scheme suggests a stricter distinction of clinical seizure (nonepileptic) events from electrographically confirmed (epileptic) seizures with respect to possible treatment interventions (Mizrahi and Kellaway, 1998). Continued refinement using novel seizure classifications is needed to reconcile disagreements between clinical and EEG criteria, which impede a correct seizure diagnosis.

Several caveats useful in the evaluation for suspected neonatal seizures are listed in Table 66-2.

Clinical criteria for neonatal seizure diagnosis were historically subdivided into five categories: focal clonic, multifocal or migratory clonic, tonic, myoclonic, and subtle seizures (Volpe, 2001). A more recent classification expands these clinical subtypes, adopting a strict temporal occurrence of specific clinical events with coincident electrographic seizures, to distinguish neonatal clinical "nonepileptic" seizures from "epileptic" seizures (Mizrahi and Kellaway, 1998) (Table 66-3).

### Subtle Seizure Activity

Subtle seizure activity—now termed *motor automatisms* and *buccolingual movements*—is the most frequently observed category of neonatal seizures. Before a seizure evaluation is initiated, the normal occurrence of alterations in cardiorespiratory regularity, body movements, and other behaviors during active sleep (rapid eye movement [REM] sleep), quiet sleep (non-REM [NREM] sleep), or waking states should be appreciated (DaSilva et al, 1998; Scher, 1996). In any event, paroxysmal activity that interrupts the expected behavioral repertoire of the newborn infant and appears stereotypic or repetitive should heighten the clinician's level of suspicion for seizures. Repetitive buccolingual movements, orbital-ocular movements, unusual "bicycling" or "pedaling," and autonomic signs are examples of this seizure category (Fig. 66-1). Periodic alterations in heart rate, blood pressure, or oxygenation or other autonomic signs are particularly helpful clues to seizure activity during pharmacologic paralysis for ventilatory care. Autonomic expressions, however, also are intermixed with somatic findings. Isolated autonomic signs such as apnea are rarely associated with coincident electrographic

**TABLE 66-1****Dilemmas Regarding Neonatal Seizures**

*Diagnostic choices*—reliance on clinical vs. electroencephalographic criteria  
*Etiologic explanations*—multiple prenatal/neonatal conditions with variable times of onset and duration  
*Treatment decisions*—who, when, how, and for how long?  
*Prognostic questions*—consider mechanisms of injury based on underlying disorder vs. intrinsic vulnerability of the immature brain to prolonged seizures

**TABLE 66-2****Caveats Concerning Recognition of Neonatal Seizures**

- Stereotypic behaviors occur in association with normal neonatal sleep or waking states, medication effects, and gestational maturity.
- Any abnormal repetitive activity may be a clinical seizure if out of context for expected neonatal behavior.
- Document coincident electrographic seizures with the suspected clinical event.
- Abnormal behavioral phenomena with inconsistent relationships with coincident electroencephalographic seizures suggest a subcortical seizure focus.
- Nonepileptic pathologic movement disorders are independent of the seizure state.

seizures (Fenichel et al, 1979). Synchronized video-EEG-polygraphic recordings are now preferred to document temporal relationships between clinical and electrographic events (Mizrahi and Kellaway, 1998; Scher, 1997a, 2001b). Despite the “subtle” expression of this seizure category, affected children may suffer significant brain injuries.

**Clonic Seizures**

Rhythmic movements of body parts that consist of a rapid flexion phase followed by a slower extensor movement may be *clonic seizures*, to be distinguished from the symmetrical “to-and-fro” movements of nonepileptic tremulousness or jitteriness (Scher, 2001b). Gentle flexion of the affected body part easily suppresses the tremor, whereas clonic seizures persist. Clonic movements can involve face, arm, leg, or respiratory or pharyngeal muscles (Fig. 66–2A and B). Generalized clonic activities also can occur but rarely consist of the classic tonic followed by clonic phases, characteristic of the generalized motor seizure noted in older children and adults. Focal clonic and hemi-clonic seizures have been described with localized brain injury, usually from cerebrovascular lesions (Clancy et al, 1985; Levy et al, 1985; Scher et al, 1986), but also can be seen with generalized or multifocal brain abnormalities. As with older patients, focal seizures in the neonate can be followed by transient motor weakness, historically referred to as a transient Todd’s paresis or paralysis, characterized by a more persistent hemiparesis over days to weeks.

Clonic movements without EEG-confirmed seizures have been described in neonates with normal electroencephalographic background rhythms, in whom neurodevelopmental outcome can be normal (Rose and Lombroso, 1970). The less experienced clinician may misclassify myoclonic as clonic movements.

**Multifocal (Fragmentary) Clonic Seizures**

The word *fragmentary* was historically applied to distinguish multifocal clonic seizures from the more classic generalized tonic-clonic seizure seen in the older child. Multifocal or migratory clonic activities spread over body parts in either a random or an anatomically appropriate fashion. Seizure movements may alternate from side to side and appear asynchronously between the two halves of the child’s body. Multifocal clonic seizures may be misclassified as myoclonic seizures, and video-EEG documentation helps with proper identification. Neonates with this seizure description often suffer death or significant neurologic morbidity (Rose and Lombroso, 1970).

**Tonic Seizures**

*Tonic seizure* refers to a sustained flexion or extension of axial or appendicular muscle groups (Fig. 66–3). Tonic movements of a limb or sustained head or eye turning may also be noted. Documentation of tonic activity during coincident electroencephalographic recording is needed, because 30% of such movements lack a temporal correlation with electrographic seizures (Kellaway and Hrachovy, 1983). Such nonepileptic activity is referred to as “brainstem release” resulting from functional decortication after severe neocortical dysfunction or damage. Extensive neocortical damage or dysfunction permits the emergence of uninhibited subcortical expressions of extensor movements (Sarnat, 1984). Tonic seizures may also be misidentified when nonepileptic movement disorders consisting of dystonia are more appropriate behavioral descriptions. Both tonic movements and dystonic posturing may simultaneously occur in the same neonate.

**Myoclonic Seizures**

Myoclonic movements are rapid, isolated jerks that can be generalized, multifocal, or focal in an axial or appendicular distribution. Myoclonus lacks the slow return phase of the clonic movement complex. Healthy preterm infants commonly exhibit myoclonic movements without seizures or a brain disorder. An EEG, therefore, is recommended to confirm the coincident appearance of electrographic discharges with these movements (Fig. 66–4A). Pathologic myoclonus in the absence of electrographically confirmed seizures also can occur in severely ill pre-term or full-term infants after severe brain dysfunction or damage (Scher, 1985). As with older children and adults, myoclonus may reflect injuries at multiple levels of the neuraxis, from spinal cord to brainstem to cortical regions. Stimulus-evoked myoclonus with either single coincident spike discharges or sustained electrographic seizures has been reported

TABLE 66-3

## Classification and Clinical Characteristics of Neonatal Seizures\*

Seizure Class	Characterization
Focal clonic	Repetitive, rhythmic contracts of muscle groups of the limbs, face, or trunk May be unifocal or multifocal May occur synchronously or asynchronously in muscle groups on one side of the body May occur simultaneously but asynchronously on both sides Cannot be suppressed by restraint <i>Pathophysiology:</i> epileptic
Focal tonic	Sustained posturing of single limbs Sustained asymmetrical posturing of the trunk Sustained eye deviation Cannot be provoked by stimulation or suppressed by restraint <i>Pathophysiology:</i> epileptic
Generalized tonic	Sustained symmetrical posturing of limbs, trunk, and neck May be flexor, extensor, or mixed extensor/flexor May be provoked or intensified by stimulation May be suppressed by restraint or repositioning <i>Presumed pathophysiology:</i> nonepileptic
Myoclonic	Random, single, rapid contractions of muscle groups of the limbs, face, or trunk Typically not repetitive or may recur at a slow rate May be generalized, focal, or fragmentary May be provoked by stimulation <i>Presumed pathophysiology:</i> may be epileptic or nonepileptic
Spasms	May be flexor, extensor, or mixed extensor/flexor May occur in clusters Cannot be provoked by stimulation or suppressed by restraint <i>Pathophysiology:</i> epileptic
Motor automatisms	
Ocular signs	Random and roving eye movements or nystagmus (distinct from tonic eye deviation) May be provoked or intensified by tactile stimulation <i>Presumed pathophysiology:</i> nonepileptic
Oral-buccal-lingual movements	Sucking, chewing, tongue protrusions May be provoked or intensified by stimulation <i>Presumed pathophysiology:</i> nonepileptic
Progression movements	Rowing or swimming movements Pedaling or bicycling movements of the legs May be provoked or intensified by stimulation May be suppressed by restraint or repositioning <i>Presumed pathophysiology:</i> nonepileptic
Complex purposeless movements	Sudden arousal with transient increased random activity of the limbs May be provoked or intensified by stimulation <i>Presumed pathophysiology:</i> nonepileptic

\*Mizrahi EM, Kellaway P: Diagnosis and Management of Neonatal Seizures. Lippincott-Raven, Philadelphia, 1998, pp 1-155.

(Scher, 1997b). An extensive evaluation must be initiated to exclude metabolic, structural, and genetic causes. Rarely, healthy sleeping neonates exhibit abundant myoclonus that subsides on arousal to the waking state (Resnick et al, 1986); this entity is termed benign *sleep myoclonus of the newborn*.

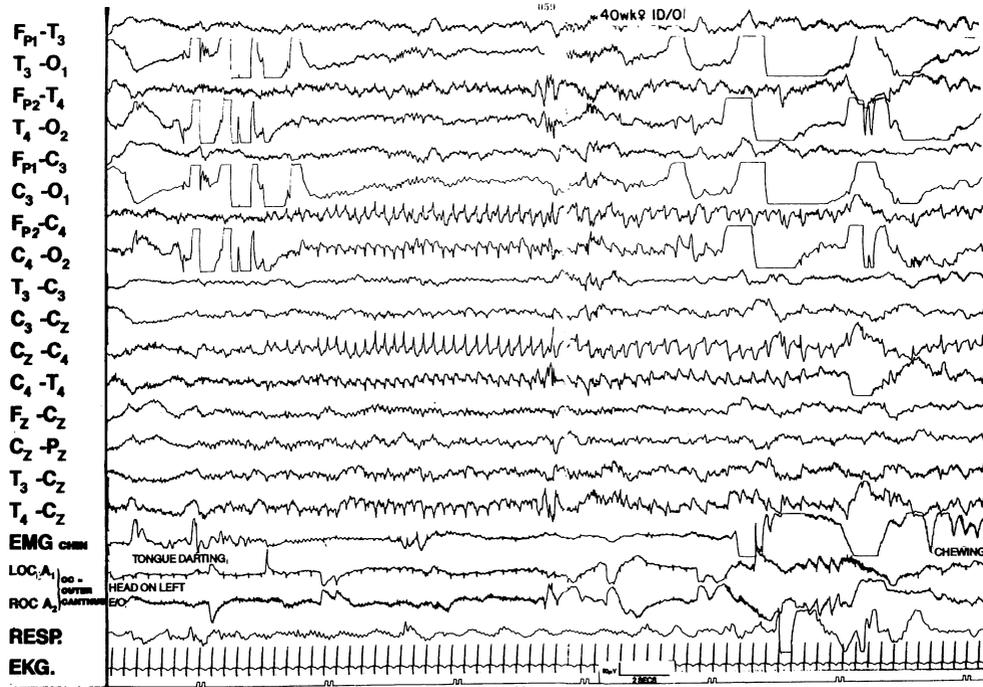

### Nonepileptic Behaviors of Neonates

Nonepileptic neonatal movement repertoires continue to challenge the physician's attempt to accurately diagnose seizures. Coincident synchronized video-EEG-polygraphic recordings are now suggested to confirm the temporal relationships between the suspicious clinical phenomena

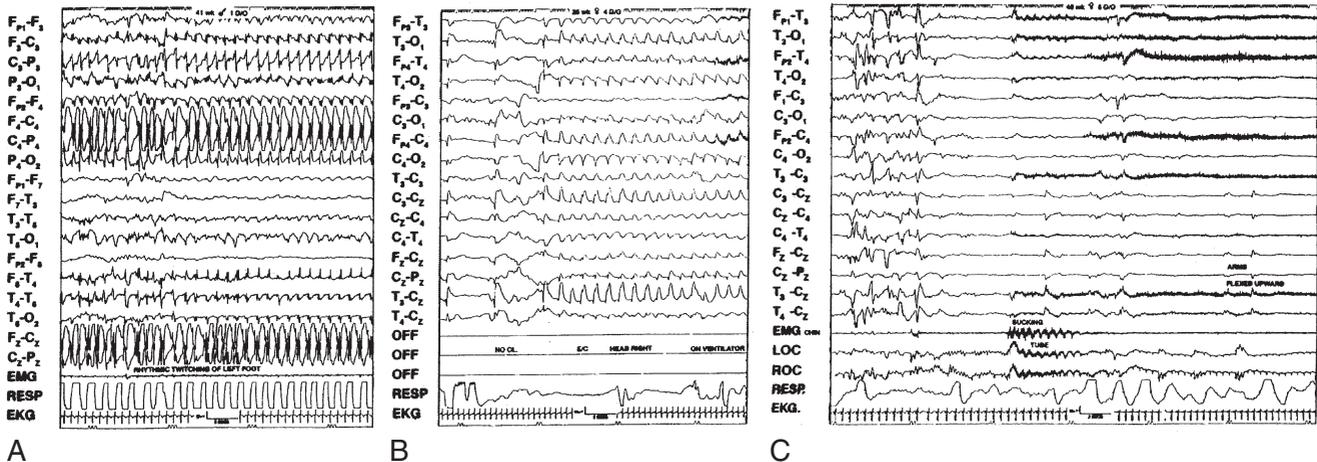

and electrographic expression of seizures (Mizrahi and Kellaway, 1998; Scher, 1997a, 2001b).

### Tremulousness or Jitteriness without Coincident Electrographic Seizures

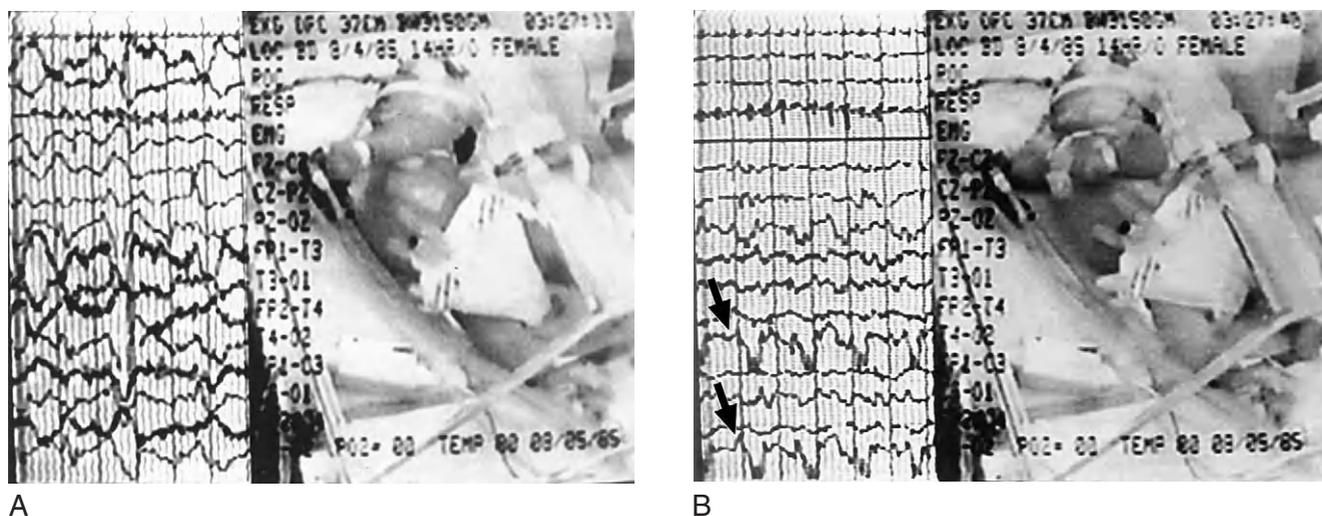

Tremors are frequently misidentified as clonic activity by inexperienced medical personnel. The flexion and extension phases of tremor are equal in amplitude, unlike the unequal phases of clonic movements. Children are generally alert or hyperalert but may also appear somnolent or lethargic as part of an encephalopathy. Passive flexion and repositioning of the affected tremulous body part will diminish or eliminate the movement. Such movements

**FIGURE 66-1.** Segment of electroencephalogram (EEG) from a 40-week-gestation, 1-day-old female infant following severe asphyxia resulting from rupture of velamentous insertion of the umbilical cord during delivery. An electrical seizure in the right central/midline region is recorded coincident with buccolingual and eye movements (see comments and eye channels on record). (From Scher MS, Painter MJ: *Electrographic diagnosis of neonatal seizures: Issues of diagnostic accuracy, clinical correlation and survival*. In Wasterlain CG, Vert P [eds]: *Neonatal Seizures*. New York, Raven Press, 1990, p 17.)

**FIGURE 66-2.** **A**, Segment of electroencephalogram (EEG) from a 41-week-gestation, 1-day-old male infant with an electroclinical seizure characterized by rhythmic clonic movements of the left foot coincident with bihemispheric electrographic discharges of higher amplitude in the right hemisphere. This seizure was documented prior to administration of antiepileptic medication. **B**, Segment of EEG from a 25-week-gestation, 4-day-old female infant with an electrographic seizure without clinical accompaniments. **C**, Segment of EEG from a 40-week-gestation, 6-day-old infant with stereotypic flexion posturing in the absence of electrographic seizures (note muscle artifact). (From Scher MS: *Pediatric electroencephalography and evoked potentials*. In Swaiman KS [ed]: *Pediatric Neurology: Principles and Practice*. St. Louis, CV Mosby, 1999, p 164.)

**FIGURE 66-3.** **A**, Segment of a synchronized video-electroencephalographic recording from a 37-week-gestation, 1-day-old female infant who suffered asphyxia demonstrates prominent opisthotonos with left arm extension in the absence of coincident electrographic seizure activity. **B**, Synchronized video-electroencephalographic recording from the same patient as in **A**, documenting electrographic seizure in the right posterior quadrant (*arrows*), following cessation of left arm tonic movements and persistent opisthotonos. (From Scher MS, Painter MJ: *Controversies concerning neonatal seizures*. In Pellock JM [ed]: *Seizure Disorders*. *Pediatr Clin North Am* 36:292, 1989.)

usually are spontaneous but can be provoked by tactile stimulation. This movement may also appear asymmetrical, with decreased expression in a weak limb following a brain injury or peripheral neuropathy. Metabolic or toxin-induced encephalopathies including those due to mild asphyxia, drug withdrawal, hypoglycemia or hypocalcemia, intracranial hemorrhage, hypothermia, and growth restriction are common clinical scenarios in which tremulous movements occur. Neonatal tremors generally diminish with increasing postconceptional age, spontaneously resolving over days to weeks, with normal neurologic outcome (Parker et al, 1990).

### Neonatal Myoclonus without Coincident Electrographic Seizures

Myoclonic movements can be bilateral and synchronous or asymmetrical and asynchronous in appearance. Benign myoclonic activity occurs more frequently during active (REM) sleep and is more predominant in the preterm infant (Hakamada et al, 1981; Scher, 1996), as well as rarely in healthy full-term infants; movements are not stimulus sensitive, have no coincident electrographic seizure correlates, and are suppressed during wakefulness. Benign neonatal sleep myoclonus must be a diagnosis of exclusion.

Infants with severe CNS dysfunction may present with nonepileptic spontaneous or stimulus-evoked pathologic myoclonus (see Fig. 66-4B). Neonates with different forms of metabolic encephalopathies such as glycine encephalopathy, cerebrovascular lesions, brain infections, or congenital malformations can present with nonepileptic pathologic myoclonus (Scher, 1985, 1997b). Encephalopathic neonates may respond to tactile or painful stimulation by either isolated focal, segmental, or generalized myoclonic movements.

Rarely, cortically generated spike or sharp wave discharges, as well as seizures, also may be noted on the electroencephalographic recordings that are coincident with these myoclonic movements. Medication-induced myoclonus as well as other stereotypic movements also have been described (Sexson et al, 1995); these abnormalities resolve when the drug is withdrawn.

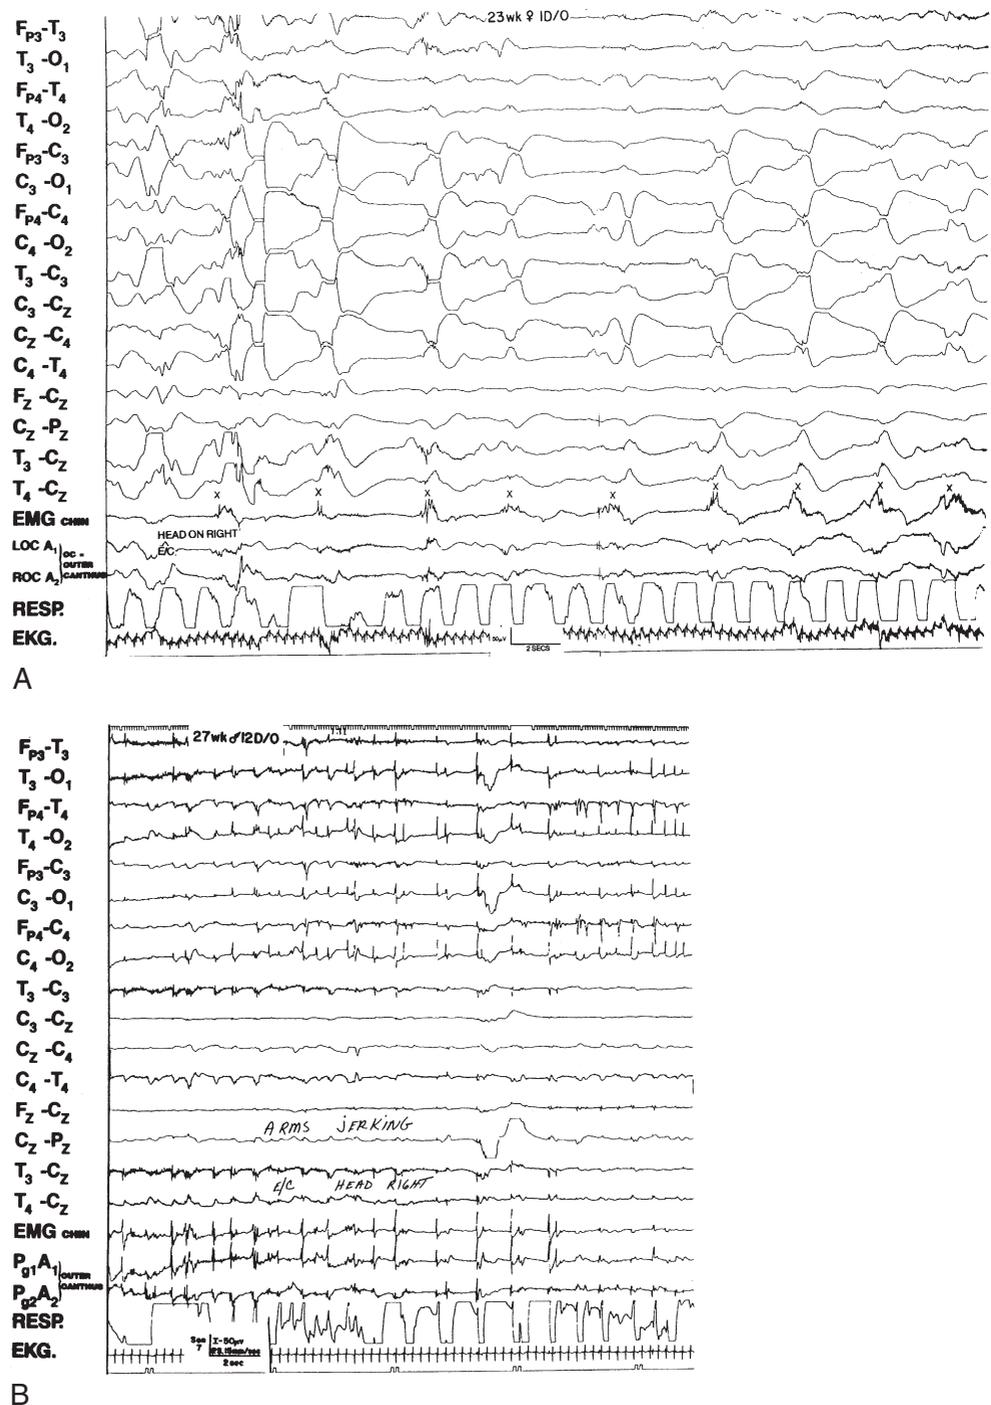

### Neonatal Dyskinesias: Dystonia or Choreoathetosis without Coincident Electrographic Seizures

Dystonia and choreoathetosis are commonly occurring movement disorders that are often misdiagnosed as seizures. These nonepileptic movement disorders are associated with either acute or chronic disease states involving basal ganglia structures, or the extrapyramidal pathways that innervate these regions. Antepartum or intrapartum adverse events such as severe asphyxia can damage the basal ganglia (i.e., status marmoratus) (Volpe, 2001); rarely, specific inherited metabolic diseases (Barth, 1992) (e.g., glutaricaciduria) also can injure these structures. Sustained posturing or dystonia also may reflect lack of functional inhibition of subcortical motor pathways due to disease or malformation of neocortex (Sarnat, 1984) (see Fig. 66-2C). Documentation of electrographic seizures by coincident video-EEG-polygraphic recordings will help avoid misdiagnosis and inappropriate treatment (see Fig. 66-3A and B)

### Electrographic Seizure Criteria

Over the last several decades, electrographic/polysomnographic studies have become invaluable tools for the assessment of suspected seizures (Mizrahi and Kellaway,

**FIGURE 66-4. A,** Segment of an electroencephalogram (EEG) from a 23-week-gestation, 1-day-old female infant with grade III intraventricular hemorrhage and progressive ventriculomegaly. An electroclinical seizure is noted with coincident with myoclonic movements of the diaphragm (x marks). **B,** Segment of an EEG from an encephalopathic 27-week-gestation, 12-day-old male infant with herpes encephalitis who exhibits nonepileptic multifocal myoclonus (myogenic potentials as electroencephalographic artifacts). (**A,** From Scher MS: *Pathological myoclonus of the newborn: Electrographic and clinical correlations. Pediatr Neurol* 1:342-348, 1985, with permission.)

1998; Pope et al, 1992; Scher, 1999, 2001b). Technical and interpretive skills for assessment of normal and abnormal neonatal EEG sleep patterns must be mastered to develop a confident visual analysis style for seizure recognition. Corroboration with the EEG technologist is always an essential part of the diagnostic process, because physiologic and nonphysiologic artifacts can masquerade as electrographic seizures. The physician also must anticipate expected behaviors for the child for gestational maturity, medication use, and state of arousal, in the context of potential artifacts.

As with the epileptic older child and adult, it is generally accepted that the neonatal epileptic seizure is a clin-

ical paroxysm of altered brain function with the simultaneous presence of an electrographic event on an EEG recording. For assessment of the suspected clinical event in the neonate, synchronized video-EEG-polygraphic monitoring is a useful tool to distinguish an epileptic from a nonepileptic event. Single-channel computerized devices for continuous prolonged monitoring (Hellström-Westas, 1992) may fail to detect focal or regional seizures if the single-channel recording is distant from the brain region involved with seizure expression. Neonatal electrographic seizures commonly arise focally from a single brain region. One brain study described 56% of neonatal seizures presenting in a single location, with

the remainder occurring in multiple locations (Bye and Flanagan, 1995).

### Ictal Electroencephalographic Patterns: A More Reliable Marker for Seizure Onset, Duration, and Severity

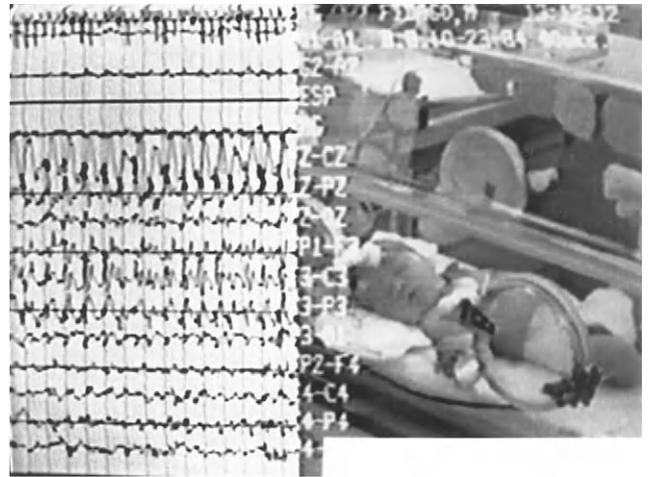

Neonatal electroencephalographic seizure patterns commonly consist of a repetitive sequence of waveforms that evolve in frequency, amplitude, electrical field, and/or morphology. Four types of ictal patterns have been described: focal ictal patterns with normal backgrounds, focal patterns with abnormal backgrounds, multifocal ictal patterns, and focal monorhythmic periodic patterns of various frequencies (Scher, 2001b). It is generally suggested that a minimal duration of 10 seconds for the evolution of discharges is required to distinguish electrographic seizures from repetitive but nonictal epileptiform discharges (Bye and Flanagan, 1995; Clancy and Legido, 1987; Scher et al, 1993) (see Fig. 66-1). Clinical neurophysiologists alternatively classify brief or prolonged repetitive discharges that lack this electrographic evolution as nonictal abnormal epileptiform patterns, which does not conform to the seizure definition.

For the older patient, status epilepticus is defined as at least 30 minutes of continuous seizures or two consecutive seizures with an interictal period during which the patient fails to return to full consciousness. This definition, however, does not easily apply to the neonate because levels of arousal are difficult to assess, particularly if sedative medications are given. Neonatal status epilepticus was reported in one third of full-term infants and in 20% of the total cohort of preterm and full-term infants (Scher et al, 1993) using a definition of status epilepticus as continuous seizure activity for 30 minutes or 50% of the recording time. If clinicians relied only on clinical criteria, status epilepticus would be underdiagnosed. Without EEG confirmation, the underdiagnosis of status epilepticus would contribute to brain injury, as discussed later in the section “Effects of Neonatal Seizures on Brain Development: Consequences of Underdiagnosis.”

Uncoupling of the clinical and electrographic expressions of neonatal seizures after antiepileptic medication administration also contributes to the underestimation of the true seizure duration and frequency of status epilepticus (Fig. 66-5). One study estimated that 25% of neonates expressed persistent electrographic seizures despite resolution of their clinical seizure behaviors after receiving one or more antiepileptic medications (Scher et al, 1994); this phenomenon is termed *electroclinical uncoupling*.

The neonate may alternately express or sustain repetitive or periodic discharges greater than 10 seconds in duration that do not satisfy the electrographic criteria for seizures. The same neonate may express both periodic discharges and electrographic seizures at other times during the same EEG recording (Scher and Beggarly, 1989).

At the opposite end of the spectrum from periodic discharges, brief rhythmic discharges that are less than 10 seconds in duration also do not satisfy electroencephalographic criteria for seizures. Some neonates with electrographic seizures also may exhibit these brief discharges. Both periodic and brief discharges are associated with compromised

**FIGURE 66-5.** Segment of a synchronized video-electroencephalographic recording from a 40-week-gestation, 1-day-old male infant with electrographic status epilepticus noted in the left central/midline regions, after antiepileptic medication administration. Focal right shoulder clonic activity was only intermittently noted, while continuous electrographic seizures were documented mostly without clinical expression. This phenomenon of uncoupling of electrical and clinical seizure activities is associated with antiepileptic drug administration (see text). (From Scher MS, Painter MJ: *Controversies concerning neonatal seizures*. In Pellock JM [ed]: *Seizure Disorders*. *Pediatr Clin North Am* 36:290, 1989.)

neurodevelopmental outcome (Oliveira et al, 2000; Scher and Beggarly, 1989).

### Subcortical Seizures versus Nonictal Functional Decortication

Experimental animal models offer conflicting evidence regarding suspicious clinical events for which coincident electrographic confirmation of seizures is absent (Scher, 2001b). Most neurologists prefer documentation of an ictal pattern by surface EEG electrodes before diagnosing a seizure. However, subcortical seizures with or without intermittent propagation to the surface may also occur. Electroclinical disassociation (ECD) is one proposed mechanism by which subcortical neonatal seizures intermittently appear on surface-recorded electroencephalographic studies (Biagioni et al, 1998; Weiner et al, 1991). ECD is defined as a reproducible clinical event that occurs both with and without coincidental electrographic seizures documented in one study as 34% of 51 neonates (Weiner et al, 1991). A clinical seizure precedes the electrographic expression, suggesting a subcortical onset before propagation to the cortical surface.

Some investigators have proposed a nonictal “brainstem release” phenomenon that explains suspicious clinical events that never have coincident EEG seizures expressed on surface recording (Mizrahi and Kellaway, 1998). These authors argue, for example, that motor automatisms have an inconsistent relationship with coincident EEG seizure activity. They alternatively speculate that functional nonictal decortication resulting from neocortical damage best explains these movements, without diagnosing epileptic seizures (Kellaway and Hrachovy, 1983).

This dilemma should encourage the clinician to use the EEG as a neurophysiologic yardstick by which more exact seizure start and end points can be assigned, before offering pharmacologic treatment with antiepileptic drugs (AEDs). Neonates can exhibit electrographic seizures that will go undetected unless electroencephalographic studies are utilized (O'Meara et al, 1995; Scher et al, 1993) (Fig. 66-6; see also Fig. 66-5). For example, in neonates who have been pharmacologically paralyzed for ventilatory assistance or in those who have received AEDs, clinical expression of seizures will be suppressed. In one cohort of 92 infants, 60% were pretreated with antiepileptic medications, and 50% of the cohort had electrographic seizures with no clinical accompaniment. Both clinical and electrographic seizure criteria were noted for 45% of 62 preterm infants and 53% of 30 full-term infants. Seventeen infants were pharmacologically paralyzed when the electrographic seizure was first documented. In a more recent cohort of 60 infants who were not pretreated with antiepileptic medications, 7% of infants had only electrographic seizures prior to AED administration (Scher et al, 1994), and 25% expressed electroclinical uncoupling after AED use.

Both overestimation and underestimation of neonatal seizure incidences are reported, depending on whether clinical or electrical criteria are used. Based on clinical criteria, seizure incidences ranged from 0.5% in term infants to 22.2% in preterm neonates (Lanska et al, 1995, 1996; Ronen et al, 1999; Seay and Bray, 1977). Discrepancies in incidence estimates reflect varying postconceptional ages of the study populations chosen, interobserver variability, and the hospital setting in which the diagnosis was made. Hospital-based studies, which will include a greater incidence of high-risk deliveries, generally report a higher seizure incidence. Population studies that include less medically fragile infants from general nurseries report lower percentages. Incidence figures based only on clinical criteria without electroencephalographic confirmation

include "false positives," consisting of cases in which the neonates had either normal or nonepileptic pathologic neonatal behaviors. Conversely, the lack of electrographic seizures may include a subset of "false negatives," in which the infants express seizures only from subcortical brain regions, without propagation to the cortical surface. Consensus between clinical and electroencephalographic criteria, therefore, is still needed to reach the best incidence estimate.

### Interictal Electroencephalographic Abnormalities

Besides use of the EEG to diagnose seizures, documentation of interictal EEG abnormalities is extremely useful for patient management and prognosis. Interictal EEG findings are not pathognomonic for particular etiologic disorders, mechanisms, or timing (Scher, 1994). The clinician must integrate historical, physical examination, and laboratory findings with the electrographic interpretation of both seizure and nonseizure pattern findings for the particular child. The depth and the severity of neonatal brain disorders, as measured by the markedly abnormal interictal findings, help to predict subsequent development of seizures (Laroya et al, 1998). Serial electroencephalographic studies help the clinician to predict long-term outcome (see later section on prognosis).

### DIAGNOSTIC DILEMMAS: IDENTIFYING CAUSES FOR SEIZURES

Diverse medical conditions in the newborn can be associated with seizure activity (Adamson et al, 1995; Kellaway and Hrachovy, 1983) (Table 66-4). Asphyxia is traditionally introduced as the representative etiologic disorder that exemplifies when seizures may occur. The asphyxial con-

dition, however, encompasses heterogeneous conditions associated with hypoxia-ischemia, which may lead to seizures over a variable timeline encompassing antepartum, intrapartum, and neonatal periods.

Neonatal seizures are not disease specific and can be associated with a variety of medical conditions occurring before, during, or after parturition. Seizures may occur as part of an asphyxial brain disorder that is expressed after birth (i.e., hypoxic-ischemic encephalopathy). Alternatively, neonatal encephalopathies may represent other etiologic disorders with incidental asphyxia. Finally, seizures can present as an isolated clinical sign secondary to a remote antepartum asphyxial stress without other signs of a postnatal encephalopathy. A logistic model developed to predict seizures emphasizes the accumulation of both antepartum and intrapartum factors that increase the likelihood of neonatal seizure occurrence in the context of asphyxia (Patterson et al, 1989). Although separately these same factors have low positive predictive values, a signifi-

cant cumulative risk profile results when maternal anemia, vaginal bleeding, asthma, meconium-stained amniotic fluid, abnormal fetal presentation, fetal distress, and shoulder dystocia all are considered. Another study of 40 neonates with clinical seizures indicated that only 37.5% of the seizures were associated with asphyxia, whereas a majority of term infants had early-onset seizures due to malformation, stroke, infection, or hemorrhage (Lien et al, 1995).

## Hypoxia-Ischemia

Hypoxia-ischemia or asphyxia is nonetheless traditionally considered the most common cause of neonatal seizures (Brown et al, 1972, 1974, 1983; Sarnat and Sarnat, 1976; Volpe, 2001). However, infants can suffer asphyxia before as well as during parturition, and 10% of neonatal asphyxia cases also result from postnatal causes (Volpe, 2001). When asphyxia is suspected during the labor and delivery

process, biochemical confirmation is required. This metabolic definition of asphyxia represents the cardinal feature of hypoxic-ischemic encephalopathy (HIE).

The American College of Obstetrics and Gynecology (ACOG) initially published guidelines that suggest four cardinal criteria to define postasphyxial neonatal encephalopathy—that is, HIE—after significant clinical depression noted at birth (ACOG, 1992). These four criteria include:

1. Profound metabolic or mixed acidemia with a pH of less than 7.00 in umbilical cord blood
2. Persistence of an Apgar score of 0 to 3 for longer than 5 minutes
3. Neonatal neurologic sequelae (i.e., seizures, coma, and hypotonia)
4. Multiorgan system dysfunction (i.e., significant cardiovascular, gastrointestinal, hematologic, pulmonary, and renal involvement)

More recent guidelines have been published which suggest stricter criteria which include the four cardinal criteria as well as four collective criteria. Clinicians now recognize antepartum (as well as peripartum reasons) for HIE (ACOG, 2003).

### Other Causes of Neonatal Encephalopathy

Diverse etiologic disorders and conditions occurring in the antepartum, intrapartum, and neonatal periods may cause neonatal encephalopathies, with or without accompanying seizures. Children certainly may exhibit altered arousal and muscle tone, as well as seizures, without meeting the suggested criteria for HIE from intrapartum causes (ACOG, 2003). These children can appear neurologically abnormal based on antepartum conditions involving maternal, placental, or fetal diseases (Adamson et al, 1995).

A case-control study of term infants with clinical seizures reported a fourfold increase in the risk of unexplained early-onset seizures after intrapartum fever (Lieberman et al, 2000). All known causes of seizures were eliminated including meningitis and sepsis. Compared with 152 controls, the 38 newborns experienced intrapartum fever as an independent risk factor on logistic regression analysis that predicted seizures. The authors speculated on the role of circulating maternal cytokines that triggered “physiologic events” contributing to neonatal encephalopathy seizures, which did not occur from asphyxia.

Postnatal medical illnesses also cause or contribute to asphyxia-induced brain injury and seizures without intrapartum HIE. Persistent pulmonary hypertension of the newborn (PPHN), cyanotic congenital heart disease, sepsis, and meningitis are several examples. In one hospital-based study conducted over a 14-year period, 62 of 247 infants presented with EEG-confirmed seizures after an uneventful delivery without fetal distress during labor or neonatal depression at birth. Twenty of these 62 infants (32%) later presented with postnatal onset of pulmonary disease, sepsis, or meningitis (Scher et al, 1994).

Placental findings may reflect chronic disease states at antepartum time points with or without metabolic acidosis and evolving HIE after birth (Scher, 2002). Although meconium passage more commonly occurs in otherwise healthy newborns, meconium-stained skin also may be associated with meconium-laden macrophages within placental membranes in the depressed newborn. Meconium staining through the chorionic to amnion layers suggests a longer-standing asphyxial stress over a 4- to 6-hour period, which may precede the labor period.

Placental weights below the 10th or above the 90th percentile suggest chronic perfusion abnormalities to the fetus over weeks. Microscopic evidence of lymphocytic infiltration, altered villous maturation, chorangiosis, and erythroblastic proliferation of villi of the placenta supports chronic asphyxial stresses to the fetus. In a study of preterm and full-term neonates (23 to 42 weeks of chronological age) with electrographically confirmed seizures, a significant association between seizures and chronic (with or without acute) placental lesions was noted by calculated odds-risk ratios, increasing to a factor of 12.1 ( $P < .003$ ) by term age. In contrast, odds ratios were not significant for infants with seizures and exclusively acute placental lesions, presumably from events closer to labor and delivery (Scher et al, 1998).

Clinical examination findings in the depressed neonate with suspected HIE may reflect antepartum disease states rather than evolving HIE (Ajayi et al, 1998). Intrauterine growth restriction, hydrops fetalis, and joint contractures (including arthrogryposis) are findings that suggest intrauterine disease conditions associated with antepartum disease states. Later intrapartum fetal distress with or without asphyxia and neonatal depression also may occur with subsequent neonatal seizures (Scher, 2001a, 2001c). Hypertonicity, often with cortical thumbs (i.e., severely adducted across closed palms), in a depressed child who then rapidly recovers over hours after a successful resuscitative effort also suggests a longer-standing fetal brain disorder. Sustained hypotonia and unresponsiveness for 3 to 7 days constitute the expected clinical repertoire of HIE after an intrapartum asphyxial stress, either with or without coincident brain injury. In encephalopathic newborns, depressed arousal and hypotonia nonetheless also may reflect an antepartum disease process with neonatal dysfunction or superimposed injury after a stressful intrapartum period. For example, this was described in 10 of 20 neurologically depressed infants with electrographic seizures and isoelectric interictal EEG pattern abnormalities, who were comatose and flaccid for days, requiring ventilator assistance after difficult deliveries (Barabas et al, 1993). All children appeared neurologically depressed after asphyxial stress during the intrapartum period (i.e., depressed Apgar scores and metabolic acidosis). Evidence of fetal brain injury from pre-existing maternal-placental diseases was documented by evidence of chronic brain lesions on neuroimaging studies and/or neuropathologic postmortem findings. Although intrapartum asphyxial stress may worsen brain injury in some children, it was impossible to differentiate the neonatal encephalopathy from pre-existing antepartum brain injury for these 10 children.

## Hypoglycemia

*Hypoglycemia* is generally defined as glucose levels of less than 20 mg/dL in preterm infants and less than 30 mg/dL in term infants (Cornblath and Schwartz, 1967; Milner, 1972). No clear consensus exists concerning a direct cause and effect for hypoglycemia with seizure occurrence (Sencor, 1973). Methods of glucose determination (i.e., dextrose stick versus serum sampling) will affect the accuracy of the value. Also, associated disturbances may coexist, such as hypocalcemia, craniocerebral trauma, cerebrovascular lesions, and asphyxia, which may contribute to lowering the threshold for seizures. Infants born to diabetic or pre-eclamptic mothers, particularly those who were small for gestational age, also are at risk for hypoglycemia. Jitteriness, apnea, and altered tone are clinical signs that may appear in children with hypoglycemia, but they are not representative of a seizure state. Cerebrovascular lesions in posterior brain regions have been reported in children who suffer hypoglycemia (Griffiths and Laurence, 1974). Vulnerability of brain to ischemic insults is enhanced by concomitant hypoglycemia, as reported in mature animals (Siemkowicz and Hansen, 1978) and neonatal infants (Griffiths and Laurence, 1974).

## Hypocalcemia

Total serum calcium levels of less than 7.5 mg/dL in preterm and less than 8 mg/dL in the term infant generally define hypocalcemia. The ionized fraction is a more sensitive indicator of seizure vulnerability. As with hypoglycemia, the exact level of hypocalcemia at which seizures occur is debatable. An ionized fraction of 0.6 or less may have a more predictable association with the occurrence of seizures. Late-onset hypocalcemia due to use of high-phosphate infant formula has been previously cited as a common cause of seizures (Keen and Lee, 1973; McInterny and Schubert, 1969; Rose and Lombroso, 1970). However, hypocalcemia now more commonly occurs in infants with trauma, hemolytic disease, or asphyxia and may coexist with hypoglycemia or hypomagnesemia. Rarely, congenital hypoparathyroidism occurring in association with other genetic abnormalities such as DiGeorge syndrome (i.e., velocardiofacial syndrome, with a 22q11 deletion associated with cardiac and brain anomalies) must be considered. Affected infants may have severe congenital heart disease, as well hypoparathyroid state with hypocalcemia and hypomagnesemia, which precipitates seizures (Lynch and Rust, 1994). Hypocalcemia of unknown etiology in infants also may be the result of maternal hypercalcemia. Ascertainment of the mother's calcium status should be considered, because maternal hypercalcemia can suppress fetal parathyroid development.

## Hypонатremia and Hypernatremia

*Hypонатremia* is a metabolic disturbance that may result from inappropriate secretion of antidiuretic hormone following severe brain trauma, infection, or asphyxia (Volpe, 2001) but is an uncommon isolated cause of neonatal seizures. *Hypernatremia* also is a rare cause of seizures,

usually associated with congenital adrenal abnormalities or iatrogenic disturbance of serum sodium balance, from the use of intravenous fluids with high concentrations of sodium.

## Cerebrovascular Lesions

Hemorrhagic or ischemic cerebrovascular lesions are associated with neonatal seizures, on either an arterial or a venous basis (Clancy et al, 1985; Levy et al, 1985; Ment et al, 1984; Rivkin et al, 1992; Scher et al, 1986, 1989). Intraventricular or periventricular hemorrhage (IVH or PVH) is the most common intracranial hemorrhagic lesion in the preterm infant and has been associated with seizures in as much as 45% of a preterm population with EEG-confirmed seizures (Scher et al, 1993). In a cohort of newborns with clinical seizures, IVH was the predominant cause of seizures in preterm infants of less than 30 weeks of gestational age (Sheth et al, 1999). Intracranial hemorrhage is usually expected within the first 72 hours of life of the preterm infant. Although IVH-PVH may occur in otherwise asymptomatic infants, the neonate with a catastrophic deterioration of clinical status will exhibit signs of apnea, bulging fontanel, hypertonia, and seizures (Volpe, 2001). Seventeen percent of preterm infants with IVH may have acute seizures during the first month of life; 10% of one cohort suffered remote seizures (after hospital discharge) (Strober et al, 1997). Full-term infants present less commonly with IVH, which usually originates from the choroid plexus or thalamus.

Another site of intracranial hemorrhage is the subarachnoid space; hemorrhage in this location may result in seizures but generally is associated with a more favorable outcome. Subdural hematoma, whether spontaneous or with craniocerebral trauma, should always be considered, particularly when focal trauma to the face, scalp, or head has occurred; simultaneous occurrences of cerebral contusion and infarction also should be considered.

Cerebral infarction has been described in neonates with seizures and can result from events during the antepartum, intrapartum, or neonatal period. Either preterm or term neonates with infarction also may present without seizure expression (DeVries et al, 1997). Seizures also can occur in otherwise healthy infants, suggesting an antepartum occurrence of cerebral infarction (Mercuri et al, 1995; Scher et al, 1991). Aggressive use of neuroimaging during the antepartum period by fetal sonography or magnetic resonance (MR) techniques, or within the first days after birth, may document remote brain lesions (Scher, 2001a, 2001c). In a group of 62 healthy infants with electrographic seizures after an uneventful delivery, 23 (37%) had cerebrovascular lesions, 18 of whom had ischemic brain lesions (Scher et al, 1995). Destructive lesions such as evolving porencephaly require approximately 5 to 7 days before becoming radiographically evident. The occurrence of injury during more recent intrapartum or neonatal periods can be supported by the presence of early cerebral edema using diffusion-weighted MR images (Forbes et al, 2000). Cerebral infarction also may occur during the postnatal period from asphyxia, polycythemia, dehydration, or coagulopathy.

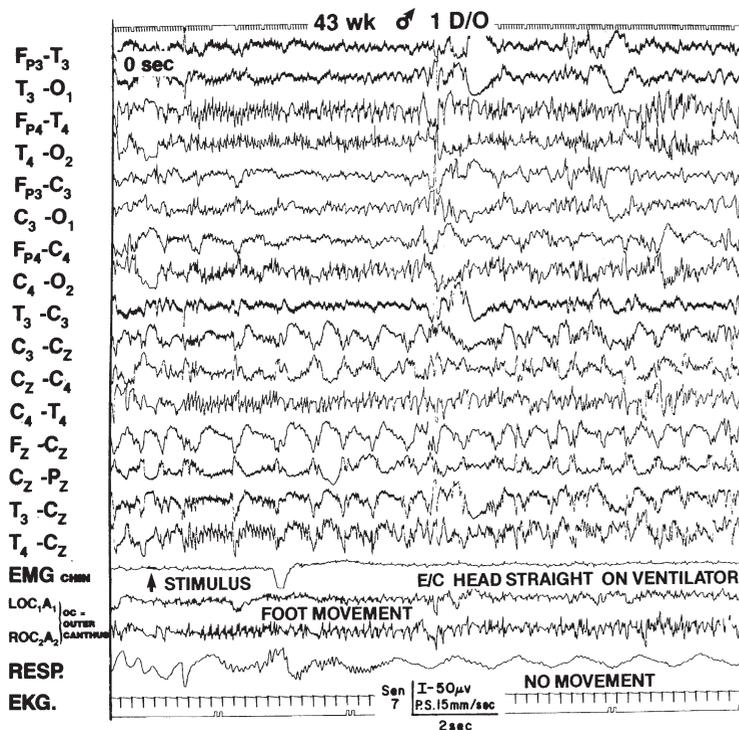

PPHN with severe and recurrent hypoxia also can be associated with cerebrovascular lesions and seizures (Scher et al, 1986) (Fig. 66-7A and B). Certain infants with PPHN will require extracorporeal membrane oxygenation (ECMO) to treat severe forms of this pulmonary disease, which does not respond to traditional ventilatory therapy. Radiographic documentation of brain lesions is needed before initiation of ECMO, because the anticoagulation required for ECMO may convert "bland" or ischemic infarctions to hemorrhagic forms, with greater risk for cerebral edema and herniation. Although meconium aspiration syndrome has historically been identified with an intrapartum/neonatal presentation of PPHN, in most affected children this lung disease generally is secondary to antepartum maternal/fetal or placental conditions that predispose the fetus to thickening of the muscular layers of the pulmonary arteries in utero, with resultant sustained increased pulmonary vascular resistance after birth (Benitz et al, 1997).

Cerebral infarction in the venous distribution of the brain may also lead to neonatal seizures (Rivkin et al, 1992; Shevell et al, 1989). Lateral or sagittal sinus thrombosis after coagulopathy can occur secondary to systemic infection, polycythemia, or dehydration. Venous infarction within

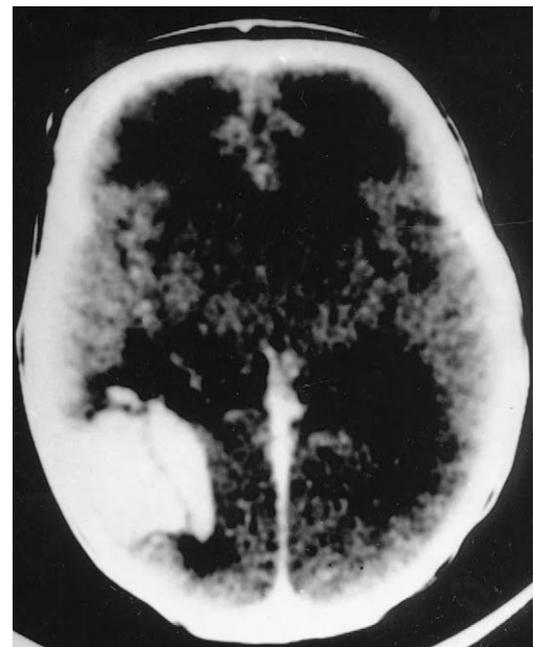

the deep white matter of the preterm infant's brain also occurs in association with IVH.

## Infection

CNS infections during the antepartum or postnatal period can be associated with neonatal seizures (Kairam and DeVivo, 1981). A specific group of congenital infections— toxoplasmosis, rubella, cytomegalic inclusion disease, and herpes (the TORCH infections)—can produce severe encephalopathic damage that results in seizures, as well as more diffuse brain disorders. Other congenital infections include those due to enteroviruses and parvoviruses. Specific infections—for instance, neonatal herpes encephalitis—may be associated with severe EEG pattern abnormalities (Mizrahi and Tharp, 1982). Rubella, toxoplasmosis, and cytomegalic inclusion disease each also can lead to devastating encephalitis, usually manifesting with microcephaly, jaundice, body rash, hepatosplenomegaly, and/or chorioretinitis. Increasing lethargy and obtundation with or without seizures may suggest the subacute presentation of encephalitis during the postnatal period. Serial cerebrospinal fluid (CSF)

The child required ventilatory care for persistent pulmonary hypertension of the neonate (see text). B, Computed tomography scan on day 6 from the patient in A, documenting a hemorrhagic infarction in the right posterior quadrant with surrounding edema. (From Scher MS, Klesh KW, Murphy TF, Guthrie RD: Seizures and infarction in neonates with persistent pulmonary hypertension. *Pediatr Neurol* 2:332-339, 1986, with permission.)

analyses document progressively increasing protein levels and/or pleocytosis.

Bacterial infections from either gram-negative or gram-positive organisms, acquired in utero or postnatally, also are associated with neonatal seizures. Infection with some organisms, such as *Escherichia coli*, group B streptococci, *Listeria monocytogenes*, and *Mycoplasma*, may produce severe leptomeningeal infiltration, with possible abscess formation and cerebrovascular occlusions. A high percentage of survivors suffers significant neurologic sequelae.

### Central Nervous System Malformations

Disorders occurring during the stages of induction, segmentation, proliferation, migration, myelination, and synaptogenesis can contribute to brain malformations. The neonate with such malformations is at increased risk for seizures in association with the stress experienced around the time of birth (Palmini et al, 1994), which presumably lowers seizure thresholds. Brain anomalies may occur as a result of either genetic causes from conception and/or acquired defects early during gestation. Specific dysgenesis syndromes, such as holoprosencephaly and lissencephaly, can be associated with characteristic facial or body anomalies. Cytogenetic studies may document trisomies or deletion defects. Unfortunately, infants may lack physical clues to the presence of a brain malformation. Therefore, a high index of clinical suspicion for this entity is warranted in evaluating neonates with persistent seizures. In one study, 9% of 356 infants who presented with neonatal seizures were found to have brain malformations (Sheth et al, 1999). Neuroimaging, preferably with MR techniques, documents brain dysgenesis in children who may also express severe electrographic disturbances including seizures. Focal or regional brain malformations are rare causes of early-onset epilepsy in neonates and young infants (Aicardi, 1985; Ohtahara, 1978). Functional imaging studies such as positron emission tomography scans (Chugani et al, 1994) may identify localized areas of altered brain metabolism, which can assist in a neurosurgical approach to seizure management, even in young children who fail to respond to AED maintenance (Pedespan et al, 1995).

### Inborn Errors of Metabolism

Inherited biochemical abnormalities are rare causes of neonatal seizures (Scher, 2001b). Intractable seizures associated with elevated lactate and pyruvate levels in blood and CSF may reflect specific inborn errors of metabolism. Dysplastic or destructive brain lesions, as documented on neuroimaging, may be associated with specific biochemical defects, such as glycine encephalopathy or branched-chain aminoacidopathies. Pregnancy, labor, and delivery histories for affected infants are commonly uneventful. The emergence of food intolerance and also increasing lethargy, stupor, coma, and seizures are early indications of an inborn metabolic disturbance during the first few days of life. The newborn with an inherited metabolic disorder may initially present as a neurologically depressed and hypotonic child with asphyxia and seizures (Barth, 1992). Some children respond to spe-

cific dietary therapies, including vitamin supplementation (Painter et al, 1984), depending on the enzymatic defect. Specific urea cycle defects such as carbamoylphosphate synthetase deficiency may manifest as coma and seizures during the first 2 days of life, with marked elevations in plasma ammonia levels. Affected infants may respond to aggressive treatment with exchange transfusion, dialysis, and appropriate dietary adjustments.

Vitamin B<sub>6</sub> or pyridoxine dependency is a rare cause of neonatal seizures (Bejsovec et al, 1967; Clarke et al, 1979). Pyridoxine acts as a cofactor in gamma-aminobutyric acid synthesis, and its absence or paucity promotes seizures. The mother occasionally reports paroxysmal fetal movements (Oslovich and Barrington, 1996). The infant who is unresponsive to conventional antiepileptic medications should promptly receive an intravenous injection of 50 to 500 mg of pyridoxine, preferably with concomitant EEG monitoring. Termination of the seizure within minutes to hours as well as resolution of EEG background disturbances suggests a pyridoxine-dependent seizure state. Prophylactic doses of pyridoxine may be needed to achieve and maintain seizure control.

Other rare causes of seizures include disorders of carbohydrate metabolism with coincident hypoglycemia (Scher, 2002) as well as peroxisomal disorders such as neonatal adrenoleukodystrophy or Zellweger syndrome. A defect in a glucose transporter protein necessary to move glucose across the blood-brain barrier also has been reported, which results in hypoglycorrhachia and seizures (DeVivo et al, 1991). Affected children may achieve seizure control with a ketogenic diet but nonetheless suffer delayed development.

Molybdenum cofactor deficiency and isolated sulfite oxidase deficiencies are other rare metabolic defects that cause neonatal seizures and associated destructive changes on neuroimaging, which may resemble findings in cerebrovascular disease or asphyxia (Slot et al, 1993).

### Drug Withdrawal and Intoxication

Newborns born to mothers with a history of prenatal substance abuse may be at increased risk for neonatal seizures (Herzlinger et al, 1977; Zelson et al, 1971). Exposure to barbiturates, alcohol, heroin, cocaine, or methadone commonly results in neurologic abnormalities that include tremors and irritability. Withdrawal symptoms, in addition to seizures, may occur as long as 4 to 6 weeks after birth (Kandall and Garner, 1974); electroencephalographic studies are useful to corroborate such movements with coincident electrographic seizures. Certain drugs such as short-acting barbiturates may be associated with seizures within the first several days of life (Bleyer and Marshall, 1972). Seizures may occur directly after substance withdrawal or may be associated with longer-standing uteroplacental insufficiency, promoted by chronic substance use and poor prenatal health maintenance by the mother. Careful review of placental/cord specimens may reveal chronic or acute pathologic lesions that contribute to antepartum or intrauterine asphyxia.

Inadvertent fetal injection with a local anesthetic agent during delivery may induce intoxication, which is a rare

cause of seizures (Dodson, 1976; Hillman et al, 1979). Patients present during the first 6 to 8 hours of life with apnea, bradycardia, and hypotonia and are comatose, without brainstem reflexes. If the obstetric history indicates pudendal administration of an anesthetic to the mother, a careful examination of the child's scalp or body for puncture marks is indicated. Determination of plasma levels of the suspected anesthetic agent will establish the diagnosis. Treatment consists of ventilatory support and removal of the drug by therapeutic diuresis, acidification of the urine, or exchange transfusion. Antiepileptic medications are rarely indicated.

### Progressive Neonatal Epileptic Syndromes

Progressive epileptic syndromes rarely manifest during the first month of life (Mizrahi and Clancy, 2000). These children usually exhibit myoclonic or migratory seizures that are poorly controlled by antiepileptic medications, with brain malformations often demonstrable on brain imaging (Ekert et al, 1997; Ohtahara, 1978). These neonatal epileptic syndromes are termed *early myoclonic encephalopathy* or *early infantile epileptic encephalopathy* (Ohtahara syndrome), and the EEG commonly documents burst suppression or markedly disorganized background rhythms. Rarely, an idiopathic group of neonates with localization-related or partial seizures without neuroimaging abnormalities presents with intractable epilepsy (Natsume et al, 1996).

With neurocutaneous syndromes such as incontinentia pigmenti and tuberous sclerosis, symptomatic epilepsy during the neonatal period may be the presenting clinical manifestation of either of these genetic disorders. Incontinentia pigmenti is accompanied by a vesicular crusting rash, which initially mimics a herpetic infection. Seizures may or may not be present. The skin lesions evolve into lightly pigmented, raised sebaceous lesions in older infants and children. Tuberous sclerosis also rarely manifests with skin lesions in the newborn period. Hypopigmented lesions, initially noted under ultraviolet light, usually appear later during infancy. Two fetal presentations of tuberous sclerosis are that of the more common cardiac tumor, usually a rhabdomyoma, and rarely that of a congenital brain tumor, both noted on fetal sonography. Neonatal seizures also may be the presenting feature (Miller et al, 1998), with documentation of intracranial lesions on postnatal neuroimaging.

### Benign Familial Neonatal Seizures

The autosomal dominant form of neonatal seizures is a rare genetic epilepsy that should be considered in the context of a positive family history (Bjerre and Corelius, 1978; Petit and Fenichel, 1980; Ryan et al, 1991). Exclusion of infectious, metabolic, toxic, or structural causes needs to be completed before this entity is considered in the diagnosis. The genetic defect was first described on chromosome 20q, specifically at the D20S19 and D20S20 loci, as well as a locus EBN2 on chromosome 8q24. By positional cloning, a potassium channel gene (*KCNQ2*) located on 20q13.3 was first isolated and found to be expressed in the brain (Bjerre and Corelius, 1978). A second

potassium channel gene (*KCNQ3*) also has been described and may explain the variability in phenotypic expression of seizures and outcome (Leppert and Singh, 1999). Recently, mutations in ion channels also have been implicated in Jervell and Lange-Nielsen syndrome, whose symptoms include congenital deafness and cardiac arrhythmias (Jentsch et al, 2000). Infant outcomes range from excellent to guarded, depending on the persistence of seizures beyond the neonatal period. Response to antiepileptic medication is generally good, although some clinicians describe variable success. Further studies are needed to clarify the relationship between phenotypic and genotypic expressions of this disorder.

### SEIZURES REFLECTING FETAL OR NEONATAL BRAIN DISORDERS: GUIDE TO DIFFERENTIAL DIAGNOSIS

The neurologist must place EEG-confirmed seizures in the context of historical, clinical, and laboratory evidence to determine both the pathogenesis and timing of a brain disorder. Seizures occurring in neonates who have experienced asphyxia support either acute intrapartum events or antepartum disease processes, or both. Does the child with seizures also have clinical and laboratory signs of evolving cerebral edema? The presence of a bulging fontanel with neuroimaging evidence of increased intracranial pressure and cerebral edema (i.e., obliterated ventricular outline and abnormal diffusion-weighted MR images), hyponatremia, and increased urine osmolality (i.e., the syndrome of inappropriate secretion of antidiuretic hormone) more strongly suggest a more recent asphyxial disease process, in or around the intrapartum period, causing acute or subacute cerebral edema.

Alternatively, failure to document evolving cerebral edema during the first 3 days after asphyxia or documentation of encephalomalacia or cystic brain lesions on neuroimaging shortly after birth (even in the encephalopathic newborn) suggests a more chronic disease process with remote antepartum brain injury. Liquefaction necrosis requires 2 weeks or longer after a presumed asphyxial event to produce a cystic cavity (Friede, 1975), before becoming visible on neuroimaging.

Isolated seizures in an otherwise asymptomatic neonate also suggest a disease process that occurred during either the postnatal or the antepartum period. Neonates present with seizures as a result of postnatal illnesses from intracranial infection, cardiovascular lesions, drug toxicity, or inherited metabolic diseases. Children with antepartum injuries may express isolated seizures after in utero cerebrovascular injury secondary to thrombolytic and/or embolic disease of the mother, placenta, or fetus. Fetal injury alternatively may occur after ischemia-hypoperfusion events from circulatory disturbances such as maternal shock, chorioamnionitis, or placental fetal vasculopathy (Miller, 2000).

Only a fraction of neonates with cerebrovascular disease present with neonatal seizures (DeVries et al, 1997). Why some children remain asymptomatic until later during childhood is unknown. Neonatal expression of seizures may reflect superimposed stress during parturition, which lowers seizure threshold in susceptible brain regions that have been previously damaged.

Following a careful review of the medical histories of the mother, fetus, and newborn, determination of serum glucose, electrolytes, ammonia, lactate, pyruvate, magnesium, calcium, and phosphorus levels may diagnose correctable metabolic conditions in newborns with seizures who will not require antiepileptic medications. CSF analyses including cell count, protein, glucose, lactate, pyruvate, amino acids, and culture studies are performed to assess for CNS infection, intracranial hemorrhage, and metabolic disease. Alternatively, metabolic acidosis on serial arterial blood gas determinations may suggest an inherited metabolic disease, particularly if intrapartum asphyxia was not judged to be severe. Absence of multiorgan dysfunction may alert the clinician to other potential causes of seizures besides intrapartum asphyxia. Signs of chronic in utero stress such as growth restriction, early hypertonicity after neonatal depression, joint contractures, or elevated nucleated red blood cell values all suggest longer-standing antepartum stress to the fetus. Genetic or syndromic conditions may contribute to the expression of neonatal encephalopathies independent of asphyxial injury (Felix et al, 2000). Careful review of placental and cord specimens also can be extremely useful to help time a brain insult. Neuroimaging, preferably using MR techniques, can locate, grade the severity of, and possibly time an insult (Leth et al, 1997) (i.e., using diffusion-weighted images). Ancillary studies may also include measurement of long-chain fatty acid and chromosomal/DNA analyses, as deemed necessary by family and clinical history. Finally, serum and urine organic acid and amino acid determinations may be needed to delineate a specific biochemical disorder for the child with a persistent metabolic acidosis. Lysosomal enzyme studies also are occasionally considered to diagnose specific enzymatic deficiencies in children with neonatal seizures.

### **CHALLENGES REGARDING PROGNOSTIC ASSESSMENTS**

The mortality rate among infants who present with clinical neonatal seizures has declined from 40% to 15% (Volpe, 2001). Studies of EEG-confirmed seizures documented mortality rates of 50% in preterm and 40% in full-term infants during the 1980s (Scher and Painter, 1990; Scher et al, 1993), with the mortality rate dropping below 20% in the 1990s in the same obstetric center (Scher, 1997a). The incidence of adverse neurologic sequelae, however, remains high; approximately two thirds of survivors are so affected. Even if major neurodevelopmental sequelae such as motor deficits and mental retardation were avoided in survivors after neonatal seizures, subtle neurodevelopmental vulnerability may manifest in late teenage years as specific learning difficulties or poor social adjustment (Temple et al, 1995), underscoring more recent experimental findings of long-term deficits in animal populations (Holmes and Ben-Ari, 2001).

Prediction of outcome should also consider the etiologic disorder for the seizures, such as severe asphyxia, significant craniocerebral trauma, and brain infections. More accurate imaging procedures (magnetic resonance imaging [MRI] in particular) have increased our awareness of destructive and

congenital brain lesions with a higher risk for compromised outcome.

Interictal EEG pattern abnormalities are also extremely helpful in predicting neurologic outcome in the neonate with seizures (Bye et al, 1997; Monod et al, 1972; Sinclair et al, 1999; Tharp et al, 1981). Major background disturbances such as burst suppression are highly predictive of poor outcome, particularly when persistent abnormalities are still present on serial electroencephalographic studies into the second week of life. Seizure patterns alone, however, are not accurate to predict outcome, unless quantified to high numbers, long durations, and multifocal distribution (McBride et al, 2000). In one study, normal findings on interictal EEGs were associated with an 86% chance of normal development at 4 years of age in 139 neonates with seizures (Rose and Lombroso, 1970); by contrast, neonates with markedly abnormal EEG background disturbances had only a 7% chance for normal outcome. Another study (Rowe et al, 1985) reported outcome in term and preterm infants with seizures, concluding that the EEG background was more predictive of outcome than the presence of isolated sharp wave discharges. Even severe electroencephalographic abnormalities on single-channel spectral EEG recordings after asphyxia carry a higher risk for sequelae (Hellström-Westas, 1992).

Neonates with seizures have an increased risk for epilepsy during childhood (Watanabe et al, 1982). On the basis of clinical seizure criteria, 20% to 25% of neonates with seizures later develop epilepsy (Holden et al, 1982). Excluding febrile seizures, the prevalence of epilepsy by 6 to 7 years of age is estimated to be between 15% and 30%, based on EEG-confirmed seizures for an inborn hospital population; two thirds of this cohort were preterm neonates (Scher et al, 1993). These findings are in contrast with an incidence of 56% with epilepsy for an exclusively outborn neonatal population of primarily full-term newborns with seizures (Clancy and Legido, 1991). Epilepsy risk therefore reflects selection bias of specific study groups, as well as referral patterns in different hospital settings.

### **DIAGNOSTIC DILEMMAS REGARDING TREATMENT CHOICES**

#### **Corrective Therapies**

Rapid infusion of glucose or other supplemental electrolytes should be initiated before antiepileptic medications are considered. Hypoglycemia can be readily corrected by intravenous administration of 5 to 10 mg/kg of a 10% to 15% dextrose solution, followed by an infusion of 8 to 10 mg/kg/minute. Persistent hypoglycemia may require more hypertonic glucose solutions. Rarely, prednisone, 2 mg/kg/day, may be needed to establish a glucose level within the normal range (Scher, 2001b).

Hypocalcemia-induced seizures should be treated with an intravenous infusion of 200 mg/kg of calcium gluconate. This dosage should be repeated every 5 to 6 hours over the first 24 hours. Serum magnesium concentrations also should be measured, because hypomagnesemia may accompany hypocalcemia; 0.2 mg/kg of magnesium sulfate should be given by intramuscular injection (Scher, 2001b).

Disorders of serum sodium are rare causes of neonatal seizures. Either fluid restriction or replacement with hypotonic solutions is generally the mode of therapy for correcting sodium dysmetabolism.

Pyridoxine dependency requires the injection of 50 to 500 mg of pyridoxine during a seizure with coincident EEG monitoring. A beneficial pyridoxine effect occurs either immediately or over the first several hours. A daily dose of 50 to 100 mg of pyridoxine should then be administered (Scher, 2001b).

### Antiepileptic Medications

If the decision to treat neonates with AEDs is reached, important questions must be addressed with respect to who should be treated, when to begin treatment, which drug to use, and for how long. Some clinicians suggest that only neonates with clinical seizures should receive medications; brief electrographic seizures need not be treated. Others suggest more aggressive treatment of electrographic seizures, because uncontrolled seizures potentially have an adverse effect on immature brain development (Dwyer and Wasterlain, 1982; Wasterlain, 1997). Others warn that early administration of an AED, such as phenobarbital, even before signs of HIE appear, may have adverse effects on outcome in term infants (Ajayi et al, 1998).

Phenobarbital and phenytoin, nonetheless, remain the most widely used AEDs; use of benzodiazepines, primidone, and valproic acid has been anecdotally reported (Scher, 2001b). The half-life of phenobarbital ranges from 45 to 173 hours in the neonate (Lockman et al, 1979; Painter et al, 1978, 1981); the initial loading dose is recommended at 20 mg/kg, with a maintenance dose of 3 to 4 mg/kg/day. Therapeutic levels are generally suggested to be between 16 and 40  $\mu\text{g/mL}$ ; however, there is no consensus with respect to drug maintenance.

The preferred loading dose of phenytoin is 15 to 20 mg/kg (Painter et al, 1978, 1981). Serum levels of phenytoin are difficult to maintain because this drug is rapidly redistributed to body tissues. Blood levels cannot be well maintained using an oral preparation. A water-soluble form, fosphenytoin, may be administered at the same loading dose. This specific agent has less harmful effects on the vein where it is injected.

Benzodiazepines also may be used to control neonatal seizures. The drug most widely used is diazepam. One early study suggests a half-life of 54 hours in preterm infants to 18 hours in full-term infants (Smith and Misoh, 1971). Intravenous administration is recommended because the drug is slowly absorbed after an intramuscular injection. Diazepam is highly protein bound; alteration of bilirubin binding is low. Recommended intravenous doses for acute management should begin at 0.5 mg/kg. Deposition into muscle precludes its use as a maintenance antiepileptic medication, because profound hypotonia and respiratory depression may result, particularly if barbiturates also have been administered.

### Efficacy of Treatment

Conflicting studies report varying efficacy with phenobarbital or phenytoin. Most studies only apply a clinical end point to seizure cessation. One study (Painter et al, 1978)

found that only 36% of neonates with clinical seizures responded to phenobarbital; another study noted cessation of clinical seizures with phenobarbital in only 32% of neonates (Lockman et al, 1979). With doses as high as 40 mg/kg (Gal et al, 1982), the rate of clinical seizure control was reported to be 85%. A more recent study reported that the earlier administration of high-dose phenobarbital in a group of asphyxiated infants was associated with a 27% reduction in clinical seizures and better outcomes than in a group of infants who did not receive high dosages (Hall et al, 1998). However, coincident electroencephalographic studies are now suggested to verify the resolution of electrographic seizures. A recent report suggests that 25% of neonates have persistent electrographic seizures after suppression of clinical seizure behaviors following drug administration (Scher et al, 1994). With use of the EEG to judge cessation of seizures, neither phenobarbital nor phenytoin was effective in controlling seizure activity (Painter et al, 1999).

The use of free or drug-bound fractions of AEDs has been suggested to better assess both efficacy and potential toxicity of these drugs in pediatric populations (Painter et al, 1987). Drug binding in neonates with seizures has only recently been reported and can be altered in a sick neonate with organ dysfunction. Toxic side effects may result from elevated free fractions of a drug, which may adversely affect cardiovascular and respiratory functions. To guard against untoward effects, evaluation of treatment and efficacy must take into account both total and free AED fractions, in the context of the newborn's progression or resolution of systemic illness.

Newer anticonvulsant alternatives to treat seizures are being suggested, with *N*-methyl-D-aspartate (NMDA) antagonists such as topiramate (Jensen, 1999) developed from experimental models of hypoxia-induced seizure activity in immature brain. Such models provide data regarding pharmacologic and physiologic characteristics of neuronal responses to an asphyxial stress, which causes excessive release of excitotoxic neurotransmitters (Jensen and Wang, 1996) such as glutamate. Specific cell membrane receptors termed *metabotropic glutamate receptors* (MGLuRs) are sensitive to extracellular glutamate release and may play a role in epileptogenesis and seizure-induced brain damage (Aronica et al, 1997). Investigation of subclasses of MGLuRs will lead to development of novel drugs that block these membrane receptors as the mode of treatment for neonatal seizures (Lie et al, 2000).

### Discontinuation of Drug Use

The clinician's decision to maintain or discontinue AED use is also uncertain. Discontinuation of drugs before discharge from the NICU is generally recommended, because then clinical assessments of arousal, tone, and behavior will not be hampered by medication effect. However, newborns with congenital or destructive brain lesions on neuroimaging or those with persistently abnormal findings on neurologic examination at the time of discharge may require a slower taper off medication over several weeks or months. In most children with neonatal seizures, the seizures rarely reoccur during the first 2 years of life,

and prophylactic AED administration need not be maintained past 3 months of age, even in the child at risk. This recommendation is supported by a recent study suggesting a low risk of seizure reoccurrence after early withdrawal of AED therapy in the neonatal period (Hellström-Westas et al, 1995). Also, older infants who present with specific epileptic syndromes, such as infantile spasms, will not respond to the conventional AEDs that were initially begun during the neonatal period. This honeymoon period without seizures commonly persists for many years in most children, before isolated or recurrent seizures appear.

The potential for damage to the developing CNS from AEDs also emphasizes the need to consider early discontinuation of these agents in the newborn period. Adverse effects on the morphology and metabolism of neuronal cells have been extensively reported from collective research performed over the last several decades (Mizrahi, 1999).

### **EFFECTS OF NEONATAL SEIZURES ON BRAIN DEVELOPMENT: CONSEQUENCES OF UNDERDIAGNOSIS**

Embedded within the controversy regarding how to diagnose neonatal seizures (i.e., clinical versus electroencephalographic) is the association of repetitive or prolonged seizures with brain damage and altered brain development. Linked to the clinician's concern for seizure duration is an appreciation of the diverse neuropathologic processes and etiologic disorders that cause neonatal seizures and have neurologic sequelae (Lien et al, 1995). CNS infections and severe asphyxia are two etiologic disorders that exemplify underlying pathophysiologic mechanisms responsible for brain damage in neonates independent of seizure expression.

Adverse effects of the seizure state on the developing brain (Holmes and Ben-Ari, 2001) have been recently reviewed. Seizures can disrupt a cascade of biochemical and molecular pathways that normally are responsible for the plasticity or activity-dependent development of the maturing nervous system. Depending on the degree of brain immaturity, seizures may disrupt the processes of cell division, migration, and myelination; sequential expression of receptor formation; and stabilization of synapses—each of which contributes to the risk of neurologic sequelae, to varying degrees (Holmes et al, 1998).

Experimental models of seizures in immature animals suggest comparatively less vulnerability to seizure-induced brain injury than in mature animals (Huang et al, 1999). In adult animals, seizures alter growth of hippocampal granule cells and of axonal and mossy fibers, resulting in long-term deficits in learning, memory, and behavior. A single prolonged seizure in an immature animal, on the other hand, results in less cell loss or fiber sprouting and consequentially fewer deficits in learning memory and behavior. Resistance to brain damage, from prolonged seizure activity, however, is age specific, as evidenced by increased cell damage after only 2 weeks of age (Sankar et al, 2000). A recent study examined developmental changes in epileptiform activity in neocortical preparations in four different age groups and using four different

pharmacologic models. The study confirmed that there are definite age-dependent differences in susceptibility to epileptiform activity in the neocortex. These developmental changes seem to relate to intrinsic network properties of the neocortex that are independent of ontogenetic differences in any specific neurotransmitter system (Wong and Yamada, 2001).

Repetitive or prolonged neonatal seizures alternatively can increase the susceptibility of the developing brain to suffer subsequent seizure-induced injury during adolescence or early adulthood, by altering neuronal connectivity rather than increasing cell death (Holmes and Ben-Ari, 2001; Holmes et al, 1998; Koh et al, 1999; Schmid et al, 1999). Neonatal animals subjected to status epilepticus have reduced seizure thresholds at later ages and demonstrate impairments of learning, memory, and activity levels after suffering seizures as adults. Proposed mechanisms of injury also include reduced neurogenesis in the hippocampus, for example, possibly because of ischemic-induced apoptosis, as well as necrotic pathways (McCabe et al, 2001). Other suggested mechanisms of injury include effects of nitric oxide synthase inhibition on cerebral circulation, which then contributes to ischemic injury (Takei et al, 1999). Neonatal seizures, therefore, may initiate a cascade of diverse changes in brain development that become maladaptive at older ages and increase the risk of subsequent damage after subsequent insults. Destructive mechanisms such as mossy fiber sprouting in the hippocampus or increased neuronal apoptosis may explain mutually exclusive pathways by which the immature brain suffers altered connectivity and reduced cell number, which is then “primed” for later seizure-induced cell loss at older ages.

The critical duration of seizures, whether cumulative or continuous, remains elusive with respect to resultant brain injury. Given that as many as one third of full-term infants experience electrographic seizures that satisfy a definition of status epilepticus (Scher et al, 1993), EEG documentation appears crucial to assign seizure duration. A recent study in 10-day-old rat pups indicated that prolonged seizures for 30 minutes after asphyxia resulted in exacerbation of brain injury specific to the hippocampus, while sparing the neocortex. Prolonged neonatal seizures do worsen damage incurred by an already compromised brain (Wirrell et al, 2001) in a region-specific manner. In a neonatal rodent model of brief recurrent seizures, Landrot and colleagues (2001) demonstrated increased mossy fiber sprouting in the granule cells of the hippocampus, which correlated with impaired cognition and reduced EEG power spectra during adolescence. A companion study from the same laboratory demonstrated alterations in cognition and seizure susceptibility within 2 weeks of the last seizure before the adult pattern of mossy fiber distribution is achieved. Therefore, therapeutic strategies to alter the adverse outcomes of neonatal seizures must be initiated during or shortly after the seizures.

The overlapping effects of brain dysgenesis or injury from specific etiologic disorders versus seizure-induced brain damage make it difficult to differentiate pre-existing brain lesions from the direct injurious effects of seizures themselves. The use of microdialysis probes in white and gray matter of piglet brains subjected to hypoxia indicates

elevated lactate-pyruvate ratios after hypoxia but no direct association with seizure activity (Thoresen et al, 1998). These findings support the conclusion that seizures themselves may not always be injurious to brain.

The dearth of well-designed clinical investigations of outcome after neonatal seizures in humans unfortunately does not permit confirmation of these experimental findings. Better definitions of neonatal seizure severity, including electrographic expression and seizure duration, are required to help resolve this controversy. A recently published investigation in human newborns with perinatal asphyxia suggests that seizure severity is independently associated with brain injury, as measured by MR spectroscopy (Miller et al, 2002), but not all subjects had electrographic confirmation of seizures.

Aggressive use of antiepileptic medications without electroencephalographic confirmation contributes to the inaccurate estimate of seizure severity in neonates and possible medication-induced brain injury. Intractable seizures generally require the use of multiple antiepileptic medications, which may still not effectively control seizures (Painter et al, 1999). Drugs also may impede the clinician's ability to recognize persistent seizures, because of the uncoupling phenomenon in which the clinical expression is suppressed while the electrical expression of seizures continues. Clinical definitions of seizure occurrence and duration consequently underestimate seizure severity, which may be associated with increased risk for brain damage (Ékert et al, 1997). AED use also has secondary harmful effects on cardiac and respiratory functions, with resultant circulatory disturbances that will contribute to brain injury because of hypoperfusion (Lien et al, 1995). Finally, AED use may have teratogenic effects on brain development with exposure over long periods of time.

# Risk Assessment and Neurodevelopmental Outcomes

Marilee C. Allen

## RISK OF NEURODEVELOPMENTAL DISABILITY

“Will my child survive?” “What kind of life will my child have?” These are the two questions most frequently asked by parents of infants in a neonatal intensive care unit (NICU). As difficult as it is to predict survival of a sick or very preterm infant, it is far more difficult to answer questions regarding quality of life for the infant who survives. How much recovery will there be? Will the child develop further complications? Most important, how will this early illness influence the child’s neurologic, sensory, and cognitive development?

Only a few conditions (e.g., some chromosome disorders, dysmorphic syndromes, brain malformations) carry certain knowledge of disability, and many of these are associated with shortened life span. For most conditions requiring neonatal intensive care, it is difficult to define the full extent (if any) of damage to or malformation of the infant’s organ systems. In addition, the newborn has a remarkable potential for recovery. Few factors hindering or contributing to this recovery have been identified. Predicting the outcome for individual children is therefore difficult.

How is quality of life defined? What is abnormal outcome? The World Health Organization has differentiated among the words *impairment*, *disability*, and *handicap* (International Classification of Impairments, Disabilities, and Handicaps, 1980). An *impairment* is a structural, psychological, or physical abnormality; a *disability* is a restriction or inability to perform normally due to impairment; and a *handicap* is a disadvantage in society due to a disability. Most commonly, *high risk* refers to likelihood of neurodevelopmental disability, which is a group of interrelated, chronic, nonprogressive disorders of the central nervous system (CNS) caused by injury to or malformation of the developing brain. They form a spectrum ranging from cerebral palsy (motor impairment) and mental retardation (cognitive impairment), to sensory impairment, to the more subtle disorders of CNS function (Table 67–1). These more subtle disorders of higher cortical function include language disorder, visual-perceptual problems, learning disability, minor neuromotor dysfunction, attention deficits, hyperactivity, and behavioral problems. They have a lesser severity and a higher prevalence in the general population

than is the case for the major disabilities (i.e., cerebral palsy and mental retardation).

Although preterm infants and sick full-term infants have an increased risk of neurodevelopmental disabilities compared with the general population, most do not develop major disability and are quite functional. Most children with disability manifest initial developmental delay. However, children may have functional limitations without delay in milestone attainment. A preterm infant who was born at 27 weeks of gestation and had a right intraparenchymal hemorrhage had no delays when seen at 14 months in neonatal follow-up. He walked independently, had a right pincer grasp, and said his first meaningful word. On careful inspection, however, circumduction of the left foot was evident on walking, with only a raking grasp with the left hand. Findings on examination—a tight left heel cord and increased tone on pronation and supination of the left arm—were consistent with a left spastic hemiplegia. Children with complex medical conditions may initially demonstrate developmental delay but not have long-term disability. An infant with chronic lung disease and mild hypotonia who is not rolling over by 6 months has delayed development and is at risk for motor and language impairment. However, his rate of development may increase as his lung disease resolves, and he may have much milder impairment than expected or even no impairment.

A large number of perinatal and demographic risk factors, with differing capacities to predict neurodevelopmental disabilities, have been identified. They are best grouped by category (Table 67–2). Socioeconomic status is strongly related to cognition but has little effect on cerebral palsy (except as it may be related to preterm birth, intrauterine growth restriction, and other biologic risk factors) (Aylward, 2002; Hack et al, 1995; Ornstein et al, 1991). A number of obstetric conditions (e.g., abruptio placentae, maternal antepartum hemorrhage, fetal distress during labor) may be catastrophic, but prompt intervention may circumvent death or disability. Neonatal conditions (e.g., encephalopathy) are better predictors of outcome than either preceding obstetric conditions or measures of the infant’s condition at the time of birth (e.g., Apgar scores, need for resuscitation) (Nelson, 2002; Weisglas-Kuperus et al, 1992). The more severe the encephalopathy, abnormalities on examination, or neuroimaging abnormalities, the higher the risk of disability (Allen and Capute, 1989; Aziz et al, 1995; Robertson et al, 1989; Rogers et al, 1994).

Multiple risk factors increase the risk of developmental disability, by either additive or multiplicative effects. The effects of prematurity and intrauterine growth restriction on cognition are greatest in infants born to parents of low socioeconomic status. Combining results of neuroimaging studies with neurodevelopmental examinations improves prediction of disability (Allen and Capute, 1989; Weisglas-Kuperus et al, 1992). Just as complications of prematurity increase with decreasing birth weight, incidence of neurodevelopmental disability also increases (Lemons et al, 2001; Vohr et al, 2000). However, the presence of multiple risk factors in the sickest infants makes it more difficult to attribute risk to individual factors.

TABLE 67-1

**Prevalence of Neurodevelopmental Disabilities in the General Population**

Disability	Descriptor	Prevalence (%)*
Major disability	CP + MR <sup>†</sup>	2-3
Cerebral palsy	Motor impairment	0.1-0.3
Mental retardation	IQ <sup>‡</sup> <70	1-2
Mild mental retardation	IQ 50-70	1.5
Severe mental retardation	IQ <50	0.5
Sensory impairments		
Visual impairment	Severe	0.4-0.6
Hearing impairment	Severe	1.5-2.0
Disorders of higher cortical function		
Language delay/speech defects		4-11
Learning disability		5-10
Attention-deficit disorder		6-20
Minor neuromotor dysfunction		5-15

\*Prevalence figures adapted from Boyle CA, Decoufle P, Yeargin-Allsopp M: Prevalence and health impact of developmental disabilities in U.S. children. From *Pediatrics*, Vol 93, pages 399-403, 1994.

<sup>†</sup>CP + MR, cerebral palsy and mental retardation.

<sup>‡</sup>IQ, intelligence quotient (2 SD below the mean varies by test, may be 68 or 70).

Neither risk nor statistical association implies causation. Prematurity, intrauterine growth restriction, or poor respiratory effort at birth may be caused by a prenatal insult or malformation. An abnormal fetus may grow poorly, precipitate preterm delivery, fail to descend properly, need stimulation to breathe at birth or nipple feed poorly. All of these risk factors predict neurodevelopmental disability, but the etiology of the disability is the fetal abnormality, which often is diffi-

cult to detect. Recent population studies of children with cerebral palsy have reported an improved ability to determine probable causes for the cerebral palsy, with a decrease in unclassifiable causes from 38% to 27% in preterm infants and from 39% to 14% in term infants (Hagberg et al, 1996, 2001). In a comprehensive long-term follow-up study of preterm infants, Drillien and colleagues (1980) found that preterm infants “who showed no evidence of early intrauterine insult and who were neurologically normal in the first year of life were largely indistinguishable from control children reared in similar homes.” This finding suggests that the causes and complications of prematurity are the etiologic disorders and conditions leading to disability.

Studies of risk factors can provide important insights into causes of neurodevelopmental disability (Allen, 2002; Nelson, 2002; O’Shea, 2002). More than half of children with cerebral palsy are full-term, half of which have prenatal causes for their cerebral palsy, including intrauterine infection, coagulopathy, placental pathology, and death of a co-twin (Cummins et al, 1993; Hagberg et al, 1996, Nelson, 2002). Among preterm children with cerebral palsy, perinatal and neonatal etiologic disorders are more frequent than prenatal causes (61% versus 12%) (Hagberg et al, 2001). Strong evidence links cerebral palsy in preterm infants to ischemic and/or cytokine-mediated brain injury, with perhaps also a role for insufficient levels of developmentally regulated neuroprotective substances (e.g., thyroxine, hydrocortisone) (O’Shea, 2002).

Although risk factors cannot diagnose neurodevelopmental disability, the absence of significant risk factors is reassuring. All children should have their development monitored during infancy and childhood because of a baseline incidence of neurodevelopmental disability (see Table 67-1). Nevertheless, absence of significant risk factors and normal findings on neuroimaging studies and on neurodevelopmental examinations can be used to help alleviate parental anxiety related to having an infant in a NICU.

TABLE 67-2

**Categories of Perinatal Risk Factors**

Background characteristics
Socioeconomic status/social class, parental education, race
Obstetric/prenatal complications
Maternal acute or chronic illness, maternal ingestion of drugs, congenital infection, multiple gestation, labor or delivery complications (e.g., abruptio placentae, cord prolapse), placental abnormalities
Physical characteristics
Prematurity, postmaturity, small for gestational age/ intrauterine growth restriction, gender, microcephaly, congenital anomalies, dysmorphic features
Condition at birth
Apgar scores, cord pH, meconium staining, need for and response to resuscitation
Neonatal complications
Hypoxia, acidosis, hypotension/shock, apnea and bradycardia, chronic lung disease, sepsis, meningitis, seizures, hypoxic-ischemic encephalopathy
Measures of central nervous system structure and function
Intraventricular hemorrhage, intraparenchymal hemorrhage, ventricular dilation, cortical atrophy, intraparenchymal cysts or echodensities (Periventricular leukomalacia), burst-suppression pattern on electroencephalogram, abnormal neonatal neurodevelopmental examination

Mildly increased risk should be acknowledged but should also be put into perspective for parents. Parents of infants with significant or multiple risk factors should be offered focused neurodevelopmental follow-up evaluation and support, especially during critical early years. A comprehensive, developmentally based, family-oriented follow-up clinic ensures early diagnosis of neurodevelopmental disability, helps to shape early intervention strategies to meet the infant's and family's evolving needs, and provides parents with continuity and ongoing support during a very difficult period of uncertainty and adjustment.

Uncertainty regarding a child's outcome is difficult for both parents and professionals. The clinician can describe to parents the range of possible outcomes and estimate their likelihood for a given infant, based on a knowledge of the literature and experience. Helping parents to recognize and cope with parental fears allows development of a realistic plan for the future, including identifying family support systems, early intervention strategies, and community resources.

## NEURODEVELOPMENTAL OUTCOME

This section describes the outcome for several groups of high-risk infants cared for in the NICU. The reported incidences of disability differ from study to study because of a number of factors: variations in study criteria, ethnic and demographic composition of the populations, obstetric and neonatal care practices, follow-up rate, length of follow-up, and assessment methodologies. High follow-up rates are preferable but difficult to attain. Low follow-up rates raise concerns about bias—for example, whether infants lost to follow-up were more impaired or had fewer problems. One study found difficulty with follow-up to be associated with lower intelligence quotients (IQs), more disability, and single parents with less education (Callanan et al, 2001).

How the children are followed, and for how long, influences what neurodevelopmental disabilities are detected. Studies that evaluate infants up to 1 year focus on the major disabilities but are inadequate for assessing mild cerebral palsy, mild mental retardation, or borderline intelligence. Evaluating older children improves diagnostic accuracy but lowers follow-up rates, and socioeconomic factors play a role in cognition by the age of 2 years. Mild to moderate sensory impairments may be missed if specific evaluations of hearing and vision are not performed. Follow-up assessments from 2 to 6 years can detect minor neuromotor dysfunction, behavioral problems, attention deficits, and language delay. Questions about learning disability and other school-related problems, however, require follow-up to school age. Follow-up to adolescence and adulthood raises questions about functional abilities and quality of life.

Longitudinal studies have found an increased incidence of school problems the longer the period of follow-up evaluation (Aylward, 2002; Msall and Tremont, 2002). The younger child with more subtle impairments often has some ability to compensate for learning difficulties or inefficiencies. The child with subtle impairments may not demonstrate a learning disability until he or she reaches

the higher grades, when the work becomes more complex, and efficiency becomes important in completing work and test-taking.

## Preterm Infants

Most preterm follow-up studies report outcomes related to birth weight because it is more reliably measured than gestational age (Tables 67–3 and 67–4). Very low-birth-weight (VLBW) infants have birth weights below 1500 g (3 pounds 5 ounces), extremely low-birth-weight (ELBW) infants have birth weights below 1000 g (2 pounds 3 ounces), and incredibly low-birth-weight (ILBW) infants have birth weights below 750 to 800 g (1 pound 1 ounce).

## Major Disability

Although preterm infants have a higher incidence of all neurodevelopmental disabilities than that reported for full-term infants, most preterm infants are free of major disability (cerebral palsy or mental retardation) (see Table 67–3). In a meta-analysis of 110 studies published between 1960 and 1990, the median incidence of cerebral palsy in VLBW infants was 7.7%, with a range of 0% to 50% (Escobar et al, 1991). Despite ongoing improvements in preterm survival, recent studies have not shown a consistent decrease: the prevalence for cerebral palsy has been 5% to 17% for infants with birth weights below 1000 g, 4% to 14% for infants with birth weights below 1500 g, 0.8% to 1.4% for infants with birth weights of 1500 to 2499 g, and 0.04% to 0.14% for infants with birth weights above 2500 g (Amiel-Tison et al, 2002; Bracewell and Marlow, 2002; Vohr et al, 2000).

One difficulty with reporting the incidence of cerebral palsy in these studies is variability in definition of cerebral palsy. The most common type of cerebral palsy in VLBW children is spastic diplegia, and it is frequently mild. There is no uniform agreement on whether the child with tight heel cords and hyperreflexia who toe-walks initially but walks independently by age 2 should be classified as having cerebral palsy (versus mild motor impairment, called here *minor neuromotor dysfunction*). Although some children require physical therapy and/or bracing (frequently, ankle-foot orthoses [AFOs]), the school and behavioral problems for which they are at higher risk may be far more devastating than their mild motor impairments (Bracewell and Marlow, 2002; Dammann et al, 1996; Khadilkar et al, 1993; Scottish Low Birthweight Study Group, 1992; Weisglas-Kuperus et al, 1994). Mild motor impairments at school age include asymmetries of leg or hand function and difficulties with balance, motor planning, and fine motor function.

Populations of preterm children demonstrate a normal range of intelligence, but VLBW and ELBW children tend to have mean IQs that are 4 to 10 points (or 0.3 to 0.6 standard deviation) below those of term children, even after adjustment for socioeconomic status and race (Aylward, 2002; Bhutta et al, 2002; Ornstein et al, 1991). The significance of a lower mean IQ is in the greater proportion of children with mental retardation, borderline intelligence, and low average intelligence who have difficulties

functioning at school and in society. Many VLBW and ELBW children with normal IQ scores have problems with attention, memory, complex verbal processing, visual-perceptual abilities, and/or executive function that interfere with school performance.

Preterm infants with lower birth weights or gestational ages have lower IQ scores and a higher incidence of neurodevelopmental disabilities (Aylward, 2002; Bhutta et al, 2002; Vohr et al, 2000). This is especially true for infants born at the lower limit of viability (see Table 67-4). Using birth weight criteria, the prevalence of disability in survivors ranges from 22% to 51% for ILBW infants with birth weights below 750 to 800 g and is as high as 69% for infants with birth weights below 500 g. Using gestational age criteria, the prevalence of disability in survivors ranges from 46% to 68% for infants born before 26 weeks

of gestation and from 58% to 67% for infants born at 23 weeks of gestation. Cerebral palsy rates are a bit higher than in VLBW, ELBW, and more mature preterm infants. Cognitive impairment appears to be much more common in infants born at the lower limit of viability. Mental retardation occurs in 15% to 48% of ILBW infants and in 13% to 20% of preterm infants born before 26 weeks of gestation. Prevalence of borderline intelligence, when reported, ranges from 11% to 31%. Among children with birth weights of 500 g or less, or those born at or before 23 weeks of gestation, only 31% to 50% are normal when evaluated in the first few years. We expect that the prevalence of disabilities will increase further if these children are studied at later ages. Although survival has improved dramatically for these infants, disability rates have changed very little (Lorenz et al, 1998).

\*Follow-up age: age at follow-up examination, either range or mean age at follow-up when range not given.

<sup>†</sup>Birth years: years during which study samples were born (e.g., 1974-1977).

<sup>‡</sup>Only severe cerebral palsy was reported.

BIQ, borderline intelligence [quotient]; with developmental or intelligence quotient 68-70 or 80-85, respectively; CP, cerebral palsy; sometimes reported as severe neurologic impairment; ILBW, incredibly low-birth-weight; MR, mental retardation; with developmental or intelligence quotient <68-70.

Any attempt to evaluate and predict outcomes at the lower limit of viability must take into account perinatal management strategies. Considerable variability exists in perceptions of viability, and in treatment strategies regarding mode of delivery, delivery room resuscitation, and initiation of neonatal intensive care. A study by Lorenz and colleagues (2001) compared outcomes in two regions in which systematically different management approaches were used. Infants born at 23 to 26 weeks of gestation in three counties of New Jersey were aggressively managed at birth, whereas the approach in the Netherlands focused

on tocolysis and prevention of prematurity. In the Netherlands, infants born at 23 to 26 weeks of gestation were less likely to be delivered by cesarean section or offered neonatal intensive care (and intensive care was withdrawn in 20%). The more aggressive resuscitation approach resulted in 24.1 additional survivors and 7.2 cases of disabling cerebral palsy and required 1372 additional ventilator days per 100 live births.

Universal agreement is lacking about what role parents should play in these complex decisions, and about whether efforts to lower the limit of viability further should continue.

Clearly, these patients require a great deal of resources, not only at birth and in the neonatal period but also throughout infancy and childhood and even into adulthood. A more compelling goal would be to develop strategies that improve quality of life for them and their families.

### Sensory Impairments

Retinopathy of prematurity continues to be a cause of severe visual impairment, especially in the most immature and smallest preterm infants (see Tables 67–3 and 67–4). Myopia and strabismus are common in preterm infants and generally necessitate intervention. The incidence of hearing impairment in very preterm infants ranges from 1% to 11%, depending on the population and definitions used. Hearing impairment is important to diagnose as early as possible, before language acquisition. Many states have implemented universal hearing screening; all preterm NICU infants should have their hearing screened in the neonatal period.

### Function at School Age

Most (95%) VLBW children attend regular schools, but 10% to 48% of VLBW children and 20% to 50% of ELBW children have diagnosed learning disabilities, require special education, or fail grades (see Table 67–3). Despite normal intelligence, children with learning disabilities may have difficulties in processing complex language, in perceiving or copying symbols, or with the fine motor control involved in drawing and writing. When compared with full-term control subjects, VLBW, ELBW, and ILBW children have higher incidences of minor neuromotor dysfunction, language delay, visual-perceptual problems, reading disability, difficulties with arithmetic, and behavioral problems. These differences persist even when only preterm children with normal intelligence and no neurologic impairments are included in the data analysis (Grunau et al, 2002; Saigal et al, 2000). ILBW children had worse language processing, gross motor function, visual motor abilities, attention, academic achievement, behavior, and social skills than children with birth weight 750 to 1499 g or full-term controls (Hack et al, 1994; Saigal et al, 2000). There is no doubt that preterm children have more school difficulties and require more special education than is documented for full-term children from similar socioeconomic environments.

Visual-perceptual abnormalities, sensorimotor integration problems, and minor neuromotor dysfunction are often striking findings in preschool and school-age preterm children (Aylward, 2002; Bracewell and Marlow, 2002; Dammann et al, 1996; Drillien et al, 1980; Khadilkar et al, 1993; Roth et al, 2001; Saigal et al, 2000; Weisglas-Kuperus et al, 1994). Many preterm children have initial motor delays and persistent mild abnormalities on examination, including asymmetries, tight heel cords, and trunk and upper extremity hypotonia consistent with minor neuromotor dysfunction. Children who have neuromotor abnormalities during the first 1 to 2 years but do not develop cerebral palsy (called *transient dystonia* by Drillien and colleagues) have a high incidence of associated school and

behavioral problems. In addition, subtle residual motor impairments can lead to day-to-day problems, including difficulties in dressing, cutting with scissors, using playground equipment, and writing. Difficulty in processing complex language makes it more difficult for a child to comprehend and follow school lessons or even directions. Preterm children have a higher incidence of attention deficit disorder and behavioral problems, which can further interfere with school functioning and interpersonal relationships. These and other functional impairments often are not adequately appreciated in preterm outcome studies, unless specifically looked for (Msall and Tremont, 2002). Studies of preterm adults continue to demonstrate a higher rate of impairments, lower IQ scores, and poorer academic achievement (Ericson and Kallen, 1998; Hack et al, 2002).

All of these subtle CNS abnormalities can have a devastating impact on self-esteem, peer relationships, and school performance. The goal of early recognition and intervention is to help the child to become more functional in his or her daily life. Alerting parents, teachers, and friends about a child's difficulties and frustrations, and the impact of these on the child's self-esteem, allows them to provide a more supportive environment. By helping to maintain a child's self-esteem and improving the child's ability to cope with the demands of school and playground, many secondary social and emotional problems can be prevented or ameliorated. Hack and colleagues (2002) found lower rates of drug and alcohol abuse, police contact, and pregnancy in preterm adults compared with full-term peers and raised the question of whether they have a closer and more supportive relationship with their parents.

### Small-for-Gestational-Age Infants

The term *small for gestational age* is an arbitrary classification that refers to an infant whose intrauterine growth is less than expected for gestational age at birth. It is, in fact, a heterogeneous category, with a wide range of causes, risk of perinatal complications, and outcomes (Allen, 1992). Small size at birth may be due to parental (especially maternal) small size; insult or injury to the fetus; fetal maldevelopment; or deprivation of supply of oxygen or nutrients due to placental insufficiency, maternal ingestion (e.g., cigarettes, alcohol, narcotics), or maternal illness. Magnitude of risk for death, perinatal complications, and neurodevelopmental disability varies with the cause of the intrauterine growth restriction (IUGR), the timing of the insult (if any), and the perinatal complications that the child encounters.

The small-for-gestational-age (SGA) infant whose mother is small is likely to be only mildly growth restricted and have no increased risk. With trisomy 18, poor fetal growth early in pregnancy is likely, with death within the first several months, or the affected child will develop multiple severe neurodevelopmental disabilities. The SGA infant with fetal alcohol syndrome has prenatal and postnatal growth deficiencies and an increased risk of congenital anomalies (e.g., characteristic facies, joint anomalies, ventricular septal defect) and CNS dysfunction (e.g., mild to moderate

mental retardation, tremors, fine motor incoordination, hyperactivity). Uteroplacental insufficiency often manifests later in pregnancy (after 27 or 28 weeks of gestation) and often causes asymmetrical growth restriction with sparing of head growth. IUGR from uteroplacental insufficiency can be viewed as an adaptation to restricted supply of nutrients. Although it may be an effective human adaptation to adverse intrauterine circumstances, there are consequences to this strategy: increased risk of perinatal complications that can affect survival and outcome (e.g., perinatal asphyxia, hypoglycemia), of hypertension later in life, of short stature, and of disability (Allen, 1992; Hollo et al, 2002; Low et al, 1992; Paz et al, 1995; Pena et al, 1988; Pryor et al, 1995; Strauss, 2000; Wocadlo and Rieger, 1994).

Studies that report developmental outcome of SGA infants generally exclude infants with congenital anomalies, genetic syndromes, or congenital infections. They follow primarily infants with placental insufficiency or unknown cause of IUGR, and they distinguish between the full-term and the preterm SGA infant. Although retrospective studies of children with disability find a higher-than-expected proportion who were SGA infants, prospective studies find only a higher incidence of academic failure (as high as 25% versus 14%) and behavior problems in full-term SGA children than in full-term appropriate-for-gestational age (AGA) children (Hollo et al, 2002; Larroque et al, 2001; Low et al, 1992; Paz et al, 1995). Lower mean IQ scores have been found in some samples of full-term SGA children, but this is not a consistent finding in IUGR infants born to mothers with pregnancy-induced hypertension and in IUGR adults (Goldenberg et al, 1996; McCowan et al, 2002, Paz et al, 1995, 2001; Pryor et al, 1995). Full-term IUGR adolescents and adults report greater disadvantage when it comes to school failures and dropout, job status, and income (Larroque et al, 2001; Paz et al, 1995; Strauss, 2000).

The preterm SGA infant has the disadvantages of both prematurity and IUGR, but it is difficult to determine how much IUGR further increases the preterm infant's risk of neurodevelopmental disability (Pena et al, 1988; Robertson et al, 1990; Thompson et al, 1993; Wocadlo and

Rieger, 1994). Preterm SGA infants have more severe IUGR than that noted in full-term SGA infants because they already manifest significant growth restriction at the time of their preterm birth. Most preterm SGA children have normal intelligence, but their mean IQ is lower than that of full-term AGA and SGA children and sometimes even preterm AGA children (depending on whether controls are matched for birth weight or gestational age) (Table 67-5). Major disability occurs in 7% to 23% of preterm SGA children. Learning disabilities occur in 36% to 50% of preterm SGA children at 8 to 11 years, and preterm SGA children are more hyperactive than preterm AGA and full-term controls (Low et al, 1992; Robertson et al, 1990). The most striking finding of these studies is that all preterm groups, whether SGA or AGA, scored worse than full-term control groups on measures of growth, intellectual function, visual-motor integration abilities, reading, arithmetic, and behavior. This finding highlights the importance of long-term follow-up evaluation to school age for children with prematurity or IUGR.

### Sick Full-Term Infants

The full-term infant may require neonatal intensive care for a variety of reasons, including complications of IUGR, perinatal asphyxia, maternal substance abuse, congenital anomalies, or infection. It is most difficult to predict outcome in infants with poorly understood illness: the newborn with sluggish but eventually good response in the delivery room, the newborn who appears septic but has negative culture results, the newborn who does not feed well initially, and others with undefined illness. Under most circumstances, these children will do well, but for some, initial illness may be a sign of a CNS disorder or systemic illness that contributes to abnormal outcome. Maternal drug use, infection, or congenital anomalies may underlie conditions that require neonatal intensive care, thereby adding to risk for disability.

One recurring scenario in the NICU is that of the full-term infant who has either subtle or florid signs of neonatal

**TABLE 67-5**

#### Neurodevelopmental Outcome in Preterm Infants Small for Gestational Age (SGA) Versus Appropriate for Gestational Age (AGA)

\*0.8/1: DQ at 40 weeks from term; neurologic outcome determined at 1 year from term.

<sup>†</sup>Significantly different from SGA infants, at least at  $P < .05$  level.

MD, major disability or neurologic impairment, as defined by authors; generally cerebral palsy and mental retardation and occasionally includes severe sensory impairment. DQ/IQ, mean developmental quotient (DQ) or intelligence quotient (IQ).

encephalopathy (see Chapter 64). Increasing attention to the difficulties of defining encephalopathy has led to an appreciation of the complexities of determining causes, effects, and outcomes (Dixon et al, 2002; Ekert et al, 1997; Ishikawa et al, 1987; Jongeling et al, 2002; Leviton and Nelson, 1992; Mercuri et al, 1999; Nelson and Leviton, 1991; Rutherford et al, 1994; Shalak et al, 2003; Thompson et al, 1997). We used the term *hypoxic-ischemic encephalopathy* (HIE) in the past, but this term described the clinical picture of the encephalopathic infant with hyperexcitability or lethargy leading to coma and often neonatal seizures. Thus, “HIE” implied that we knew the cause, but the reality is that many of these infants did not have a clear history of an asphyxiating insult. They may have had low Apgar scores or low cord pH or may have required resuscitation at delivery, but these findings indicate infant response, not the nature of the insult. Accordingly, the more neutral term *neonatal encephalopathy* is preferred.

Severity of neonatal encephalopathy is the best predictor of neurodevelopmental outcome (Dixon et al, 2002; Ekert et al, 1997; Ishikawa et al, 1987; Jongeling et al, 2002; Mercuri et al, 1999; Robertson et al, 1989; Rutherford et al, 1994; Yeo and Tudehope, 1994). Infants with severe encephalopathy die or develop major disabilities. Major disabilities tend to be severe and multiple, including severe mental retardation, spastic quadriplegia or mixed cerebral palsy, microcephaly, seizure disorder, cortical blindness, and/or hearing impairment. Children with moderate encephalopathy have an increased incidence (21% to 46%) of major disabilities. Many without major disabilities have lower scores on tests of intelligence, visual-motor integration, vocabulary, reading, spelling, and arithmetic than such scores achieved by either healthy peers or children with mild encephalopathy. Findings of abnormalities on physical examination, neuroimaging studies (especially magnetic resonance imaging [MRI]), and electroencephalography (EEG) can be helpful in predicting neurodevelopmental outcome for infants with neonatal encephalopathy.

Infants with persistent pulmonary hypertension have a higher risk of major disability (13% to 24%), mild impairments (minor neuromotor dysfunction, borderline intelligence, and attention problems in up to 30%), and hearing impairment (Marron et al, 1992; Walsh-Sukys et al, 1994). The hearing loss can be progressive, which highlights the need for serial audiologic evaluations in addition to neurodevelopmental follow-up evaluation in this population. Likewise, neonates treated with extracorporeal membrane oxygenation (ECMO) have a variety of life-threatening conditions that carry an increased risk of neurodevelopmental disability (Bernbaum et al, 1995; Bulas et al, 1995; Lago et al, 1995; Revenis et al, 1992; Robertson et al, 1995; Stolar et al, 1995). From 2% to 26% of survivors of ECMO develop major disability, and 3% to 21% develop hearing impairment. Mild disability, including borderline intelligence, language delay, visual impairment, and minor neuromotor dysfunction, occurs in 8% to 49%. Glass and colleagues (1995) found that 5-year-old ECMO survivors had an 11% incidence of mental retardation (1% profound mental retardation), 5% cerebral palsy (most had mild cerebral palsy), 2% severe learning disabilities, and a lower mean IQ than that in 37 healthy control children (96 versus 115,  $P < .001$ ). Adverse neurodevelopmental

outcome was associated with lower birth weight, sepsis, congenital diaphragmatic hernia, and abnormal findings on neuroimaging studies.

Infants with congenital anomalies have an increased risk of neurodevelopmental disability. Children with hypoplastic left heart syndrome, for example, can have cognitive, adaptive and behavioral abnormalities related to maldevelopment, hypoxia/ischemia, and a prolonged circulatory arrest time during cardiac surgery (Ikle et al, 2003; Kern et al, 1998; Rogers et al, 1995). Much more research is needed to understand the scope of neurodevelopmental deficits in NICU infants with these and other congenital anomalies.

## HEALTH AND GROWTH

Although NICU infants are much improved at the time of discharge, many have lingering medical problems that require close follow-up evaluation by their primary care providers. They remain vulnerable to infections, further complications, difficulty feeding, and poor growth. Rehospitalization for illness (especially respiratory illness) or surgery (e.g., umbilical hernia repair, gastrostomy, Nissen fundoplication) is common (Combs-Orme et al, 1988; Lefebvre et al, 1988; Survanta Multidose Study Group, 1994; Teplin et al, 1991).

Adequate nutrition is essential for growth of the developing infant, especially for brain growth. Good weight gain, linear growth, and head growth are good measures of nutrition. Preterm infants are frequently below the 5th percentile for chronologic age, but they should grow along their own parallel curve, and some growth curves specific to LBW infants have been developed (Casey et al, 1991). Although most infants catch up in their growth within several years, some infants with extreme prematurity, IUGR, severe neonatal illness, or syndromes such as fetal alcohol syndrome always remain small for their age.

Infants who exhibit significant deviation below normal on growth curves should be evaluated for undetected or inadequately treated gastrointestinal, pulmonary, urologic, or cardiac conditions. Gastroesophageal reflux can lead to discomfort from esophagitis, irritability, extensor posturing, and poor growth. Some children with genetic syndromes or who were critically ill as newborns demonstrate decreased appetite, food refusal, and poor growth. Oromotor dysfunction, with poorly coordinated suck and swallow, must be considered in NICU newborns with poor growth, food refusal behaviors, or neurologic abnormalities. Infants with chronic lung disease or congestive heart failure may tire with feedings and require frequent interruptions because of exercise intolerance.

An oromotor evaluation by an occupational therapist or speech pathologist may include a radiographic swallow study to pinpoint the problem, to determine if oral feeding is safe, and to assess how the infant handles liquids versus solid foods. The cause of the feeding problem determines treatment: positioning, thickening liquids, medications, and possibly surgery for infants with gastroesophageal reflux; calorically dense food for poor appetite and growth; behavior management program for food refusal behavior not due to organic causes; supplemental

oxygen for children with intermittent hypoxia; and gastrostomy for children who chronically aspirate, have severe oromotor dysfunction, or demonstrate food refusal unresponsive to behavioral interventions. Children fed totally or primarily by gastrostomy require an oromotor stimulation program to maintain feeding skills and prevent oromotor hypersensitivity. When NICU infants are discharged with gastrostomy, continuous feedings, special formulas, or dietary supplements, they require specific nutritional or gastrointestinal follow-up evaluation to address changing needs and parental concerns.

Chronic lung disease (i.e., bronchopulmonary dysplasia) occurs in 11% to 40% of VLBW preterm infants, 7% to 9% of more mature preterm infants, 7% to 35% of full-term infants with persistent pulmonary hypertension, 15% to 40% of infants treated with ECMO, and 63% of infants with congenital diaphragmatic hernia (Bernbaum et al, 1995; Ferrara et al, 1991; Glass et al, 1995; Hack et al, 1994; Revenis et al, 1992; Survanta Multidose Study Group, 1994; Walsh-Sukys et al, 1994). These children are vulnerable to respiratory infections, and they frequently require bronchodilators, oxygen supplement, or diuretics. The experienced clinician uses clinical history, physical examination, evidence of growth, signs of exercise intolerance, and pulse oximetry (especially during feeding and sleep) in making decisions regarding tapering oxygen supplements and diuretics. Infants who are well oxygenated at rest may be relying on their reserves and have difficulties when nipple feeding or sleeping. Some infants with chronic lung disease have transient increases in oxygen requirements during periods of accelerated growth.

Developmental interventions for medically fragile infants should be home based whenever possible to reduce the risks of infection. Infants should be shielded from friends and family with infectious illnesses. Therapists who provide early intervention should be skilled in working with these infants, should recognize the signs of exercise intolerance or increasing distress, and should be trained in how to respond promptly in an emergency (e.g., cardiopulmonary resuscitation training). Infants on supplemental oxygen may need an increase in oxygen when handled.

Preterm infants and other high-risk infants need the protection from childhood illnesses that is conferred by immunization. Immunizations should be given according to the recommended schedule (Saari et al, 2003). Even in extremely preterm infants, full doses appropriate for chronologic age should be used. Infants who are still in the NICU or who are immunocompromised (or whose family includes an immunocompromised person) should not be given live viral vaccines. Pertussis protection should be deferred only for infants with signs of neurologic deterioration or uncontrolled seizure disorder, although it may be postponed pending diagnostic evaluation in a child with recent onset of seizures.

### **FOLLOW-UP EVALUATION OF THE HIGH-RISK INFANT**

The high-risk NICU infant's medical problems, increased risk of neurodevelopmental disability, and uncertainty regarding outcome necessitate long-term follow-up evaluation.

### **Importance of Discharge Planning**

Good discharge planning aims to smooth the infant's transition from hospital to home and to provide the health care, developmental, and parental supports needed by the infant and family. A parent conference that reviews the infant's hospital course and plans for discharge provides an opportunity to discuss the infant's risk status, to assess the parent's understanding, to appreciate the infant's progress, and to begin to make plans for discharge home. In the review of the infant's various risk factors, an honest but sensitive discussion puts the infant's risk for neurodevelopmental disabilities into perspective, giving the range of possible outcomes. Parents should be reassured whenever possible, given the opportunity to hope, and provided with perspective on their infant's risks.

Discharge teaching includes well-baby care (for first-time parents); techniques of cardiopulmonary resuscitation (useful for all parents); use of any special equipment or medication; and recommendations regarding infant car seats, bedding, feeding, positioning, and handling. Plans for follow-up care after hospital discharge should address both the infant's and the family's special needs. All infants discharged from a NICU should have a designated primary care provider who can follow the infant closely and address the infant's special needs as they emerge. Preterm infants with retinopathy of prematurity, incompletely vascularized retinas, congenital infection, or cortical abnormalities require ophthalmologic follow-up evaluation. Infants who failed or did not receive audiologic screening require audiologic follow-up evaluation. Infants with specific medical conditions may require pediatric surgical, pulmonary, gastrointestinal, nutritional, cardiologic, neurologic, orthopedic, or other subspecialty follow-up evaluations.

### **Comprehensive Developmental Follow-up Evaluation**

Criteria for referral of high-risk NICU infants for comprehensive developmental follow-up vary widely, based on available resources, funding, geography, and family needs. Ideally, all NICU infants should be viewed as high risk and offered comprehensive developmental follow-up evaluations through school age. Incentives for families to return for follow-up evaluations encourage high follow-up rates, thereby providing NICUs with accurate outcome data for specific conditions. Close relationships between a NICU follow-up clinic and community health, educational, and social services promote coordination of intervention services based on the child's and family's needs. Limited resources and funding, organizational difficulties, and time constraints all interfere with ideal comprehensive, coordinated, family-focused follow-up and intervention efforts. Although often considered dispensable, developmental follow-up evaluations and early intervention should be viewed as an essential part of the continuum of care provided to high-risk infants and their families.

The goals of comprehensive, coordinated developmental follow-up are to help the family optimize the child's growth and development; to help integrate the child into the family, school, and community; and to intervene when possible to reduce future medical, social, and emotional costs. These

goals are promoted by the recognition that each child is an individual with unique qualities, strengths, impairments, and abilities, and that each family differs in background, social supports, finances, and personal coping mechanisms.

Follow-up is a dynamic process that evolves as the child grows, develops, and increasingly interacts with his or her environment. Recognition of impairments, disabilities, and handicaps relies on parental reports, an appreciation of individual variability in the normal pattern of development over time, and the examiner's assessment skills and ability to determine the significance of abnormalities or deviations from the normal pattern. Once recognized, problems should be discussed with parents, including a nonmedical definition of specific diagnoses (e.g., cerebral palsy, learning disability) and identification of specific intervention strategies.

Assessing the development of the high-risk infant relies on the basic tools of medicine: the history and the physical examination. The focus of the developmental history is to obtain information about the infant's behavior (e.g., sleep, feeding, temperament, behavior problems) and developmental milestone acquisition. The physical examination is expanded to a neurodevelopmental examination

that includes an assessment of posture, muscle tone, reflexes, and functional abilities.

The developmental milestones should be viewed in terms of the major streams of development: gross motor, fine motor, adaptive, and language abilities (Tables 67–6 and 67–7). Gross and fine motor abilities are used to assess motor development and to screen for cerebral palsy and minor neuromotor dysfunction. Children with cerebral palsy generally have significant motor delay and persistent neuromotor abnormalities. Children with minor neuromotor dysfunction have milder or no delay and mild neuromotor abnormalities on examination. Delay in adaptive, or self-help, skills may be seen with mental retardation, cerebral palsy, minor neuromotor dysfunction, or environmental or behavioral causes (e.g., the child's mother did not introduce a fork or took it away). Delay in language abilities can signal mental retardation, hearing impairment, or language disorder and requires an audiologic evaluation.

Assessing milestone acquisition in preterm infants raises the controversial question of whether to correct for the degree of prematurity. This issue is most important early in life and in extremely preterm infants. Consider

**TABLE 67–6****Gross and Fine Motor Milestone Attainment**

Milestone	Motor Milestone Attainment (in months)	
	Mean Age*	Delay Criterion†
<b>Gross Motor Abilities</b>		
Roll over prone to supine	3.6	5.5
Roll over supine to prone	4.8	7.25
Sit with arm support‡	5.3	8.0
Sit without arm support§	6.3	9.5
Creep	6.7	10.25
Come to sit¶	7.5	11.25
Crawl**	7.8	11.75
Pull to stand on furniture	8.1	12.25
Cruise††	8.8	13.25
Walk independently	11.7	17.25
Walk backwards	14.3	
Run	14.8	
<b>Fine Motor Abilities</b>		
Unfisted	3	
Brings hands to midline	3	
Unilateral reach and grasp	4	
Transfers object from hand to hand	5	
Raking grasp	6	
Three-finger grasp (picks up pellets)	8	
Mature pincer grasp	11	
Good voluntary release	12	

\*Gross motor milestone mean ages of attainment from a longitudinal study of 381 normal full-term children, followed from birth to 2 years (Capute et al, 1985).

†Delay criteria from Allen and Alexander, 1994.

‡Sit with arm support uses arms to maintain balance in sitting but not propped up with pillows.

§Sit without arm support means good independent sitting, without using arms for balance.

||Creep means pulling self forward on abdomen, using arms and legs for propulsion.

¶Come to sit means independently getting into a sitting position from supine or prone, without pulling up on furniture.

\*\*Crawl means good reciprocal crawl, up on hands and knees.

††Cruise means walking holding onto furniture.

TABLE 67-7

## Language Milestone Attainment

Milestone	Milestone Attainment: Mean Age (mo)	Standard Deviation
Alert to sound*	0.25	0.3
Social smile*	1.2	0.5
Coo (musical vowel sounds)	1.5	0.6
Orient (turn) to voice*	2.8	1.2
Say "ah-goo"	4.0	1.6
Make raspberry (razz, "Bronx cheer")	4.4	1.6
Babble (repetitive consonant sound)	6.3	1.4
"Mama"/"Dada" indiscriminately	7.7	1.7
Gesture language (e.g., peekaboo)*	8.6	1.5
"Dada" discriminately	10.5	2.5
"Mama" discriminately	11.1	2.7
Follow one-step command with gesture*	11.1	1.7
First meaningful word (not a name)	11.3	2.3
Immature jargon (no words)	12.2	2.1
Second meaningful word (no names)	12.4	2.2
Third meaningful word (no names)	13.2	2.2
Follow one-step command without gesture*	13.6	2.1
Use four to six words (not including names)	14.7	2.5
Mature jargon (includes words)	16.5	2.9
Point to five body parts when asked*	16.7	2.8
Use 7- to 10-word vocabulary	16.9	2.9
Use novel two-word combinations	19.2	3.0
Use two- to three-word sentences	20.9	3.0
Use 50-word vocabulary	20.9	3.2

\*Receptive language milestones; the remainder are expressive language milestones.

Data from Clinical Linguistic and Auditory Milestone Scale (CLAMS), Capute and Accardo (1978), and Capute et al (1986a).

the following example: An infant born at 27 weeks of gestation is now 6 months old and not yet rolling over but plays with her hands in midline, and can support herself on her forearms in prone position (see Table 67-6). Her motor quotient (i.e., developmental age divided by chronological age) is 50 (i.e., 50% of normal—therefore delayed). If one corrects for degree of prematurity (using her term age equivalent/adjusted age/corrected age), her motor quotient is 100 (i.e., normal). Her developmental status at this age is determined by whether one corrects for degree of prematurity. At 5 years, correction is no longer important, because children between 57 and 60 months of age do not significantly differ.

When considering correction for degree of prematurity, the clinician should evaluate each stream of development separately because they may differ in responsiveness to environmental stimulation. Earlier exposure to the extrauterine environment may have greater effect on the development of language than on motor development. Language, a component of cognition, may be accelerated by early extrauterine experience (Eilers et al, 1993).

Traditionally, psychologists do correct for degree of prematurity in preterm infants when assessing cognition. They do not agree on full versus partial correction or on how long to correct: for 1 year, 2 years, or indefinitely (Allen, 2002; Aylward, 2002). There is some concern that correcting for degree of prematurity overestimates a

child's cognitive abilities and may fail to identify those infants who would benefit from early intervention (Den Ouden et al, 1991; Thompson et al, 1993). Nevertheless, most agree to correct for degree of prematurity for at least 2 years. This issue is important early in infancy and with the most immature infants, but it influences outcomes until 8.5 years (Rickards et al, 1989). Preterm children with language or cognitive abilities consistently below their age corrected for degree of prematurity should be referred for multidisciplinary evaluation and early intervention.

Using age at attainment of the motor milestones is a quick, practical, and inexpensive method of identifying infants at highest risk of having cerebral palsy (Allen and Alexander, 1994, 1997). It is most effective when a history of motor milestone attainment is obtained at each child care visit, when correction for degree of prematurity is done, and when 50% delay criteria are used (see Table 67-7). Infants identified as demonstrating motor delay warrant a comprehensive neurodevelopmental examination, multidisciplinary evaluation, and often referral for physical and occupational therapy.

Language assessments such as the Clinical Linguistic and Auditory Milestone Scale (CLAMS) (see Table 67-7) can be used to follow language development and to screen for cognitive delays (Capute and Accardo, 1978; Capute et al, 1986a, 1986b; Rossman et al, 1994; Wachtel

et al, 1994). Infants identified as having language delays should then be referred for both hearing assessment and neuropsychological testing. Many follow-up clinics rely on neuropsychologists to assess the cognition of high-risk infants, either with sequential assessments or with one or two carefully timed assessments (e.g., at 12, 18, or 24 months). A number of frequently used cognitive tests developed for use in infants and children are listed in Table 67-8.

### Referral for Multidisciplinary Evaluation and Early Intervention Services

Infants with identified developmental delays should be referred for a multidisciplinary evaluation that assesses all aspects of development. Brain injury is more likely to be diffuse than focal, and more than one stream of development may be affected. Although the most obvious abnormality is identified first, this may not be the most disabling of the child's problems. A preterm infant who presents with delayed walking and tight heel cords may be diagnosed with mild spastic diplegia. This child has an excellent prognosis for walking, running, and good motor function. Problems associated with cerebral palsy (e.g., learning disability, myopia, attention deficit) may have far more impact on the child's quality of life and adult functioning than will the presenting motor impairment.

Part H of Public Law (PL) 99-157 passed by the U.S. Congress in 1986, followed by the Individuals with Disabilities Education Act (IDEA, PL 101-476 and PL 102-119) in 1990, encouraged and then required states to provide a comprehensive, coordinated interagency system of early intervention services for infants and toddlers with developmental delays and with conditions that lead to

developmental delays (e.g., Down syndrome, fetal alcohol syndrome). Some states also provide services for high-risk infants and their families. Infants may be referred by NICUs, NICU follow-up clinics, pediatricians, or families. Each child who is referred is entitled to a multidisciplinary assessment and a service coordinator to help coordinate the assessment and services. If the child is eligible for the program, the parents, service coordinator, and multidisciplinary team devise an individualized family service plan (IFSP) that identifies the child's and family's needs and what services will be used to address these needs. This program recognizes the importance of (1) viewing each child as a unique individual, (2) evaluating not only needs but also strengths, (3) including the family in the planning process, and (4) coordinating all intervention services.

Early intervention strategies minimize secondary complications and provide much-needed parental support in coping with disability or uncertainty. The choice of interventions is determined by the individual child's developmental profile and health, the needs of the family, and available resources. Programs or services that enable the family to meet the child's needs better (e.g., drug counseling, transportation, parent support groups) also are identified.

Although a number of studies have demonstrated beneficial effects of early intervention programs, there is no proof that early intervention prevents neurodevelopmental disability (Achenbach et al, 1993; Bennett and Guralnick, 1991; Brooks-Gunn et al, 1994; Infant Health and Development Program, 1990; Palmer et al, 1988; Piper et al, 1986; Ramey et al, 1992; Rothberg et al, 1991). One difficulty lies with the use of the global term *early intervention*, which covers many different intervention strategies. Early intervention can be as nonspecific as providing social work support and parent classes

**TABLE 67-8**

#### Cognitive Tests for Infants and Children

\*MDI, mental developmental index. The Bayley also has a motor and behavior scale.

<sup>†</sup>DQ, developmental quotient, including both a CLAMS DQ and CAT DQ.

<sup>‡</sup>GCI, general cognitive index, a composite of the verbal, perceptual/performance, and quantitative scales.

<sup>§</sup>FS IQ, full-scale intelligence quotient; VIQ, verbal intelligence quotient; PIQ, performance intelligence quotient. The Wechsler tests have 13 subtests that compose its verbal and performance scales, and these two scales are combined to give the full-scale IQ.

on infant development or as specific as a physical therapy intervention aimed at facilitating coming to a sitting position from supine in a child with the prerequisite skills and postural reactions. Early intervention for a child with severe spastic quadriplegia would include recommendations for positioning and handling the child and providing adaptive equipment for sitting, traveling, eating, and communication. Designing good intervention trials that evaluate the efficacy of specific intervention strategies is complicated by the fact that each person is so unique. This makes it difficult to define study sample criteria and outcomes and to match disabled children for randomization.

Nevertheless, each intervention strategy must be evaluated for efficacy in a well-defined population. Both hearing and visual impairments are responsive to early intervention services that can dramatically improve the child's functioning and quality of life, especially if begun early. Infants with severe hearing impairments may benefit from wearing hearing aids, learning to respond to and to use sign language, specific educational interventions using multiple sensory modalities and parental support. Studies have shown that a focused educational intervention for preterm infants has beneficial initial effects on cognition and behavior, although long-term benefits have not been proved (Achenbach et al, 1993; Brooks-Gunn et al, 1994; Infant Health and Development Program, 1990; Ramey et al, 1992). Few early intervention studies have evaluated whether there is an effect on function at school or at home. These functional abilities may be not only the most responsive to early intervention but also the most important outcome variables. Studies have been limited to short-term interventions. It stands to reason that most benefit can be derived from long-term, continuous interventions.

## SUMMARY

Although children who required neonatal intensive care have a higher incidence of neurodevelopmental disabilities and health sequelae, most survivors are healthy and function well. The likelihood, type, and severity of disability vary with the condition requiring neonatal intensive care, with various perinatal and demographic risk factors, and perhaps with availability of developmental supports for the child and social supports for the family. It is impossible to diagnose neurodevelopmental disabilities with certainty in the neonatal period. Absence of risk factors and neurologic abnormalities is reassuring. Multiple or severe risk factors can identify infants at high risk for disability.

The uncertainty regarding an infant's outcome and the dynamic nature of early infant and child development necessitate careful medical and developmental follow-up evaluation of high-risk NICU infants during infancy and childhood. Survival is not the only goal of neonatal intensive care. Because the NICU is but the first step in an infant's life, follow-up (or perhaps follow-through) is an important component of the continuum of care that should be offered to high-risk infants. The goals of follow-up are to assist the family to optimize the child's growth

and development so that the child is as functional as possible and to help integrate the child into the family, school, and community.

## NUTRITION

Editor: ROBERTA A. BALLARD

CHAPTER  
68Enteral Nutrition for  
the High-Risk Neonate

Richard J. Schanler

In the neonatal period, high-risk premature infants have greater nutritional needs to achieve optimal growth than at any time in life. The circumstance of preterm delivery results in decreased nutrient deposition in the infant. The medical condition of these infants also imposes additional burdens on nutrient supply. Impediments to growth include the stress of common pathophysiologic events (hypertension, hypoxia, acidosis, infection, surgical intervention) and their therapies (corticosteroids), as well as physiologic immaturity (decreased gastrointestinal motility and delayed enzyme expression). There is also the fear, despite the lack of evidence-based data, that aggressive feeding may produce pathologic conditions such as feeding intolerance and necrotizing enterocolitis (NEC), and that some nutritional regimens may produce toxic effects on organ development. Finally, intense support is needed to correct growth restrictions present at birth and to continue appropriate weight gain, which is nearly double that in a term infant. Thus, the premature infant requires specialized nutritional support to meet these great demands for growth.

Special considerations regarding nutrient needs of premature infants arise at birth. Because of limited body stores, increased expenditure, severity of illness, and/or immaturity and inability to tolerate enteral feedings, premature infants are given parenteral nutrient mixtures immediately from birth. Enteral feedings are often precluded because of the multiplicity of medical problems, but gastrointestinal priming with minimal quantities of milk is used to stimulate intestinal function. As the infant matures physiologically and the medical condition stabilizes, parenteral nutrition is slowly replaced with enteral nutrition. This chapter describes the enteral nutrition support for high-risk neonates.

**GOALS FOR NUTRITIONAL SUPPORT**

The nutritional reference standard for the term newborn is the exclusively breast-fed infant. A similar standard is not available for premature infants. Instead, the reference

standard for the premature infant is the estimated nutrient intrauterine accretion rate achieved at corresponding stages during the last trimester of pregnancy. Data derived from the chemical analyses of fetal cadavers have been used to construct normative curves of net nutrient deposition or retention during the last trimester of pregnancy. From analyses of smoothed curves, these data have been computed on a daily basis per kilogram of body weight (Table 68–1). Although the original data were derived from human fetal cadaver analyses, the data for several minerals have been corroborated by noninvasive neutron activation techniques (Ellis et al, 1993).

The intrauterine accretion data provide a reference for nutrient deposition. In the absence of direct experimental verification, one way to determine the advisable intake for a particular nutrient is to use the factorial approach (Table 68–2). This method includes a summation of the quantity of the nutrient deposited and an estimate of nutrient losses. For infants receiving parenteral nutrition only, the advisable intake includes estimates of nutrient deposition, cutaneous and urinary losses, and an additional allowance to account for variability. For enteral nutrition, the factorial approach is amended to account also for the bioavailability of the particular nutrient. The intrauterine data also provide a minimal estimate of the postnatal rate of weight gain and incremental increases in length and head circumference that parallel the growth of the last-trimester fetus (Table 68–3).

**GASTROINTESTINAL PRIMING**

The lack of enteral nutrients poses several problems for the development of the intestinal tract. In several animal species, the absence of enteral nutrients is associated with diminished intestinal growth, atrophy of intestinal mucosa, delayed maturation of intestinal enzymes, and increases in permeability and bacterial translocation. A lack of enteral nutrients also affects intestinal motility, perfusion, and hormonal responses. The hormonal response to feeding premature infants has been evaluated by measuring the plasma concentrations of a variety of gastrointestinal hormones in response to milk feeding during the first week after birth (Lucas et al, 1986). Significant hormonal surges were noted after milk feeding, but no response was observed in the absence of feeding. The responses to feeding were observed in both healthy premature infants and those with respiratory distress. In further investigations, it was observed that hormonal surges of gastrin, gastric inhibitory polypeptide (GIP), and enteroglucagon occurred after the feeding of small quantities of milk (24 mL), but

**TABLE 68-1****Estimated Intrauterine Nutrient Accretion Rates**

Nutrient*	Units/kg/day
Calcium (mg)	105
Copper ( $\mu$ g)	50
Magnesium (mg)	2.7
Nitrogen (mg)	325
Phosphorus (mg)	70
Potassium (mEq)	0.7
Sodium (mEq)	1.2
Zinc ( $\mu$ g)	240

\*Values averaged from last trimester, adjusted for body weight.

motilin surges were not observed until the cumulative milk intake was 700 mL (Lucas et al, 1986).

The foregoing observations prompted prospective randomized clinical studies of the effects of small volumes of milk given as early minimal enteral feeding, or trophic feeding, in premature infants. When studied in the first or second week after birth, infants who received "early" milk feedings had a better feeding tolerance when feedings were advanced, required a shorter duration of parenteral nutrition, and had a lower incidence of conjugated hyperbilirubinemia compared with similar infants given only parenteral nutrition during the same interval (Dunn et al, 1988; Stagle and Gross, 1988). Probably because of better tolerance to feeding, premature infants receiving the trophic feedings had cumulatively greater milk intakes, which were associated with lower serum alkaline phosphatase activity (Dunn et al, 1988). The lower alkaline phosphatase activity, primarily of bone origin, was observed for 14 weeks, well beyond the initial intervention in the first week. Significant stimulation of gastrointestinal hormones, such as gastrin and GIP, also was reported following the early feeding of small quantities of milk (Meetze et al, 1992). Intestinal motility patterns matured more rapidly in premature infants receiving early enteral feeding (Berseeth, 1992). Subsequent investigations demonstrated

**TABLE 68-2****Estimating Optimal Nutrient Intake: Factorial Approach**

Example: Calcium	
Net calcium deposition	105 mg/kg/day
Urinary losses	5 mg/kg/day
Cutaneous losses	2 mg/kg/day
Subtotal	112 mg/kg/day
Net absorption	50%
Variability	10%
Total	246 mg/kg/day

Thus, by adding deposition and losses and accounting for absorption and variability coefficients, the advisable calcium intake for a particular formula is 246 mg/kg/day.

**TABLE 68-3****Growth Guidelines**

Weight gain	>15 g/kg/day for infants <2.0 kg >20 g/day for infants >2.0 kg
Length gain	0.7-1.0 cm/wk
Head circumference gain	0.7-1.0 cm/wk

that trophic feeding was associated with greater absorption of calcium and phosphorus, greater lactase activity, and reduced intestinal permeability (Schanler et al; Shulman et al, 1998a, 1998b). The meta-analysis of several studies of gastrointestinal priming indicated that its use was associated with a shorter time to regain birth weight, fewer days when feeding was withheld, and a shorter duration of hospitalization but no increase in the incidence of NEC (Table 68-4). Noteworthy in the studies of minimal enteral nutrition is that the subject population consisted of premature infants selected because they had the greatest risk of feeding intolerance and NEC. Feedings were administered during mechanical ventilation and while umbilical arterial and venous catheters were in place (Davey et al, 1994; Dunn et al, 1988; Slagle and Gross, 1988). The infants also had the usual pathologic conditions of patent ductus arteriosus, intraventricular hemorrhage, and systemic hypotension. These data suggest that by the end of the first week after birth, and in the absence of evidence of cardiovascular instability (severe acidosis, hypotension, hypoxemia), small volumes of milk can be administered to premature infants. In general, for infants who are ill, the small volumes of 10 to 20 mL/kg/day continue for approximately 4 to 7 days before there is any consideration of advancing the milk volume (Schanler et al, 1999a). The decision for advancement of feedings, however, is made after clinical feeding tolerance is proved and clinical stability is achieved.

**TABLE 68-4****Advantages of Gastrointestinal Priming**

Shortens time to regain birth weight
Improves feeding tolerance
Reduces duration of parenteral nutrition
Enhances enzyme maturation
Reduces intestinal permeability
Improves gastrointestinal motility
Matures hormone responses
Improves mineral absorption, mineralization
Lowers incidence of cholestasis
Reduces duration of phototherapy
Earlier use of mother's milk
Mother begins milk expression earlier
Infant receives more mother's milk
Psychological advantage for mother
Safety

## ENTERAL NUTRITION

### Energy

The energy needs of the neonate are derived from a computation of the energy expenditure, energy storage (growth), and energy losses. Energy expenditure consists of the energy needed to cover the resting metabolic rate, activity, thermoregulation, new tissue synthesis, and thermic effect of feeding. Energy storage consists of the energy (fat and lean mass) deposited for growth. Energy losses usually are due to incomplete absorption of nutrients and are greater in premature infants than in term infants or adults (Groh-Wargo, 2000).

The daily energy needs for the growing premature infant are summarized in Table 68-5. The values are not absolute. The range in resting energy expenditure has been reported from 49 to 60 kcal/kg/day at 8 to 63 days of postnatal age (Sinclair, 1978). When nourished parenterally, the premature infant has less fecal energy loss, generally fewer episodes of cold stress, and somewhat lesser activity so that the actual energy needs for growth are lowered to approximately 80 to 100 kcal/kg/day. In circumstances of chronic disease, such as bronchopulmonary dysplasia, the resting energy expenditure rises significantly (Weinstein and Oh, 1981; Yunis and Oh, 1989). Total energy needs in premature infants with bronchopulmonary dysplasia are increased because of greater energy expenditure, activity, and fecal energy losses. It is not surprising to find that these infants may require 150 kcal/kg/day to achieve weight gain.

After protein and essential fatty acid needs are met, the remaining energy needs are divided equally between fat and carbohydrate. A balanced distribution of fat and carbohydrate calories is appropriate to avoid potential effects on respiratory metabolism, especially in infants who are ill. A distribution of calories favoring glucose (and thus lower in fat) or a surplus of glucose calories such that glucose is converted to fat will increase the production of carbon dioxide, increase alveolar minute ventilation, and raise the respiratory quotient and may increase oxygen consumption (Bresson et al, 1991; Piedboeuf et al, 1991). In addition, a balanced distribution of glucose-lipid calories favors protein accretion, whereas glucose-only solutions are associated with protein oxidation and poor nitrogen

utilization (Salas-Salvadó et al, 1993). Daily monitoring of the intakes for all energy sources is essential to ensure a relatively balanced distribution of calories derived from glucose and fat.

### Protein

#### Milk Composition

In the first few weeks after birth, the protein content of milk from mothers who deliver premature infants (preterm milk) is greater than that of milk obtained from women delivering term infants (term milk) (Atkinson et al, 1978). The protein content of both milks declines over time, such that beyond 2 weeks it levels off to that of what we call mature milk. The quality of protein—the proportion of whey and casein—in human milk is particularly suitable for the premature infant. Human milk contains 70% whey and 30% casein, whereas bovine milk contains 18% whey and 82% casein. A whey- and/or casein-dominant commercial formula, therefore, refers to these proportions of bovine milk. The whey fraction of milk consists of soluble proteins that are digested more easily. Human milk and then whey-dominated bovine milk, in that order, promote more rapid gastric emptying than occurs with casein-dominated milk (Billeaud et al, 1990). Elevated concentrations of potentially toxic amino acids (phenylalanine, methionine, and tyrosine) are reported in premature infants fed formulas with high casein content (Gaull et al, 1977; Rassin et al, 1977). Hepatic enzyme immaturity may explain the higher plasma amino acid concentrations. Because we infer that elevations of particular amino acids may be toxic to brain development, there may be a concern when premature infants are fed a casein-dominant milk, especially at a high protein intake.

The compositions of the whey fractions of human and bovine milks differ significantly. The major human whey protein is  $\alpha$ -lactalbumin, a nutritional protein for the infant and a component of mammary gland lactose synthesis. Lactoferrin, lysozyme, and secretory immunoglobulin A (sIgA) are specific human whey proteins that are particularly resistant to hydrolysis, and, as such, line the gastrointestinal tract to play a primary role in host defense (Schanler et al, 1986). These proteins, therefore, may be suitable for the premature infant who is exposed to multiple pathogens in the nursery environment. The three host defense proteins are present in only trace quantities in bovine milk. The major whey protein in bovine milk is  $\beta$ -lactoglobulin, the protein often blamed for bovine milk protein allergy and colic (Savilahti and Kuitunen, 1992).

The major amino acid for the fetus and in human milk is glutamine, which is not found in commercial formula because of problems with stability of the free amino acid. Glutamine, however, is an important amino acid for cell growth, specifically intestinal epithelial growth; has a role in immune function; and is a precursor in glutathione synthesis. When commercial formula was supplemented with glutamine under experimental conditions, premature infants had better feeding tolerance and a significantly lower incidence of sepsis than were found in infants fed unsupplemented formula (Neu et al, 1997). Further research efforts

**TABLE 68-5**

#### Partition of Energy Needs for Growing Premature Infants

Component	kcal/kg/day
Resting energy expenditure	50
Intermittent activity (+30% above resting)	15
Occasional cold stress (thermoregulation)	10
Thermic effect of feeding (synthesis)	8
Fecal loss (10% of intake)	12
Growth allowance (energy storage)	25
Total	120

are under way to define how to supply this amino acid if human milk is not fed to premature infants.

### **Protein Needs**

The quantity and quality of protein needed for premature infants have been investigated (Raiha et al, 1976). Formulas providing protein intakes of 2.25 and 4.50 g/kg/day as either whey- or casein-dominant preparations and pasteurized human milk with a protein intake of approximately 1.6 g/kg/day were compared. Although absolute growth rates reportedly were similar during the in-hospital study, hospitalization periods were longer for the infants fed human milk, suggesting a slower rate of weight gain than that of infants fed formula (Gaull et al, 1977; Rassin et al, 1977). Those infants receiving protein intakes of 4.5 g/kg/day, as well as infants given casein-dominant milk, had more abnormalities in plasma amino acids and protein indices of nutritional status (elevated blood concentrations of urea nitrogen and ammonia, acidosis, lethargy, and fever) suggesting excessive protein intake (Moro et al, 1989). Although generally considered an excessive protein intake, 4.5 g/kg/day was provided, with relatively low energy (115 kcal/kg/day) and mineral intakes. Some investigators comment that the low energy and mineral intakes may have limited the ability to utilize the protein and that such protein intakes may be appropriate if the total diet is adjusted.

The appropriate protein intake for premature infants has been defined further from evaluations of weight gain, nitrogen retention, and serum biochemical indicators of protein nutritional status (Kashyap et al, 1986, 1988). Protein intakes of 2.2 and 2.8 g/kg/day resulted in lower serum indices, weight gain, and nitrogen retention, and intakes of 3.8 g/kg/day appeared to be somewhat excessive. Therefore, protein intakes of approximately 3.5 g/kg/day at 120 kcal/kg/day seem appropriate for the otherwise normal premature infant (Kashyap et al, 1986).

An alternative way to compute the protein needs of the premature infant is to use the factorial approach to add the needs for tissue deposition, derived from intrauterine accretion rates of 1.8 to 2.2 g/kg/day, to the postnatal losses of protein from the skin (approximately 0.2 g/kg/day) and the urine (1.0 g/kg/day). As approximately 85% of the protein is absorbed, the calculated enteral protein intake is 3.5 to 4.0 g/kg/day (Tables 68–6, 68–7, and 68–8).

The previously mentioned studies were conducted using formulations with whole or intact protein. Although fetal nitrogen uptake is composed primarily of amino acids, no data suggest that postnatal formulations include hydrolyzed protein formulations or free amino acids. Whey-dominant protein formulations are well absorbed, and hydrolyzed protein formulations, usually casein-derived, for the otherwise healthy premature infant are not indicated (Table 68–9).

Protein needs should be considered in conjunction with energy. Protein synthesis requires energy. If energy intake is inadequate, protein synthesis may be depressed and amino acid oxidation increases (Groh-Wargi, 2000). Protein retention, or balance, generally is a function of protein intake if energy intake is inadequate (Zlotkin et al,

1981). Excessive protein intake is more of a risk if energy intake is limited.

### **Human Milk Protein Needs**

The aforementioned studies demonstrated that the lowest plasma concentrations of amino acids, albumin, and urea nitrogen and the slowest rates of weight gain were found in human milk–fed premature infants (Kashyap et al, 1990; Raiha et al, 1976). These observations suggest that after the first 2 weeks of feeding, the lower protein intakes in human milk–fed infants may become a concern. To meet protein needs, the human milk–fed premature infant needs a protein supplement (see Table 68–7). Growth rates and serum protein and urea nitrogen concentrations in premature infants increase when human milk is fortified with protein to achieve a protein intake of at least 3 to 3.5 g/kg/day (Polberger et al, 1989). This range of protein intake is adequate if no protein deficit has arisen as a result of a prolonged or deficient parenteral nutrition phase. Even greater intakes of protein may be necessary for premature infants to allow for catch-up protein nutritional support. Thus, intakes closer to 4 g/kg/day, with adequate energy and mineral intakes, often may be indicated.

## **Fat**

### **Milk Composition**

The lipid system in human milk is structured in a way that facilitates fat digestion and absorption. In human milk, fat exists as organized fat globules containing an outer protein coat and an inner lipid core. The type of fatty acids (high palmitic 16:0, oleic 18:1, linoleic 18:2 $\omega$ -6, and linoleic 18:3 $\omega$ -3), their distribution on the triglyceride molecule (16:0 at the 2 position of the molecule), and the presence of bile salt–stimulated lipase (Jensen and Jensen, 1992) are important components of the lipid system in human milk. Because the lipase is heat labile, the superior fat absorption from human milk is reported only when unprocessed milk is fed (Jensen and Jensen, 1992).

The most variable nutrient component in human milk is fat, the major energy source, comprising nearly 50% of the calories. The fat content of human milk varies among women, changes during the day, rises slightly during lactation, and increases dramatically within a single milk expression (Table 68–10) (Neville et al, 1984). The variability in total fat content is unrelated to maternal dietary fat intake. Because it is not homogenized, the fat separates out of human milk on standing. The separated fat may adhere to collection containers, feeding tubes, and syringes. The loss of fat, therefore, robs the premature infant of needed energy. The greatest losses of fat occur in continuous milk infusion systems. Care should be taken in using the continuous milk infusion system to ensure the inclusion of only a short length of tubing. If the system contains a cassette interface, much of the fat will be lost when the tubing system is changed. Milk infusion systems that use a syringe and a small infusion pump, in which the syringe is oriented upright, will allow more complete delivery of fat (Greer et al, 1984).

<sup>o</sup>Vitamin K, 0.5-1.0 mg given at birth.

The following conversion factors are used:

Calcium: 40 mg = 1 mmol = 2 mEq

Phosphorus: 31 mg = 1 mmol

Magnesium: 24 mg = 1 mmol = 2 mEq

Sodium: 23 mg = 1 mmol = 1 mEq

Potassium: 39 mg = 1 mmol = 1 mEq

Chloride: 35 mg = 1 mmol = 1 mEq

Vitamin A: 1 μg retinol = 3.33 IU vitamin A = 6 μg beta-carotene = 1.83 μg retinyl palmitate = 1 retinol equivalent (RE)

Vitamin E: 1 mg alpha-tocopherol = 1 IU vitamin E

Vitamin D: 1 μg vitamin D (cholecalciferol) = 40 IU vitamin D (cholecalciferol)

Niacin: 1 mg niacin = 1 niacin equivalent (NE) = 60 mg tryptophan

Data from Tsang RC, et al (eds): Nutrition of the Preterm Infant: Scientific Basis and Practical Guidelines. Cincinnati, Digital Educational Publishing, in press.

Manufacturers of infant formulas modify their fat blends to mimic the fat absorption from human milk. This accounts for the differences in the constituent fatty acids between human milk and cow's-milk based formulas. Generally, commercial formulations have a greater quantity of medium-chain fatty acids (MCFA) to compensate for the absence of lipase and the unique structure of triglycerides in human milk (Innis, 1992; Jensen and Jensen, 1992). In human milk, saturated fatty acids, particularly palmitic acid, are esterified in the 2 position of the triglyceride molecule. The end product of digestion of the triglyceride is a 2-monoglyceride and minimal free fatty acid. The 2-monoglyceride is absorbed better than the free fatty acid. This enhanced absorption is important because free

palmitic acid has a great tendency to bind with minerals to form soaps. In that event, both fat and mineral absorption would be limited. Thus, the overall structure of human milk is designed to provide optimal fat and mineral absorption.

### Essential Fatty Acids

The essential fatty acids, linoleic and linolenic acids, are present in ample quantities in human milk and commercial formula. Without an adequate intake of these fatty acids, essential fatty acid deficiency (thrombocytopenia, dermatitis, increased infections, and delayed growth)

develops in 1 week. Approximately 0.5 g/kg/day (~4% of total energy intake) of essential fatty acids will prevent the deficiency (Gutcher and Farrell, 1991). Derivatives of linoleic and linolenic acids are arachidonic acid (20:4 $\omega$ -6) and docosahexaenoic acid (22:6 $\omega$ -3). The very-long-chain polyunsaturated fatty acids (PUFA), which are found in human but not bovine milk, are components of phospho-

lipids found in brain, retina, and red blood cell membranes (Clandinin et al, 1992; Uauy and Hoffman, 1991). Arachidonic and docosahexaenoic acids functionally have been associated with body growth, vision, and cognition (Carlson et al, 1993; Uauy and Hoffman, 1991). In addition, the fatty acids are integral parts of prostaglandin metabolism. When their diet was supplemented with PUFA, formula-fed premature infants had red blood cell concentrations of 22.6 $\omega$ -3 paralleling those of similar infants fed human milk (Clandinin et al, 1992). Follow-up studies of such supplemented infants suggest improvements in visual acuity compared with unsupplemented infants, but of similar magnitude to that in infants fed human milk (Carlson et al, 1993). PUFA are now added to many commercial formulas.

### Medium-Chain Fatty Acids

The proportion of MCFA, here defined as carbon length 6:0 to 12:0, is less than 12% of total fatty acids in human milk but approaches 50% in preterm formulas (see Table 68-7). MCFA are not essential fatty acids. Previous reports suggested that MCFA were absorbed passively and to a greater extent than long-chain fatty acids (LCFA) and affected growth and mineral absorption positively (Roy et al, 1975; Tantibhedhyangkul and Hashim, 1978). Data comparing premature infants receiving MCFA at 42% versus 7% of total fatty acids in a crossover design

Data from Valentine CJ, Hurst NM, Schanler RJ: Hindmilk improves weight gain in low-birth-weight infants fed human milk. *J Pediatr Gastroenterol Nutr* 18:474-477, 1994.

demonstrated no differences in either absorption of fat or weight gain (Hamosh et al, 1989). Similarly, no differences in nitrogen retention, weight gain, and energy digestibility, expenditure, and storage were found in premature infants participating in a randomized, crossover study of formulas with MCFA at 46% versus 4% (Whyte et al, 1986). Other reports also confirm the lack of effect of MCFA on weight gain and mineral absorption compared with exclusively LCFA diets (Huston et al, 1983). When used in a high proportion, MCFA may be incompletely oxidized and contribute to increased urinary dicarboxylic acid excretion and metabolic inefficiency compared with LCFA (Rebouche et al, 1990; Wu et al, 1986). When added exogenously to milk, MCFA have been reported to adhere to feeding tubes, thereby diminishing fat delivery to the infant (Mehta et al, 1988). Thus, no compelling data exist to suggest that a high proportion of MCFA is needed for preterm formulas. Indeed, formulas containing a very high proportion of MCFA (>80%) may produce essential fatty acid deficiency if fed for a prolonged period of time.

### Hindmilk

The variability in the fat content of human milk may be used to advantage in the premature infant. Most milk transfer during a feeding occurs in 10 to 15 minutes, but continued milk expression yields a milk with a progressively higher fat content—the hindmilk—than that of the earlier foremilk. The fat content of hindmilk may be 1.5- to 3-fold greater than that of foremilk. The use of hindmilk in selected cases may provide the premature infant with additional energy. Fractionation of each milk expression into two portions, foremilk and hindmilk, is practical if the mother's milk production is greater than that needed by the infant. The additional fat from hindmilk, resulting in increased energy intake, has been shown to improve body weight gain in premature infants (Valentine et al, 1994). The composition of foremilk and hindmilk has been exam-

ined (see Table 68–10). No differences between fractions were observed for the concentration of nitrogen, calcium, phosphorus, sodium, or potassium. Copper and zinc concentrations declined by approximately 5% from foremilk to hindmilk.

The differences between foremilk and hindmilk also should be considered in terms of the distribution of calories. Fat and protein compose 42% and 12%, respectively, of calories in foremilk and 55% and 9% of calories in hindmilk. Theoretically, the long-term feeding of hindmilk could exert a negative effect on protein status. A greater proportion of protein calories (10% to 12%) is recommended for premature infants. Usual commercial human milk fortifiers (Table 68–11; see also Table 68–7), when mixed with hindmilk, raise the proportion of protein calories in hindmilk to approximately 12%. Therefore, the use of hindmilk can be recommended for premature infants whose rate of weight gain is low (below 15 g/kg/day).

### Carnitine

Carnitine is synthesized from lysine and methionine and serves as an important effector of fatty acid oxidation in the mitochondria. The provision of carnitine in the diet results in improved fatty acid oxidation (Bonner et al, 1995). Human milk contains abundant carnitine, and all infant formulas are supplemented with carnitine.

### Carbohydrate

The carbohydrate fraction of human milk is composed of lactose (90% to 95%) and oligosaccharides (5% to 10%). The lactose content of human milk rises from 55 g/L in colostrum to 70 g/L in mature milk. Studies in term infants demonstrate a small proportion of lactose in the feces; the presence of lactose is assumed to be a normal physiologic effect of feeding human milk. A softer stool consistency, more nonpathogenic bacterial fecal flora, and

Data from Ross Products Division, Abbott Laboratories, Columbus, OH, 2003.

improved absorption of minerals have been attributed to the presence of small quantities of unabsorbed lactose in feces (MacLean and Fink, 1980). Dietary lactose also has been associated with increased mineral absorption (Ziegler and Fomon, 1983). Theoretical concerns that lactose may not be digested adequately by premature infants of less than 34 weeks of postmenstrual age may be unfounded, as clinical studies indicate that they tolerate the feeding of lactose-containing milk. Premature infants absorb more than 90% of the lactose in human milk (Atkinson et al, 1981). The feeding of milk and, in particular, human milk to premature infants stimulates intestinal lactase activity compared with no feeding or formula feeding (Shulman et al, 1998a). Thus, early feeding of human milk also may be beneficial to promote better lactose utilization.

Because of conflicting data regarding lactose utilization by premature infants, and as a result of attempts to reduce the osmolality of the milk, preterm formulas contain a large proportion of carbohydrate as corn syrup solids (glucose polymers) (Ziegler and Fomon, 1983). The usual lactose-glucose polymer mixture is 50:50. Glucose polymers are well absorbed by premature infants.

### Calcium and Phosphorus

Calcium and phosphorus are primary components of the skeleton, accounting for 99% and 85%, respectively, of bone mass. The goal for premature infant nutrition is to achieve a bone mineralization pattern similar to that in the fetus, to avoid osteopenia and fractures. Preterm human milk contains approximately 250 mg/L and 140 mg/L, respectively, of calcium and phosphorus (Butte et al, 1984). In contrast, the calcium and phosphorus contents of enteral products designed for premature infants in the United States are significantly greater (see Tables 68-7 and 68-8). In human milk, calcium and phosphorus exist in ionized and complexed forms that are easily absorbed. Thus, in the design of commercial formulas, greater quantities of these minerals are added to compensate for their poorer bioavailability. However, distinct from the term infant, the premature infant requires significantly greater quantities of calcium and phosphorus than can be provided in human milk.

For the human milk-fed premature infant, calcium and phosphorus are deficient throughout lactation, and levels are far below those necessary to achieve respective intrauterine accretion rates (Schanler, 1991). Skeletal radiographs may reveal poor bone mineralization, rickets, and fractures in the premature infant fed human milk (Koo et al, 1988). Deficient intakes of calcium and phosphorus are associated with biochemical markers such as low serum and urine phosphorus concentrations, elevated serum alkaline phosphatase activity, and elevated serum and urine calcium concentrations (Atkinson et al, 1983). Usually, serum phosphorus concentrations are the best indicators of calcium and phosphorus status in human milk-fed premature infants (Aiken et al, 1993). Prolonged deficiency of these minerals tends to stimulate bone resorption to normalize serum calcium concentrations. This bone activity often is correlated with elevated serum alkaline phosphatase

activity. It has been reported that a majority of premature infants who had an elevated serum alkaline phosphatase activity were those fed human milk (Lucas et al, 1989). Moreover, follow-up evaluations of the same infants at 9 and 18 months noted that linear growth was significantly lower in the group that had the higher serum activity of alkaline phosphatase in the neonatal period (Lucas et al, 1989). A high alkaline phosphatase value in the neonatal period is a negative predictor of height in 9- to 12-year-old adolescents (Fewtrell et al, 2000).

The supplementation of human milk with both calcium and phosphorus not only improves the net retention of both minerals but also improves bone mineral content (Horsman et al, 1989; Salle et al, 1986). Current management of human milk-fed premature infants emphasizes the need for supplements of both calcium and phosphorus (Schanler and Garza, 1987). A linear relationship exists between calcium (or phosphorus) intake and net retention in enterally fed premature infants (Schanler and Rifka, 1994). Premature infants receiving unfortified human milk never achieve intrauterine accretion rates for calcium and phosphorus. Intakes of approximately 200 and 100 mg/kg/day, respectively, of calcium and phosphorus can be achieved with the use of specialized human milk fortifiers and preterm formulas, thus making it possible to meet intrauterine estimates (see Tables 68-7, 68-8, and 68-11). However, term infant formulas and specialized (not "preterm") formulas provide inadequate quantities of calcium and phosphorus to meet the needs of growing premature infants (see Tables 68-8 and 68-9). Several factors affect the absorption of calcium and phosphorus, including postnatal age and intake of calcium, phosphorus, lactose, fat, and vitamin D. Vitamin D, however, is responsible for only a small component of calcium absorption in premature infants (Bronner et al, 1992).

The time to supply sufficient calcium and phosphorus stores for premature infants is during the initial hospitalization, before their discharge and the beginning of exclusive breast-feeding. However, because of the need for prolonged parenteral nutrition and the inability to provide "catch-up" quantities of calcium and phosphorus in milk, some infants may benefit from additional calcium and phosphorus after hospital discharge (see later section, "Postdischarge Nutrition").

### Magnesium

Approximately 60% of body magnesium is in bone. Preterm human milk contains approximately 30 mg/L of magnesium (Butte et al, 1984). The absorption of magnesium is significantly greater from unfortified human milk (73%) than from formula (48%) (Schanler and Refka, 1994). Net magnesium retention in human milk-fed premature infants meets intrauterine estimates. Thus, the data from balance studies and biochemical monitoring suggest that magnesium supplements are not needed for premature infants fed human milk (Schanler and Abrams, 1995). Similar studies in premature infants fed preterm formula indicate that, despite lower absorption compared with human milk, intrauterine estimates for magnesium accretion are surpassed.

## Trace Elements

### Zinc

Several factors affect the zinc needs of the enterally fed premature infant. Fetal accretion of zinc is approximately 0.85 mg/kg/day. Growth is a major determinant of zinc needs. The major excretory route is via the gastrointestinal tract. Infants with large gastrointestinal fluid losses may become zinc deficient. Premature infants receiving pooled pasteurized human milk (zinc intake of ~0.7 mg/kg/day) are in negative zinc balance for 60 days postnatally and never meet the intrauterine accretion rate (Dauncey et al, 1977). In contrast, intakes of 1.8 to 2 mg/kg/day are associated with a net retention of zinc that surpasses intrauterine accretion rates (Ehrenkranz et al, 1989; Schanler et al, 1999b; Tyrala, 1986). The classic signs of zinc deficiency include an erythematous skin rash involving perioral, perineal, and facial areas, as well as the extremities (Groh-Wargo, 2000). Although there are limitations to the assay, plasma zinc values lower than 50 µg/dL are highly suggestive of deficiency (Groh-Wargo, 2000). A very low serum alkaline phosphatase activity, a zinc-dependent enzyme, also is suggestive of deficiency. Reports of symptomatic zinc deficiency in unsupplemented human milk-fed premature infants serve as a reminder of the decline in milk zinc concentration as lactation advances. The infants reported to be zinc deficient were several months of age (Bilinski et al, 1987).

### Copper

No universally accepted methods exist to assess copper status clinically. Balance study data provide only an estimate of copper retention at one point in time. Premature infants receiving pooled pasteurized human milk (copper intakes of ~85 µg/kg/day) are in negative copper balance for 30 days postnatally and never meet the intrauterine accretion rate (Dauncey et al, 1977). Fortified human milk provides a copper intake of as much as 180 µg/kg/day, and balance study data surpass intrauterine accretion rates (Schanler et al, 1999b). Copper retention was quite variable in studies using formula providing intakes of 200 to 300 µg/kg/day (Schanler et al, 1999b; Tyrala, 1986). Several premature infants with those intakes, however, achieved the intrauterine accretion rate. Symptoms of copper deficiency include osteopenia, neutropenia, and hypochromic anemia. As copper is excreted in bile, cases of severe cholestasis warrant limiting copper intakes.

### Iron

The iron needs of the premature infant are determined by birth weight, initial hemoglobin, rate of growth, and magnitude of iron loss and/or volume of transfused blood (Groh-Wargo, 2000). Postnatal iron metabolism occurs in three phases. In the first phase, there is decreased erythropoiesis. The hemoglobin concentration declines to a nadir, “physiologic anemia of prematurity,” which is at approximately 2 to 3 months of postnatal age. In the second phase, the hemoglobin rises as active red cell produc-

tion is occurring. In this phase, iron is needed. The third phase is an exhaustion of iron stores, or “late anemia of prematurity,” observed if iron supplementation is inadequate (Groh-Wargo, 2000).

The concentration of iron in human milk declines through lactation, from approximately 0.6 mg/L at 2 weeks to 0.3 mg/L after 5 months of lactation (Siimes et al, 1979). The absorption of iron is affected adversely by blood transfusion (Dauncey et al, 1978). Premature infants fed human milk are in negative iron balance, which, in the absence of transfusion, corrects with iron supplements (Dauncey et al, 1978). Iron absorption also appears to be facilitated by a modest degree of anemia (Moody et al, 1999). Thus, the usual recommendations for premature infants suggest delaying iron supplementation until 2 to 3 months of postnatal age, when hemoglobin concentrations are at a nadir (Lundström et al, 1977). However, the provision of small doses of iron at 2 mg/kg/day beginning 2 weeks postnatally has been demonstrated, in the absence of blood transfusions, to prevent the development of iron deficiency at 3 months of postnatal age (Lundström et al, 1977). When recombinant erythropoietin for the treatment of anemia of prematurity is used, higher doses of iron are needed, in the range of 6 mg/kg/day, to support the more rapid rate of erythropoiesis (Ehrenkranz et al, 1994).

Generally, ferrous sulfate (elemental iron, 2 mg/kg/day) drops are used in human milk-fed premature infants beginning soon after the achievement of complete enteral feedings. Formula-fed premature infants should receive iron-fortified formula from the onset of milk feeding.

### Sodium and Potassium

Premature infants generally need more sodium per unit of body weight than is needed by term infants (Groh-Wargo, 2000). This increased need is due to immature renal sodium conservation mechanisms. Sodium wasting is inversely related to gestational age. A comparison of sodium intakes of 2.9 and 1.6 mEq (mmol)/kg/day in premature infants suggested that the former intake provided more appropriate serum sodium concentrations (Roy et al, 1976). Hyponatremia also may occur in premature infants primarily fed human milk because the sodium content of preterm milk continues to decline through lactation (Roy et al, 1976). The need for these electrolytes may increase during or after diuretic usage.

### Vitamins

The fat-soluble vitamins A, D, E, and K are stored in the body, and large doses may result in toxicity. Water-soluble vitamins—thiamine, riboflavin, niacin, vitamin B<sub>6</sub>, folate, vitamin B<sub>12</sub>, pantothenic acid, biotin, and vitamin C—are not stored in the body, and excess intakes are excreted in the urine or bile (vitamin B<sub>12</sub>). The intake of water-soluble vitamins, therefore, should be at frequent intervals to avoid deficiency states. Vitamin A and riboflavin concentrations decline in human milk under conditions of light exposure and after passage through feeding tubes (Bates et al, 1985). As a consequence of exposure to air,

ascorbic acid concentrations are lower in pooled human milk (Heinonen et al, 1986). Supplementary vitamins are provided in human milk fortifiers and in preterm formulas (Schanler, 2002). There is no indication for additional multi-vitamin supplements for infants receiving adequate intakes of fortified human milk, preterm formula, or enriched formula. Once feedings in the premature infant change to unfortified human milk or standard formula, a multi-vitamin supplement should be added. The supplemental vitamins should be continued until the infant is consuming 300 kcal/day or weighs more than 2.5 kg.

## HUMAN MILK

The American Academy of Pediatrics acknowledges that human milk also is beneficial in the management of premature infants. The beneficial effects generally relate to improvements in host defenses, digestion and absorption of nutrients, gastrointestinal function, neurodevelopment, and maternal psychological well-being. However, the special needs of the premature infant that arise as a result of metabolic and gastrointestinal immaturity, immunologic compromise, and associated medical conditions must be considered so that adequate nutrition can be provided to meet the needs for intrauterine rates of growth and nutrient accretion. Human milk is capable of satisfying most of the needs of premature infants if careful attention is given to nutritional status.

### Benefits of Unfortified Human Milk

Clinical studies in nurseries throughout the world have suggested a decrease in the rate of a variety of infections, including sepsis, NEC, and urinary tract infection, in premature infants fed human milk compared with those fed formula (Contreras-Lemus et al, 1992; Narayanan et al, 1980).

NEC, the devastating acute intestinal inflammatory disease in premature infants, occurs less frequently when feedings consist of human milk than when formula is used. A large, nonrandomized study of hospitalized premature infants reported that the incidence of NEC was significantly lower in infants fed human milk, either exclusively or partially, compared with infants fed formula (Lucas and Cole, 1990). That study reported clinical cases as well as cases confirmed at surgery or autopsy, and in both circumstances, the incidence of NEC was significantly greater in premature infants solely fed formula. These data provide some encouragement for the potential prevention of NEC.

Specific factors such as sIgA, lactoferrin, lysozyme, oligosaccharides, cytokines (such as interleukin-10 [IL-10]), enzymes (such as acetylhydrolase), growth factors (such as epidermal growth factor), and cellular components may affect host defense mechanisms in the premature infant. One of the major protective effects of human milk in the infant operates through the enteromammary immune system. It is reasonable to expect that exposure of the mother to the environment of the neonatal nursery through skin-to-skin contact with her premature infant may be advantageous to the infant. In this manner, mothers potentially

may be “induced” to make specific antibodies against the nosocomial pathogens in the nursery environment.

### Limitations in the Use of Unfortified Human Milk

A major impediment to advocating human milk for premature infants is the difficulty many mothers experience in providing sufficient quantities of milk. Several explanations have been given for the low milk production, including biologic immaturity of the mammary gland, maternal stress and/or illness, and difficulty maintaining a supply without a suckling infant. Another reason of concern is that nutrient intake is limited by the milk volume restrictions imposed on premature infants, because they cannot feed ad libitum and also because their medical condition warrants fluid restriction. The most compelling reason for concern is that nutrient intake is inadequate to meet the very great needs of the premature infant. Unfortified human milk may not supply sufficient quantities of nutrients for several reasons. Because of differences in the methods of milk expression and storage, the feeding of “spot” samples (individual samples of expressed milk from one or both breasts or milk partially expressed from one breast), the use of feeding tubes, and the differences in length of lactation, the macronutrient composition of human milk used in feeding premature infants varies greatly. Much of the variation in energy content, for example, is a result of differences in fat content of the unfortified milk (2.2 to 4.7 g/dL).

In addition, significant declines in the contents of protein and sodium occur through lactation (Schanler and Oh, 1980). The content of other nutrients (calcium, phosphorus) is too low to meet the great needs of the premature infant. Moreover, for technical reasons associated with the collection, storage, and delivery of milk to the infant, the quantity of available nutrients (fat, vitamin C, vitamin A, riboflavin) is decreased. Accordingly, it should not be a surprise that the inadequacies of calcium, phosphorus, protein, sodium, vitamins, and energy are observed in the premature infant fed unfortified human milk. Thus, the exclusive feeding of unfortified milk in premature infants, generally infants with birth weights less than 1500 g, has been associated with poorer rates of growth and nutritional deficits, during and beyond the period of hospitalization (Atkinson et al, 1981, 1983; Cooper et al, 1984; Gross, 1983; Kashyap et al, 1990).

### Human Milk Fortification

Growth and nutrient deficits in the premature infant can be corrected with the addition to human milk of multinutrient supplements or fortifiers (Greer and McCormick, 1988; Horsman et al, 1989; Polberger et al, 1989; Schanler et al, 1985a). Mineral supplementation during hospitalization prevents a decrease in linear growth and increases bone mineralization during and beyond the neonatal period (Abrams et al, 1989). Supplementation with both calcium and phosphorus results in normalization of biochemical indices of mineral status: serum calcium, phosphorus, and alkaline phosphatase activity and urinary excretion of calcium

and phosphorus (Schanler and Garza, 1987). Sodium supplementation results in normalization of serum sodium (Kumar and Sacks, 1978). Protein and energy supplementation is associated with improved rates of weight gain and indices of protein nutritional status: blood urea nitrogen, serum albumin, and transthyretin (Kashyap et al, 1990; Polberger et al, 1989).

Current practice suggests the use of multinutrient fortification of human milk. Nutritional outcomes of feeding fortified milk in the United States indicate that premature infants receive less volume but greater intakes of proteins and minerals and experience greater gain in weight and increment in linear growth than is the case in infants fed unfortified human milk exclusively (Greer and McCormick, 1988; Lucas et al, 1996; Schanler and Abrams, 1995; Schanler et al, 1999b). Balance study data indicate that the use of fortified human milk results in net nutrient retention that approaches or is greater than expected intrauterine rates of accretion. Fat absorption with the use of some fortifiers, however, has been lower than expected (Schanler and Garza, 1987; Schanler et al, 1985b). Fat absorption may be augmented by newer human milk fortifiers that contain fat (Barrett-Reis et al, 2000).

Questions have been raised about whether the addition of bovine-derived human milk fortifiers affects feeding tolerance in premature infants. Gastric residual volumes often are used to assess feeding tolerance. When assessed throughout hospitalization, the use of fortified human milk was not associated with feeding intolerance, as manifested by abdominal distention, vomiting, changes in stool frequency, or volume of gastric aspirate (Lucas et al, 1996). Comparisons with preterm formula have been made, and no major differences in feeding tolerance have been attributed to human milk fortification (Moody et al, 2000; Schanler et al, 1999b).

A major concern with human milk fortification is that the added nutrients may affect the complex system of host defense. The effects of nutrient fortification on some of the general host defense properties of the milk have been evaluated (Jocson et al, 1997). Fortification did not affect the concentration of IgA. Bacterial colony counts do not increase with 24 hours of refrigerator storage of fortified human milk.

The relationship between the feeding of fortified human milk and the incidence of illness (infection and NEC) in premature infants has been examined. Human milk-fed infants had a 26% incidence of documented infection, compared with 49% in formula-fed infants (Hylander et al, 1998). The use of fortified human milk was not associated with an increased incidence of either confirmed infection or NEC, compared with control-supplemented human milk (Lucas et al, 1996). When these two events were combined, however, the group fed fortified human milk had more events than the control-supplemented group. Although it is difficult to conclude that the use of fortifiers is harmful, these data indicate the need for continued surveillance of these events (Schanler, 1996).

In a comparison of fortified human milk and preterm formula, premature infants fed exclusively fortified human milk had a significantly lower incidence of NEC and/or late-onset sepsis, fewer positive blood cultures, and

less antibiotic usage than those fed preterm formula (Schanler et al, 1996b). Infants fed exclusively fortified human milk had more episodes of skin-to-skin contact with their mothers and a shorter duration of hospitalization. These data suggest that feeding premature infants fortified human milk can have a marked effect on the cost of medical care. The data further suggest that skin-to-skin contact may promote an enteromammary response in the premature infant. It may well become the practice to encourage mothers to practice skin-to-skin contact to enhance their capacity to synthesize specific factors that counter the pathogens in the nursery environment.

### Comparison of Human Milk Fortifiers

Human milk fortifiers are designed to be mixed with human milk. A variety of fortifiers are available globally, but no head-to-head comparison has been published. Most fortifiers are powdered nutrient preparations that contain protein, carbohydrate, calcium, phosphorus, magnesium, and sodium; the contents of zinc, copper, and vitamins are variable (see Table 68–11). Inherent in the design is the adequacy of the mother's milk production to meet the needs of the infant. The use of pasteurized donor human milk has not been advocated routinely because of concerns with contamination, lack of sufficient supply, and cost. If there is an inadequate amount of mother's milk, two options are currently available. One option is to alternate the feeding of fortified human milk with preterm formula, and a second option is to mix mother's milk with preterm formula.

One study examined the nutrient adequacy of a liquid human milk fortifier mixed 1:1 with human milk (Schanler et al, 1988). Nitrogen, energy, calcium, and phosphorus retentions were below intrauterine rates of accretion. More beneficial outcomes may be observed if preterm formula is alternately fed with fortified mother's milk.

### FEEDING TOLERANCE

Limitations in the ability to tolerate enteral feedings constitute a major problem for premature infants. Moreover, the infants' tolerance of enteral feeding is a primary concern of neonatologists because it affects their decision to initiate, advance, and discontinue feedings. Because of these concerns, feeding intolerance may be a major factor affecting the duration of hospitalization. The fetus experiences swallowing of amniotic fluid from early gestation, but postnatally, many premature neonates do not appear to share as "simple" a tolerance for enteral fluid, even diluted fluid mixtures. Several factors affect how feedings are tolerated: immature intestinal motility, digestive enzyme immaturity, medical complications, too great a volume intake, and hyperosmolar medications/feedings.

Despite its importance, universally agreed-upon criteria to judge feeding tolerance in premature infants are lacking. Clinical criteria of feeding intolerance (Table 68–12) generally include physical findings on examination, including abdominal distention and tenderness, presence or absence and quality of bowel sounds, and signs of residual gastric fluid aspirated from the feeding tube just prior to the next feeding, emesis, and changes in stool output

**TABLE 68-12****Potential Criteria Used to Assess Feeding Tolerance**

Abdominal distention
With visible bowel loops
Without visible bowel loops
Abdominal tenderness
Emesis
Gastric residual volume
>2 mL/kg
>50% of 3 hours of feeding
Any change from previous pattern
Gastric residual characteristics
Green, bilious
Red, blood-tinged
Stool output
Increased frequency
Decreased frequency
Feeding withheld
Document reasons feedings withheld
Assess number of feedings withheld
Clinical condition
Any worsening in previous medical condition

(Jadcherla and Kleigman, 2002). Occasional associated signs that may suggest intolerance to a feeding include increased episodes of apnea and bradycardia, diminished oxygen saturation (desaturation events), and lethargy.

The gastric residual volume, usually measured prior to the next feeding, is an indication of milk remaining in the stomach several hours after a feeding (Mihatsch et al, 2002). The gastric residual volume indicates the rapidity of gastric emptying and appears to be affected by any changes in the clinical condition that results in decreased gastric emptying. The nonspecific nature of this assessment is reflected in the fact that changes in the clinical examination may or may not be related to intestinal pathology. Gastric residual volume has been quantitated on the basis of body weight (for example, a volume of greater than 2 mL/kg per feeding is abnormal) or the volume of feeding (for example, greater than 50% of volume for 3 hours of feeding is abnormal) (Schanler et al, 1999a). Some premature infants have measurable gastric residual volumes before every feeding, whereas others never have any measurable volume. In the latter infants, therefore, any small change might indicate a change in feeding tolerance. Furthermore, gastric residual volume would be difficult to interpret in infants receiving continuous gastric milk infusions. Such is not always the case, as these infants generally empty their stomachs rapidly and should still be evaluated every 2 to 4 hours in a manner similar to that used for infants fed by the intermittent bolus technique (Schanler et al, 1999a).

Assessment of the quality of the gastric residual also has been discussed as a tool to determine feeding tolerance. Gastric residuals that are green or bilious could indicate intestinal obstruction but more often indicate overdistention of the stomach and retrograde reflux of bile into the stomach. A blood-tinged residual could indi-

cate an inflammatory process but may indicate a slight mucosal irritation from the indwelling gastric tube.

Unfortunately, the aforementioned criteria have little prognostic significance. In one study, infants who had more gastric residuals and emesis episodes were just as likely to reach the milestone of full enteral tube feeding than infants who did not have any increases in these measurements (Moody et al, 2000).

Most clinicians use the pattern of the previously mentioned criteria, as opposed to a single measurement, as an aid to determine feeding status. In several instances, the infant's feedings may be withheld because of one or more of the aforementioned signs. Often a single feeding is discarded. Careful assessment and examination prior to the next feeding generally aid the decision to continue feedings. A withheld feeding, however, does not imply that further enteral feeding should be terminated. Too often, feedings are withheld for prolonged periods of time, which hastens the complications of parenteral nutrition and intestinal atrophy.

The evaluation of the infant with a large gastric residual, for example, would include the following considerations. Has the medical condition worsened, such that gastric emptying is delayed because of systemic disease? Is the infant's feeding tube in the correct location? If the feeding tube is high in the esophagus or is of too small a caliber, then swallowed air may not be evacuated. Large amounts of swallowed air may cause gastric overdistention with displacement of ingested milk, resulting in emesis and/or large residuals. Body positioning also may play a role. In some cases, gastric emptying is improved by placement of the infant in the prone position or in the right lateral decubitus position, rather than the supine position. At times, tolerance is corrected by lowering milk intake somewhat.

## FEEDING METHODS

Tube feeding is an essential tool in enteral nutrition because the premature infant may be unable to suck and/or coordinate suck-swallow-breathe. Tube feeding methods include continuous and intermittent bolus methods. Any of various approaches may be used including orogastric, nasogastric, transpyloric, and gastrostomy. The selection of practice relates to the duration of the proposed therapy: premature infants will eventually suckle, so a temporary oro(naso)gastric tube is used; infants with major congenital anomalies may require a semipermanent gastrostomy.

The bolus feeding method mimics the normal adult feed-fast routine and is associated with greater hormonal responses than those occurring with continuous infusions (Aynsley-Green et al, 1982). The bolus technique does not require an infusion pump. Differences between continuous and intermittent bolus methods have been evaluated. Premature infants had more feeding tolerance and a slower rate of weight gain with continuous infusion than with the bolus technique (Schanler et al, 1999a). Neither method enhanced nutrient absorption.

Occasionally, intolerance is observed in the bolus-fed premature infant. In some instances, duodenal motility decreases following the bolus feeding (DeVilleville et al,

1993). Giving a bolus feeding over a longer time interval, such as 30 to 120 minutes, results in a return of motility and improved tolerance.

Continuous infusion technique has been associated with increased nutrient absorption in infants with gastrointestinal disease (Parker et al, 1981). It seems prudent to use this method in infants who have had intestinal surgery and in infants receiving milk via a transpyloric tube. In some infants with persistent gastric residuals or emesis in the absence of an obvious intestinal pathologic process, the use of transpyloric feeding tubes has been successful.

## FEEDING ISSUES

Enteral feeding and concomitant use of an umbilical arterial catheter have been subjects of much concern. However, most infants had an indwelling catheter in the most recent studies of gastrointestinal priming, and no untoward events were reported (Dunn et al, 1988; Schanler et al, 1999a). Infants were no more likely to develop intolerance or NEC if they received enteral feedings while they had an umbilical arterial catheter in place than if they received enteral feedings 24 hours after the catheter was removed (Davey et al, 1994). Moreover, fewer evaluations for sepsis and less frequent use of central venous catheters were observed in the group receiving feedings while the catheter was in place. Thus, there appears to be no increased risk associated with enteral feeding while an umbilical arterial catheter is in place as long as the catheter is functioning optimally.

The use of diluted milks has been suggested for feeding premature infants. In one study, however, intestinal motility responses to feeding were initiated earlier and persisted longer following the use of full-strength formula than with use of one-third and two-thirds dilutions of the formula (Koenig et al, 1995). The use of water for enteral feeding also has been shown not to affect intestinal motility as compared with milk (Berseth et al, 1992). Thus, initiating feedings with full-strength milk appears to be tolerated and appropriate.

The advancement of daily feeding volumes also has been investigated, especially with respect to the development of NEC. When compared with matched case controls, infants with NEC were more likely to have received enteral nutrition with daily intakes greater than 20 mL/kg, averaging 46 mL/kg (McKeown et al, 1992). One study examined the morbidity of low-birth-weight infants whose daily increments in feeding volume were 15 or 35 mL/kg/day (Rayyis et al, 1999). In infants whose feedings were advanced rapidly, the duration of time to achieve full tube feeding and regain birth weight was shorter than in infants whose feedings were advanced slowly, and no difference in morbidity was noted.

## NUTRITIONAL ASSESSMENT

Neonatal nutritional assessment is an emerging interest that requires a knowledge of both nutritional biochemistry and neonatal medical conditions. The nutritionist is a key person to provide input on a daily basis that is compatible with the medical condition of the infant.

The nutritional status of the premature infant (Table 68-13) is monitored by daily assessments of fluid and energy intake and evaluation of the rate of growth in weight, length, and head circumference. Growth parameters are plotted on graph paper or a specific chart for premature infants' growth. The charts are helpful, but equally important is the computation of the weekly rate of growth (Usher and McLean, 1969) (see Table 68-3). Once the infant reaches a weight of 2.5 kg, a daily weight gain of 20 to 30 g/day is appropriate.

The nutritional status of the premature infant also is monitored by serial evaluations of biochemical indices. These assessments include serum calcium, phosphorus, and alkaline phosphatase activity to assess bone mineral status and albumin and urea nitrogen to assess protein status. If more specific indices of protein status are needed, as when additional protein supplementation is used, the serum prealbumin (transthyretin) is measured before and 1 week after the supplementation. Serum sodium, chloride, and bicarbonate are evaluated in infants receiving diuretics, those whose intakes are limited, or those with slow growth. The hemoglobin and reticulocyte counts are monitored to assess for anemia. Specific determinations of plasma zinc and copper are not routinely useful, but zinc may be measured in infants with unusual losses, such as after gastrointestinal surgery and from enterostomies. The pattern of changes in biochemical indices may be more reflective of nutritional status than are isolated values.

**TABLE 68-13**

### Nutritional Assessment of the Enterally Fed Premature Infant

Component Measured	Frequency
Fluid intake (mL/kg/day)	Daily
Parenteral intake	
Enteral intake	
Nutrient intake (units/kg/day)	Daily
Energy intake (kcal)	
Protein intake (g)	
Specific nutrient (unit)	
Anthropometry	
Body weight (g)	Same time each day
Length (cm)	Weekly
Head circumference (cm)	Weekly
Biochemical monitoring	
Hemoglobin, hematocrit	Weekly
Reticulocyte count	Weekly
Serum electrolytes	Twice weekly, then every 2 weeks*
Calcium, phosphorus	Twice weekly, then every 2 weeks
Alkaline phosphatase	Twice weekly, then every 2 weeks
Albumin, blood urea nitrogen	Twice weekly, then every 2 weeks†
Other assessments	
Renal ultrasound examination‡	At 2 months of age

\* If infant is receiving human milk or diuretics.

† Add prealbumin if abnormal.

‡ To evaluate for nephrocalcinosis.

Occasionally, renal ultrasound examination to determine the presence of nephrocalcinosis and wrist x-ray studies to identify rickets are warranted.

### POST-DISCHARGE NUTRITION

Some evidence suggests that the quality of early nutrition support has long-term implications for infant health and development. The goal of in-hospital nutritional support is to meet intrauterine rates of nutrient accretion. Accordingly, the premature infant should receive fortified human milk or preterm formula during the hospitalization period. Hospital discharge, however, frequently occurs before the completion of the intrauterine growth phase (up to approximately 36 weeks). Moreover, during hospitalization, despite what we may consider to be optimal nutrient support, growth deficits emerge, such that at discharge, the infant is well below the 10th percentile on corresponding growth charts (Wilson et al, 1997). Thus, concerns about nutrition support extend into the postdischarge period. Unfortunately, unlike in the term infant, whose needs are modeled after the healthy breast-fed infant, and the premature infant, whose needs are determined by the intrauterine growth model, there are no references to determine the nutritional needs of the premature infant at discharge.

Nutrition should be discussed at all times when discharge planning is done. Certain key questions need to be answered so that an appropriate nutritional plan can be devised. If the infant continues to manifest adequate weight gain on feedings of unfortified human milk or term infant formula taken ad libitum, then those diets can be recommended. In addition, if the prior biochemical model of nutritional status shows no unusual pattern suggesting nutrient inadequacy, then the routine diets can be recommended.

More often, especially in infants with bronchopulmonary dysplasia, adequate intake is not achieved, and biochemical markers of nutritional status reveal deficits. These infants cannot be discharged on the routine diets. If they are formula fed, enriched formulas will provide multinutrient needs (Carver et al, 2001) (see Table 68–8). In addition, these formulas can be concentrated to 24 to 30 kcal/ounce formulations to meet the needs for fluid restriction. The breast-feeding infant needs further attention. It may suffice to allow unrestricted breast-feeding but then to add 2 to 3 feedings of the enriched formula, prepared as 24 to 30 kcal/ounce formulations. In all cases, follow-up visits for assessment of nutritional status are recommended at 1 week and 1 month after discharge. Rates of growth should exceed 20 g/day for weight and 0.7 cm/week for length and head circumference increments. Biochemical monitoring to assess mineral and protein status is indicated at these follow-up visits (Hall, 2001).

### SUMMARY OF NUTRITIONAL SUPPORT

A comprehensive enteral nutrition pathway for premature infants has been described. The approach is multifaceted, beginning with minimal enteral, or trophic, feeding to enteral nutrition, and continuing to full enteral feeding and hospital discharge. This approach does not increase

the risks already associated with prematurity. Indeed, the use of an aggressive approach to nutritional support has resulted in improved growth, with fewer infants falling below the 10th percentile on standard growth charts (Wilson et al, 1997). Although improvements are found in growth, no increase in sepsis or NEC is associated with the more aggressive approach to nutritional support (Wilson et al, 1997).

## Parenteral Nutrition

Brenda B. Poindexter and Scott C. Denne

Effective nutritional support of premature and critically ill infants is largely dependent on parenteral nutrition, especially in early postnatal life. In practice, the supply of nutrients to preterm neonates—especially extremely low-birth-weight (ELBW) infants—is rarely adequate, and these infants accumulate major deficits in the first 2 weeks after birth (Berry et al, 1997). A recent large multicenter study documented that 99% of ELBW infants were below the 10th percentile for weight after 10 weeks in the neonatal intensive care unit (NICU) (Lemons et al, 2001). However, growing evidence indicates that early use of parenteral nutrition may minimize protein losses and improve growth outcomes (Van Goudoever et al, 1995; Wilson et al, 1997). For example, Wilson and colleagues (1997), in a randomized clinical trial in 125 sick very low-birth-weight (VLBW) infants, demonstrated that early aggressive parenteral nutrition combined with early enteral feeding reduced growth failure without an increased incidence of adverse clinical consequences or metabolic derangements. Parenteral nutrition solutions, although still imperfect, have improved markedly from the early days of use, and complications are less common. At present, improved growth outcomes in preterm infants appear to require a more sustained effort at providing parenteral nutritional support, especially in early postnatal life. This means initiating parenteral nutrition within the first 24 hours, continuing until enteral nutrition supplies at least 75% of the total protein and energy requirements, and reinstating parenteral nutrition quickly whenever enteral feeding is suspended.

### COMPONENTS OF PARENTERAL NUTRITION

#### Protein

The initial goal of parenteral nutrition is to minimize losses and preserve existing body stores; this is particularly important for protein. Protein losses are significant in all neonates in the absence of amino acid intake, and these losses are the highest in the most immature neonates. For example, 26-week-gestation infants lose 1.5 g/kg/day of body protein; protein losses in term infants are approximately half that rate (0.7 g/kg/day) (Denne et al, 1996). These high rates of loss in extremely premature infants result in substantial protein deficits. If extremely premature infants are provided with no amino acid supply, they lose over 1.5% of their body protein per day when they should be accumulating protein at a rate of 2% per day. After only 3 days of no protein intake, a 10% protein deficit results.

Fortunately, there is good evidence that early amino acid intake can compensate for high rates of protein loss and thus preserve body protein, even at low caloric intakes (Kashyap and Heird, 1994; Rivera et al, 1993; Saini et al, 1989; Van Lingen et al, 1992). Amino acid intakes of 1.1 to 2.3 g/kg/day at caloric intakes of 30 to 50 kcal/kg/day change the protein balance from significantly negative to neutral or positive in sick VLBW infants (Rivera et al, 1993; Saini et al, 1989; Van Lingen et al, 1992). Additional studies carried out in ELBW infants in early neonatal life support this conclusion (Denne et al, 1996). Nevertheless, in multiple controlled trials evaluating the effect of early amino acid intake in premature infants, no differences in ammonia concentrations, acid-base status, or blood urea nitrogen (BUN) levels were observed between infants who received amino acids and those who did not (Paisley et al, 2000; Rivera et al, 1993; Saini et al, 1989; Van Lingen et al, 1992). The fact that BUN concentrations do not correlate with amino acid intake in multiple trials demonstrates that these levels in early postnatal life are related primarily to fluid status and that increased BUN levels should not be used as an indication of protein excess. These data indicate that providing parenteral amino acids at a rate of 1.5 to 2 g/kg/day as soon as possible after birth (within hours) can preserve limited body protein stores in sick premature and ELBW infants, even at low caloric intakes.

It is important to point out that even though parenteral amino acid administration is beneficial at low caloric intakes, increasing caloric intake is likely to improve protein accretion. Older studies in premature infants have suggested that increasing caloric intake from 50 to 80 kcal/kg/day can significantly improve protein balance (Pineault et al, 1988; Zlotkin et al, 1981a). Preliminary data in ELBW infants indicate that protein balances are not further improved when daily parenteral energy intake is increased from 70 kcal/kg to 90 kcal/kg (Poindexter et al, 2000). Therefore, currently available data suggest that 70 to 80 kcal/kg/day may be sufficient to maximize protein accretion. However, additional energy beyond this amount probably is necessary to produce appropriate fat accretion (see “Energy” section).

The ultimate goal of parenteral amino acid administration is to achieve the rate of fetal protein accretion. Based on a variety of studies measuring protein losses and balance, 3.5 to 4.0 g/kg/day of amino acids is a reasonable estimate of parenteral protein requirements in ELBW infants (Denne et al, 1996; Ziegler, 1994) (Table 69–1). Recent evidence suggests that up to 4.0 g/kg/day of amino acids is well tolerated by ELBW infants (Porcelli and Sisk, 2002). For premature infants with birth weights of over 1000 g, estimated parenteral protein requirements are 3.0 to 3.5 g/kg/day. Estimates for term infants are 2.5 to 3 g/kg/day. Parenteral amino acid intake recommendations for premature infants are shown in Table 69–1.

The composition of currently available amino acid solutions is shown in Table 69–2. These amino acid solutions were designed to mimic plasma amino acid concentrations in healthy 30-day-old breast-fed term infants (Trophamine) or fetal or neonatal cord blood amino acid concentrations (Primene). No convincing information exists

## Suggested Daily Parenteral Intakes for ELBW and VLBW Infants

Component (units/kg/day)	ELBW			VLBW		
	Day 0*	Transition†	Growing	Day 0*	Transition†	Growing
Energy (kcal)	40-50	75-85	105-115	40-50	70-80	90-100
Protein (g)	2	3.5	3.5-4	2	3.0-3.5	3.0-3.5
Glucose (g)	7-10	8-15	13-17	7-10	8-15	13-17
Fat (g)	1	1-3	3-4	1	1-3	3
Na (mEq)	0-1	2-4	3-7	0-1	2-4	3-5
Potassium K (mEq)	0	0-2	2-3	0	0-2	2-3
Chloride (mEq)	0-1	2-4	3-7	0-1	2-4	3-7
Calcium (mg)	20-60	60	60-80	20-60	60	60-80
Phosphorus (mg)	0	45-60	45-60	0	45-60	45-60
Magnesium (mg)	0	3-7.2	3-7.2	0	3-7.2	3-7.2

\*Recommended parenteral intakes on the first day of life.

†Period of transition to physiologic and metabolic stability. For most premature neonates, this occurs between 2 and 7 days.

ELBW, extremely low-birth-weight; <1000 g; VLBW, very low-birth-weight, <1500 g.

to support the superiority of one neonatal amino acid solution over another.

Although the current neonatal amino acid solutions represent a substantial advance over previous casein hydrolysates and early crystalline amino acid mixtures, specific deficiencies remain. Glutamine, an amino acid abundantly supplied by breast milk and potentially conditionally essential in premature infants, is not included in

any available amino acid solution because of issues of stability. Tyrosine has very limited solubility, so little is included in current amino acid solutions. Trophamine contains a soluble derivative of tyrosine (*N*-acetyltyrosine), but this derivative appears to have poor bioavailability. A variety of studies in premature infants suggest that the tyrosine supply may not be optimal in current amino acid solutions (Brunton et al, 2000). Cysteine is not included in

TABLE 69-2

## Composition of Commercial Parenteral Amino Acid Solutions

Amino Acid*	Concentration: mg/dL			
	Aminosyn-PF (Abbott)	TrophAmine (B. Braun)	Primene (Baxter)†	Premasol (Baxter)†
Histidine	312	480	380	480

most amino acid solutions because it is not stable for long periods. However, a cysteine hydrochloride supplement that can be added to the parenteral nutrition solution just prior to delivery is commercially available. A number of studies have suggested that the addition of cysteine can improve protein accretion, although some conflicting information exists (Poindexter et al, 2000; Rivera et al, 1993; Zlotkin et al, 1981b). The addition of cysteine hydrochloride also improves the solubility of calcium and phosphorus in parenteral nutrition solutions and also may improve the status of the important antioxidant glutathione. For these reasons, the addition of cysteine hydrochloride (40 mg/g of amino acid, up to a maximum of 120 mg/kg) is recommended. Cysteine hydrochloride can result in a metabolic acidosis, but this possibility can be appropriately countered by the use of acetate in the parenteral nutrition solution as a buffer (Peters et al, 1997).

### Energy

The initial goal of parenteral nutrition in early postnatal life is to provide sufficient energy intake to at least match rates of energy expenditure in order to preserve body energy stores. Measures of energy expenditure in premature infants weighing greater than 1000 g have ranged between 45 and 70 kcal/kg/day, so an intake of 70 to 80 kcal/kg/day is a reasonable initial clinical goal to achieve neutral or slightly positive energy balance in these infants. Data assessing energy expenditure in ELBW infants are sparse, but preliminary information suggests that energy expenditure in these infants may be close to 80 kcal/kg/day (Carr et al, 2000). Although 80 kcal/kg/day is a reasonable clinical goal, because of glucose and lipid intolerance this intake may not be able to be achieved for a number of days after birth. Nevertheless, maximizing energy intake within the limits of glucose and lipid tolerance can minimize accumulating energy deficits.

To support normal rates of growth, a positive energy balance of 20 to 25 kcal/kg/day must be achieved (Denne, 2001). This requires 90 to 100 kcal/kg/day for preterm infants with birth weights of less than 1000 g and 105 to 115 kcal/kg/day for ELBW infants (see Table 69–1). A parenteral intake of 80 to 90 kcal/kg/day is most often sufficient for term infants. Most of the parenteral calories are best supplied by a balanced caloric intake of lipid and glucose. Parenteral energy requirements are less than those required for enteral nutrition because no energy is lost in the stools. Recommendations for parenteral energy intake are shown in Table 69–1.

### Glucose

Glucose is typically the first parenteral nutrient provided to the preterm infant, and glucose administration is begun minutes after birth in order to maintain glucose homeostasis and preserve endogenous carbohydrate stores. Although the precise definitions of hypoglycemia and hyperglycemia remain a topic of debate, maintaining glucose concentrations of above 40 mg/dL and below 150 to 200 mg/dL is a reasonable clinical goal (Cornblath et al, 2000). Hypoglycemia is easily avoided in preterm infants by maintaining a constant intravenous glucose delivery, but hyper-

glycemia is more often problematic, especially in ELBW weight infants shortly after birth. A recent study suggested that approximately 40% of sick VLBW infants experience at least one episode of hyperglycemia within the first week of life (Wilson et al, 1997).

Glucose infusion rate of 4 to 7 mg/kg/minute (70 to 110 mL/kg/day of 10% dextrose in water [D<sub>10</sub>W]) is an appropriate starting point for most infants. This rate of glucose infusion approximates or slightly exceeds the rate of endogenous glucose release from the liver in term and premature infants with birth weights of greater than 1000 g; therefore, this rate of glucose infusion serves to preserve the limited carbohydrate stores in these infants. For ELBW weight infants, a rate of 8 to 10 mg/kg/minute is required to match endogenous glucose production (Hertz et al, 1993). Unfortunately, many infants will not tolerate this rate of glucose infusion for several days without hyperglycemia. Because ELBW infants often have fluid requirements in excess of 100 mL/kg/day, beginning with 5% dextrose is usually necessary to maintain glucose infusion rates in the range of 4 to 7 mg/kg in order to achieve glucose homeostasis.

A gradual increase in glucose intake over 2 to 7 days, up to 13 to 17 g/kg/day, is usually tolerated when the glucose is combined with amino acid intake. An infusion rate of 18 g/kg/day is a reasonable maximum for intravenous glucose delivery, as higher rates probably exceed the glucose oxidative capacity (Chessex et al, 1995; Jones et al, 1993). Exceeding glucose oxidative capacity will drive extensive lipogenesis, an energy-expensive process. Supplying appropriate amounts of glucose rarely requires glucose solution concentrations in excess of 12.5%, unless infants are fluid restricted. Recommendations for glucose intake during parenteral nutrition are provided in Table 69–1.

Some ELBW infants have difficulty tolerating even moderate rates of glucose delivery. This problem usually can be overcome by a temporary reduction in the glucose infusion rate. The use of insulin in this situation remains a controversial practice. Collins and associates (1991), in a small randomized controlled trial, demonstrated increased weight gain in infants who received insulin infusions. No differences in head circumference or length were observed between these infants and controls, suggesting that insulin may have produced increases in fat mass but not in lean tissue. Poindexter and colleagues (1998) evaluated the effect of insulin on protein metabolism using a euglycemic hyperinsulinemic clamp. Insulin infusion resulted in no improvement in protein balance and unexpectedly produced significant lactic acidosis. At present, the ability of exogenous insulin to produce appropriate growth and body composition in extremely premature infants is unclear, and exogenous insulin cannot be recommended in routine practice. Nevertheless, there are rare ELBW infants who remain hyperglycemic despite very low glucose infusion rates; these infants may require exogenous insulin beginning at 0.05 unit/kg/hour for a short period of time to produce normoglycemia.

Meeting the goal of 13 to 17 g/kg/day of intravenous glucose will result in a caloric intake of 45 to 60 kcal/kg/day, which is insufficient by itself to meet total energy needs. Intravenous lipids are necessary to supply the rest of the nonprotein calories. A balanced glucose and lipid approach to supplying nonprotein calories has a number of advantages: it better approximates the carbohydrate-to-fat ratio in enteral feedings, it may improve overall protein accretion,

and it minimizes overall energy expenditure (Nose et al, 1987; Van Aerde et al, 1989).

## Lipids

Intravenous lipids are made up of triglycerides, phospholipids from egg yolk to emulsify, and glycerol, which is added to achieve isotonicity. Intravenous lipid solutions commercially available in the United States are derived from soybean oil (Intralipid) or a combination of soybean oil and safflower oil (Liposyn II); these solutions contain long-chain triglycerides. Some lipid preparations available in Europe include medium-chain triglycerides (Medialipid) and a combination of olive oil and soybean oil (Clinoleic). Differences in lipid source result in a slightly different fatty acid profile; the compositions of available intravenous lipid solutions are shown in Table 69–3. All available intravenous lipid products have a fatty acid profile substantially different from that of human milk. At present, there is not convincing information that any of the solutions produce clinically different outcomes. Some theoretical advantages exist for the use of medium-chain triglycerides, including more rapid hydrolysis. However, a recent study in preterm infants demonstrated that medium-chain triglyceride-containing lipid emulsions may not be as effective as long-chain triglyceride-containing emulsions in promoting protein accretion (Liet et al, 1999).

Intravenous lipid solutions contain lipid particles similar in size to endogenously produced chylomicrons. These particles are hydrolyzed by lipoprotein lipase into free fatty acids. Lipoprotein lipase activity and triglyceride clearance is reduced in preterm infants of less than 28 weeks of gestation (Brans et al, 1990). Although heparin can release lipoprotein lipase from the endothelium into the circulation, at present no evidence exists that this increases lipid utilization in preterm infants (Spear et al, 1988). In the absence of any information demonstrating clinical benefit of heparin administration, the routine addition of heparin in lipid infusions is not recommended.

Linoleic and linolenic acids cannot be endogenously synthesized and therefore are essential fatty acids for

humans. Biochemical evidence of essential fatty acid deficiency may be noted in preterm infants within 72 hours of birth (Foote et al, 1991). Essential fatty acid deficiency can be avoided if 0.5 to 1.0 g/kg/day of intravenous lipid is provided. Additional intravenous lipid beyond these amounts is necessary if the energy requirements of preterm infants are to be met in early postnatal life.

The early administration of intravenous lipids to preterm infants has been the subject of discussion and debate; this debate has centered primarily on the acute metabolic effects of early intravenous lipids and the potential long-term consequences. Gilbertson and colleagues (1991) evaluated the short-term metabolic effects of early intravenous lipids in a randomized controlled trial. This study examined 29 infants requiring mechanical ventilation with an average gestational age of 28 weeks and an average birth weight of 1.1 kg. One group received intravenous lipid at 1.0 g/kg/day beginning on day 1; this was gradually increased to 3.0 g/kg/day by day 4. The control group received intravenous lipid only after day 8. There were no differences in PO<sub>2</sub>, PCO<sub>2</sub>, hyperglycemia, bilirubin concentrations, thrombocytopenia, or free fatty acid concentrations between the two groups. In addition, triglyceride concentrations were similar in both groups. Another trial using a slightly different study design produced similar results (Murdock et al, 1995). Current evidence strongly suggests that intravenous lipids can be administered to sick preterm infants in early postnatal life without causing acute metabolic derangements.

Concern about the long-term safety of early intravenous administration of lipids, particularly the possibility of an increase in mortality and bronchopulmonary dysplasia, was raised by some early observational studies. Subsequently, however, six randomized control trials have been performed evaluating this question, and none have demonstrated an increase in bronchopulmonary dysplasia or mortality in preterm infants who received early intravenous lipids. A meta-analysis of these studies confirmed this conclusion (Fox et al, 1998). In view of these data and of the essential fatty acid and caloric needs of sick premature infants, early intravenous lipid administration (on day 1 of life) is a recommended clinical practice.

**TABLE 69–3**

### Compositions of Commercial (20%) Intravenous Lipid Emulsions

Component	Intralipid	Liposyn-II	Medialipid	Clinoleic
TG (g/L)	200	200	200	200

Linoleic acid C18:2	54	66	27	17
Linolenic acid C18:3	8	4	4	0.3

PL, phospholipids; TG, triglycerides.

The rate of intravenous lipid infusion is important, and plasma lipid clearance is improved when intravenous lipid is given as a continuous infusion over 24 hours (Putet, 2000). Lipid infusion rates in excess of 0.25 g/kg/hour are associated with decreases in  $PO_2$  (Brans et al, 1986). Lipid infusion rates well under this value can easily be achieved in clinical practice if lipids are provided over 24 hours in an amount not exceeding 3 to 4 g/kg/day. This level of lipid intake is usually sufficient to supply the caloric needs of preterm infants (in combination with glucose) and is usually tolerated by premature infants. Triglyceride concentrations are most often used as an indication of lipid tolerance, and maintaining triglyceride concentrations below 150 to 200 mg/dL seems desirable. Recommendations for parenteral lipid intake are provided in Table 69-1.

Numerous studies have documented superiority of 20% over 10% lipid emulsions (Putet, 2000). Lipid clearance is improved with the 20% solutions because these solutions have half the amount of phospholipid emulsifier relative to the same amount of triglycerides. Phospholipids can combine with cholesterol to form lipoprotein X, which ultimately interferes with the clearance of infused triglycerides. Consequently, the use of 10% lipid emulsions should be avoided.

Concern has been expressed about the use of intravenous lipids in infants with hyperbilirubinemia, as free fatty acids may displace bilirubin from albumin-binding sites, potentially increasing the risk of kernicterus. In vitro studies have shown that no free bilirubin is released if the free fatty acid-to-serum albumin ratio is less than 4 (Thiessen et al, 1972). In vivo, free bilirubin is not generated until the molar ratio of free fatty acids to bilirubin exceeds 6 (Andrew et al, 1976). In clinical practice, free fatty acid-to-bilirubin ratios above 6 have not been measured, and a relationship between free fatty acid concentrations and unbound bilirubin has not been documented (Rubin et al, 1995). At present, withholding intravenous lipids from jaundiced premature infants does not seem warranted.

Intravenous lipid emulsions may undergo lipid peroxidation, with the formation of organic free radicals, potentially initiating tissue injury. Light, especially phototherapy, may play some role in increasing lipid peroxidation in intravenous lipid emulsions (Neuzil et al, 1995). However, multivitamin preparations included in the intravenous solutions are major contributors to a generation of peroxides, and lipid emulsions may have only a minor additive effect (Lavoie et al, 1997). On the basis of these findings, some clinicians protect intravenous lipid solutions from light, although the importance or efficacy of this practice is unclear.

Carnitine facilitates transport of long-chain fatty acids through the myocardial membrane and thereby plays an important role in their oxidation. Premature infants receiving parenteral nutrition have low carnitine levels, but the clinical significance of this finding remains uncertain. Meta-analysis of the studies evaluating carnitine supplementation in parenteral nutrition showed no evidence of effect on ketogenesis, lipid utilization, or weight gain (Cairns and Stalker, 2002). At present, insufficient information is available to support a recommendation for the

routine supplementation of parenterally fed neonates with carnitine.

### **Electrolytes, Minerals, Trace Elements, and Vitamins**

Sodium needs are low in the first few days of life because of the expected free water diuresis. For ELBW infants, addition of sodium to the parenteral nutrition solution may not be necessary until about day 3 of life. It is, however, necessary to frequently measure sodium concentrations and water balance. After the initial diuresis, 2 to 4 mEq/kg/day is usually sufficient to maintain serum sodium in the normal range, but ELBW infants sometimes require higher sodium intakes to compensate for larger renal sodium losses. Chloride requirements follow the same time course as for sodium requirements and also are 2 to 4 mEq/kg/day. Once electrolytes are added to the parenteral nutrition solution, chloride intake should not be less than 1 mEq/kg/day, and all chloride should not be omitted when sodium bicarbonate or acetate is given to correct metabolic acidosis. Potassium requirements again are low on the first few days of life, and potassium should probably be omitted from parenteral solutions in ELBW infants until renal function is clearly established. Potassium intakes of 2 to 3 mEq/kg/day are usually adequate to maintain normal serum potassium concentrations.

Parenteral nutrition solutions usually require the addition of anions, as either acetate or chloride. In general, excess anions should be provided as acetate in order to prevent hyperchloremic metabolic acidosis. A randomized controlled trial demonstrated that acetate in parenteral nutrition solutions effectively ameliorates acidosis (Phelps and Cochran, 1989).

Supplying calcium and phosphorus in parenteral nutrition remains a significant clinical challenge because of limited solubility. It is currently not possible to supply enough calcium and phosphorus to support adequate bone mineralization in preterm infants using the solutions available in the United States. In other countries organophosphate preparations are available (e.g., glycerophosphate), and calcium and phosphorus can be supplied in parenteral nutrition solutions in amounts that approximate enteral intakes. Precipitation of calcium and phosphorus remains an issue in the United States, however, and the solubility of calcium and phosphorus in parenteral nutrition solutions depends on temperature, type and concentration of amino acid, glucose concentration, pH, type of calcium salt, sequence of addition of calcium and phosphorus to the solution, the calcium-to-phosphorus ratio, and the presence of lipid. Adding cysteine to parenteral nutrition solutions lowers the pH, which improves calcium and phosphorus solubility. Currently, recommendations are to use parenteral nutrition solutions containing 50 to 60 mg/dL of elemental calcium (12.5 to 15 mmol/L) and 40 to 47 mg/dL of phosphorus (12.5 to 15 mmol/L). At typical fluid intakes (100 to 150 mL/kg/day), this composition will provide 50 to 90 mg/kg/day of calcium and 40 to 70 mg/kg/day of phosphorus (Koo et al, 1993). A calcium-to-phosphorus ratio of 1.7:1 by weight (1.3:1 by molar ratio) appears to be optimal for bone mineralization.

In general, calcium and phosphorus should be added to parenteral nutrition solutions in early postnatal life. Magnesium also is a necessary nutrient and should be supplied at 3 to 7.2 mg/kg/day. Calcium, phosphorus, and magnesium serum concentrations should be frequently monitored.

Recommendations for trace elements for term and preterm infants are primarily derived from the American Society for Clinical Nutrition (ASCN) guidelines from 1988 (Greene et al, 1988). There is reasonable consensus that zinc should be included early in parenteral nutrition solutions (250 µg/kg/day for term infants, 400 µg/kg/day for preterm infants). Other trace elements probably are not needed until after the first 2 weeks of life.

The recommended intakes of trace elements for term and preterm infants are shown in Table 69–4. Zinc and copper are available in the sulfate form and can be added separately to parenteral solutions. Several pediatric trace metal solutions are available that contain zinc, copper, magnesium, and chromium in various proportions; these solutions are usually provided at 0.2 mL/kg/day. When trace metal solutions are used, additional zinc usually is needed to provide the recommended intake for preterm infants. Supplementation with selenium is suggested after 2 weeks of age, because preterm infants can become selenium deficient after 2 weeks of exclusive parenteral nutrition. In infants with cholestasis, copper and manganese should be discontinued, and chromium and selenium should be used with caution and in smaller amounts in infants with renal

dysfunction. At present, parenteral iron is recommended only when preterm infants are nourished exclusively by parenteral solutions for the first 2 months of life.

The recommended intakes of vitamins for term and preterm infants on parenteral nutrition are shown in Table 69–5. Currently only one pediatric multivitamin preparation is available, and it is delivered with a standard dosage of 2 mL/kg/day (maximum 5 mL/day) in preterm infants and 5 mL/day in term infants. These dosages provide higher amounts of most of the B vitamins and lower amounts of vitamin A relative to the recommendations.

### Complications of Parenteral Nutrition

Although a wide variety of complications associated with parenteral nutrition were reported in the early days of use, most of these are now rare with current parenteral solutions. Many of the complications (electrolyte and glucose imbalance) can be prevented or corrected by manipulating the constituents of the infusate. The primary complications of parenteral nutrition as currently used are cholestasis and those related to the infusion catheter.

Cholestatic jaundice as a result of hepatic dysfunction is a well-recognized complication of parenteral nutrition. The initial histologic lesion is cholestasis, both intracellular and intracanalicular, followed by portal inflammation and progressing to bile duct proliferation after several weeks of parenteral nutrition. With prolonged administration, portal fibrosis and ultimately cirrhosis may develop. There is very little recent information about the incidence of cholestasis in preterm infants. Older studies suggest that cholestasis may be more prevalent at lower birth weights, with approximately 50% of ELBW infants exhibiting cholestasis after 2 weeks of parenteral nutrition (Beale et al, 1979). The incidence of cholestasis in infants receiving parenteral nutrition for longer than 90 days is over 90% regardless of birth weight. At present, the risk of cholestasis appears to be highest in premature infants receiving exclusively parenteral nutrition for prolonged periods.

The precise cause of cholestasis is unknown and probably is multifactorial. Critically ill premature infants experience a variety of insults, including hypoxia, hemodynamic instability, and infection. A higher incidence of sepsis has been reported in infants affected by cholestasis. Perhaps an equally if not more important factor in the development of cholestasis is the prolonged lack of enteral nutrition; there is growing evidence that enteral feedings, even at low caloric intakes, can reduce the incidences of cholestasis.

The clinical manifestations of cholestasis are hyperbilirubinemia and jaundice, and histologic changes in the liver occur much earlier. A sensitive but nonspecific indicator of early cholestasis is an increase in gamma-glutamyltransferase (GGT) (Nanji and Anderson, 1985); elevations of hepatic transaminases—*aspartate transaminase (AST) (serum glutamic-oxaloacetic transaminase [SGOT])* and *alanine transaminase (ALT) (serum glutamate-pyruvate transaminase [SGPT])*—occur later. Cholestasis most often resolves after discontinuation of parenteral nutrition and initiation of enteral feedings. Some rare instances of irreversible liver failure have been documented, but this seems to occur only after several months of use.

**TABLE 69–4**

#### Recommended Parenteral Intake of Trace Elements for Term and Preterm Infants

Trace Element	Term (µg/kg/day)	Preterm (µg/kg/day)
Chromium <sup>o</sup>	0.20	0.2
Copper <sup>†</sup>	20	20
Iron <sup>‡</sup>	—	—
Fluoride <sup>§</sup>	—	—
Iodide	1	1
Manganese <sup>†</sup>	1	1
Molybdenum	0.25	0.25
Selenium <sup>o</sup>	2	2
Zinc <sup>  </sup>	250	400

<sup>o</sup>Renal dysfunction can cause toxicity.

<sup>†</sup>Impaired biliary excretion can cause toxicity.

<sup>‡</sup>Recommendation is made with caution because of very limited experience with intravenous iron in infants and lack of a safe, acceptable intravenous preparation (estimated daily intravenous requirement is 100 µg/kg for term infants and 200 µg/kg for preterm infants).

<sup>§</sup>Because of a lack of information on the compatibility of fluoride with TPN and on the contamination level of fluoride in TPN solutions, firm recommendations cannot be made; with long-term TPN (longer than 3 months), a dosage of 500 µg/day may be important in preterm infants, who already have a higher incidence of subsequent dental caries.

<sup>||</sup>The only trace element recommended on day 1 of parenteral nutrition. If the infant requires TPN for longer than 3 months, the dosage must be reduced to 100 µg/kg/day.

ASCN, American Society for Clinical Nutrition; TPN, total parenteral nutrition.

Data from the American Society for Clinical Nutrition, Subcommittee on Pediatric Parenteral Nutrient Requirements, from the Committee on Clinical Practice Issues: *Am J Clin Nutr* 48:1324-1343, 1988.

TABLE 69-5

## Recommended Parenteral Intake of Vitamins for Term and Preterm Infants

Vitamin	Term (daily dose)		Preterm (dose/kg/day)*	
	Recommended	MVI-Pediatric (1 vial: 5 mL)	Recommended	MVI-Pediatric (40% of vial: 2 mL/kg/day)
<b>Fat-Soluble</b>				
Vitamin A (IU)	2300	2300	1640	920
Vitamin D (IU)	400	400	160	160
Vitamin E (IU)	7	7	2.8	—
Vitamin K ( $\mu$ g)	200	200	80 <sup>†</sup>	80
<b>Water-Soluble</b>				
Vitamin B <sub>6</sub> ( $\mu$ g)	1000	1000	180	400
Vitamin B <sub>12</sub> ( $\mu$ g)	1	1	0.3	0.4
Vitamin C (mg)	80	80	25	32
Biotin ( $\mu$ g)	20	20	6	8
Folic acid ( $\mu$ g)	140	140	56	56
Niacin (mg)	17	17	6.8	6.8
Pantothenate (mg)	5	5	2	2
Riboflavin ( $\mu$ g)	1400	1400	150	560
Thiamin ( $\mu$ g)	1200	1200	350	480

\*Maximum not to exceed dosage for term infant. Note: American Society for Clinical Nutrition (ASCN) recommendations (1988) currently are not achievable because no ideal intravenous vitamin preparation is available for preterm infants; 40% of a vial (2 mL/kg/day) of MVI-Pediatric (Armor, USA; Rorer, Canada) is the closest intake that can be achieved.

<sup>†</sup>This does not include the 0.5-1 mg of vitamin K to be given at birth, as recommended by the American Academy of Pediatrics.

Data from the American Society for Clinical Nutrition, Subcommittee on Pediatric Parenteral Nutrient Requirements, from the Committee on Clinical Practice Issues: Am J Clin Nutr 48:1324-1343, 1988.

Some infants with cholestasis will require continued parenteral nutrition. In these infants, the use of small-volume enteral feeding in combination with parenteral nutrition may stabilize or improve hepatic function. The use of phenobarbital and ursodeoxycholic acid has been shown to be beneficial in some studies of older children and adults. However, a recent study in preterm infants demonstrated that tauroursodeoxycholic acid did not prevent the development of parenteral nutrition-associated cholestasis and was ineffective in reducing cholestasis once it occurred (Heubi et al, 2002). At present, the routine use of ursodeoxycholic acid or phenobarbital in parenteral nutrition-associated cholestasis cannot be recommended.

Catheter-related complications remain an important problem with parenteral nutrition; the major complication is infection. Two of the most common bacterial pathogens are *Staphylococcus epidermidis* and *Staphylococcus aureus*. Fungal infections also occur, *Candida albicans* and *Malassezia furfur* being the most common agents. The incidence of sepsis during parenteral nutrition is higher at the lower gestational ages and also increases with the duration of parenteral nutrition. Parenteral nutrition-associated sepsis is likely to be a product of many factors, not the least of which is that the most immature and critically ill patients are most likely to receive parenteral nutrition for prolonged periods. In infants who have developed cholestasis while receiving parenteral nutrition, the rate of sepsis may be increased. The infusate itself also may play a role in the development of sepsis; an association has been reported between the use of intravenous lipid and coagulase-negative staphylococcal bacteremia and *M. furfur* fungemia (Freeman et al, 1990; Redline

et al, 1985). At present, avoiding parenteral nutrition-associated infections is best accomplished by meticulous attention to sterile technique in catheter care and early initiation and advancement of enteral nutrition. Prophylactic low-dose vancomycin may diminish the incidence of parenteral nutrition-associated sepsis, but in view of concerns about toxicities and the potential for antibiotic resistance, this approach cannot be recommended (Craft et al, 2002).

Complications specifically related to the catheter also have been reported. Broviac catheters are difficult to place and are associated with thrombosis in neonates (Sadiq et al, 1987). In most NICUs, Broviac catheters have largely been replaced by small-bore Silastic catheters placed percutaneously. However, all central catheters, including the small-bore variety, have produced life-threatening complications. Pericardial tamponade and significant plural effusions are known complications of the use of central catheters in neonates (Aiken et al, 1992; Giacoia, 1991). Although these are uncommon events, clinical awareness and early recognition of these complications can prevent mortality.

### USE OF PARENTERAL NUTRITION IN THE NEONATAL INTENSIVE CARE UNIT: A PRACTICAL APPROACH

The preceding portion of this chapter has presented the scientific basis for recommendations regarding provision of parenteral nutrition to neonates. The following paragraphs present a practical approach to the administration

of parenteral nutrition, with a particular emphasis on ELBW infants.

Every clinician caring for ELBW infants must recognize the urgent need to initiate intravenous amino acids shortly after birth. As mentioned previously, the ELBW infant loses 1.5% of total body protein each day that amino acids are withheld. Consequently, the goal of early parenteral nutrition should be to limit catabolism and preserve endogenous protein stores. Numerous studies have clearly demonstrated both the safety and efficacy of early amino acids in accomplishing this goal, even at low caloric intakes.

We recommend starting with a minimum of 1.5 to 2.0 g/kg/day of amino acids on the first day of life. This can be accomplished simply by adding one of the crystalline amino acid solutions designed for use in neonates (Aminosyn-PF, Primene, Premasol, or TrophAmine) to glucose to use as the initial maintenance fluid in ELBW infants. In infants with rapidly changing fluid, dextrose, and electrolyte needs, one approach is to give the amino acids in 5% dextrose at a volume of 60 to 80 mL/kg/day. Additional fluids with or without electrolytes and/or a higher concentration of dextrose can then be “Y’d in,” with adjustments as needed for the individual infant’s fluid, dextrose, and electrolyte requirements, eliminating the need to discard the bag of parenteral nutrition fluid for such changes in status. In nurseries with standard “hang times” for parenteral nutrition and/or those that outsource this aspect of patient care, bags with 5% dextrose and 1.5 to 2.0 g/kg/day of amino acids can be made in advance so that intravenous amino acids are not delayed in a newly admitted neonate. This mixture of glucose and amino acids can be given via a peripheral intravenous line, umbilical venous line, or percutaneous central venous catheter. Increased usage of percutaneously placed central venous catheters has certainly facilitated early and widespread usage of parenteral nutrition in premature infants. In our nursery, strong consideration is given to percutaneous central venous line placement in ELBW infants early in their postnatal course.

To meet growth requirements, 2.7 to 4.0 g/kg/day of amino acids is required. It is important to point out that such amounts are merely estimates, and protein requirements to sustain optimal growth in ELBW weight infants may be even higher. Once administration of amino acids is initiated, intake can be advanced to meet requirements for growth over a relatively short period. We typically advance amino acid intake by 1.0 g/kg/day until the goal is reached. No data are available, however, to support the clinical practice of slowly advancing amino acid intake over several days. It would be equally reasonable to initiate parenteral amino acids at 3.0 to 3.5 g/kg/day. Given the available data, we also recommend the addition of cysteine to the amino acid solution (40 mg/g of amino acids, to a maximum of 120 mg).

Glucose should be supplied in a quantity sufficient to maintain normal plasma glucose concentrations. As discussed previously, glucose production and utilization rates are highest in the most premature infants; their glucose needs are in the range of 6 to 8 mg/kg/minute, whereas the term infant’s needs are approximately 3 to 4 mg/kg/minute. Giving 10% dextrose at 100 mL/kg/day provides a glucose

infusion rate of 7 mg/kg/minute. Starting infants with birth weights less than 1000 g on 5% dextrose is likely to be prudent if their total fluid requirements are greater than 120 to 150 mL/kg/day.

Lipids should be started within the first 24 hours of life, usually at 1.0 g/kg/day. We typically start lipids at 1.0 g/kg/day and advance by 0.5 to 1.0 g/kg/day to a usual maximum of 3 g/kg/day while monitoring and maintaining serum triglycerides at less than 200 mg/dL. Given the numerous advantages over 10% solutions, 20% lipid emulsions should always be used. To facilitate clearance and to avoid impairment of oxygenation, lipids should be infused over a 24-hour period. There is currently no evidence to support the use of cyclic infusion in the acute setting of the NICU.

Caloric goals during parenteral nutrition are lower than with enteral feeds. To achieve optimal protein retention, approximately 80 to 90 kcal/kg/day is a reasonable goal. To optimize growth, somewhat higher caloric intakes may be necessary. The non-protein balance between carbohydrate and lipid should be approximately 60:40. These goals can usually be achieved using glucose solutions with concentrations no greater than 12.5% (Table 69–6).

There is a paucity of data related to monitoring laboratory tests during provision of parenteral nutrition. Suggested monitoring for infants receiving parenteral nutrition in our institution is shown in Table 69–7. All of these laboratory tests may not be appropriate in ELBW infants due to constraints related to blood sampling.

The use of parenteral nutrition should be accompanied by the early initiation of enteral feeds (within the first 1 to 3

**TABLE 69–6**

**Caloric Value of Parenteral Nutrition Solutions**

Composition*	kcal/kg/day	% of Non-protein Calories
<b>Example 1</b>		
Total fluids at 110 mL/kg/day		
10% dextrose	37	55
3 g/kg/day lipid	30	45
3.5 g/kg/day amino acids	14	—
Total	81	—
<b>Example 2</b>		
Total fluids at 80 mL/kg/day		
12.5% dextrose	34	53
3 g/kg/day lipid	30	47
3.5 g/kg/day amino acids	14	—
Total	78	—
<b>Example 3</b>		
Total fluids at 140 mL/kg/day		
12.5% dextrose	60	67
3 g/kg/day lipid	30	33
3.5 g/kg/day amino acids	14	—
Total	104	—

\*Dextrose: 3.4 kcal/g; protein: 4 kcal/g; lipid (20% emulsion): 10 kcal/g.

TABLE 69-7

**Suggested Monitoring During Parenteral Nutrition**

Parameter	Frequency
Weight	Daily
Length and OFC	Weekly
Serum glucose	1 ×/shift during week 1, then daily
Serum Na, K, Cl, BUN, Ca, P, Mg, hematocrit	2-3 ×/week during week 1, then weekly
Alkaline phosphatase, ALT (SGPT), GGT, fractionated bilirubin	Weekly

ALT; alanine transaminase; BUN, blood urea nitrogen; GGT, gamma-glutamyl transferase; OFC, occipitofrontal circumference; SGPT, serum glutamate-pyruvate transaminase.

days of life). Parenteral nutrition should be continued until enteral feedings are well established and providing approximately 100 to 110 kcal/kg/day, although availability of intravenous access may necessitate earlier termination of parenteral nutrition in some circumstances. As enteral feeds are advanced, the protein and lipid contents of the parenteral nutrition can be gradually decreased. In addition, careful and prompt attention to reinstatement of parenteral nutrition during episodes of intolerance of enteral feeds cannot be overemphasized. Infants with intolerance of enteral feeds in whom nothing-by-mouth (NPO) status is frequently necessary present an additional challenge. In such infants, it may be prudent to determine full-volume parenteral nutrition needs as for NPO status and to then run the parenteral nutrition solution at a lower rate if enteral feeds are administered. With this approach, if a change to NPO status becomes necessary after administration of the parenteral nutrition fluid has begun, the volume can be safely increased and caloric and protein intake is not compromised.

## CHAPTER 70

### Developmental Anatomy and Physiology of the Gastrointestinal Tract

Carol Lynn Berseth

#### STRUCTURAL AND FUNCTIONAL DEVELOPMENT

The gastrointestinal tract is formed as a result of invagination and folding of the embryo as early as the fourth week of gestation. When the buccopharyngeal and cloacal membranes rupture, complete continuity is established between the primitive gastrointestinal tract and the exterior environment. A series of evaginations, elongations, and dilations result in the ultimate formation of the esophagus, stomach, duodenum, liver, and pancreas from the foregut; the jejunum, ileum, and ascending and transverse segments of the colon from the midgut; and the descending and rectosigmoid colon from the hindgut. As the gut rapidly elongates during the first trimester, it herniates into the umbilical cord. It reenters the abdominal cavity and rotates counterclockwise around the superior mesenteric artery, achieving its final position by 20 weeks of gestation (Fig. 70–1). All of the anatomic structures of the gastrointestinal tract are recognizable and well formed by the second trimester. Functional maturation of these structures, however, occurs well after anatomic maturation. Many functions are still immature at birth in the term infant and are not established until 2 to 4 years of age (Table 70–1).

As late as the 1980s, maturation and growth of the gastrointestinal tract were considered to be regulated by genetic endowment, the biologic clock, endogenous events such as the release of hormones, and exposure to exogenous factors such as amniotic fluid or enteral feedings. We now know that these four factors are reflective on a molecular level of various transcription events and intercellular cross-talk. The gastrointestinal tract also is in continuity with the intrauterine environment, as the fetal gut is bathed in amniotic fluid as early as 4 weeks of postconceptional age. By 20 weeks, 15 mL of amniotic fluid traverses the fetal gut; this volume rapidly increases to 400 to 500 mL by term. Amniotic fluid contains nutrients as well as hormones and growth

factors that may provide stimulation for maturation. Functional maturation occurs along axes directed proximodistally and aborally. Concurrently, vascular and neural structures migrate along similar axes to support and regulate intestinal function. Vascular supply is provided by the celiac, superior mesenteric, and inferior mesenteric arteries. Enteric neurons are derived from neuroblasts that originate in the vagal region of the neural crest and migrate along the gastrointestinal tract with the descending fibers of the vagus nerve.

Because structural development appears to develop asynchronously with functional development, a brief review of structural development precedes a description of functional development for each anatomic entity discussed.

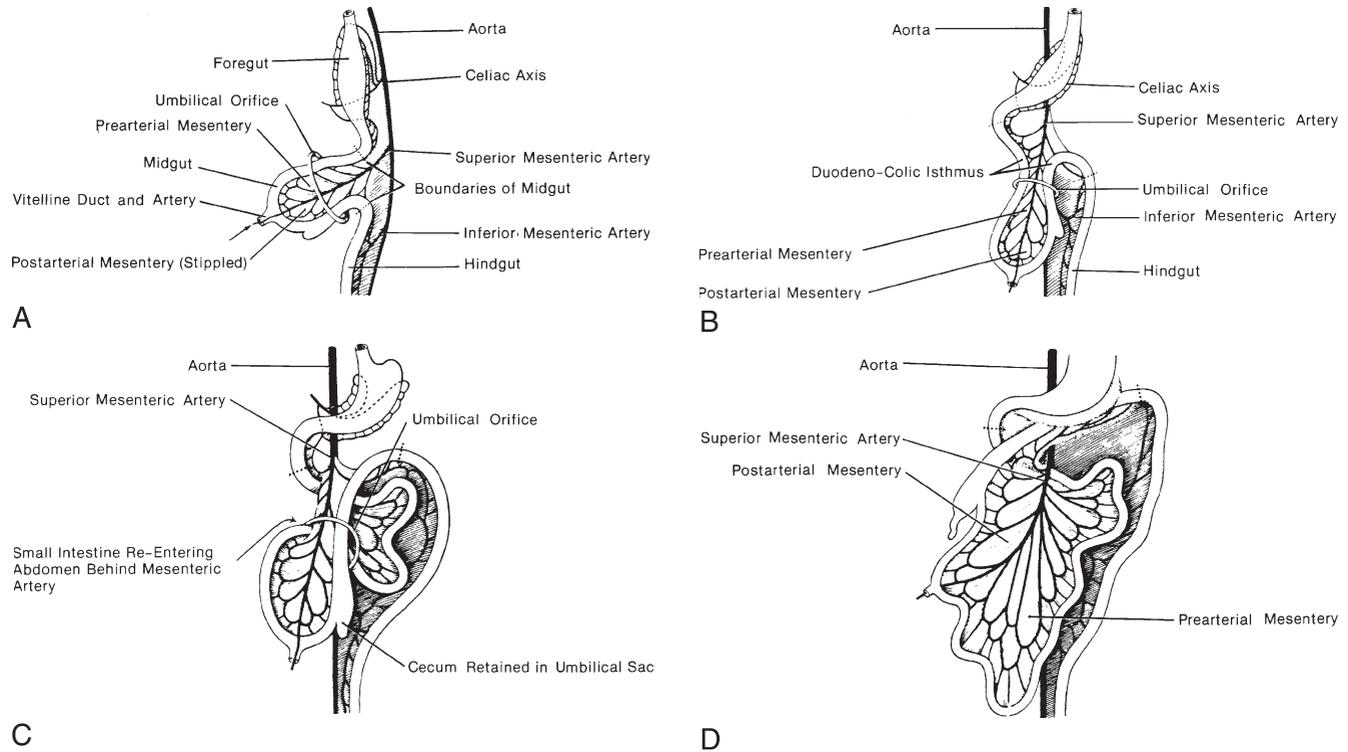

#### Oropharynx and Esophagus

Non-nutritive sucking begins at approximately 20 weeks of gestation (Herbst, 1983). It is characterized by mouthing movements that may or may not be coordinated with swallowing. Nutritive sucking, which does not appear until 32 to 34 weeks of gestation, consists of prolonged bursts of sucking that also contain swallows. Swallowing frequency is significantly lower in preterm infants whose postconceptional age is 30 to 35 weeks than in infants whose gestational age exceeds 35 weeks (Schrank et al, 1998), and maturation of various characteristics of sucking is related to gestational age rather than postnatal age (Gewolb, 2001). Such features include the percent of sucks that are part of “runs” of sucks, duration of sucking runs, and rate of sucking (Gewolb, 2001). Lau and coworkers (2000) have characterized sucking and swallowing in terms of maturation of function; they defined five distinct stages based on the presence or absence of suction and the rhythmicity of suction and expression of milk into the posterior pharynx. Using this staging system, they have shown that oral feeding performance improves as an infant matures from stage 1 to stage 5.

Superficial glands are present in the pharyngeal and esophageal mucosa by 20 weeks and squamous cells by 28 weeks. Mucous and lingual lipases also are secreted. The upper esophageal sphincter is present by 32 weeks. The neuroblasts and circular muscle throughout the body of the esophagus appear by the end of the first trimester, and esophageal peristalsis is present in the preterm infant.

#### Stomach

The structure of the stomach is well established by 6 weeks; the circular and longitudinal muscles appear by 9 weeks; and the endocrine, chief, mucous, and parietal

**FIGURE 70-1.** Diagram showing normal rotation of alimentary tract. **A**, Fifth week of intrauterine life (*lateral view*). The foregut, midgut, and hindgut are shown with their individual blood supply supported by the common dorsal mesentery in the sagittal plane. The midgut loop has been extruded into the umbilical cord. **B**, Eighth week of intrauterine life (*anteroposterior view*). The first stage of rotation is being completed. Note the narrow duodenocolic isthmus from which the midgut loop depends and the right-sided position of the small intestine and left-sided position of the colon. Maintenance of this position within the abdomen after birth is termed *nonrotation*. **C**, About the 10th week of intrauterine life, during the second stage of rotation (*anteroposterior view*). The bowel in the temporary umbilical hernia is in the process of reduction; the most proximal part of the prearterial segment entering the abdomen to the right of the superior mesenteric artery is held forward close to the cecum and ascending colon, permitting the bowel to pass under it. As the coils of small intestine collect within the abdomen, the hindgut is displaced to the left and upward. **D**, Eleventh week of intrauterine life at the end of the second stage of rotation. From its original sagittal position, the midgut has rotated 270 degrees in a counterclockwise direction about the origin of the superior mesenteric artery. The essentials of the permanent disposition of the viscera have been attained. (**A-D**, From Gardner CE Jr, Hart D: *Arch Surg* 29:942, 1934. Copyright 1934, American Medical Association.)

cells appear by 12 weeks. By 16 weeks, all of these cells are secreting their respective substances: hydrochloric acid, intrinsic factor, pepsin, gastrin, and mucus. Although acid secretion is present shortly after birth in preterm and term infants, it is approximately 10% of that seen in adults. Adult values are achieved by 3 months of postnatal age. Acid secretion is less in preterm infants than in term infants (Fig. 70-2).

### Pancreas

The rotation and fusion of the dorsal and ventral buds of the pancreas are complete by 7 weeks. Differentiation of the endocrine and exocrine structure is present by

14 weeks. By 14 weeks, immunoreactive insulin is detected and pancreatic zymogen granules are present in the acini. By 16 weeks, amylase is present. Trypsin, lipase, and amylase are secreted into the duodenum by 31 weeks (Zoppi et al, 1972). Concentrations of these enzymes are lower in preterm than in term infants and, in turn, are significantly lower in term infants than in children (Fig. 70-3). Postnatally, trypsin increases in concentration, followed by chymotrypsin, carboxypeptidase, lipase, and amylase (Lebenthal and Lee, 1980). Postprandial release of these enzymes initially is blunted at birth and cannot be stimulated by specific nutrients. For example, high-protein diets can increase trypsin and lipase secretion, but a high-fat diet does not stimulate lipase secretion (Zoppi et al, 1972).

TABLE 70-1

## Anatomic and Functional Maturation of the Gastrointestinal Tract

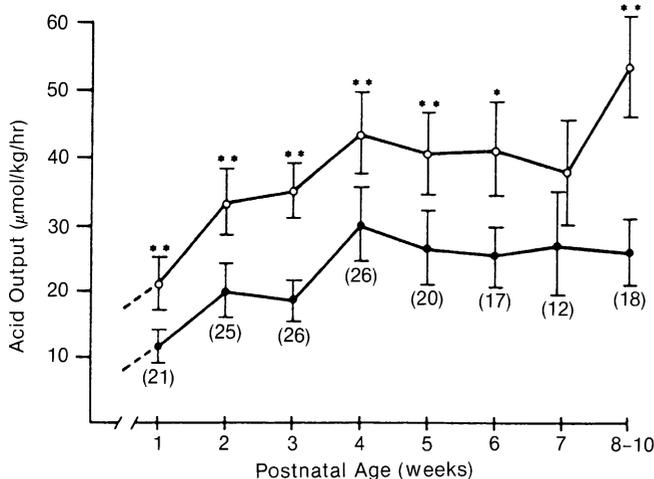

Postconceptional Age (weeks)					
15	20	25	30	35	40
Mouth	Salivary glands	Swallow	Lingual lipase	<i>Sucking</i>	
Esophagus	Muscle layers present	Striated epithelium present	<i>Poor lower esophageal sphincter tone</i>		
Stomach	Gastric glands present	G cells appear	<i>Gastric secretions present</i>	<i>Slow gastric emptying</i>	°
Pancreas	Exocrine and endocrine tissue differentiate	Zymogen present	<i>Reduced trypsin, lipase</i>		°
Liver	Lobules form	<i>Bile secreted</i>	<i>Fatty acids absorbed</i>		°
Intestine	Crypt and villus form	<i>Glucose transport present</i>	<i>Dipeptidase, sucrase, and maltase active</i>	<i>Lactase active</i>	
Colon		Crypts and villi recede		<i>Meconium passed</i>	

\*Full functional maturation occurs postnatally.

*Italics indicate functional maturation.*

### Liver

The liver is derived as an outbudding from the duodenum. The cranial portion of the bud differentiates into hepatic parenchyma, and the caudal portion, into the gallbladder. Lobules and bile canaliculi are present by 6 weeks; bile acids are synthesized by 12 to 14 weeks and are actively secreted by 22 weeks. There are qualitative and quantitative differences in bile acid synthesis in preterm infants. First, bile acid synthesis is decreased in the preterm infant compared with that in the term infant. Synthesis in the term infant, in turn, is approximately half of that seen in adults (Watkins et al, 1975) (Fig. 70-4). Similarly, bile acid pool size in preterm infants is approximately one-third that seen in term infants. Pool size in term infants, in turn, is approximately one-half that seen in adults. Hepatic hydroxylation is not fully developed

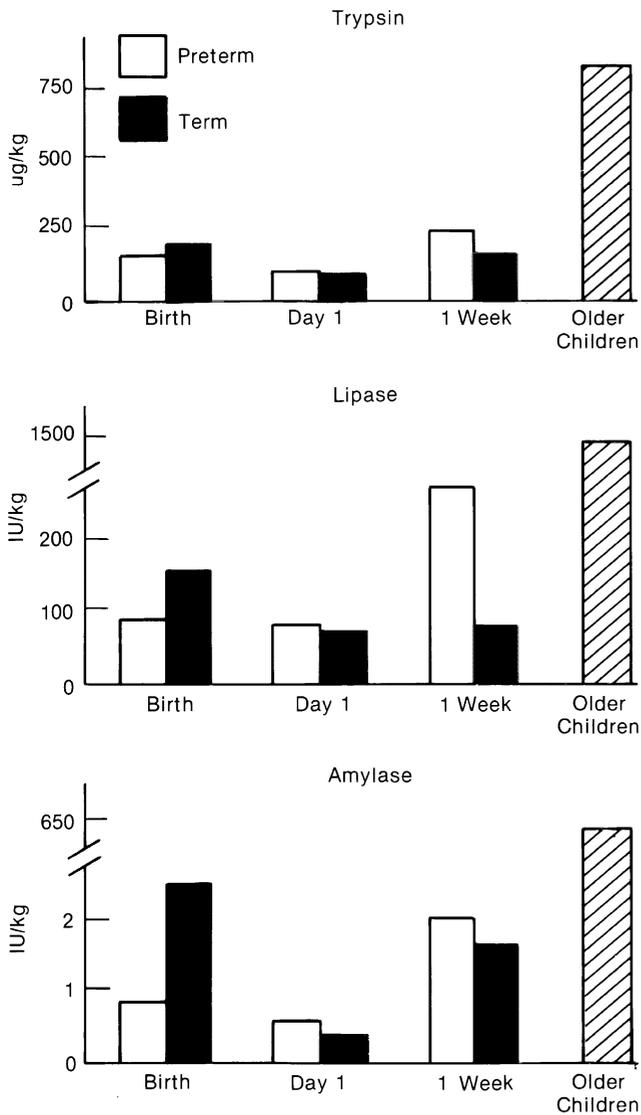

**FIGURE 70-2.** Basal acid output (○) and pentagastrin-stimulated acid output (●) in preterm infants. Number of subjects studied at each age is given in parentheses. \* $P < .05$ . \*\* $P < .01$ . (From Hyman PE, Clarke DD, Everett SL: Gastric acid secretory function in preterm infants. *J Pediatr* 106:468, 1985.)

in the fetus, and there is a decreased cholic acid-to-deoxycholic acid ratio. It also has been noted that atypical bile acids are present in the fetus; these are formed using fetal biosynthesis pathways. These compounds are not typically seen in adults and represent only a small percentage of bile acids by term (Nakagawa and Setchell, 1990). Degradation of bile salts also differs in preterm infants, in that preterm and term infants rely on taurine conjugation rather than glycine conjugation as in the adult. The active ileal transport mechanism of bile salts is present but immature (Heubi and Balistreri, 1980). Because hepatic uptake, secretion, and transport are not yet fully functional in the newborn, serum bile acid concentrations are elevated. These elevated levels persist for 6 to 8 weeks postnatally and slowly decline to adult values by 6 months (Suchy et al, 1981). Because hepatic processing of bile salts at multiple sites is immature, newborns are prone to develop cholestasis in response to stresses such as sepsis, mildly hepatotoxic drugs, or exposure to parenteral nutrition. This topic is reviewed in depth in Chapter 69.

### Small Intestine

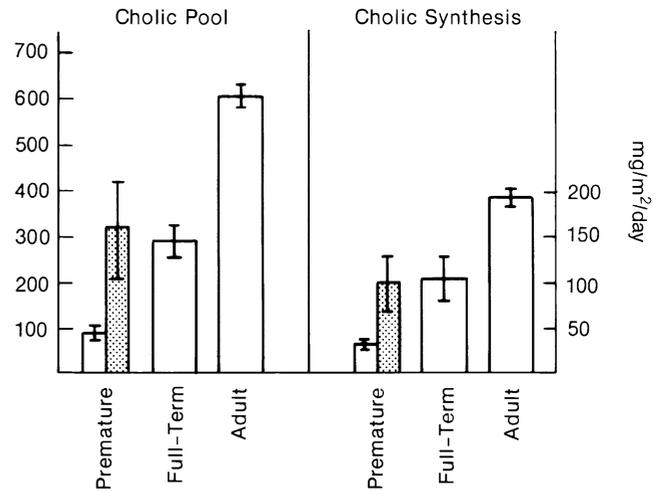

By the time the intestine elongates, rotates, and returns to the abdominal cavity, the mucosal and muscular structures are well developed. The crypt and villus structure is present throughout. Because of rapid proliferation of epithelial tissue, the duodenum is transiently obstructed, but it is fully patent by 12 weeks. During the second trimester, the glycocalyx has appeared, and the brush border is structurally well defined. Endocrine cells are well established, and granules containing gastrin, secretin, cholecystokinin, motilin, serotonin, somatostatin, and substance P are present by 12 to 18 weeks. Gastrin, secretin, motilin, and gastrin inhibitory polypeptide are localized to duodenum and jejunum, whereas enteroglucagon, neurotensin, somatostatin, and vasoactive intestinal polypeptide are distributed throughout the intestines. Brush border

**FIGURE 70-3.** Pancreatic enzyme activity in preterm (32 to 34 weeks of gestational age) and full-term infants fed a balanced formula. Data represent mean values. (Data from Zoppi G, Andreotti G, Pajno-Ferrara F, et al: *Exocrine pancreas function in premature and term infants. Pediatr Res* 6:880, 1972.)

membrane function, however, is immature. Although alpha-glucosidases, dipeptidases, and sucrase are functional by the end of the second trimester, lactase does not appear until 32 to 34 weeks of gestation. By 13 to 20 weeks of gestation, sucrase and maltase activities are 50% to 75% of those found in term infants and adults.

Lactase activity is present by 9 weeks (Fig. 70-5). By 24 weeks, however, lactase activity is still less than 25% of that found in term infants (Antonowicz et al, 1974; Auricchio et al, 1965). The abrupt rise in lactase activity that is noted to occur from 32 to 34 weeks of gestation coincides with an increase in lactase mRNA, implying that its delay in appearance is due to transcriptional control (Villa et al, 1992). When lactase first appears, its activity is distributed throughout the small intestine in a uniform manner. Shortly thereafter, a proximal gradient is established (Lacroix et al, 1984). Thus, lactase has been observed to be present in

**FIGURE 70-4.** Comparison of bile acid pool size and synthesis rate in premature infants, full-term infants, and adults, corrected for body surface area. Shaded bars refer to premature infants whose mothers had received prenatal treatment with dexamethasone or phenobarbital. Data are means  $\pm$  standard error (SE). (Courtesy of Dr. John B. Watkins, Children's Hospital, Philadelphia. Values for premature infants are from Watkins JB, Szczepanik P, Gould JB, et al: *Bile salt metabolism in the premature infant: Preliminary observations of pool size and synthesis rate following prenatal administration of dexamethasone and phenobarbital. Gastroenterology* 69:706, 1975. Values for term infants are from Watkins JB, Ingall D, Szczepanik P, et al: *Bile-salt metabolism in the newborn: Measurement of pool size and synthesis by stable isotope technique. N Engl J Med* 288:431, 1973. Values for adults are from Vlahcevic et al, 1971.)

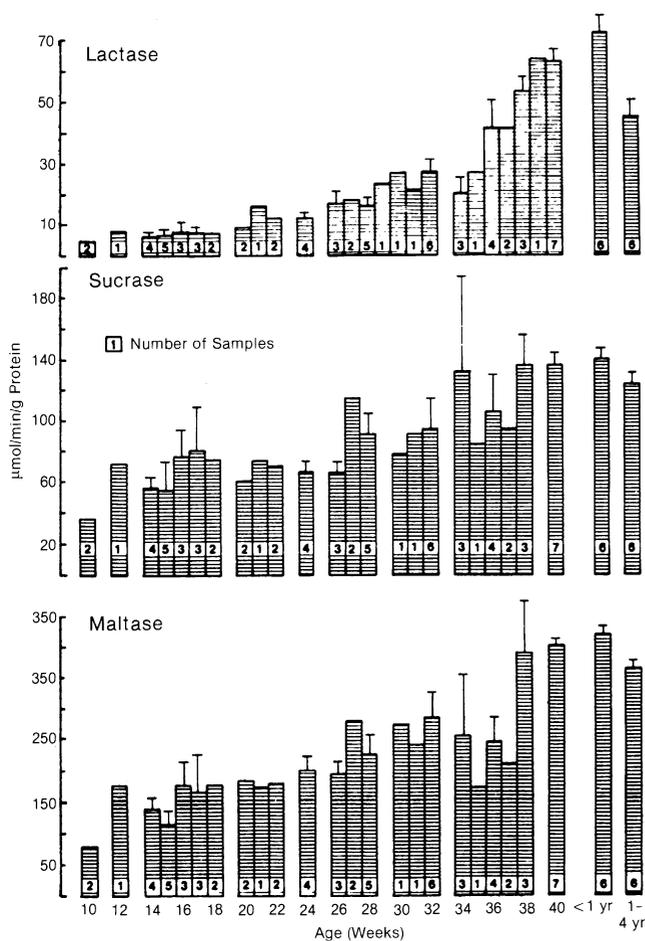

the colon at 13 to 20 weeks of gestation (Ménard and Pothier, 1987).

Sucrase and maltase also are present by 9 weeks of gestation. The activities of these enzymes achieve levels as high as 75% of those found in term infants by the end of the second trimester. Sucrase-isomaltase exists in a single high-molecular-weight form (Triadoru and Zweibaum, 1985). Glucoamylase, which is responsible for absorption of starches and glucose polymers, is present by the end of the second trimester, with activities approximately half those found at term (Antonowicz et al, 1974).

All of the numerous brush border peptidases, including alpha-glutamyl transpeptidase, aminopeptidase, oligoaminopeptidase, dipeptidylaminopeptidase IV, and carboxypeptidase, are present by the end of the second trimester. Thus, active glucose transport occurs by 10 weeks (Jirsova et al, 1996) and amino acid uptake by 12 weeks (Levin et al, 1968).

## Colon

The cecal dilation that forms the hindgut appears by 4 weeks, and by 12 weeks haustra and taeniae appear. When the rotation of the midgut is completed at 12 weeks, the cecum descends into the right iliac fossa. The rectum forms by 8 weeks, and formation of complete muscle layers and neural migration of ganglia cells are accomplished by 24 weeks. Morphologically, the premature colon

**FIGURE 70-5.** Developmental patterns of jejunal disaccharidase activities in human fetuses. (From Antonowicz I, Lebenthal E: *Developmental pattern of small intestinal enterokinase and disaccharidase activities in the human fetus. Gastroenterology* 72:1301, 1977.)

contains villi and crypts, and disaccharidase activities are present until 22 weeks of gestation. Although the villi and disaccharidase activities decrease and then disappear by term, sucrase and glucoamylase activities may still be present as late as 28 to 32 weeks of gestation (Raul et al, 1986).

### Gastrointestinal Hormones and Peptides

Numerous regulatory gut peptides are produced in the gastrointestinal tract. Several function as true hormones, including gastrin, cholecystokinin, motilin, pancreatic polypeptide, and somatostatin. Others have paracrine or neurocrine function, including gastric inhibitory polypeptide, bombesin, vasoactive intestinal polypeptide, neurotensin, enteroglucagon, and peptide YY. All of these peptides are present in the fetal intestine by the end of the first trimester. Adult distribution of these peptides may not be established until the end of the third trimester. All of these peptides have been identified in the plasma of preterm and term infants (Lucas et al, 1980). However, some concentrations are similar to those seen in adults, whereas others are lower or higher (Berseth, 1992).

Earlier studies evaluated the plasma concentrations of peptides in the fasting state. Because several of these peptides function as true hormones, more recent studies have evaluated whether these peptides are released in response to feeding. It appears that these hormones are released in response to feeding (Berseth, 1998); however, their releases are limited in the newborn compared with the adult (Berseth et al, 1992; Lucas et al, 1980) (Fig. 70-6). With routine enteral feedings, release of these peptides becomes brisker and more intense over the first postnatal month (Berseth, 1992; Lucas et al, 1980).

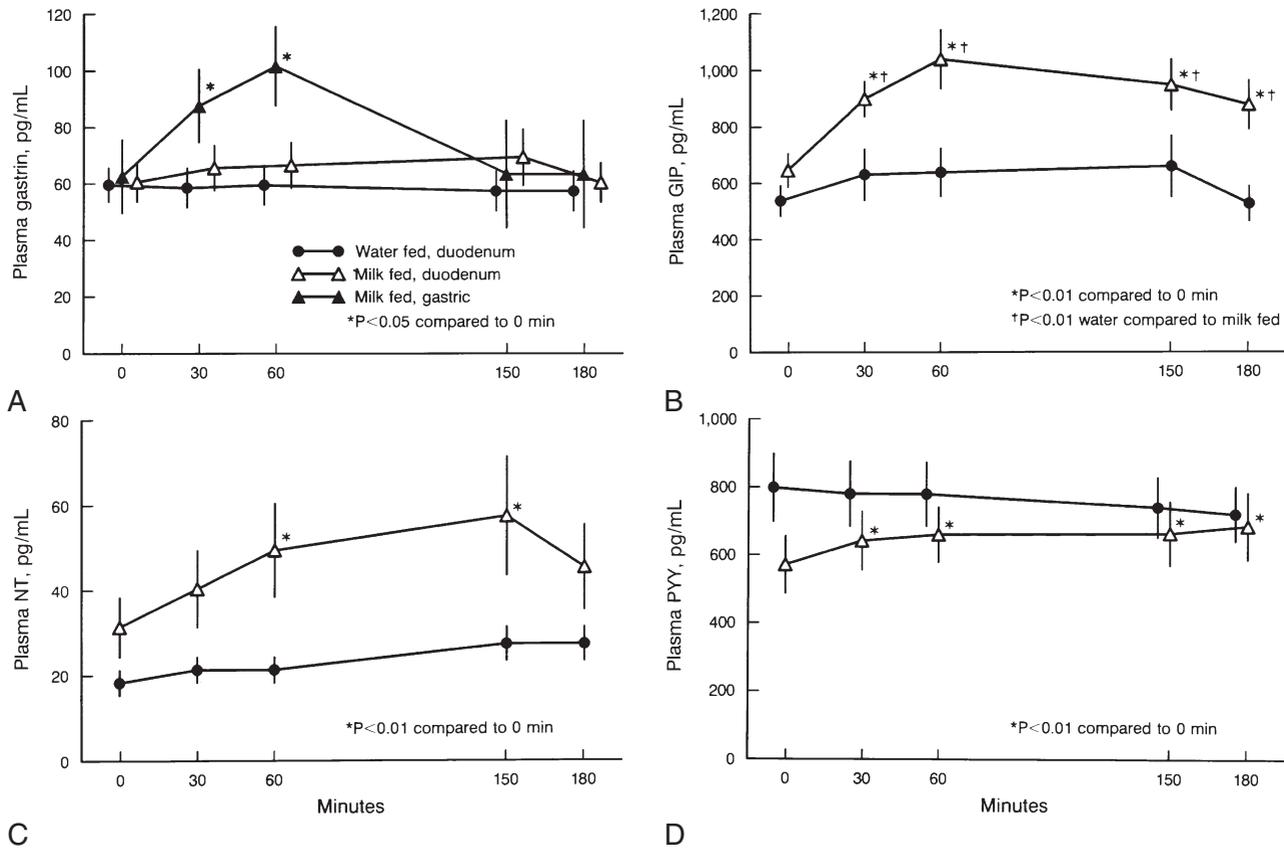

## PROCESSING OF NUTRIENTS

### Digestion of Carbohydrates

Carbohydrates contribute approximately 40% of the caloric intake in healthy term infants. Lactose present in breast milk and formulas is the predominant source of carbohydrate. Some preterm formulas also contain glucose polymers. Although preterm infants have relatively low levels of lactase activity, they display normal growth with little diarrhea when they are fed lactose-containing milk and formula (MacLean and Fink, 1980). It is speculated that the relative absence of lactase activity is compensated for by the conversion of malabsorbed lactose by colonic bacteria to volatile organic acids, which are subsequently absorbed. It is not unusual, however, for stools of breast-fed preterm infants to contain disaccharides. Glucose polymers require amylase for hydrolysis. Because pancreatic amylase levels are quite low, these polymers probably are hydrolyzed by salivary amylase or absorbed directly at the mucosal level via mucosal glucoamylase, which has its maximal activity against polymers with chain lengths of 5 to 9 units (Kerzner et al, 1981). Once lactose and polyose are hydrolyzed to glucose, active glucose transport occurs by 17 weeks via two systems: a low-affinity, high-capacity sodium-glucose cotransport system found along the entire length of the intestines and a low-affinity, high-capacity system localized to the proximal small intestine (Malo, 1988).

### Digestion of Lipids

Fat provides 50% of the caloric intake of the newborn. Fat absorption is important not only for use in structural growth and cell membrane integrity but also in facilitating the absorption of fat-soluble vitamins. Fat processing has two components: (1) that occurring in the lumen of the intestine and (2) that occurring at the level of the mucosa. In the lumen, fats must be emulsified and hydrolyzed to form free fatty acids and monoglycerides. This process is achieved by bile acids and lipases, both of which are limited in amount or function (or both) in the preterm infant. Alternate mechanisms for fat hydrolysis appear to be present in the newborn. Lingual lipases and gastric lipases are present by 26 weeks of gestation. Serous glands located in the posterior third of the tongue produce lingual lipases, and non-nutritive sucking is a mechanism for its release. Lingual lipase tolerates the low gastric pH of 3.5 to 5.5. Gastric lipase, secreted by gastric glands, also contributes to luminal hydrolysis of fats in newborns (Cohen

**FIGURE 70-6.** Plasma concentrations of four gastrointestinal peptides in response to a 2-hour slow infusion feeding. Values for infants fed water intraduodenally (●) and for infants fed formula intraduodenally (Δ) are plotted in **A** to **D**. Plasma concentrations of gastrin (**A**), gastric inhibitory polypeptide (GIP) (**B**), neurotensin (NT) (**C**), and peptide YY (PYY) (**D**) are similar during fasting and postprandial sampling. When infants were fed milk, plasma concentrations of gastrin did not increase with intraduodenal feeding. When feedings were given intragastrically, shown in **A** (▲), plasma gastric concentrations increased significantly over fasting values. (Data summarized in Berseth CL, Nordyke CK, Valdes MG, et al: Responses of gastrointestinal peptides and motor activity to milk and water feedings in preterm and term neonates. *Pediatr Res* 31:587, 1992.)

et al, 1971). Additional lipases also are present in breast milk. The major breast milk lipase is bile salt-stimulated lipase. In contrast to endogenous lipases, this lipase is capable of hydrolyzing all three ester bonds of triglycerides. A second lipase that resembles lipoprotein lipase also has been thought to be present in breast milk. Thus, it appears that these lipases substitute for the absence of pancreatic lipase. Furthermore, in contrast with pancreatic lipases, these three lipases function well in an environment that has low bile salt concentration, as is the case in the preterm infant. Because of decreased bile acid synthesis by the liver, intraluminal bile acid concentration in the preterm infant is 1 to 2 mmol/L (Katz and Hamilton, 1977), or approximately half of the critical micellar concentration required for adequate fat absorption. Thus, these alternate lipases appear to be well adapted for function in the immature environment of the gastrointestinal tract of the preterm infant.

There is also a relationship between intraluminal  $\text{Ca}^{2+}$  concentration and fat absorption. In newborns, a high calcium intake impairs fat absorption, and for this reason the high calcium content of cow milk can cause malabsorption

of fats (Hanna et al, 1970). Conversely, high fat intake may also impair  $\text{Ca}^{2+}$  absorption. Therefore, the optimal relationship of dietary fat and calcium has not yet been identified for the preterm infant.

The source of dietary fat also influences absorption. Preterm infants digest and absorb fats derived from human milk better than formula-derived fats (Foman et al, 1970). Vegetable fats are absorbed better than animal fats. Unsaturated fats are absorbed better than saturated fats. Medium-chain and short-chain triglycerides are absorbed better than long-chain triglycerides (Roy et al, 1975).

Once the luminal phase of fat processing is completed, the mucosal phase of absorption must occur. The mucosal phase involves the passage of mixed micelles through the unstirred water layer at the mucosal cell surface. Monoglycerides and free fatty acids diffuse directly into the cells. Both of these processes appear to be well developed in the preterm infant. Thus, the inefficiency of fat absorption in the preterm infant, which ranges from 40% to 90%, largely reflects immaturity of intraluminal processing.

## Digestion of Proteins

Although proteins contribute less than 10% of ingested calories, they provide important “bricks” for the structure of somatic growth. Initial digestion of protein begins in the stomach, where dietary protein is denatured by gastric acid and cleaved to large polypeptides by pepsin. Because acid secretion is significantly lower in the preterm infant, it is not known how efficient this initial processing is. Gastric contents then are expelled into the upper intestine, where pancreatic proteases are capable of fairly efficient splitting of the peptides to oligopeptides and amino acids. As detailed previously, most of the brush border peptidases and cytosolic peptidases are well developed in the preterm infant, and the peptide transport system is efficient. In addition, there appears to be an alternate method for protein uptake in the intestine. Macromolecules can be actively taken up by pinocytosis by the neonatal intestine (Walker, 1978). In fact, preterm infants have been demonstrated to absorb intact lactoferrin of maternal origin (Hutchens et al, 1991).

## FACTORS INFLUENCING GASTROINTESTINAL FUNCTION

### Vascularization

Development of the mesenteric circulatory system parallels that of the intestine. Arterial supply occurs as a series of unpaired ventral outbuddings of vessels from the aorta to form the celiac axis, superior mesenteric artery, and inferior mesenteric artery. The celiac trunk originates at the level of T12 to L1, passes next to the median arcuate ligament of the diaphragm, and splits to form the splenic, left gastric, and hepatic arteries. Branches of the left gastric artery supply the lesser curvature and greater curvature of the stomach. Vessels from the hepatic artery supply the pancreas and duodenum. The superior mesenteric artery arises at L1 just caudal to the celiac trunk and supplies flow to the jejunum and ileum. Smaller branches form a series of arcades before entering the wall of the intestine. Therefore, collateral flow is considerable, and there are additional anastomoses with branches from the inferior mesenteric artery. The inferior mesenteric artery originates at L3 and supplies branches to the colon and rectum. Although rich collaterals are present throughout the gastrointestinal tract, watershed areas of marginal supply exist, as in the areas of the distal transverse colon and the upper rectum. In addition, the mucosa has the greatest need for vascular supply because of its high metabolic activity. Thus, it is the layer most sensitive to impairment of blood supply.

Regulation of mesenteric blood flow occurs at two points: the arteriole and the precapillary sphincter. Control is exerted on both intrinsic and extrinsic levels. Intrinsic control by local factors regulates blood flow in response to changes in arterial pressure and, consequently, tissue oxygenation. Vasodilation, for example, occurs in response to occlusion (reactive hyperemia) or feeding (functional hyperemia) and involves tonic changes at both the arteriolar and the precapillary levels. Extrinsic regulation is mediated by the splanchnic nerves by sympathetic input. In addition,

circulating endogenous and exogenous factors, such as hormones, histamine, and prostaglandins, may modulate vascular tone. Two basic aspects of vascular regulation are the maintenance of basal vascular tone, or resistance, and vascular responses to stress.

It appears that postnatal change in intestinal basal vascular resistance in the neonate results from a transition from neonatal to a more mature pattern of regulation. All of the following information pertains to sheep and swine, which are considered to have postnatal maturation of vascular regulation that is similar to that found in humans. In the fetus, intestinal basal vascular resistance is higher than in the neonate. Blood flow—and its obligatory oxygen delivery—is twofold higher in the neonate than in the fetus (Edelstone and Holzman, 1983), and this change supports the intense metabolic activity in the neonate needed for nutrient absorption. Vascular resistance then increases during the second to fourth postnatal weeks, with a corresponding fall in blood flow and oxygen delivery (Reber et al, 2002).

Basal vascular resistance in the neonate is mediated by nitric oxide (NO), which in turn causes vasodilation and the myogenic response, and endothelin, both of which regulate vasoconstriction. Rates of NO production are high during the immediate neonatal period, but the role of NO in determining vascular tone lessens over the first postnatal month (Reber et al, 2000). The myogenic response refers to the onset of vasoconstriction in response to increases in intravascular pressure. It is mediated by vascular smooth muscle cell contracting in response to stretch via stimulation of a  $Ca^{2+}$ -induced phosphorylation of myosin light chain kinase (Davis and Hill, 1999). Endothelin, produced by the vascular endothelium, binds to endothelin A ( $ET_A$ ) receptors and triggers vasoconstriction. As is the case for NO, endothelin production is high in the immediate neonatal period and declines thereafter (Nankervis and Nowicki, 2000).

These three mechanisms of regulation of intestinal vascular resistance dissipate by the end of the first postnatal month. Thereafter, intestinal growth causes increases surface area, which decreases vascular resistance, and extrinsic adrenergic innervation matures (Gootman et al, 1983).

The second set of mediators present in the gut vascular bed regulates vascular responses to hypoxemia and the presence of nutrients. In the intact animal, there appears to be a two-step response to hypoxemia. In response to modest hypoxemia ( $PO_2$  of 50 mm Hg), the gut vascular bed dilates, increasing perfusion. In response to severe hypoxemia ( $PO_2$  of <40 mm Hg), vasoconstriction, gut ischemia, and tissue hypoxia occur (Nowicki et al, 1988). Also present is a phenomenon called the *autoregulatory escape* (Shepherd and Granger, 1973). When gut blood flow is decreased by stimulating periaarterial mesenteric nerves (i.e., the extrinsic system) or by infusion of norepinephrine, it is restored within minutes by the intrinsic regulation (Shepherd et al, 1973). This escape mechanism is present in newborn swine (Nowicki et al, 1991) and presumably in human newborns as well.

The presence of nutrients in the gut triggers the postprandial hyperemic response, which consists of brisk vasodilation and increased blood flow and oxygen delivery. This response occurs in neonatal swine (Crissinger and Burney,

1992) and also in preterm infants (Martinussen et al, 1996). In addition, studies involving small numbers of patients have suggested that drugs such as indomethacin or caffeine may cause reductions in the intensity of this response (Hoeker et al, 2002; Lane et al, 1999; Zhang et al, 1999).

### Motor Function and Neural Regulation

Motor activity is responsible for the forward movement of nutrients throughout the alimentary tract. For the infant to feed successfully, there must be coordinated sucking and swallowing, an ability to empty the stomach, coordinated propagation of nutrients through the intestine, and expulsion of waste products from the colon. All of these tasks are achieved by motor activity, which requires intact function of muscle, the nerves that regulate them, and the hormones that modulate their activity. Aboral movement of luminal contents requires the coordinated contractions of muscle, which in turn are regulated by the enteric nervous system (ENS), or nerves located in the gastrointestinal tract. The muscle layers of the alimentary tract are present by 14 weeks and the nerves and endocrine components by 20 to 24 weeks. Muscle mass is less in the preterm infant than in the term infant, however; thus, forcefulness of contraction also is less.

Control of gastrointestinal functions is provided primarily by the ENS. The ENS is a subsystem of the autonomic nervous system and is composed of complex neural circuits located within the gut wall. The basic unit of the ENS is the nerve cell, which functions by releasing neurotransmitters to other neurons or to effector cells (i.e., striated or smooth muscle). In general, the neurotransmitter acetylcholine is involved in excitatory synaptic events and norepinephrine in inhibitory synaptic events. Although the central nervous system and the ENS function in an integrated manner to regulate gastrointestinal events, the final common regulation for effectors is via the ENS. Thus, the ENS is capable of regulating gastrointestinal function independent of the central nervous system or spinal nerves.

The nerves that form the ENS are embryologically derived from cells that migrate from the vagal, truncal, and sacral regions of the neural crest. Cells from the vagal nerves populate the entire gastrointestinal tract, whereas those from the truncal nerves populate the foregut and those from the sacral nerves populate the distal gut. Neural crest cells first enter the outer gut mesenchyme and then later migrate to the mucosa. During this process of migration, neural cells proliferate. In addition, they are pluripotent and express catecholamines. When they reach the gut wall late in gestation, they differentiate into mature enteric neurons that no longer express catecholamines. The ENS consists of a variety of plexuses of nerve cell bodies and interneuronal circuits. The myenteric plexus is located between the longitudinal and circular muscle layers. The submucosal plexus is located between the (lamina) muscularis mucosae and the circular muscle layer. All of the differentiated neurons express serotonergic and peptidergic neurotransmitters, such as serotonin, substance P, and neuropeptide Y. Finally, some of the neural crest cells and/or neuronal precursors cluster to form ganglia. The normal distribution of ganglion cells is present by

24 weeks. However, the density of these ganglia may change over the first several postnatal years (Wester et al, 1999).

Another structure formed during fetal life is the interstitial cell of Cajal. These are specialized cells that differentiate from muscle cells (Young, 1999). These cells are interspersed between muscle cells and have intimate connections to neural cells, and they are responsible for maintaining the pacemaker function of the intestinal muscle. Thus, the denervated gut muscle has a basal contraction rate, as is the case for cardiac muscle. However, the coordination of this basal contraction is directly regulated by neural input. Fekete and colleagues (1995, 1996) have characterized the ontogeny of neural maturation in fetal tissues. At 10 weeks of postconceptional age, the circular muscle layer is formed, followed by the appearance of a primitive myenteric plexus and the longitudinal smooth muscle layer (Fekete et al, 1996). At 10 weeks, most neural cells in the gut myenteric plexus are still neuroblasts, with few specific contacts with muscle and few synaptic vesicles. By 18 weeks, however, both neuroblasts and ganglion cells are present. Neural cells have axoaxonic synapses and contain synaptic vesicles. Moreover, functional neural transmission appears to be present, as gut tissues display intense amine-specific fluorescence and nicotinamide adenine dinucleotide (NADH)-diaphorase staining, indicating that neurotransmitters are being produced (Fekete et al, 1995). Neurotransmitters are present by immunohistochemical staining by 24 weeks. The adult distribution along the length of the intestine of the transmitters may not be achieved until close to term.

Abnormalities in neural migration are reflected in clinical disease. Neural structures are abnormal in patients with Chagas disease, achalasia, chronic intestinal pseudo-obstruction, and Hirschsprung disease (Cohen, 1974; Schuffler and Jonah, 1982). Chemical ablation of myenteric neurons in rats results in hypertrophy of the longitudinal and circular muscle and, subsequently, enhanced myoelectric activity (Holle and Forth, 1990). In fetal sheep that have had artificial exteriorization of the bowel in utero to stimulate gastroschisis, profound disruption of the myenteric plexus occurs concurrently with the presence of highly disturbed motility (Holle and Forth, 1990). An absence of NO has been demonstrated among infants who have pyloric stenosis and Hirschsprung disease. NO is thought to provide inhibitory input to the ENS as a nonadrenergic, noncholinergic neurotransmitter. Hence, its absence results in increased muscle tone.

### Motility of the Digestive System

Sucking and swallowing involves the use of skeletal and smooth muscle. Maturation of sucking was reviewed earlier under "Esophagus." This section focuses on motor function in the gastrointestinal tract from the distal esophagus onward. The major limitation to enteral alimentation appears to be not digestion or absorption but the propulsion of chyme along the gastrointestinal tract. The human fetus can swallow as early as 17 weeks of gestation, and swallowing appears to play an important role in the regulation of amniotic fluid volume. For example, hydramnios is often seen in pregnancies in which fetal swallowing is

impaired, such as when esophageal atresia or upper intestinal atresia is present. Exposure to factors in amniotic fluid appears to be important for gastrointestinal development. Mucosal maturation in the stomach is delayed in rabbit fetuses if the esophagus is ligated, and maturation returns to normal if the esophagus is exposed to amniotic fluid or epidermal growth factor.

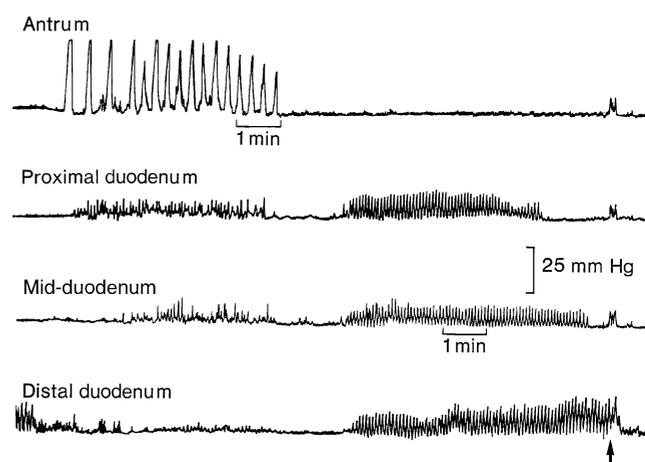

Once milk or formula is ingested, it must be propelled distally past the lower esophageal sphincter into the stomach. The lower esophageal sphincter, which is responsible for preventing reflux of gastric content, is a 0.6- to 1-cm area of increased muscular tone located in the distal esophagus. Lower esophageal sphincter basal pressures range from 20 to 40 mm Hg in term infants and are as low as 5 mm Hg in infants born at 27 weeks of gestation (Newell et al, 1988). Coordinated activity constitutes a small proportion of the esophageal contractions in preterm infants (Omari et al, 1995); however, it does not appear that this is a limiting factor for the neonate ingesting formula or milk.

Motor activity in the preterm stomach and intestine has been extensively studied. The stomach fundus is responsible for dilation and accommodation of ingested milk or formula, and the antrum is responsible for mixing and expelling contents into the duodenum. Little is known about gastric accommodation. Zangen and colleagues (2001) have shown that compliance is increased in the newborn term stomach. Thus, accommodation is poor, but it improves rapidly within 24 to 48 hours. Gastric emptying requires that antral motor activity and duodenal motor activity be adequate and that their actions be coordinated. Antral motor activity is similar in the 24-week preterm infant and in the term infant (Ittman et al, 1992). Duodenal motor activity as well as its coordination with antral activity, however, differs in preterm and in term infants. The absence of coordination of antral and duodenal motor activity thus appears to reflect immaturity of duodenal function rather than of antral function. When term infants ingest a feeding, a brisk onset of duodenal contraction is noted. Approximately only 25% to 50% of preterm infants have this mature motor response to feeding (Al-Tawil and Berseth, 1996). Rather, in most preterm infants, duodenal contractions cease in response to a feeding. When this cessation of motor contractions occurs, gastric emptying is delayed (DeVillie et al, 1998). Gastric emptying is delayed in the preterm infants compared with that seen in the term infants (Anderson and Berseth, 1996; Cavell, 1979). As in adults, meal composition also affects gastric emptying, with delay occurring as caloric density increases. Emptying also is delayed more with glucose or lactose than with glucose polymers and with long-chain triglycerides than with medium-chain triglycerides (Siegal et al, 1985). This last finding, however, has not been documented in preterm infants of fewer than 32 weeks of gestation.

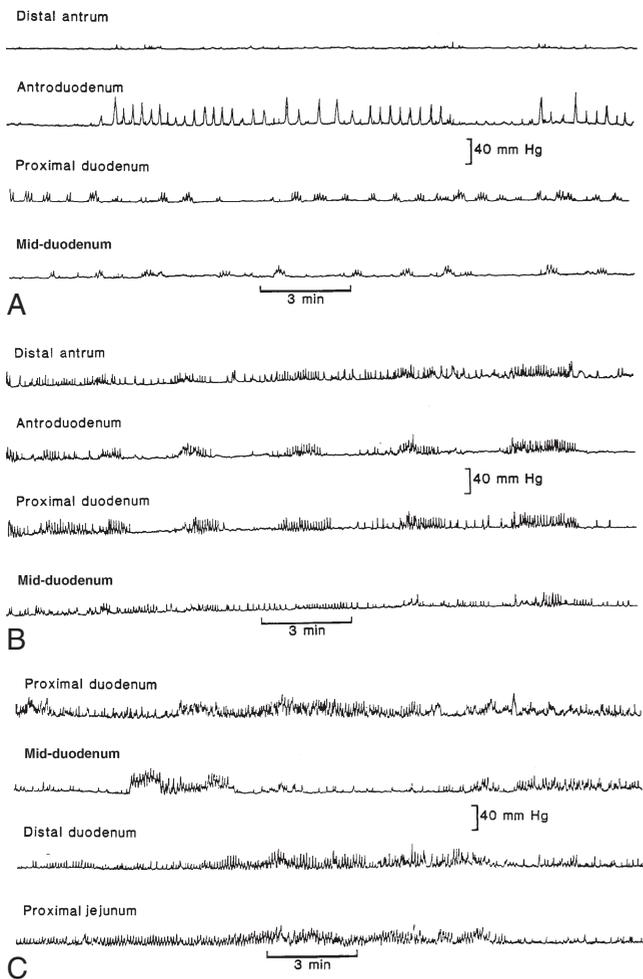

McLain (1963), in one of the earliest studies of small bowel motility in human newborns, suggested that motility increases with advancing gestational age. Until 30 weeks, contrast material did not progress through the small intestine of the fetus; however, at 32 weeks, contrast material passed through the small bowel to the colon in 9 hours, compared with a transit time of 4.5 to 7 hours in term infants. More recent work has shown that transit times in the

preterm infant may range from 0.5 to 7 days (Baker-Wills and Berseth, 1996).

In the adult, motor activity cycles through three patterns every 60 to 90 minutes. Often the muscle is still or quiescent for 10 to 20 minutes. This quiescence is then replaced by irregular contractions, which are replaced in turn by an episode of intense regular contractions that migrate distally through the bowel. This entire sequence of patterns is called the *interdigestive cycle* (Fig. 70-7). Complete interdigestive cycles are present in term infants (Amarnath et al, 1989). They are rarely seen in preterm infants, however. In extremely premature infants (24 to 28 weeks of gestation), unorganized irregular contractions are seen, and little quiescence is present (Berseth, 1992) (Fig. 70-8). In older preterm infants (28 to 32 weeks), motor quiescence begins to appear, and motor activity is organized into short bursts of phasic activity called *clusters* (Baker and Berseth, 1995). In more mature preterm infants (32 to 36 weeks), motor patterns become increasingly more organized, episodes of motor quiescence as well as clusters lengthen (Baker and Berseth, 1995), and migrating activity occasionally is seen (Berseth, 1992). Migrating motor complexes (MMCs), first seen around 33 weeks of gestation, are an interdigestive phenomenon that functions to sweep gut contents over long segments of intestine between meals. Eating inhibits this pattern, which initiates postprandial mixing-type contractions. In the term infant, the time between MMCs is 44 minutes, or about half the time observed in older children. The propagation rate, however, is 3.1 cm per minute in term infants, compared with 8.2 cm per minute for older children, and the duration is 10.9 minutes in infants, compared with 7.2 minutes for older children. Berseth (1992) has suggested that early feeding may be important in hastening the maturation of motility in preterm infants. In addition, she also has shown that the composition of feeding may alter motor

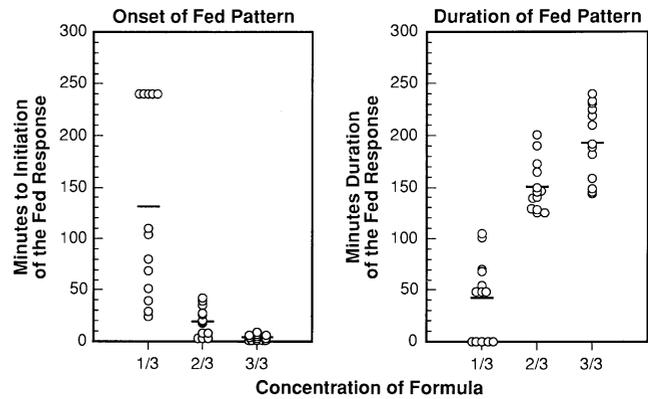

**FIGURE 70-7.** Migrating motor complex in a term infant. **Upper tracing,** Motor contractions recorded from the antrum. **Lower three tracings,** Motor contractions recorded from the duodenum. Phasic activity present in the antrum is temporally associated with the appearance of intense phasic activity that migrates distally to the three duodenal leads. (From Ittman PI, Amarnath R, Berseth CL: *Maturation of antroduodenal motor activity in preterm and term infants. Dig Dis Sci* 37:14, 1992.)

**FIGURE 70-8.** Serial gastrointestinal manometric tracings from an individual infant: **A**, at birth (32 weeks); **B**, at 2 weeks of postnatal age (34 weeks); and **C**, at 4 weeks of postnatal age (36 weeks). In **A**, clusters of phasic contractions occur in the two duodenal leads. Clusters are of short duration (approximately 0.75 minute), have low amplitude (approximately 12 mm Hg), and recur frequently. **B**, Two weeks later in the same infant, clusters are present in all leads. Individual clusters have a longer duration (approximately 2.5 minutes), have a higher amplitude (approximately 20 mm Hg), and recur less often. **C**, At 4 weeks of age, only one cluster can be displayed because its duration is now prolonged. (From Berseth CL: *Gestational evolution of small intestinal motility in preterm and term infants. J Pediatr* 115:649, 1989.)

responses. For example, duodenal motor activity normally increases in response to feeding. When the preterm infant is fed diluted formula, motor responses are delayed in onset and are less intense (Fig. 70-9).

Just as gastric emptying can be affected by nutrient composition, small intestinal motor function can be influenced by many of the medications routinely given to preterm infants. For example, mydriatics used for routine screening eye examinations slow gastric emptying and cause significant feeding intolerance (Bonthala et al, 2000). Antenatal steroids may hasten maturation of motor patterns (Baker-Wills and Berseth, 1996). The chronic use of

**FIGURE 70-9.** Motor activity responses to feeding formula diluted to one-third strength or two-thirds strength or full strength. **Left panel**, There is an increasing delay of the onset of the fed response as progressively more diluted formula is given ( $r = .62$ ;  $P < .01$ ). **Right panel**, The duration of the fed response is progressively longer as more concentrated formula is given ( $r = .49$ ;  $P < .01$ ). (From Koenig WJ, Amarnath RP, Hench V, Berseth CL: *Manometrics for preterm and term infants: A new tool for old questions. Pediatrics* 95:203, 1995.)

opioids, such as morphine, can change intestinal transit time (Berseth, 1996). In adults, the initiation of the MMC is triggered by the hormone motilin. This hormone is released in a cyclic fashion, with concentrations peaking every 60 to 90 minutes. The hormone binds to motilin receptors located in the distal antrum and proximal duodenum, which triggers the MMC. Plasma concentrations of motilin do not cycle in the neonate (Jadcherla et al, 1995), but administering low-dose erythromycin, which competitively binds to motilin receptors, triggers MMCs in preterm infants whose gestational ages exceed 31 weeks (Jadcherla et al, 1995). These findings are consistent with the conclusion that the absence of the cyclic release of the hormone motilin underlies the absence of the MMC in older preterm infants.

Colonic motility has not been studied in preterm infants. In a single study in preterm primates, colonic motor responses to feeding were less robust in preterm animals than in term animals (Cannon and Cheung, 1989). In children, colonic motor patterns are similar to those seen in adults (DiLorenzo et al, 1995).

Meconium is the thick black material that collects in the distal portion of the small intestine and colon of the fetus and consists of intestinal secretions, bile, desquamated cellular debris, and amniotic fluid. Ninety-four percent of newborns pass a meconium stool within 24 hours after birth. However, passage of meconium is often delayed in preterm infants with birth weights less than 1500 g (Wang and Huang, 1994). Meetze and colleagues (1993) have shown that passage of meconium may be delayed up to 10 days in infants with birth weights less than 1250 g.

## Host Defenses

Because the gut is in continuity with the neonatal environment, it is constantly exposed to antigens and bacteria. A complex series of host defenses, both immune and nonim-

immune in nature, are present in the newborn. The nonimmune system is also called the innate immune system, as it responds in a nonspecific fashion. The immune system is composed of specific humoral and cellular responses that are activated in response to specific antigens.

The innate immune system constitutes the first line of host defense in the neonate in that it prevents many potential antigens and organisms from reaching the intestinal mucosa. The components of the innate system include physical barriers, cells, and chemical barriers.

First, intestinal motility is an important factor in moving nutrients aborally so that they do not have time to establish colonization in the lumen of the gut. As described in the previous section (“Motor Function and Neural Regulation”), the MMC, which is responsible for propelling luminal contents forward through the small intestine, often is absent in the preterm infant (Amarnath et al, 1989; Berseth, 1992). As a result, overall intestinal transit times are delayed in the preterm infant (Baker-Wills and Berseth, 1996; Berseth et al, 2003).

The release of gastric acid and pancreaticobiliary secretions also is an important component of the innate system. These secretions inhibit bacterial growth and activate proteolysis, which alters antigen structure. There are concerns that withholding enteral feedings in preterm infants results in a decreased release of these secretions and thereby may impair an important function of host defense in the preterm infant. Hyman and associates (1983) have confirmed that basal and maximal gastric acid production is significantly lower in unfed infants, and rates of infection are higher among infants whose gastric acid production is suppressed by histamine H<sub>2</sub> blockers (Beck-Sague et al, 1994).

Another physical barrier is created by mucus, which contains mucins, glycoproteins, immunoglobulins, glycolipids, and albumin. These constituents form a protective gel over the surface of the intestine. Mucus presents a slippery surface that enhances forward propulsion of antigens and inhibits the diffusion of large molecules.

Cells that provide innate immune defense are the epithelial cells and other cells located close to them, including the goblet cells, the M cells, and subepithelial cells. The intestinal epithelial cells are closely approximated to one another by a series of tight junctions. These junctions allow for the physiologic passage of fluids and electrolytes but prevent the passage of larger proteins. In addition, microvilli form a physical barrier, as they prevent or retard the cellular penetration of large macromolecules and charged particles. In animals, glycosylation of the microvillus membrane glycoconjugates is not fully functional in neonates (Ozaki et al, 1989), which predisposes the neonate to increased pathologic bacterial colonization (Schiffirin et al, 1993). However, these findings have not been confirmed in human neonates. M cells are epithelial cells that lack well-developed microvilli, which permits macromolecular transport. They are present only in follicles that overlie lymphoid tissue and serve to deliver foreign antigens and microorganisms to the lymphoid tissue. Goblet cells are interspersed among the epithelial cells, and they secrete mucus.

Subepithelial cells include follicular dendritic cells, Peyer patches, and mast cells. Follicular dendritic cells, which are

located in the lymphoid follicles, present antigens to T and B cells. Peyer patches, which are clusters of lymphoid tissue, are present by 19 weeks of gestation and become more abundant between 24 and 40 weeks (Cornes, 1965).

The immune system of host defense is composed of cellular components and secretory components. T cells, B cells, and macrophages are present in the fetal intestine by 20 weeks of gestation. Lymphocytes proliferate in response to a mitogen as early as 12 weeks, and M cells that specialize in the antigenic processing of macromolecules are present by 17 weeks. Antigenic stimulation of lymphoid tissues, however, cannot be demonstrated until 46 weeks. This deficiency is of most concern because the preterm gut absorbs macromolecules directly by pinocytosis. Although plasma immunoglobulin A (IgA) is relatively low in the newborn, secretory IgA is present by 22 weeks of gestation. The newborn intestine has few IgA-producing plasma cells, however, and when preterm infants are fed exogenous protein they are unable to form antibodies (Rieger and Rothberg, 1985).

When an antigen stimulates the host defense system, a variety of soluble proteins regulate growth and differentiation of lymphocytes. These proteins are called *cytokines* and include the interleukins (ILs), tumor necrosis factors, interferons, and platelet-activating factor. Cytokines play important roles in stimulating chemotaxis of neutrophils, promotion of IgA expression, and epithelial cell proliferation after mucosal injury. When cultured fetal enterocytes (18 to 21 weeks) are stimulated by the general chemotoxin lipopolysaccharide, they release significantly greater amounts of the proinflammatory cytokine IL-8 (Nanthakumar et al, 2000), suggesting that there may be an imbalance of release of pro- and anti-inflammatory cytokines in response to a stimulus in the preterm infant.

A number of host defense functions appear to be mediated by enteral nutrients. Among those that have been recently studied are glutamine, arginine, long-chain fatty acids, nucleotides, and nutrients called probiotics and prebiotics.

Glutamine plays an important role in maintaining epithelial cell integrity, cell growth, and inflammatory responses. Glutamine and nucleotides appear to act in concert in regulating intestinal epithelial proliferation and differentiation and in this manner may play important roles in mounting inflammatory responses as well as active healing and recovery from insults. When the availability of glutamine is artificially reduced, intestinal cell growth is retarded; these results are reversed by adding nucleotide supplements (He et al, 1994). When endogenous glutamine synthesis is inhibited, small intestinal interepithelial junctional integrity is impaired (Wiess and associates, 1999). In vivo studies in neonatal rats show that feeding a diet that is glutamine deficient increases bacterial translocation (Neu, 2001). Finally, a randomized-masked trial was conducted in 68 very low-birth-weight infants during the first postnatal month. The incidence of sepsis was only 11% among infants who were given glutamine supplementation, compared with 30% in the control group, in which infants were given no supplement (Neu et al, 1997). These differences in outcome can effect a significant cost reduction (Dallas et al, 1998).

Another amino acid that has been investigated is arginine. This amino acid also plays an important role in immune function and growth. Plasma concentrations of arginine are lower among preterm infants who subsequently develop necrotizing enterocolitis (NEC) than among those who do not (Becker, 2000; Zamora, 1997). Arginine supplementation has been shown to reduce severity of NEC in piglets (DiLorenzo et al, 1995) and in human infants (Amin et al, 2002).

Recent studies also have evaluated the role of long-chain fatty acids (Caplan et al, 2001) and nucleotides (Pickering et al, 1998). Although some infant formulas are now supplemented with nucleotides, no large clinical trials have been performed to date in preterm infants. Another study demonstrated that formulas supplemented with egg phospholipid reduced the occurrence of NEC but not sepsis (Carlson et al, 1998).

Two classes of “nutrients” that recently have been shown to influence host defense are prebiotics and probiotics. *Probiotics* are live organisms that can compete with and overgrow pathogenic organisms. The bowel flora of infants fed breast milk contains a predominance of bifidobacteria (Harmsen and Wildeboer-Veloo, 2000). Thus, researchers have speculated that colonizing the gut with these less pathogenic bacteria may reduce the incidence of sepsis and necrotizing enterocolitis. The chronic administration of *Lactobacillus* GG reduces antibiotic-induced diarrhea in children (Vanderhoof et al, 1999; Arvola et al, 1999) and reduces the incidence of diarrhea in undernourished children (Oberhelman et al, 1999). Formula-fed infants given formula supplemented with *Bifidobacterium* had fecal pH and bacterial flora that were similar to those seen in breast fed infants (Pahwa and Mathur, 1987). Chronic administration of *Lactobacillus* results in colonization of the preterm gut (Millar, 1993; Reuman et al, 1986), and daily administration of *Lactobacillus* reduced the incidence of NEC in preterm infants in a recent study (Hoyos, 1999). Although the mechanism by which these probiotics achieve these outcomes is not yet known, studies in animals have shown that *Lactobacillus* modulates immune response and bowel flora (Schultz and Sartor, 2000) and reduces intestinal permeability in children who have Crohn’s disease (Gupta et al, 2000). Other investigators hypothesize that probiotics bind competitively to epithelial receptors and essentially prevent pathogenic bacteria from establishing the first foothold in the process of translocation (Alvarez-Olmos and Oberhelman, 2001).

Several concerns limit the therapeutic use of probiotics. First, there is a need to establish the efficacy for each specific probiotic strain. Second, the quality control required in commercial preparation of therapeutic products is costly. Third, large clinical trials are needed to assess their efficacy and safety. Fourth, continuous administration is required to maintain colonization.

For these reasons, attention has shifted from probiotics to prebiotics. *Prebiotics* are defined to be nondigestible substrates that preferentially enhance the growth of non-pathogenic organisms. For example, breast milk contains galacto-oligosaccharides, which favor the growth of bifidobacteria. Fructo-oligosaccharides increase bifidobacterial counts and colonic metabolic activity in adults (Gibson et al, 1995).

## Gut Flora

The gut is sterile in utero, but colonization begins at birth. The pattern of bacterial growth reflects the maternal and neonatal environment, and enteric bacteria colonize the human infant in an oral-to-anal direction (Rotimi and Duerden, 1981). In healthy infants, aerobic organisms appear within a few hours. Anaerobic organisms are present by 24 hours and increase in number over the first 3 weeks (Cooperstock and Zedd, 1983). Because the route of access of organisms to the intestine is by ingestion, stools of breast milk-fed infants have a predominance of *Bifidobacterium*, whereas stools of formula-fed infants have a predominance of *Escherichia coli* and *Klebsiella* (Harmsen and Wildeboer-Veloo, 2000). These organisms are capable of metabolizing bile acids as well as nonabsorbed proteins, lipids, and carbohydrates and thus may potentially play an important role in further processing of nutrients in the preterm newborn. Consequently, alterations in gut flora due to certain drugs or to shortened bowel length may result in profound intestinal dysfunction.

# Structural Anomalies of the Gastrointestinal Tract

Carol Lynn Berseth and Dan Poenaru

## DISORDERS OF THE TEETH, MOUTH, AND NECK

### Teeth

Infants may be born with one or more erupted teeth. These natal teeth should be extracted because their roots are poorly formed and they present a danger of aspiration when they loosen.

### Mouth

Tiny cystic lesions may be visible in the mouths of 80% of newborns. Those located on the hard palate on either side of the raphe are called *Epstein pearls*, and those located on the mandibular and maxillary alveolar ridges are called *Bohn nodules*. A *ranula* is a retention cyst of the sublingual salivary gland that presents as a pea-sized mass on the anterior floor of the mouth. Most cysts disappear within 1 month, but larger ones that interfere with feeding may require surgical excision.

Tumors of the mouth are rare in the newborn; however, when they are present, careful evaluation with computed tomography (CT) is necessary to define the anatomy and to determine if a connection with the central nervous system is present. An *epignathus* is any type of growth that arises from the upper jaw or palate and projects from the mouth. Although most of these tumors are polyps, dermoids, or teratomas, they often cause respiratory or feeding difficulty. The definitive treatment is surgical removal.

*Congenital epulis* is a misnamed tumor that arises from the upper or lower jaw and projects into the mouth so that normal sucking is impaired. These tumors are covered with squamous epithelium and contain vascular connective tissue, large polyhedral round cells, and spindle-shaped cells (Langley and Davson, 1950), and they are considered to be benign. Histochemical staining of these tumors demonstrates that these tumor cells represent early mesodermal cells that express pericytic and myofibroblastic features (Damm et al, 1993).

Salivary gland lesions are rare in the newborn. Tumors or infection of the salivary gland (sialadenitis) may arise anywhere salivary gland tissue is present, including the floor of the mouth and the parotid regions. Hemangiomas are the most common tumors found in this region, and lymphangiomas are the second most common (Welch and Trump, 1979). Both of these benign lesions typically are confined to the intracapsular portion of the gland, although surface sentinel lesions may be present. Management

consists of confirmation of a histologic diagnosis via open biopsy and long-term observation of the lesion. Juxta-parotid lymphangiomas that invade the gland should be locally excised. Suppurative parotitis may present during the first month of life and may involve one or both parotid glands. Pus may be expressed from the Stensen duct by putting gentle pressure on the gland. The infant may become septic; extension to the submaxillary gland is not uncommon. The offending organism is usually *Staphylococcus aureus* or *Escherichia coli*, but broad-spectrum antibiotic coverage is necessary until the organism has been identified and sensitivities have been established.

### Tongue

Aglossia congenita, or congenital absence of the tongue, has been described. Taste sensation is present, and these children can learn to speak. Ankyloglossia inferior (“tongue-tie”) is common in newborns. The frenulum of the newborn is normally short, but this does not usually interfere with sucking and swallowing. Because the frenulum lengthens with postnatal age, it should not be cut unless inadequate bottle- or breast-feeding persists.

Ankyloglossia superior, attachment of the tongue to the roof of the mouth, is a rare anomaly that must be recognized at birth because respiratory obstruction may occur. Other lesions, such as micrognathia, macroglossia, and cleft palate, are frequently associated with this anomaly (Spivack and Bennett, 1968).

True macroglossia, or enlargement of the tongue, results in continuous protrusion of the tongue from the mouth, making feeding difficult and respiration noisy. Macroglossia often is present in infants who have Down syndrome or Beckwith-Wiedemann syndrome. Lymphangioma and idiopathic muscular hypertrophy are additional common causes of macroglossia. Characteristically, the gross appearance of a lymphangioma is that of a raised, firm mass in the tongue, which has a warty-looking surface. The treatment for lymphangioma is surgical removal, if possible, or reduction of the tumor bulk with reshaping of the tongue. Infants with idiopathic muscular hypertrophy should be treated conservatively because the relative size of the tongue often becomes smaller as the mandible grows postnatally.

Thyroid tissue may persist as a solid or cystic mass in the posterior midline of the tongue or under it. Because the presence of this mass represents a failure of migration of normal thyroid tissue, no other thyroid tissue may exist. A thyroid scan should be performed during evaluation of midline lingual tumors.

### Nasopharynx

Nasopharyngeal tumors are rare and are polyps, dermoids, or teratomas. Often these lesions are on a stalk and project into the mouth. Those not projecting externally may be palpated as movable, sausage-shaped masses in the pharynx. These lesions should be removed urgently because acute respiratory distress may occur if the nasopharynx is obstructed.

## Neck

Cystic hygroma is the most common lateral neck mass in the newborn (Fig. 71–1). Derived from lymphatic tissue, these multilobular, multicystic masses may rapidly enlarge and cause respiratory compromise. Magnetic resonance imaging (MRI) is useful in identifying their extent and ruling out intrathoracic extension. Excision is the treatment of choice, with sclerotherapy reserved for very large or recurrent tumors (Samuel et al, 2000). Prenatally diagnosed giant lymphangiomas impairing the airway may require removal using an “ex utero intrapartum technique” (the EXIT procedure) (Mychaliska et al, 1997).

Branchial cleft anomalies may manifest as skin tags, pits, sinuses, fistulas, or cysts in the preauricular and lateral cervical regions. Most are remnants of the second branchial cleft and pouch, and 10% to 15% occur bilaterally (Bill and Vadheim, 1955). Sinuses and fistulas may be discovered during the newborn period, but cysts require time to fill and usually are not recognized until childhood. Ultrasound or CT scan of the neck may be useful to define anatomic relationships, and surgical removal is the treatment of choice.

The so-called “sternomastoid tumor” can be seen and palpated within the body of the sternocleidomastoid muscle as a hard, smooth oval mass. Histopathologic study reveals that these lesions result from endomysial fibrosis and deposition of collagen and fibroblasts around individual muscle fibers that subsequently undergo atrophy. The cause is unknown, but the incidence is seven times higher following breech delivery (Ling and Low, 1973) and among infants who have had specific fetal positioning in utero (Rosegger and Steinwendner, 1992). Torticollis is not always present; instead, there may be rotation of the head to the side opposite the tumor. Cranial and facial asymmetry may also occur. In most infants, the lesion resolves within 6 to 12 months. Surgical correction is rarely indicated, in cases when severe hemihypoplasia develops (Wirth et al, 1992).

**FIGURE 71–1.** Hygroma of the neck and tongue.

Midline neck masses in newborns include cystic hygromas, hemangiomas, dermoid cysts, teratomas, goiter, ectopic thyroid tissue, and ectopic thymic tissue (Fig. 71–2). Goiters may be visible at birth and may be associated with hypothyroidism, hyperthyroidism, or euthyroidism. The second most common location for ectopic thyroid tissue is the anterior midline of the neck, just at or below the hyoid bone (Meyerowitz and Buchholz, 1969). Although this tissue may be easily mistaken for a thyroglossal duct cyst, such cysts are rarely present in the newborn. Before removal of ectopic thyroid tissue, it must be determined if this tissue is the infant's only functioning thyroid tissue.

Thymic tissue arises high in the cervical region of the embryo as two lateral buds. The buds migrate caudad and join in the anterior mediastinum. Abnormal migration results in ectopic location or cyst formation (or both); the aberrant tissue or cyst may manifest as a lateral or midline neck mass (Thompson and Love, 1972) and requires surgical removal.

## DISORDERS OF THE ESOPHAGUS

### Esophageal Atresia with Tracheoesophageal Fistula

#### Definition

Esophageal atresia and tracheoesophageal fistula may occur as separate congenital defects, but more frequently they are seen together as a compound defect (Fig. 71–3). Esophageal atresia with distal tracheoesophageal fistula is by far the most common form, accounting for 85% of the cases.

#### Epidemiology

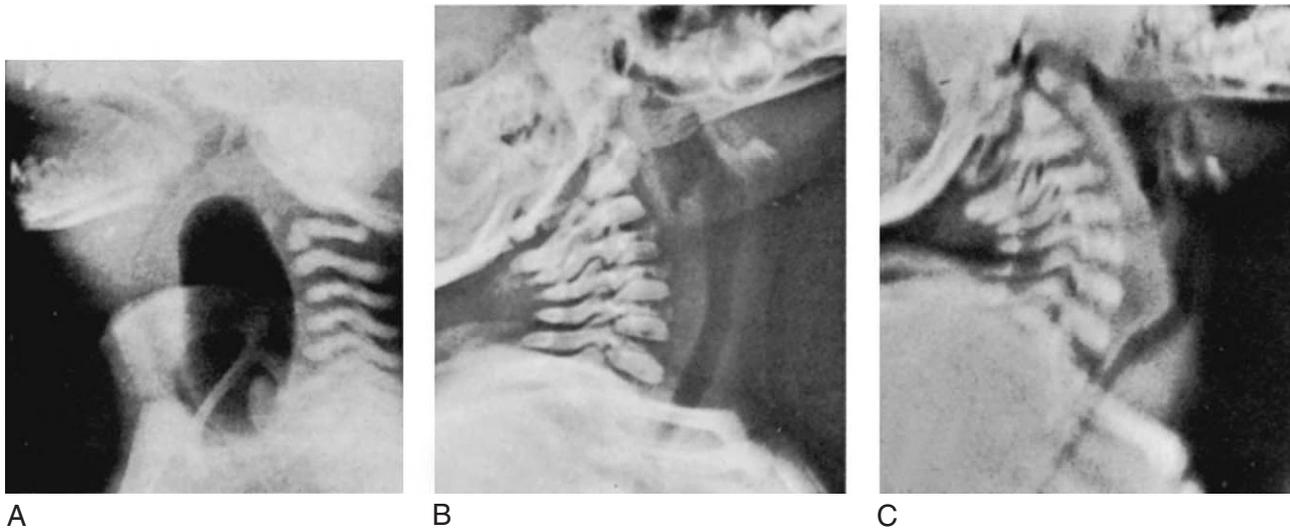

The incidence of esophageal atresia with tracheoesophageal fistula (EA/TEF) ranges from 1/3000 to 1/4000 live births (Meyers, 1974; Raffensperger, 1990). Most series show a slight male predominance and an increased incidence in premature infants (Reckham, 1981). The role genetic factors play is unclear; however, this anomaly has been described in siblings as well as in identical twins (Hausmann et al, 1957; Woolley et al, 1961). In addition, two kindreds with autosomal dominant transmission have been reported (Pletcher et al, 1991).

#### Etiology

The anomaly occurs before the eighth week of gestation, but the exact mechanism is unknown. The foregut divides into a ventral and a dorsal tube when the lateral walls invaginate, giving rise to the trachea and esophagus. When this process of division is abnormal or when there is compression of these primitive tubes by an extrinsic structure such as an anomalous blood vessel, esophageal atresia or tracheoesophageal fistula (or both) may result. Additional anomalies occur in a majority of these infants, as outlined later in the “Treatment” section.

#### Diagnosis

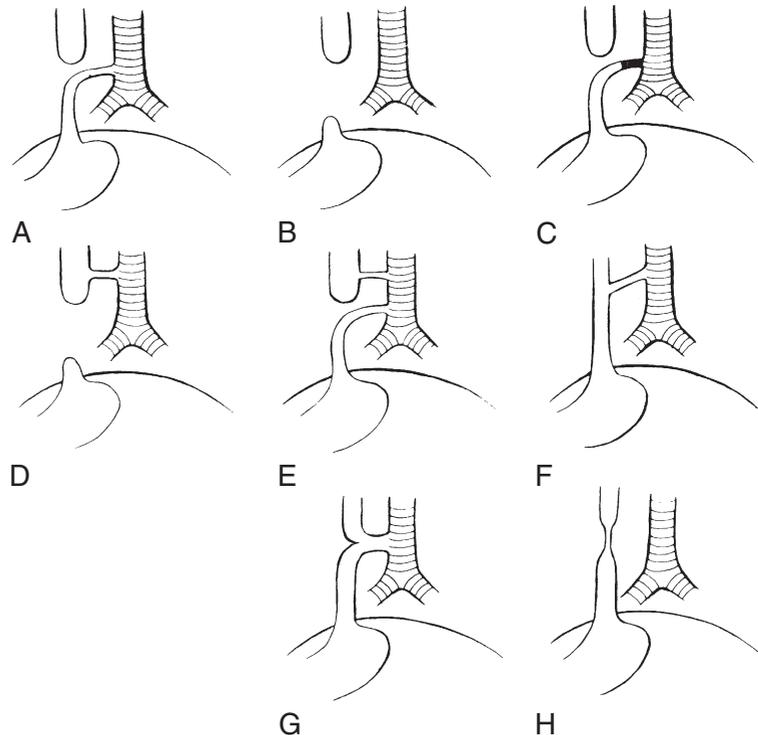

Polyhydramnios is present in approximately one third of pregnant women carrying fetuses with esophageal atresia because the fetus is unable to swallow amniotic fluid.

**FIGURE 71-2.** **A**, Lateral radiograph of the neck shows an air-containing cyst displacing the air passages and esophagus forward. **B**, Lateral view of the neck obtained with patient quiet demonstrates straight, unobstructed tracheal air column. **C**, Lateral view of the neck obtained with patient crying demonstrates mass lesion between the manubrium and the trachea, displacing the lower cervical trachea backward and moderately narrowing this portion of the trachea. (From Thompson RE, Love WC: *Persistent cervical thymoma apparent with crying*. *Am J Dis Child* 124:761, 1972. Copyright 1972, American Medical Association.)

Within hours after birth, these infants accumulate large amounts of oral secretions, which may precipitate coughing, choking, and respiratory distress. The infants vomit when they are fed, and in cases with a distal tracheoesophageal connection, abdominal distention may ensue as the intestine fills with air. The presence of a flat or gasless abdomen should suggest an isolated esophageal atresia without tracheoesophageal fistula (see Fig. 71-3B). Some

patients with a gasless abdomen, however, may have a tracheoesophageal fistula that is partially obliterated and still requires surgical ligation (Goh et al, 1991). The most dramatic presentation of tracheoesophageal fistula occurs when the fistula is proximal to the esophageal atresia (see Fig. 71-3D, E, G). These infants develop life-threatening respiratory failure from aspiration almost immediately after birth.

**FIGURE 71-3.** Types of tracheoesophageal fistulas. **A** is overwhelmingly the most common, accounting for 85% of esophageal malformations. **B** is next most common and can be distinguished from **A** by the absence of air in the intestinal tract on radiograph. All the other types have been noted sporadically. (From Avery ME, et al: *The Lung and Its Disorders in the Newborn Infant*, 4th ed. Philadelphia, WB Saunders, 1981.)

Infants with the so-called H-type tracheoesophageal fistula (see Fig. 71-3F) usually do not develop symptoms in the newborn period. Instead, these infants frequently present with a history (over months to years) of mild respiratory distress related to feeding or recurrent pneumonias.

If a diagnosis of esophageal atresia is suspected, a soft 5 or 8 French feeding tube can be passed into the esophagus until it meets an obstruction. On occasion, the tube coils in a blind pouch, creating the false impression that the esophagus is patent. A plain film confirms the position of the tube and frequently demonstrates the presence of an air-filled upper esophageal pouch (Fig. 71-4). The presence of gas in the abdomen suggests that a distal tracheoesophageal fistula is present.

### Treatment

Preoperative care of the infant with esophageal atresia includes the insertion of a sump suction catheter into the proximal esophageal pouch for the continuous evacuation of secretions. The infant also should be placed in the upright position to decrease the reflux of gastric secretions through the fistula and into the lungs. Hydration is maintained by intravenous fluids, and surgical repair is undertaken when the infant's general condition permits. Thus, surgical repair in preterm infants may be delayed postnatally until the patient is clinically stable enough for surgery.

The preoperative pulmonary complications associated with EA/TEF occur because of aspiration of oral contents or reflux of gastric contents into the airway. Placing a Replogle tube with continuous suction into the proximal esophageal pouch can minimize the aspiration of saliva. Elevating the infant's head and minimizing any positive pressure ventilation can minimize reflux of gastric contents. If gastric distention, with reflux, becomes an important problem in the sick, small infant, a decompressive gastrostomy can be performed with local anesthesia at the bedside (Holder, 1993). If the fistula is large, there may be a significant loss of tidal volume if the infant requires positive pressure ventilation. This volume loss can usually

**FIGURE 71-4.** Anteroposterior view of the chest of a female infant with esophageal atresia and tracheoesophageal fistula. A large upper pouch is outlined by air and by a curled nasogastric tube. Air is seen within the abdomen.

be controlled by connecting the gastrostomy to a chest tube system under water seal (Fann et al, 1988). In extreme cases in which the infant may not tolerate a thoracotomy and definitive procedure, a Fogarty catheter can be passed with a bronchoscope to occlude the fistula (Filston et al, 1982).

Preoperative evaluation should include a search for additional anomalies, as they occur in 50% to 70% of patients with EA/TEF (Holder, 1993; Rowe et al, 1995; Rejjal, 1999). The VACTERL association is present in 25% to 30% of children with EA/TEF (Rowe et al, 1995). The VACTERL association, previously referred to as the VATER syndrome, consists of vertebral anomalies, anal agenesis (imperforate anus) (Figs. 71-5 and 71-6), cardiac defects (most commonly patent ductus arteriosus, atrial septal defect, and ventricular septal defect), tracheoesophageal fistula, renal anomalies, and limb anomalies (most often radial anomalies) (Corsello et al, 1993; Manning et al, 1986; Quan and Smith, 1973). Infants with EA/TEF and the VACTERL association tend to have higher proximal pouches, more complications, and a higher mortality rate than those in infants with isolated EA/TEF (Fig. 71-7) (Greenwood and Rosenthal, 1976; Holder, 1993; Touloukian and Keller, 1988; Weber et al, 1980). Cardiac defects often are repaired before the EA/TEF (Spitz, 1993). Gastrointestinal anomalies occur in 15% of patients (Rowe et al, 1995). Anal atresia is the most common gastrointestinal anomaly seen and requires a diverting colostomy at the time of the first general anesthetic procedure (Holder, 1993). Duodenal atresia also may occur (Holder, 1993).

The operative strategy is based on the anatomy and the presence of associated anomalies. Although it is preferable to correct the anomaly at the first anesthetic, staged procedures may be used in small infants (Alexander et al, 1993). In general, the infant who lacks significant associated anomalies and has a reasonably stable pulmonary status should undergo primary repair of the atresia and ligation of the fistula. To accomplish this, an extrapleural

**FIGURE 71-5.** (See also Color Plate 71-5.) Perineum of male newborn with low imperforate anus and anocutaneous fistula. The fistula is seen as a dark meconium-filled track along the median raphe of the scrotum.

**FIGURE 71-6.** (See also Color Plate 71-6.) Perineum of female newborn with low imperforate anus and rectovestibular fistula. The fistula is evident as the meconium-stained site within the posterior vestibule.

or transpleural approach is used, the fistula is divided, and an anastomosis between the proximal and distal esophageal segments is achieved using an end-to-end anastomosis. Infants with the lowest probability of survival are likely to benefit from a staged approach. For infants with extreme pulmonary compromise or significant associated anomalies, an initial gastrostomy for decompression with later repair of the EA/TEF may be indicated.

Postoperative care consists of respiratory support, antibiotics, and intravenous nutritional support. Enteral feedings via a gastrostomy or a transpyloric tube may be started on the third or fourth postoperative day. These feedings initially are given by continuous infusion. Bolus feedings usually are introduced once full enteral alimentation is achieved, and oral feedings are started 7 to 10 days postoperatively after confirmation by radiographic contrast study that there are no esophageal anastomotic leaks. A recent study has questioned whether contrast studies are necessary for infants who remain free of clinical symptoms of postoperative complications (Yancher et al, 2001).

Five significant complications can occur after repair of EA/TEF: esophageal anastomotic leak, esophageal stricture, gastroesophageal reflux, recurrent fistula, and tracheal obstruction. The incidence of anastomotic leak is around 10% to 15% (Rowe et al, 1995). The diagnosis usually is made by noting the presence of saliva in the chest tube and is confirmed by a contrast swallow study (Rowe et al, 1995). The treatment is expectant, because most of these leaks close spontaneously (Rowe et al, 1995). A minor esophageal stricture is almost universal after repair of an EA/TEF. Significant strictures occur in 5% to 10% of infants (Rowe et al, 1995). The diagnosis is confirmed by barium swallow examination. Treatment is with esophageal dilatation, either with Jackson dilators or by balloon dilatation (Benjamin et al, 1993; Shah and Berman, 1993). Gastroesophageal reflux occurs in 40% to 70% of these children (Holder, 1993; Pieretii et al, 1974). Clinically significant tracheal obstruction may occur in as many as 25% of children with EA/TEF as a consequence of tracheomalacia (Corbally et al, 1993; Rowe et al, 1995). The onset of symptoms (cyanosis, bradycardia, and apnea, usually with or immediately after feeding) usually is in the months following repair of EA/TEF but may be in the immediate

postoperative period (Holder, 1993). The diagnosis of tracheal obstruction due to tracheomalacia is made by bronchoscopy (Holder, 1993). In the child without significant distress, most symptoms subside over the first year or two of life (Holder, 1993). The surgical treatment of severe tracheomalacia is aortopexy, or suspension of the aorta (and therefore the anterior trachea) to the posterior surface of the sternum (Corbally et al, 1993; Holder, 1993). The incidence of recurrent fistula is probably less than 10% (Rowe et al, 1995). The tracheoesophageal fistula probably recurs in the immediate postoperative period, but the diagnosis may not be made for months or years. The manifestations of a recurrent fistula are the same as those of gastroesophageal reflux: aspiration, coughing with feeds, and recurrent pulmonary infections. Small fistulas may close spontaneously, but if a fistula persists for longer than 4 weeks, surgical closure is indicated (Rowe et al, 1995). Most surgeons prefer to wait 3 to 6 months after the initial EA/TEF repair, if possible, to decrease inflammation and edema (Holder, 1993).

### Prognosis

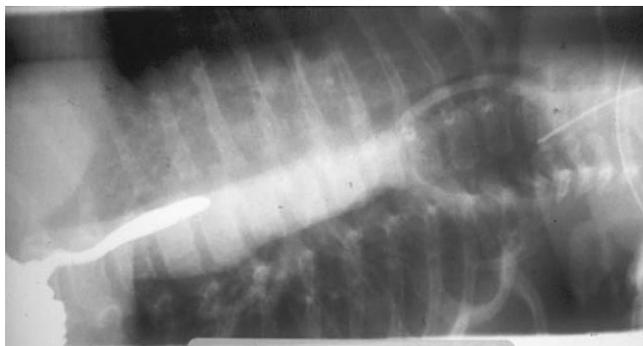

The overall survival rate in term infants without respiratory complications preoperatively approaches 95% (Holder and Ashcraft, 1970). Among premature infants or those with moderate to severe respiratory disease, survival is 85%. Infants with multiple anomalies or those with severe respiratory disease have a 75% survival rate.

Virtually all infants with esophageal atresia have residual problems with strictures and abnormal esophageal motility and swallowing. Esophageal strictures at the anastomotic site should be suspected if feeding difficulty develops, particularly after the third week. Repeated dilatation may be necessary to relieve the stricture.

Gastroesophageal reflux occurs in up to 70% of patients after tracheoesophageal fistula repair (Roberts et al, 1980), owing to lower esophageal sphincter incompetence or abnormal motility in the body of the esophagus (Whittington et al, 1977). Medical therapy may be successful initially, but many patients require antireflux surgery.

### Tracheoesophageal Fistula without Esophageal Atresia

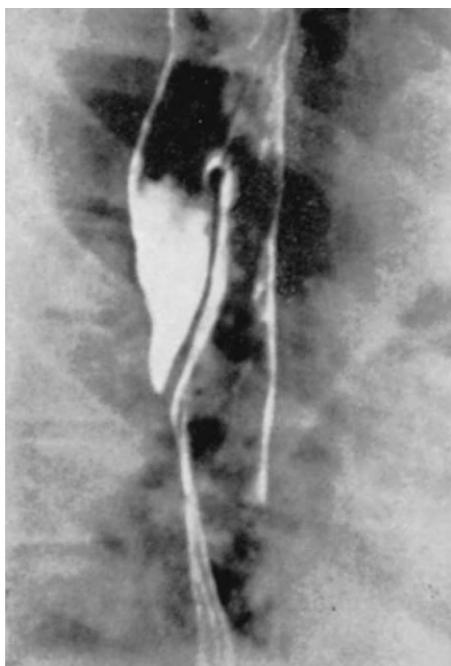

Only 5% of tracheoesophageal fistulas occur in the absence of esophageal atresia. Most of these fistulas are located superior to the second thoracic vertebra and can be repaired via a neck incision. Symptoms include coughing and cyanosis with feeding and recurrent episodes of pneumonia. If the diagnosis of tracheoesophageal fistula is suspected, oral feedings should be withheld and replaced by gavage feedings. A specialized contrast study is required to demonstrate the lesion, using a catheter gradually withdrawn through the esophagus (Fig. 71-8). If this is unsuccessful, simultaneous endoscopic examinations of the trachea and esophagus may be done; the injection of a small amount of methylene blue into the trachea and its subsequent appearance in the esophagus is diagnostic. The treatment involves surgical ligation of the fistula, usually performed through a right cervical approach.

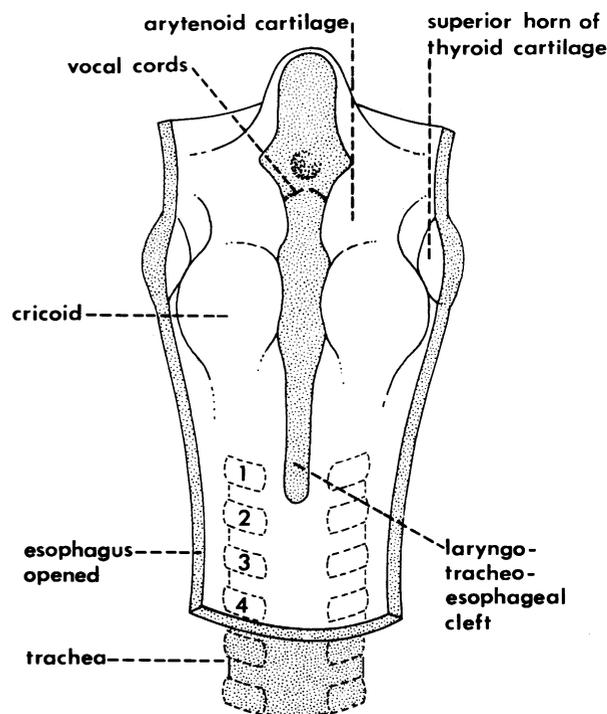

**FIGURE 71-7.** Anteroposterior view of chest of female newborn with isolated esophageal atresia. Air outlines the distended upper pouch; contrast material introduced via a gastrostomy fills the lower esophagus. There is a long gap in the esophagus, extending for more than the length of four vertebral bodies.

### Laryngotracheoesophageal Cleft

Laryngotracheoesophageal cleft is a communication of the larynx and trachea with the esophagus. The defect varies in length, with the shortest being the length of the arytenoid cartilages and the longest extending the entire length of the trachea (Fig. 71-9). These clefts form between the fifth and seventh weeks of gestation when there is a failure of the rostral advance and fusion of the lateral ridges of the laryngotracheal groove. One fifth of the clefts are associated with esophageal atresia and tracheoesophageal fistula. Clinical presentation occurs early in the newborn period and is similar to that for EA/TEF except that stridor also may be present. A carefully done

**FIGURE 71-8.** Radiograph after barium swallow, showing diverticulum before operation. The fistula is not demonstrated. (From Robb D: *Aust N Z J Surg* 22:120, 1952.)

**FIGURE 71-9.** Illustration of the anatomy of a laryngotracheoesophageal cleft. (From Burroughs N, Leape LL: *Laryngotracheoesophageal cleft: Report of a case successfully treated and review of the literature. Pediatrics* 53:517, 1974. Reproduced by permission of *Pediatrics*.)

esophageal dye study should establish the diagnosis. Tracheal spillover, however, may be misinterpreted to be due to the presence of a high H-type fistula or the presence of incoordination of the swallowing mechanism. Patients with clefts should undergo bronchoscopic evaluation with immediate surgical repair. A temporary tracheostomy is often placed because breakdown of the closure is common.

### Congenital Esophageal Stenosis

Congenital esophageal stenosis is a very rare anomaly caused by inborn malformation of the esophageal wall musculature (Nihoul-Fekete et al, 1987). It may take the form of a membranous web or diaphragm or a fibromuscular thickening or may be secondary to tracheobronchial remnants in the wall of the esophagus. The last-named is the most common form and typically occurs in the distal esophagus. Most infants so affected are asymptomatic until solids are introduced into the diet; occasionally, the condition may manifest neonatally with severe regurgitation and respiratory distress syndrome. The diagnosis may be difficult to establish, although a contrast esophagogram will usually reveal the narrowing. Fibromuscular hypertrophy and occasionally webs can be treated with repeated dilatations; surgical resection is the treatment of choice for all other lesions. An antireflux procedure is added for distal lesions, and results are generally satisfactory.

## Esophageal Duplication Cysts

Esophageal duplications are very rare, representing 10% to 15% of all gastrointestinal duplications. The current hypothesis invokes formation of vacuoles during the early developmental obliteration of the esophageal lumen. If these vacuoles coalesce during recanalization, duplications are formed. The cysts are usually small and may be located anywhere in the posterior mediastinum or neck. Cysts often manifest asymptotically during childhood, or with digestive or respiratory signs and symptoms even in the neonatal period (Stewart et al, 1993). Associated vertebral anomalies suggest the presence of a neurenteric cyst, which may have a connection to the spinal canal. Diagnosis is confirmed by CT, and treatment involves surgical excision.

## Cricopharyngeal Dysfunction

Some newborns aspirate at times despite having what appears to be a normal sucking and swallowing mechanism. If the problem is persistent, evaluation with a cineradiographic swallowing study is indicated. Diagnostic considerations include cricopharyngeal achalasia, familial dysautonomia, and myasthenia gravis. Cricopharyngeal achalasia is a rare disorder that may manifest as severe dysphagia in the newborn (Salib et al, 1999). Its treatment consists of a cricopharyngeal myotomy. Linde and Westover (1962) noted that infants with familial dysautonomia may have pharyngeal dysfunction at birth that causes chronic aspiration. In addition, poor esophageal peristalsis delays esophageal emptying.

## Rupture of the Esophagus

Esophageal perforation occurs in premature infants secondary to malpositioned endotracheal tubes as well as stiff nasogastric tubes (Krasna et al, 1987). Several newborns also have been described with spontaneous rupture of the esophagus. Hematemesis, hydropneumothorax, or both may be presenting manifestations. An esophagram can confirm the diagnosis, and urgent surgical repair is necessary.

## DISORDERS OF THE STOMACH

### Gastric Duplication

Gastric duplications are spherical or hollow tubular structures that (1) are lined by a mucosal layer composed of gastric, small bowel, or colonic epithelium; (2) contain a smooth muscle coat contiguous with the muscle of the stomach; and (3) are contiguous with the stomach wall. Most duplications do not communicate with the gastric lumen and are located along the greater curvature. Embryologically the lesion arises during the fourth week of gestation when normally the embryonic notochordal plates and endoderm separate. A band between them may cause a traction diverticulum, leading to gut cyst formation. In addition, associated anomalies occur in 50% of

these patients, the most common being esophageal duplication and vertebral abnormalities. Infants may present with nonbilious vomiting or hematemesis (Holcomb et al, 1989). The treatment is complete surgical excision of the cyst.

### Congenital Gastric Outlet Obstruction

This rare condition may be caused by either a membrane or atresia, located in either the antrum or the pylorus. An incomplete web or diaphragm may also be present, causing partial obstruction. Maternal polyhydramnios occurs in half of the cases. The defect may be due to vascular compromise early in gestation, similar to that causing intestinal and colonic atresias. Associated anomalies are frequent, including epidermolysis bullosa (Okoye et al, 2000). The presence of a gasless abdomen on a plain film and the failure of contrast material to leave the stomach on an upper gastrointestinal series are suggestive of the diagnosis and warrant urgent operative intervention. Treatment involves excision of the defect with a pyloroplasty, but some patients may require a gastroduodenostomy.

### Pyloric Stenosis

#### Definition and Epidemiology

Idiopathic hypertrophy of the pyloric muscle in early infancy results in partial gastric outlet obstruction. The incidence is 1/1000 to 3/1000 live births, and males are affected four times more often than females. First-borns account for half of the cases. Whites are at greater risk than blacks (Laron and Horne, 1957). Premature infants are affected with the same frequency as term infants.

#### Etiology

The exact cause of pyloric stenosis is unknown. Hereditary factors may play a role because there is a 7% incidence of pyloric stenosis among the siblings of affected patients.

#### Diagnosis

Vomiting is the primary presenting symptom. It may occur from birth to 12 weeks, but most often the onset is between the third and the fifth weeks. In premature infants, the onset follows the same pattern postnatally, regardless of the postconceptual age. At first, vomiting may occur infrequently. With time, the frequency and volume of the emesis increase, and projectile vomiting develops. Weight loss, dehydration, and metabolic alkalosis may occur as a consequence of the vomiting. Gastric peristaltic waves may be seen passing obliquely from the left upper quadrant across the midline when the infant is fed. Jaundice may occasionally occur, but indirect hyperbilirubinemia recedes 5 to 10 days after pyloromyotomy. In most instances of pyloric stenosis, a definite tumor, or "olive," can be felt either in the epigastric area or just to the right of the midline in the right upper quadrant. Ultrasound examination is confirmatory, having replaced the upper

gastrointestinal series as the diagnostic modality of choice (Fig. 71–10) (Hallam et al, 1995).

### Treatment

The stomach should be decompressed, and dehydration and metabolic alkalosis should be corrected with intravenous fluids before surgery. Pyloromyotomy involves splitting the hypertrophied pyloric muscle, and may be performed through a periumbilical incision or laparoscopically (Shankar et al, 2000). Feedings may be resumed 6 to 12 hours after surgery and advanced toward a regular schedule.

### Prognosis

Surgery is curative. Complications may include incomplete pyloromyotomy and perforation.

## Pylorospasm

The diagnosis of infantile pylorospasm is made by radiographic or ultrasonographic evaluation, and it must be differentiated from pyloric stenosis (Cohen et al, 1998). Radiographically, infants with pylorospasm show a narrow distal antrum, but in contrast with pyloric stenosis, the caliber of the channels intermittently narrows and widens. Peristalsis is present in the affected area, and there are no features of muscular hypertrophy, as seen with pyloric stenosis. The cause of pylorospasm is unknown. Conservative medical management consisting of atropine sulfate given intravenously before meals may be more successful than

**FIGURE 71–10.** Ultrasonographic study of the right upper quadrant in a 1-month-old infant with a 1-week history of vomiting. The length (from + to +) of the pylorus is 18.4 mm (normal up to 16 mm), and wall thickness (H) is 4.5 mm (normal is up to 4.0 mm). The *arrows* outline the muscular wall and point to the lumen (L). A is the antral lumen. (Courtesy of Dr. Ronald M. Cohen, Children's Hospital, Oakland, Calif.)

metoclopramide in relieving the spasm. Pylorospasm usually is transient and resolves within 1 to 2 weeks.

## Peptic Ulcer Disease

### Definition and Epidemiology

Ulceration of the gastric or duodenal mucosa is rare in the newborn. Peptic ulcers may be classified as primary if they occur in otherwise healthy persons or secondary if they are seen in association with underlying systemic disorders. In the newborn, most ulcers are secondary and are found in the duodenum (Bell et al, 1981).

### Etiology

The cause of peptic ulcer disease is unknown but is probably multifactorial even in patients with secondary ulcers (Byrne, 1985). Genetic factors, emotional factors, dietary and environmental factors, the amount of hydrochloric acid, and local tissue resistance factors contribute to ulcer formation in the older child and adolescent. In the newborn, a breakdown of local tissue resistance plays the major role. Normally the mucosal cell is protected by a complex barrier, which includes gastric mucus, the secretion of bicarbonate by the mucosal cell, the *alkaline tide*, mucosal blood flow, and prostaglandins. Drugs, such as indomethacin, that block prostaglandin synthesis or conditions such as acidosis and shock, affect blood flow and bicarbonate production, which precipitates events that disrupt this barrier and thus permits mucosal cell destruction, inflammation, and ulcer formation to occur.

### Diagnosis

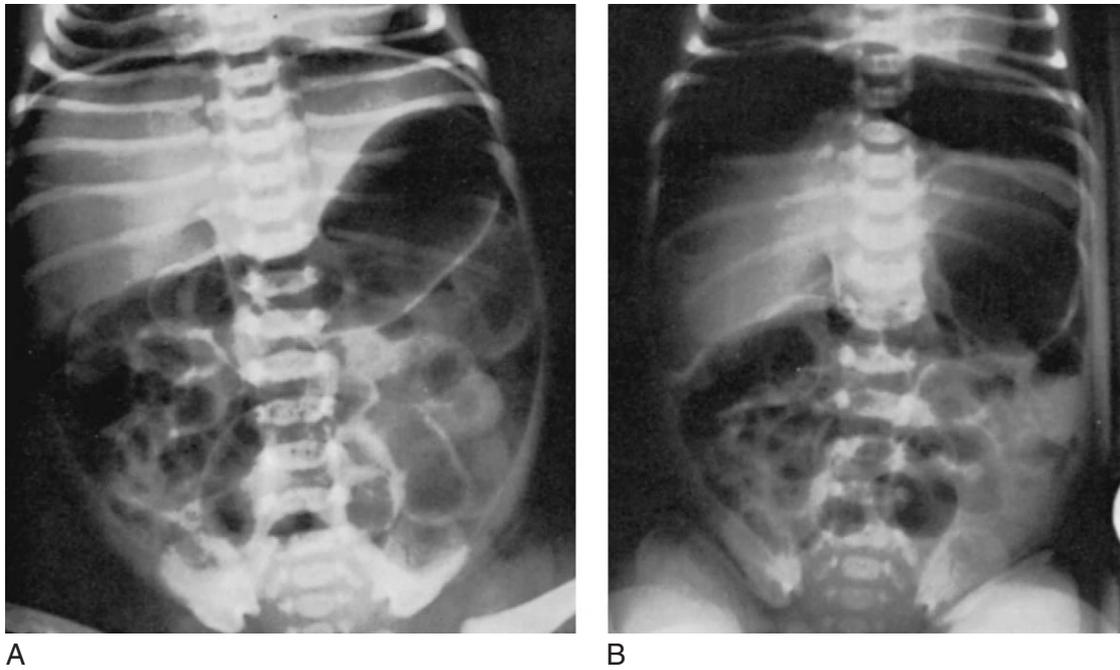

In the newborn, hematemesis, hematochezia, and perforation of the stomach or duodenum are presenting clinical manifestations. At times, the loss of blood may be considerable, causing a rapid drop in the hematocrit and the development of shock. At other times, bleeding may be gradual and recognized only by the presence of "coffee grounds" emesis or a Hemocult-positive stool. In general, radiographic studies in the newborn are not useful in demonstrating the presence of ulceration or gastritis. Upper gastrointestinal fiberoptic endoscopy can be done in the smallest of infants and is therefore the modality of choice.

### Treatment

Blood loss into the gastrointestinal tract requires prompt and adequate replacement. A nasogastric tube should be passed and the stomach lavaged with room-temperature saline (Andrus and Ponsky, 1987). Antacid therapy and/or therapy with histamine H<sub>2</sub> blockers is then begun. If there is no further bleeding after 24 hours, feedings may be resumed. The antacids should be continued at the same dose and given 1 hour after each feeding for 6 to 8 weeks.

## Gastric Perforation

Spontaneous perforation of the stomach in the newborn occurs most often during the first few days of life (Fig. 71–11) (St.Vil et al, 1992). Perinatal stress leading to

**FIGURE 71-11.** **A**, Anteroposterior view of abdomen obtained with the infant in the erect position at 72 hours of age. Air is present in the stomach and intestine, and there is a distinct impression that some of the air is outside the lumen of the bowel. A layer of air is clearly visible above the liver and below the diaphragm. **B**, Ten hours later. By now, there is a huge accumulation of air between the diaphragm and the liver.

localized ischemia appears to be the causative mechanism in most cases, although in others no cause can be identified. Potential causes include rapid overdistention, trauma from passage of a nasogastric tube, and spontaneous rupture of weak points in the gastric wall along the greater curvature where muscle is deficient.

Signs and symptoms that typically occur by the second to fifth day include refusal to suck, vomiting, and abdominal distention. Plain films of the abdomen show the presence of free air. Immediate decompression, fluid resuscitation, and broad-spectrum antibiotic administration should be followed by immediate surgical intervention to close the tear. Early recognition and treatment result in a high survival rate.

## DISORDERS OF THE INTESTINE

### Mechanical Obstruction

Complete or partial obstruction of the small bowel or colon is not unusual in the newborn. A variety of lesions, intrinsic or extrinsic, may be responsible (Table 71-1). Success or failure in terms of morbidity and mortality depends not so much on pinpointing the exact location of the lesion as on correctly diagnosing obstruction as the cause of the clinical symptoms and then instituting prompt operative intervention.

Vomiting, particularly of bile-stained material, with abdominal distention and the failure to pass meconium are highly suggestive of the presence of intestinal obstruction. If the obstruction is high or complete, symptoms start soon after birth. Vomiting of bile suggests that the lesion is located distal to the ampulla of Vater, whereas sporadic vomiting may be seen in patients with partial

obstruction caused by malrotation, duplications, or annular pancreas. Abdominal distention may be present soon after birth, reaching a peak at 24 to 48 hours with visible peristaltic waves. Failure to pass meconium within 24 hours after birth suggests the presence of a colonic lesion. Infants with high obstruction or even those with obstruction as low as the ileum pass meconium, so this finding by

**TABLE 71-1**

### Causes of Intestinal Obstruction in the Newborn

Mechanical		
Congenital	Acquired	Functional
Intrinsic	Necrotizing enterocolitis	Hirschsprung disease
Atresias	Intussusception	Meconium plug syndrome
Stenoses	Peritoneal adhesions	Ileus
Meconium ileus		Peritonitis

Extrinsic		Intestinal pseudo-obstruction syndrome
Volvulus		
Peritoneal bands		
Annular pancreas		
Cysts and tumors		
Incarcerated hernias		

itself does not exclude obstruction. Prenatal diagnosis of gastrointestinal obstruction has been successful (Langer et al, 1989) and has become more common.

The initial radiographic studies should be plain films obtained with the infant in the supine and left lateral positions. Normally, air fills the stomach immediately after birth, the small bowel within 12 hours, and the colon within 24 hours. When obstruction exists, the air pattern stops abruptly at that point, leaving the remainder of the bowel airless. Obstruction at the pylorus produces one large bubble outlining the dilated stomach, whereas duodenal obstructions produce a “double-bubble” appearance (Fig. 71–12). Distal obstructions show a series of dilated, air- and fluid-filled loops of intestine. Obstruction resulting from meconium ileus is an exception in that air-fluid levels usually are not seen. In an incomplete obstruction, gas may be seen distal to dilated loops of bowel.

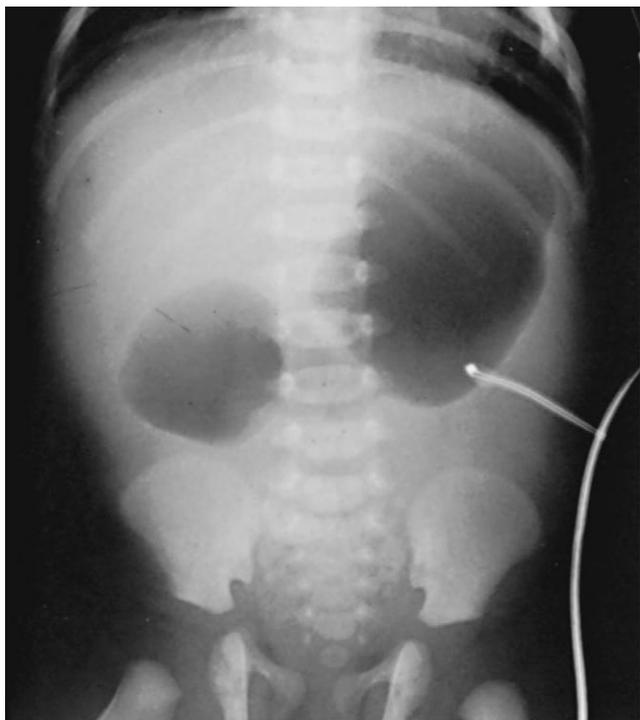

If the diagnosis is in doubt or a meconium plug is suspected, a contrast enema can be done. The finding of a microcolon is suggestive of small bowel atresia or meconium ileus. An upper gastrointestinal series is done only if the plain film and enema are nondiagnostic.

## Intrinsic Obstruction

### Atresias

#### Definition and Etiology

*Atresia*, complete obstruction of the lumen of the bowel, should be distinguished from *stenosis*, which is a narrowing of the lumen. Atresias account for one third of all

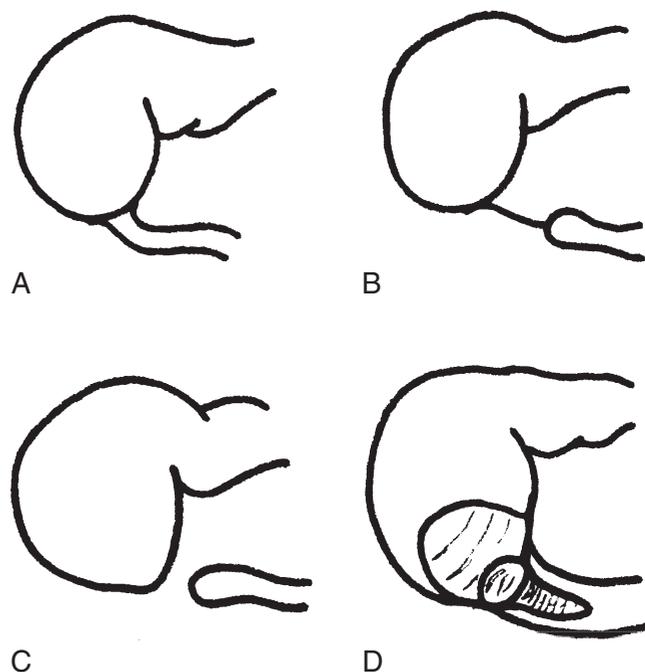

**FIGURE 71–12.** Abdominal film from a 12-hour-old infant with vomiting. A “double-bubble” sign is present. At laparotomy, duodenal atresia was found. (Courtesy of Dr. Ronald M. Cohen, Children’s Hospital, Oakland, Calif.)

intestinal obstructions in the newborn, occurring in 1 of every 1500 live births. Sites of occurrence, in order of frequency, are jejunoileal, duodenal, and colonic. Failure of the gut to recanalize during the eighth to tenth weeks of gestation seems to be the most likely cause for duodenal atresia. In the jejunum, ileum, and colon, vascular compromise early in gestation may be responsible for bowel atresias (Louw, 1966). Other potential causes in utero include incarceration of the physiologic umbilical hernia, localized volvulus, intussusception, focal peritonitis, and peritoneal band formation.

## Duodenal Atresia

Thirty percent of all atresias occur in the duodenum, and most are distal to the ampulla. Most infants with duodenal atresia also have other associated anomalies including Down syndrome, cardiovascular malformations, malrotation, esophageal atresia, small bowel lesions, and anorectal lesions (Dalla Vecchia et al, 1998). Annular pancreas also may be found but is often incidental and not the cause of the obstruction. Anatomically, duodenal atresia may occur in several forms (Fig. 71–13). Prenatal ultrasound diagnosis is becoming increasingly frequent (Stoll et al, 1996).

Bile-stained vomiting on the first day of life and a history of polyhydramnios are common presenting features. Abdominal distention is usually absent. Dehydration with a metabolic alkalosis rapidly ensues. The diagnosis may be made on plain abdominal films with the appearance of the “double-bubble” sign (see Fig. 71–12).

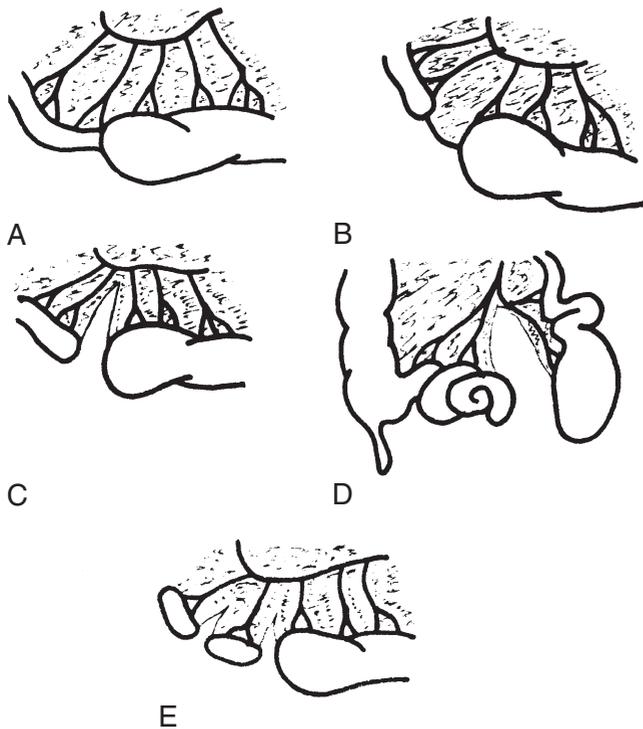

**FIGURE 71–13.** Forms of intrinsic duodenal obstruction. **A**, Duodenal atresia with continuity of the bowel wall. **B**, Duodenal atresia with a fibrous cord joining segments. **C**, Complete atresia with two separate segments. **D**, Windsock deformity.

Medical therapy consists of the passage of a nasogastric tube and correction of dehydration and electrolyte abnormalities. Prompt surgical intervention is necessary, although with a clear diagnosis, surgery may be delayed in very low birth-weight (VLBW) infants. Because of the high incidence of multiple atresias (15%), inspection of the entire bowel is carried out before bypassing the obstruction with a duodenoduodenostomy (Weber et al, 1986). An excessively distended proximal duodenum may need to be tapered as well, in an effort to reduce the duodenal dysmotility that often delays the start of normal feeds. The outcome for these infants generally is good but depends on their associated anomalies.

### Jejunioileal Atresia

Fifty percent of intestinal atresias occur in the jejunum or ileum. Associated extraintestinal anomalies, including gastroschisis, intrauterine volvulus, and meconium ileus, are infrequent (occurring in 7% of cases) (Dalla Vecchia et al, 1998). Atresias are thought to be most likely the result of a late intrauterine mesenteric vascular accident. They are equally distributed between the jejunum and ileum and are multiple in 10% to 20% of cases (Grosfeld et al, 1979). A useful classification is shown in Figure 71-14 (Grosfeld et al, 1979). Intestinal length may be significantly decreased in type IIIb atresias (so-called “apple peel” or “Christmas tree” deformity) and in type IV multiple atresias (“string of sausages” appearance). Prenatal ultrasound diagnosis is possible but is less accurate than in duodenal atresia.

**FIGURE 71-14.** Classification of intestinal atresias. **A**, Mucosal atresia with intact bowel wall and mesentery. **B**, Blind ends joined by a fibrous cord. **C**, Blind ends separated by a mesenteric defect. **D**, Blind ends with the “apple peel” atresia. **E**, Multiple atresias.

Signs and symptoms of small bowel atresia include maternal polyhydramnios, bilious vomiting, abdominal distention (which may not become obvious until the second or third day of life), failure to pass meconium, and jaundice. Passage of meconium does not exclude an atresia, as 20% to 40% of newborns with the condition will pass some meconium. Plain abdominal radiographs show varying amounts of dilated, thumb-sized loops of bowel (“rule of thumb”), air-fluid levels, and absence of rectal gas (Fig. 71-15). Peritoneal calcification signifies the presence of meconium peritonitis, the result of a prenatal intestinal perforation. Contrast enema (usually using water-soluble contrast material) is the diagnostic test of choice. Contrast material may not reach the obstruction, but the appearance of a microcolon in the normal anatomic position is strong evidence that other lesions, such as malrotation, colonic atresia, and aganglionosis, are unlikely. Meconium ileus should be excluded by careful evaluation, as in most such cases the infant can be managed nonoperatively.

The type of surgical procedure depends on the lesion, but most often it involves resection of the atretic segment(s) with primary end-to-end anastomosis. Significant luminal discrepancies between the proximal and distal ends are addressed by amputation of large blind pouches, tapering enteroplasty, and/or end-to-oblique anastomosis. A certain degree of functional obstruction may still be encountered postoperatively, especially in proximal atresias. Prognosis is excellent, except with types IIIb and IV atresias, in which significant mesenteric defects may result in a short bowel syndrome.

**FIGURE 71-15.** Anteroposterior view of abdomen of male newborn with intestinal atresia. Multiple dilated bowel loops are present. Rectal contrast shows microcolon.

## Colonic Atresia

Less than 10% of atresias occur in the colon, and stenosis is even less common. Associated anomalies may occur in one third of the infants. In up to 20% of cases, colonic atresia is accompanied by other intestinal atresias, and these must be sought carefully. Clinical signs and symptoms of colonic atresia include abdominal distention and vomiting beginning on the second or third day of life and failure to pass meconium. On plain radiographs, dilated loops of bowel are present, often with a distal cutoff. Pneumoperitoneum from intestinal perforation is found in 10% of cases. A contrast enema is essential for diagnosis, showing a distal microcolon. The preferred surgical approach involves resection of the atretic segment and primary anastomosis (Davenport et al, 1990). This approach has replaced various staging procedures in stable patients without peritonitis. Outcome generally is very good.

## Meconium Ileus

### Definition and Etiology

*Meconium ileus* refers to an intraluminal intestinal obstruction produced by thick inspissated meconium. Ninety percent of patients with meconium ileus have cystic fibrosis (CF). Indeed, in 10% to 15% of cases of CF, the patient presents with meconium ileus. DNA markers for the CF gene have been identified and localized to chromosome 7 (Rommens et al, 1989; Mornet et al, 1988) showed different haplotypic variants for CF chromosomes in families with meconium ileus from those in families with no meconium ileus.

Severe pancreatic involvement is not a consistent finding in CF cases in which the patient presents with meconium ileus (Waters et al, 1990). In utero, some CF fetuses produce exceptionally viscid secretions from the mucous glands of the small intestine. The meconium formed is dry and contains higher-than-usual concentrations of protein, including albumin (Schwachmann and Antonowicz, 1981). The abnormal meconium adheres firmly to the mucosal surface of the distal small bowel, creating an intraluminal obstruction. Histologically, the goblet cells and mucous glands are prominent and distended with an eosinophilic material that merges with the intraluminal meconium for a cast of the crypts and villi. Proximal to the obstruction there may be intestinal muscular hypertrophy.

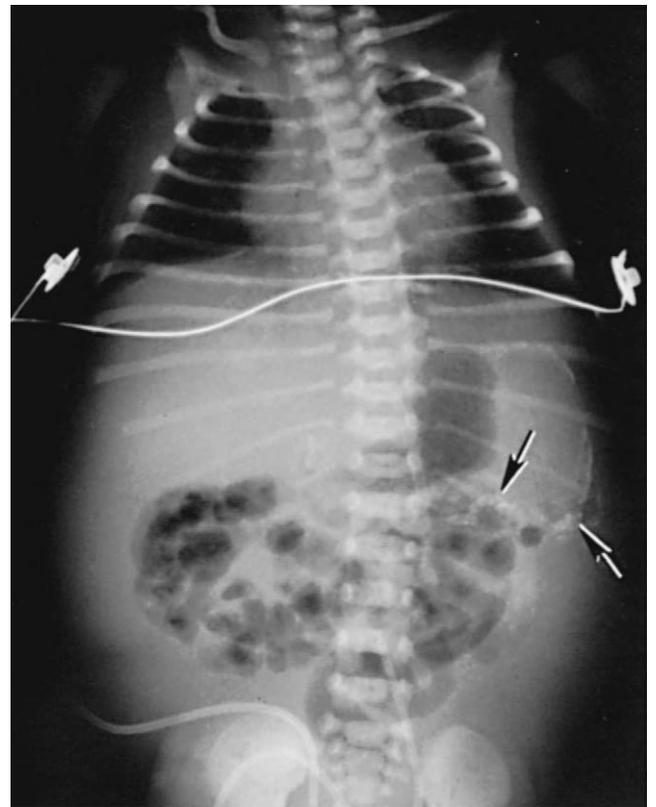

### Diagnosis

Prenatal diagnosis of CF is possible (Lemna et al, 1990). A family history of CF should alert the clinician to the possibility of meconium ileus. In the simple form in which obstruction occurs in the middle and distal ileum without perforation and peritonitis, signs of obstruction appear within the first 48 hours in an otherwise healthy infant. Abdominal distention is noticed between 12 and 24 hours, after which vomiting occurs. No meconium is passed. Physical examinations may reveal firm palpable masses throughout the abdomen that are freely movable in any direction (“doughy abdomen”). Meconium ileus complicated by volvulus, atresias, meconium peritonitis, or pseudocyst formation is found in one third to one half of

the patients (Rescorla and Grosfeld, 1993). Newborns with these complications present earlier than those with simple meconium ileus. They usually appear more ill, often with severe vomiting, signs of neonatal sepsis, and more marked distention causing respiratory distress.

Radiographic examination shows dilated loops of bowel. Fluid levels are inconspicuous because of the viscous nature of the meconium, which produces a coarse granular appearance (“ground-glass” appearance or “soap bubble” sign), typically in the right lower quadrant. The abdominal film may show, in addition to the distended gas-filled loops, intra-abdominal calcification indicative of meconium peritonitis (Fig. 71-16). The presence of air-fluid levels suggests the presence of jejunal or ileal atresia. The presence of a single grossly distended loop of bowel suggests the presence of postnatal volvulus. Perforations after birth result in free intraperitoneal air. Newborns suspected of having meconium ileus or with any other distal bowel obstruction should undergo a contrast enema study. In meconium ileus, this study typically shows a microcolon and obstruction by multiple filling defects in the terminal ileum.

All newborns with meconium ileus should be evaluated for CF. Boat and coworkers (1989) have reviewed the clinical, physiologic, and genetic aspects of CF. The identification and cloning of the primary CF gene and the ability to identify mutations causing CF have advanced

**FIGURE 71-16.** Ten-hour-old infant with ascites and abdominal calcification (arrows) secondary to meconium peritonitis. No gas is present in the rectum. The infant had ileal atresia, and a subsequent sweat chloride test was positive for cystic fibrosis. (Courtesy of Dr. Ronald M. Cohen, Children’s Hospital, Oakland, Calif.)

the clinician's ability to provide accurate diagnosis as well as counseling (Kerem et al, 1989b; Lemna et al, 1990; Rommens et al, 1989).

### Treatment

In simple meconium ileus, approximately 60% of the infants have their obstruction successfully relieved by the diagnostic contrast enema, ideally using Gastrografin (Kao and Franken, 1995). Before the hyperosmolar enema is given, other complications, such as perforation, volvulus, or atresia, must be excluded. The hypertonic enema draws water into the intestinal tract, dislodging and breaking up the meconium. Because of rapid fluid shifts, great care must be taken to maintain fluid and electrolyte balance. Failure of the contrast to dislodge the inspissated meconium after two attempts is an indication for surgical intervention. If the enema is successful, acetylcysteine, 5 mL every 6 hours, may be given via a nasogastric tube to help complete the clean-out.

Surgical intervention in simple meconium ileus usually consists of enterotomy with acetylcysteine irrigation and immediate closure. Other procedures such as resection of the ileum, with or without construction of various defunctioning ileostomies, are rarely indicated (Rescorla and Grosfeld, 1993). Complicated meconium ileus always requires surgical intervention, and the choice of operative procedure depends on the pathologic findings.

### Prognosis

Operative mortality is minimal for simple meconium ileus. Perforation and electrolyte imbalance are the main complications of hyperosmolar enemas (Kao and Franken, 1995). Longer-term outcome is influenced by the severity of pulmonary involvement.

Meconium plug syndrome is a similar entity not related to CF. Affected infants present similarly clinically, yet on contrast enema the obstruction is colonic and uniformly relieved during the study. Because of the diagnostic similarity and the fact that some children with CF may present with this pattern, testing for CF is indicated in all newborns with meconium obstruction (Rosenstein, 1978).

## **Anorectal Malformations**

### Definition and Epidemiology

Anorectal anomalies occur in 1 of every 5000 births and are slightly more common in males (deVries and Cox, 1985). Associated anomalies occur in more than half of affected infants and are more frequent in "high" forms (see under "Etiology," next). Most frequent are vertebral, genitourinary, and gastrointestinal malformations (Kiely and Pena, 1998).

### Etiology

The proctoderm comprises the anus and a canal that extends cephalad a short distance to meet the blind end of the hindgut, which has simultaneously moved caudad. Around the seventh to eighth week of gestation these should make contact, separated only by an anal membrane.

At the same time, the lower urinary tract develops alongside the lower intestinal tract, separated by the urorectal membrane. Anal malformations arise locally from maldevelopment within the proctoderm. Atresias, stenoses, and fistulas arise from imperfect resolution of the anorectal membrane with or without concomitant failure of the urorectal membrane to separate completely the rectal and genitourinary components.

Anorectal malformations have traditionally been classified on the basis of the level of the rectal pouch (above the levator sling, or "high," and below it, or "low") and the presence or absence of an associated fistula. This classification is, however, arbitrary and too simplistic. A descriptive listing of the anomalies as presented in Table 71-2 is therefore suggested (Pena, 1997). A fistula is present in 95% of the cases, either externally as an anocutaneous fistula or internally as a rectourethral or rectovesical fistula.

### Diagnosis and Treatment

Diagnosis is based on careful perineal examination, with imaging studies reserved for cases of diagnostic uncertainty and for evaluation of associated anomalies. The two key considerations in the assessment are the need for a colostomy and the presence of significant associated anomalies. The level of the defect may be clinically identifiable. Infants with low defects may have cutaneous fistulas, a bulging anal membrane, and well-formed buttocks. Females will pass meconium through a perineal, vestibular, or vaginal fistula, or the anomaly may manifest as a cloaca ("one-hole perineum") (see Fig. 71-6). Cutaneous fistulas in males may track along the midline raphe toward the penis, discharging a tiny epithelial "pearl" or a meconium drop (see Fig. 71-5). Finding meconium in the urine or air in the bladder may identify the presence of an internal fistula.

Plain abdominal radiographs may show progressive distal bowel obstruction. The traditional "invertogram" used to identify the distance between the rectal pouch and the skin has been replaced by a cross-table prone film obtained with the pelvis elevated, although this study should not be done in the first 24 hours of life, as the radiographic appearance may suggest a falsely increased gap (Kiely and Pena, 1998). Perineal ultrasound examination may prove to be more accurate than plain films. Abdominal ultrasonography, cardiac echography, and skeletal films may be required to rule out associated anomalies. The management of low defects includes several procedures aimed at restoring the anorectal canal, by "cut-back" of a cutaneous fistula, anal transposition, or limited posterior sagittal anorectoplasty (Kiely and Pena, 1998). High and so-called intermediate defects require an immediate colostomy, followed by elective repair. Before the final repair a distal colostogram allows the precise localization of the fistula. Although there are multiple approaches to the definitive correction of anorectal malformations, the aim of all is to close any fistula and then tunnel the rectal pouch through the anatomic sphincter muscle to the anoderm. The posterior sagittal anorectoplasty popularized by Pena has become the most frequent procedure worldwide (Kiely and Pena, 1998).

TABLE 71-2

**Anatomic Classification of Anorectal Malformations**

	Lesion	Frequency (%)			Survival (%)
		Overall	Male	Female	
Low (below the levator)	Anal stenosis	8			100
	Imperforate anal membrane	6			95
	Anal agenesis	36			84
	No fistula	7	7	0	
	Fistula	29	8	21	
	Anovulvar		1	14	
Anoperineal		8	7		
High (above the levator)	Rectal agenesis	47			72
	No fistula	13	11	2	
	Fistula	31	21	10	
	Rectourethral		24		
	Rectovesical		1		
	Rectovaginal			8	
	Rectocloacal			3	
	Rectal atresia	3	1	2	57
Overall				80	

Data from Kiesewetter WB, Chang JHT: Imperforate anus: A five to thirty year follow-up perspective. *Prog Pediatr Surg* 10:81-90, 1977.

**Prognosis**

Although the surgical mortality rate is low and primarily dependent on associated anomalies, functional long-term results are variable. Children born with low defects often will be chronically constipated; incontinence may occur in 30% to 35% of patients with high defects (Ditesheim and Templeton, 1987). Furthermore, quality of life correlates closely with whether continence can be established (Ditesheim and Templeton, 1987). Nevertheless, a majority of these children can be rendered functionally continent through a bowel management program, anorectal biofeedback, and antegrade enemas via a cecostomy in selected patients (Paidas, 1997).

**Enteric Duplications**

Duplications of the gastrointestinal tract are relatively rare. Developmentally, the most favored hypothesis is the split notochord, resulting from adherence between ectoderm and endoderm in the neural plate (Pang et al, 1992).

Duplications may occur anywhere from the mouth to the rectum, although a majority are found in the small bowel. Associated anomalies, especially of the intestinal tract, are common. Duplications are generally located on the mesenteric side of the lumen, are lined by intestinal mucosa, and share a common wall and mesenteric blood supply with the adjacent intestine. Most duplications are spherical, presenting as cysts occasionally communicating with the main enteric lumen. Tubular duplications may involve long segments of bowel but are rare.

Many duplications manifest in the neonatal period, usually with obstructive signs in the presence of a palpable mass (Stringer and Spitz, 1995). Esophageal duplications may cause respiratory distress, whereas ectopic gastric tissue may cause rectal bleeding from peptic ulceration. Plain

films of the abdomen may show displacement of adjacent viscera by a mass. Upper and/or lower gastrointestinal contrast studies may demonstrate a filling defect or, rarely, a communication between the cyst and normal bowel. Ultrasound diagnosis is possible both prenatally and postnatally, based on a characteristic appearance of the wall of the mass. CT or MRI is the modality of choice for imaging thoracic duplications.

The treatment of choice is surgical excision with primary anastomosis, although partial excision with destruction of residual enteric lining may be necessary for long tubular duplications (Stringer and Spitz, 1995).

**Extrinsic Obstruction****Malrotation and Midgut Volvulus****Presentation**

Anomalies of intestinal rotation occur in 1/6000 live births. Malrotation of the gut occurs between the eighth and tenth weeks of gestation, when the elongating intestine returns to the abdominal cavity. If the mesenteric attachments do not develop properly, the midgut lies free, attached to the posterior abdominal wall at only two points: at the duodenum and at the proximal colon. It may therefore twist in either direction, but when volvulus occurs it is usually in the clockwise direction. Midgut volvulus may occur at any time postnatally, but 80% of cases are found in the neonatal period (Seashore and Touloukian, 1994).

The newborn with midgut volvulus presents with high intestinal obstructive symptoms, often in the first week of life. Sudden bilious vomiting with abdominal distention in a previously well newborn is particularly suspicious. Mesenteric vascular compromise of the midgut leads to rapidly progressive peritonitis, sepsis, and shock. Laboratory

investigations usually reveal biochemical signs of visceral ischemia and sepsis.

Plain abdominal films may show a high intestinal obstruction, although the closed-loop obstruction produced may fail to show air-fluid levels, as the compromised bowel often is filled with fluid alone (Fig. 71-17). Findings on plain radiographs may therefore be variable and cannot be used to rule out a midgut volvulus. A “gasless abdomen” finding is particularly worrisome. The stable infant with suspected volvulus should undergo an urgent upper gastrointestinal contrast study to document the position of the duodenojejunal flexure and to identify any proximal obstruction. Ultrasound examination may reveal the “whirlpool sign” in an acute volvulus or may document the correct or reversed position of the superior mesentery artery and vein (Pracros et al, 1992). The infant with peritonitis and suspected midgut volvulus should be promptly resuscitated and taken for immediate laparotomy.

### Treatment

At laparotomy, the volvulus is reduced by counterclockwise rotation, and intestinal viability is carefully assessed. Frankly necrotic bowel is removed, followed by either primary anastomosis or stoma creation. A Ladd procedure also is carried out, including lysis of peritoneal bands, appendectomy, and replacement of the bowel in a malrotated position. Recurrent volvulus after this procedure is very unusual.

**FIGURE 71-17.** Anteroposterior view of abdomen of male infant with midgut volvulus. The contrast material shows the duodenojejunal junction to be to the right of the spine, indicative of underlying malrotation. The proximal jejunum is obstructed in the “coil spring” appearance of acute midgut volvulus.

The infant with necrosis of the entire midgut presents a particularly challenging problem. A second-look laparotomy in 12 to 36 hours is often undertaken to assess intestinal viability. Options in the case of minimal intestinal recovery include short-gut protocols and bowel-lengthening procedures, intestinal transplantation, and compassionate care alone.

### Intussusception

*Intussusception* is the invagination of one loop of bowel into a loop distal to it. Although intussusception is a relatively common cause of intestinal obstruction in infants 6 to 18 months of age, it is very rare in neonates. Prenatal intussusception is responsible for some cases of intestinal atresia (Wang et al, 1998). In premature infants, intussusception may manifest without a specific leading point and with a picture mimicking that of necrotizing enterocolitis (Mooney et al, 1996). In the full-term newborn, a colonic leading point often is encountered (Wang et al, 1998).

Should a diagnosis of intussusception be entertained, ultrasound examination and/or contrast enema are indicated. Hydrostatic reduction is not usually successful in neonates, and therefore a laparotomy with operative reduction or resection is necessary.

### Meconium Plug Syndrome

Meconium plug syndrome originally was described as an intestinal obstruction in the newborn that is relieved by the passage of an inspissated gray plug of meconium from the distal colon (Ellis and Clatworthy, 1966). It was initially thought that the meconium itself was abnormal. However, this syndrome has come to be considered a form of colonic dysmotility without an abnormality of intramural ganglion cells. Affected infants pass no meconium for the first 24 to 48 hours of life, and eventually symptoms of distal intestinal obstruction develop. Contrast enema is both diagnostic and therapeutic.

## Physiologic and Inflammatory Abnormalities of the Gastrointestinal Tract

Carol Lynn Berseth

### ASCITES AND PERITONITIS

#### Ascites

Generalized abdominal enlargement may be due to intestinal distention, hepatomegaly, tumors, peritonitis, or ascites. Therefore, the presence or absence of each of these entities must be determined in evaluating the infant for suspected ascites. Imaging techniques such as radiography, ultrasonography, and computed tomography scanning may be useful in determining whether abdominal masses are present and in defining the type of ascites present. In addition, paracentesis to obtain peritoneal fluid for laboratory analysis provides additional clues to the cause of ascites. Most commonly, ascitic fluid in newborns is analyzed for content of red blood cells, white blood cells, protein, and fat, but additional analysis, as shown in Table 72–1, can be useful.

Ascites may be identified early in fetal life by obstetric ultrasound examination. Accumulation of fluid in the abdomen of the fetus may be so massive as to necessitate delivery by cesarean section. The presence of ascites may produce respiratory distress after birth (Fig. 72–1). Immediate paracentesis to aspirate ascitic fluid may be diagnostic as well as therapeutic. Ascites may be chylous, urinary, biliary, or pancreatic. It may be secondary to neonatal hydrops or congestive heart failure or caused by the rupture of a large ovarian cyst in the fetus during delivery. Although hyponatremia is found in 70% of these infants, electrolytes commonly are normal at birth because of the normalizing effect of the maternal-placental circulation. Postnatally, however, the presence of ascitic fluid containing high concentrations of urea, creatinine, and potassium triggers physiologic equilibration with the extracellular fluid, which may result in dramatic shifts of free water and solutes. Thus, sodium moves from the vascular compartment to the peritoneal cavity, causing hyponatremia.

#### Chylous Ascites

The most common type of neonatal ascites is chylous ascites, which occurs more often in males. In the newborn, chylous ascites usually is due to a congenital failure of the lymphatic channels to communicate (Cochran et al, 1985).

The initial paracentesis may yield clear fluid, but after enteral feedings are initiated, subsequent paracenteses yield a milky fluid that is high in triglyceride content. Leukocyte counts also may be elevated, and protein content is variable. Because chylous ascites may accompany intestinal malrotation and incomplete volvulus, appropriate imaging should be done to rule out the presence of intestinal malrotation. Treatment consists of repeated paracentesis to relieve distention, which will avoid respiratory embarrassment. The use of a formula containing medium-chain triglycerides decreases the formation of chyle. If chyle formation persists despite the specialized formula, intravenous alimentation may be necessary. In most patients, the ascites remits spontaneously, and the prognosis is excellent.

#### Urinary Ascites

Urinary ascites accounts for 25% of all cases of neonatal ascites, and it is due to an obstructive uropathy. Posterior urethral valves are the most common cause (Mann et al, 1974), but other lesions that can cause urinary ascites include ureterocele, urethral atresia, bladder neck obstruction, neurogenic bladder, and bladder hematoma. Although the most common cause of disruption of the urinary collecting system is the presence of a tear in the collecting system itself, most often located at the caliceal fornix, perforation of the bladder has also been described.

Paracentesis yields urine (i.e., fluid) containing elevated concentrations of urea, creatinine, and potassium and low-to-normal concentrations of sodium and chloride (Arnold, 1986). Evaluation should include an abdominal ultrasound study, intravenous pyelogram, and voiding cystourethrogram to characterize the abnormalities in the urinary tract and its collecting system. Surgical decompression of the urinary tract or definitive correction of the causative lesion should be performed with urgency. The immediate prognosis for these infants is excellent, and renal function in the neonatal period and infancy is excellent (Farhat et al, 2000). The long-term prognosis often is poor, however. In a recent report of outcomes in 10 consecutively treated infants, 7 progressed to end-stage renal disease by their preteen years (Roth et al, 2000).

#### Biliary Ascites

Biliary ascites is caused by spontaneous perforation of the biliary tree. In 68% of the cases, the perforation occurs in the main biliary tree. In the remainder, the perforation is located at the junction of the cystic and common ducts or in an accessory bile duct. Two clinical forms are apparent. In the acute form, the infant presents with abdominal distention, vomiting, absence of bowel sounds, and unstable vital signs. Clinical jaundice may not be present. In the more chronic form, which occurs in about 80% of reported cases, clinical jaundice appears early, followed by gradual abdominal distention. Paracentesis reveals fluid with a bilirubin content above 4 g/dL, and the diagnosis is confirmed by scintigraphy or sonography (Banani et al, 1993). Laparotomy with a biliary drainage procedure is essential for survival. Survival rate after surgery is 80%.

TABLE 72-1

**Laboratory Studies Useful in the Evaluation of Ascites**

Routine	Special
Red cell count	Triglycerides
White cell count with differential	Amylase
Specific gravity	Bilirubin
Total protein	
Culture	

**Pancreatic Ascites**

Pancreatic ascites, an extremely rare lesion, may be the presenting manifestation of pancreatitis secondary to a pancreatic duct anomaly. Except for the presence of abdominal distention, infants are asymptomatic. The concentrations of amylase, fat, and protein in the ascitic fluid may be elevated. Urine and serum amylase levels may be normal. Most infants require a surgical drainage procedure.

**Ruptured Ovarian Cyst**

Ahmed (1971) reported the complication of ruptured ovarian cyst in a review of newborns with ovarian cysts. The presenting symptoms at birth included ascites and hemoperitoneum.

**Peritonitis**

Peritonitis in the newborn can be classified as either bacterial or chemical (Bell, 1985). Chemical peritonitis occurs as an inflammatory response to the presence of

**FIGURE 72-1.** Full-term infant at 2 hours of age with massive ascites, which subsequently proved to be chylous. The distention was controlled with repeated paracentesis and an elemental diet. By 6 months of age, paracentesis was no longer necessary. At 13 months of age, the infant remains on an elemental diet and is growing and developing normally.

a caustic material. The two most common forms of chemical peritonitis are due to the presence of meconium and bile, respectively, as a result of spillage from the intestine and biliary tree.

Meconium peritonitis may result from intestinal perforation that occurs in utero or shortly after birth. Most typically these cases of intestinal perforation are secondary to bowel obstruction; almost half are due to meconium ileus (Bell, 1985). Its presence is not commonly diagnosed prenatally (Yang et al, 1997), and at autopsy or surgery, the tear may be obvious or may have healed over. Although uncommon, other causes of meconium peritonitis are intussusception, volvulus, incarcerated internal hernia, imperforate anus, and meconium plugs.

Infectious peritonitis may be primary or secondary. Primary peritonitis occurs as a result of hematogenous or lymphatic spread, and secondary peritonitis occurs as a result of a primary abdominal catastrophe, such as necrotizing enterocolitis, appendicitis, biliary tract disease, rupture of a visceral abscess, or infection of indwelling foreign objects. Bacterial peritonitis in newborns is most commonly secondary. Thus, the organisms involved are mixed anaerobic and aerobic (Brook, 1989). The pathogenesis of peritonitis is multifactorial. First, many gut bacteria produce endotoxins, which activate inflammatory mediators such as tumor necrosis factor, interleukins, leukotrienes, and the complement system, all of which can cause increased vascular permeability and coagulation abnormalities. Anaerobes do not produce endotoxin but instead adhere to epithelial cells and produce exoenzymes such as hyaluronidase and protease. In addition, anaerobes possess capsules, which reduce the ability of immunoregulatory T cells to contain and compartmentalize infection. Moreover, there is a synergism of anaerobic and aerobic bacteria that is enhanced in the presence of irritants such as hemoglobin or bile. Finally, the exudation of intraperitoneal fluid that is triggered by these infections results in large fluid shifts, mechanical compromise of pulmonary function, and presence of a fibrinous glue, which may result in adherence of peritoneal surfaces to mesentery, resulting in abscess formation.

A new organism that has emerged as a causative agent of peritonitis is *Candida*, which is present in approximately 10% of cases of bowel perforation. Fungal peritonitis is more likely to occur in those infants who are extremely premature, require prolonged umbilical artery catheterization, have prolonged exposure to antibiotics, or require prolonged intubation (Karlowski, 1993).

Management includes surgical drainage and antibiotics. Antifungal therapy also may be considered. In addition, aggressive rehydration and correction of electrolyte abnormalities must be provided. Mortality rates range from 33% to 80%, depending on the underlying cause (Bell, 1985).

**GASTROESOPHAGEAL REFLUX****Physiology**

Gastroesophageal reflux (GER) refers to the retrograde movement of gastric contents into the distal esophagus. GER is a physiologic event that permits the clearance of air and other noxious materials from the stomach. Because gastric contents are acidic, and acidic material composes

the wall of the air bubble cleared into the distal esophagus, mechanisms for returning acidic material to the stomach also must be present. Thus, these normal physiologic events require that the structures as well as the neural networks that mediate their function be intact and integrated. When this integrated system fails, acid reaches the distal esophagus, where it causes erosion. When this occurs, the patient is said to have gastroesophageal reflux disease (GERD). Many aspects of regulation of physiologic GER are limited in the neonate, but it remains unclear whether neonates have GER or GERD.

When food is ingested, swallowing triggers a series of sequential contractions that progress from the proximal esophagus to the distal esophagus, pushing the food bolus toward the stomach. The lower esophageal sphincter (LES) is a 1- to 2-cm segment of the distal esophagus that is identified functionally as an area of high pressure. Its primary function is to prevent reflux of gastric contents into the distal esophagus when active swallowing is not occurring. When a food bolus reaches the distal esophagus, interneuronal messages inhibit the tonic contraction of the LES. The LES relaxes and the food bolus is propelled into the stomach. The tone of the LES is further splinted by the diaphragmatic crura, which surround the LES like an elastic sling.

Only a minority of the peristaltic contractions in the esophagus of preterm infants are sequentially coordinated (Omari et al, 1995). In addition, the resting LES tone is low in the neonate, ranging from 5 to 10 mm Hg in the neonate, compared with 10 to 30 mm Hg in the adult (Novak, 1996). However, most infants with GERD have normal LES pressure (Kawahara et al, 1997). Factors other than intrinsic muscle tone affect LES pressure, including gastric distention, acute or chronic brain injury, position of the sphincter, angle of the indentation of the esophagus at entry of the stomach, and factors that alter sphincter circumference, such as edema, increases in intra-abdominal pressure, and delayed gastric emptying.

The diaphragmatic crura may offer limited splinting to the neonatal LES, as the LES is located 2 cm above the diaphragm for the first 6 postnatal months until it descends into the abdominal cavity (Moroz et al, 1976). Thus, when deep inspiration or straining causes increases in intra-abdominal pressure, this splinting mechanism may be limited in the neonate. Absence of the splinting mechanism may contribute to the high incidence of GERD among surviving infants with diaphragmatic hernia (Fasching et al, 2000).

Most episodes of physiologic GER occur during spontaneously during episodes of transient LES relaxation (TLESRs). It is thought that gastric distention triggers interneuronal pathways that trigger LES relaxation primarily to vent air (Cucchiara et al, 1998). Although LES relaxation can be triggered by swallows independently of peristaltic esophageal contractions, 82% of episodes of GER in preterm infants are associated with spontaneous TLESRs (Omari et al, 1998).

Once material has refluxed into the distal esophagus, mechanoreceptors and/or acid receptors trigger a series of peristaltic contractions in the distal esophagus to propel material back into the stomach. In addition, they trigger increased swallowing, which in turn provides a larger volume of saliva to buffer the acid (Helm et al, 1984). Thus,

GERD may be the result of either increased GER or impaired clearance mechanisms.

### Presentation

In non-newborns, GER is clinically suspected when infants exhibit poor weight gain owing to regurgitation, nonspecific irritability, and apnea. Because of the use of parenteral nutrition to promote weight gain, neonates with GER rarely present with failure to thrive (Frakaloss et al, 1998). Newborns cannot verbalize pain; thus, GER also may manifest as recurrent fussiness, feeding aversion, bradycardia, or cyanotic episodes. However, many of these signs and symptoms are nonspecific, and trained observers cannot reliably identify the presence of GER using these indicators (Snel et al, 2000). GER occurs frequently in infants who have central nervous system abnormalities, bronchopulmonary dysplasia, cystic fibrosis, and esophageal atresia (Balson et al, 1998; Blecker et al, 1995; Dudley and Phelan, 1976; Lew et al, 1981). In addition, other neonatal intensive care unit (NICU) therapies may alter normal physiologic regulation and anatomic relationships to predispose the infant to developing GERD. Xanthines, used to treat apnea, reduce LES tone and increase gastric acid secretion (Berquist et al, 1984; Vandenplas et al, 1986). The use of gastric tubes may reduce LES pressure (Berezin et al, 1986). Increasing intra-abdominal pressure by delivering chest physiotherapy also may reduce LES pressure, increasing the occurrence of reflux (Newell et al, 1987). Infants spend considerably more time sleeping than do in children and adults, and LES basal pressure often falls during sleep (Sondheimer and Hoddes, 1992). There is also an association of GER with respiratory symptoms. GER occurs more commonly among infants with bronchopulmonary dysplasia and who have experienced acute life-threatening events (Gioffre et al, 1987; Veereman-Wauters et al, 1991). Moreover, the instillation of acidic agents into the distal esophagus can induce bronchospasm (Herve et al, 1986). The strong temporal association of GER and respiratory disease, however, has not been shown to be a causal one, and the mechanism for this association has not been delineated.

### Evaluation

Controversy currently surrounds issues related to diagnostic testing for GERD. Several techniques are available. Because of the limitations of the diagnostic techniques for newborns, many gastroenterologists proceed to a trial of therapy before extensive diagnostic studies are performed.

The barium swallow is the first study that should be done to evaluate GER. It is a poor method to demonstrate the presence of GER; rather it is used to confirm the presence of normal esophageal, gastric, and intestinal anatomy, because congenital anomalies in any of these structures may cause mild episodes of vomiting. Because this study is not performed under physiologic conditions (i.e., the patient is supine on a cold table, often crying or struggling, and provocative maneuvers such as abdominal compression may be used) and because the patient is monitored fluoroscopically for a brief period (generally <5 minutes), the frequency of GER demonstrated during these evaluations has little relationship with the presence of real reflux disease.

The pH probe is the most commonly used diagnostic test to evaluate GER. Testing is done by positioning a pH probe in the distal esophagus and measuring the frequency and duration of episodes of esophageal acidification over 18 to 24 hours. Placement of the probe is documented fluoroscopically or by estimation using the Strobel formula (Strobel et al, 1979). The neonatologist should be aware that interpretation of pH probe studies is limited by several factors. First, the ability to detect pH changes may be altered by the anatomic location of the probe. If the probe is located too proximally relative to the gastroesophageal junction, it may not detect reflux adequately; conversely, if it is located too distally, it inappropriately identifies the presence of acid. Second, the ability to detect acidosis up to 2 hours postprandially in infants is limited because milk buffers any acid contained in refluxate (Mitchell et al, 2001). As a result, as many as 85% of neonates may have false-negative studies (Hampton et al, 1990; Lee et al, 1999). Third, variability of infant position may alter variability of pH probe results (Hampton et al, 1990; Vandenplas and Sacre-Smits, 1985). The reflux index (RI), which consists of the sum of the periods in which pH is less than 4 as a percent of recording time, is the most widely used scoring system. An RI greater than 5% is abnormal in newborns (Vandenplas and Sacre-Smits, 1987).

Because all healthy persons have GER, a variety of techniques for scoring pH probe studies have been proposed (Orenstein et al, 1987a; Sutphen and Dillard, 1986; Vandenplas and Sacre-Smits, 1987). In general, the number of acid reflux episodes, the average duration of such episodes, and the overall proportion of time that the pH is less than 4 are quantified.

Esophagoscopy may be performed in larger neonates to visualize the distal esophagus and to obtain a biopsy specimen. A normal appearance does not exclude the presence of a histologic pathologic process (Biller et al, 1983). Acid exposure may cause basal zone hyperplasia and increased papillary length (Black et al, 1990).

Laryngoscopy and bronchoscopy may be helpful in evaluating infants with respiratory symptoms, as GER can occur in the absence of esophageal abnormalities (Blecker et al, 1995). Laryngoscopy may reveal the presence of vocal cord erosion or inflammation. Bronchoscopy may reveal the presence of milk-laden macrophages (Ahrens et al, 1999; Knauer-Fischer et al, 1999).

Technetium scintigraphy can be used to monitor for reflux, pulmonary aspiration, or both. Its ability to detect episodes is limited because it is performed during a single feeding and for a 2- to 3-hour postprandial period. Esophageal manometry rarely is used in the neonatal age group.

### Treatment

Conservative treatment to minimize GER includes positioning and dietary changes. A decade ago, infants with GER were positioned upright supine. This position for preterm newborns may place them at risk for airway obstruction if the head drops down on the chest (Orenstein et al, 1983). In a large controlled study, head elevation showed no benefit over the flat prone position

(Orenstein, 1990). However, placing infants in the left lateral position may be safer and equally effective (Tobin et al, 1997). A supine position improves gastric emptying and decreases aspiration.

Because gastric distention may contribute to the occurrence of GER, infants may experience less GER if they are fed smaller volumes more frequently. Reflux occurs more typically postprandially, however, and the risk for GER may be increased with this practice. Another dietary manipulation is to add rice cereal to the milk. Although this measure does not reduce reflux, it does decrease emesis (Bailey et al, 1987; Orenstein et al, 1987b). Cow's milk protein allergy also can manifest with vomiting (see later section in this chapter). Thus, a 2-week trial of a hypoallergenic formula may be warranted (Iacono et al, 1996).

Transpyloric feeding can be used to provide enteral nutrition to premature infants who are not ready to feed orally and have GER associated with orogastric feeding. This feeding method may reduce symptoms sufficiently to allow enteral nourishment. Because GER in many healthy preterm infants is related to immaturity, the use of transpyloric feedings for 2 to 3 weeks may permit maturation to occur and avoid the complications that are associated with parenteral nutrition. The technique consists of placement of an unweighted Silastic tube in a transpyloric position under fluoroscopic guidance. This type of tube can be used without replacement for as long as 30 days. Milk is administered by slow continuous infusion.

Acid-suppressive agents may be used with or without prokinetics. Agents include histamine H<sub>2</sub> receptor antagonists, such as ranitidine or famotidine, and proton pump inhibitors. A randomized trial has shown H<sub>2</sub> receptor antagonists to be effective (Simeone et al, 1997). Trials using proton pump inhibitors, however, have not yet been done in neonates.

Prokinetic agents may enhance esophageal sphincter pressure and accelerate gastric emptying. However, no pharmacologic agent currently used can reduce the occurrence of transient LES relaxations. Bethanechol, a cholinergic drug, increases LES basal tone and overall forcefulness of esophageal peristalsis (Sondheimer and Arnold, 1986); however, it has not demonstrated consistent efficacy in clinical trials (Orenstein et al, 1986; Sondheimer et al, 1984), and it has a potential for exacerbating bronchospasm, which limits its use in infants with bronchopulmonary dysplasia. Metoclopramide, a dopamine antagonist, also increases gastric emptying and augments LES basal tone. Its efficacy is unknown, and it has been shown to increase episodes of reflux in one small trial (Machida et al, 1988). In addition, metoclopramide causes central nervous system side effects, an important limitation in infants recovering from respiratory distress syndrome who are trying to establish normal sucking skills (Putnam et al, 1992). Domperidone may be used as an alternative agent in countries where it is available, as central nervous system side effects are far less common with this drug. The U.S. Food and Drug Administration no longer approves cisapride, a noncholinergic nonantidopaminergic agent, for clinical use.

Surgical therapy is reserved for infants who have severe GER that results in recurrent pneumonia or life-threatening reactive airway disease, or has resulted in an acute life-threatening event (Ahrens et al, 1999; Orenstein, 2000). The

most commonly used procedure is the Nissen fundoplication. Recent reports have shown that this procedure can be done laparoscopically (Esposito et al, 2001; Rothenberg, 1998). Kubiak and colleagues (1999) conducted a prospective follow-up evaluation of 66 infants to assess the efficacy of the procedure. They reported that improvement in clinical symptoms occurred in 90% of infants with isolated GER but in only 66% of infants who had primarily respiratory symptoms (i.e., apnea) and 58% of infants who had additional anomalies. In addition, 24 of their patients required revision of their fundoplication. Postoperative complications are common (Esposito et al, 2001; Subramaniam and Dickson, 2000; Wilkinson et al, 1987) and include failure of the wrap, overtightness of the wrap, and delayed gastric emptying. Because tincture of time provides improvement in GER in most patients, consideration should be given to the use of transpyloric feedings on a temporary basis in this population of infants to obviate the need for surgery.

## HIRSCHSPRUNG DISEASE

### Physiology

Hirschsprung disease, or congenital aganglionic megacolon, accounts for 20% to 25% of cases of neonatal intestinal obstruction. It is caused by agenesis of ganglion cells in the myenteric and submucosal plexuses. Recent data also suggest that the motility dysfunction is the result of reduced expression of the neuronal nitric oxide synthase gene at the messenger RNA level (Puri and Wester, 1998). The anus always is involved, with variable lengths of distal intestine affected. In 80% to 90% of the patients, involvement does not extend more proximally than the sigmoid colon, but in 8% to 10% of cases, the entire colon is involved. Because neural inhibitory input to affected areas is lacking, these areas of bowel are maintained in a tonic state, resulting in areas of functional intestinal obstruction.

It occurs in approximately one of 5000 births, with a 4:1 male-to-female incidence. Approximately 20% of infants with Hirschsprung disease have other, associated problems such as Down syndrome, Waardenburg syndrome, Smith-Lemli-Opitz syndrome, and central hypoventilation syndrome (Bonnet et al, 1996; Cass, 1990; Passarge, 1967; Rohrer et al, 2002).

Increasing evidence suggests that Hirschsprung disease may result from mutations in any of several genes, singly or in combination. Mutations of these genes may give dominant, recessive, or polygenic patterns of inheritance (Badner et al, 1990; Hofstra et al, 1997). Numerous genetic mutations have been identified to result in the common phenotype of Hirschsprung disease. Two groupings of genes, *RET/GDNF/NTN* and *EDNRB/EDN3/ECE-1*, are involved in signaling pathways, whereas another, *SOX10*, encodes a transcription factor. A truncating mutation of *SOX10* has been found in patients with Waardenburg syndrome with Hirschsprung disease (Touraine et al, 2000). From 30% to 50% of patients with familial Hirschsprung disease carry *RET* mutations, and 20% carry mutations in *EDNRB* (Chakravarti, 1996). In addition, Fujimoto and colleagues (1989) have shown that extracellular matrices in the human embryonic gut may influence final growth and

maturation after neurons have completed migration and have “settled” in the gut.

### Presentation

Although Hirschsprung disease is congenital in etiology, only 15% of patients are actually diagnosed during the first month of life. Rather, a majority are diagnosed by 4 months, with some diagnoses delayed until early preschool age. During the newborn period, infants with Hirschsprung disease may pass their first meconium stool beyond 48 hours, have infrequent stooling, reluctance to feed, abdominal distention, or bilious vomiting. These signs and symptoms may be delayed in the preterm infant whose enteral feedings are initiated beyond the immediate newborn period. A small number of neonates will present with frank enterocolitis with diarrhea, dehydration, and shock.

Abdominal radiographs may demonstrate dilated gas- or fluid-filled loops of intestine. A barium enema may not be diagnostic in the newborn, as only 60% of studies will show the characteristic narrow rectosigmoid distal to a dilated sigmoid. The typical “transition zone” does not become apparent until the infant is 3 or 4 weeks of age. However, persistence of contrast in the rectosigmoid for more than 24 hours after the examination is highly suggestive of Hirschsprung disease. One should be aware that the barium enema is nondiagnostic in infants with total-colon Hirschsprung disease (De Campo et al, 1984).

The definitive diagnosis is made on rectal biopsy; suction biopsies performed at the bedside usually yield adequate specimens (Andrassy et al, 1981). A full-thickness biopsy at laparoscopy or laparotomy may be necessary in a small number of infants.

Hirschsprung disease results from the absence of the intrinsic innervation of the distal colon, and both the myenteric and submucosal plexuses are absent. In contrast to the absence of the intrinsic innervation, the extrinsic innervation (i.e., the sympathetic and parasympathetic nerves derived from the spinal cord) may be increased as a result of the lack of feedback inhibition by the intrinsic nerves. These extrinsic neural trunks contain acetylcholinesterase, and staining for acetylcholinesterase has aided the accuracy of diagnosis, especially beyond 3 weeks of postnatal age, when the acetylcholinesterase-positive fibers have proliferated into the lamina propria. For the most accurate diagnosis, it is recommended that some diagnostic biopsy sections be stained with hematoxylin and eosin and some with acetylcholinesterase. Hirschsprung disease is diagnosed if neurons are absent in the hematoxylin and eosin-stained sections and the acetylcholinesterase stain is positive (Nakao et al, 2001).

### Treatment

Although the definitive treatment is surgical repair, there are three alternatives for initial treatment: rectal irrigation (Carcassonne et al, 1982), colostomy, and primary repair (Teitelbaum et al, 2000). Rectal irrigation may be used several times per day in patients whose aganglionic segments do not extend above the sigmoid. These irrigations decompress the intestine until further evaluation and growth are achieved in preparation for a definitive surgical repair. Alternatively, a colostomy is created proximal to the aganglionic

segment, which is identified by performing serial biopsies. This procedure also permits decompression of the bowel and permits the infant to grow larger until a definitive repair can be done approximately 12 months later. As anesthetic techniques have improved, there has been a recent shift to attempt primary repair in the neonatal period, reserving the use of the colostomy for those patients who present with enterocolitis. In these latter patients, the colostomy permits the decompression of the bowel and permits time for the inflammatory changes from the enterocolitis to resolve.

Regardless, whether repair is done using two operations (i.e., the colostomy followed by a definitive repair) or one (i.e., primary repair), the classic operation for Hirschsprung disease consists of removal of the aganglionic segment and pulling the normally innervated bowel down to the anus. The major procedures are those of Swenson Duhamel, Soave-Boley, and Georgeson. For infants who have total colonic aganglionosis, total colectomy with creation of an ileostomy is usually performed. Regardless of the surgical technique used, infants may lose significant amounts of water and electrolytes postoperatively.

The most common cause of postoperative morbidity and mortality is the occurrence of enterocolitis (Reding et al, 1997). Infants with enterocolitis typically present with abdominal distention, diarrhea, and signs and symptoms of sepsis. Treatment includes rectal irrigations and antibiotics. Other complications that may occur are anal stricture, constipation, and cuff abscess.

### Prognosis

Although survival is excellent, long-term fecal continence may be problematic. Outcome is often related to the length of intestine affected (Reding et al, 1997). Outcome for total colonic aganglionosis is poor (Coran and Teitelbaum, 2000), as many of the affected infants will require multiple operations, experience poor growth, and fail to achieve fecal continence as adults (Tsuji et al, 1999).

## OTHER OBSTRUCTION SYNDROMES

The chronic idiopathic intestinal pseudo-obstruction syndrome comprises a group of motility disorders of both muscular and neurogenic origin, including the histologic entities called intestinal neuronal dysplasia (IND) and maturational arrest. Histologically, IND is characterized by hyperplasia of the enteric nerve plexuses, abnormal distribution of the neural elements, the presence of giant ganglia or ectopic ganglia, and increased acetylcholinesterase activity (Puri and Wester, 1999). The presence of ganglioneuromas usually is associated with multiple endocrine neoplasia type IIB. Maturational arrest is characterized by hypoganglionosis and/or deficiency of neural and glial cell elements (Meier-Ruge et al, 1999). Patients may become symptomatic at any time, including during the neonatal period (Anuras et al, 1986). There is little correlation of clinical findings with histologic findings. Symptoms include abdominal distention and vomiting. Prokinetics may provide some improvement. Laxatives and enemas may relieve symptoms due to IND or MA. In general, surgical intervention usually is not successful; however, internal sphincter myectomy may be helpful for some patients with

IND (Dickson and Variend, 1983). Treatment consists of long-term parenteral nutritional support.

A variant of pseudo-obstruction is the megacystis–microcolon–intestinal hypoperistalsis syndrome, as described by Berdon and associates (1976). In newborns, this condition has been termed the “neonatal hollow visceral myopathy syndrome” by Puri and colleagues (1983), who also provided a review. Rarely seen in males, this disorder manifests in the newborn period with signs of a bowel obstruction. In addition, bilateral flank masses (hydronephrotic kidneys) and a single large midline abdominal mass (megacystis) suggest an obstructive uropathy. Ultrasound examination, voiding cystourethrogram, and barium enema are diagnostic. Surgical exploration usually reveals a massively dilated bladder and a short, malfixed small intestine with a microcolon. Adequate peristalsis never returns, so that long-term parenteral nutrition is necessary.

## COW'S MILK PROTEIN ALLERGY

### Definition

Cow's milk protein allergy (CMPA) has been defined as an adverse reaction occurring after the ingestion of cow's milk as a result of immunologic hypersensitivity to milk protein(s) (Hill et al, 1986). Adverse reactions may have a wide range of clinical manifestations, including gastrointestinal processes such as colitis and protein-losing enteropathy and more poorly defined symptoms including bronchitis, colic, and atopic dermatitis (Odze et al, 1995; Walther and Kootstra, 1983).

### Epidemiology

The frequency of CMPA ranges from 2% to 6% (Hill, 1996; Hill and Hosking, 1997; Host et al, 1988). It occurs more frequently in infants fed cow's milk or a cow's milk–based formula than in those fed human milk. Nonetheless, it does occur in approximately 0.5% of breast-fed infants (Jakobsson and Lindberg, 1979) because of maternal ingestion of cow milk protein and transfer of antigenic proteins to human milk (Host et al, 1988; Saarinen et al, 1999).

Although the specific cause of CMPA is unknown, it frequently displays a familial incidence (Cookeston, 1998). Several studies have also suggested that ingestion of cow's milk formula in the first weeks of life may increase the incidence of allergic symptoms (Host et al, 1988); however, this effect has not been confirmed by others (Lindfors and Enocksson, 1988). Acute infectious gastroenteritis also has been identified as a risk factor for developing CMPA (Cow's milk allergy [Italian Collaborative Study], 1988) because of the increased absorption of macromolecules during an acute infection (Stintzing et al, 1986).

### Differential Diagnosis

Symptoms of CMPA tend to be nonspecific. Approximately 50% to 60% of infants present with gastrointestinal or skin symptoms and 30% with respiratory symptoms (Sampson, 1997). The diagnosis of CMPA is confirmed when clinical improvement occurs when a milk-free diet is given and relapse occurs when a milk challenge is given (Goldman et al, 1963).

There are no specific biochemical tests for CMPA. Some investigators have found evaluation of immunoglobulins to be helpful but not diagnostic (Cow's milk allergy [Italian Collaborative Study], 1988). The presence of cow's milk-specific IgE and an index of lymphocyte stimulation with beta-lactoglobulin is the most sensitive (88%) and specific (67%) test for predicting whether a clinical reaction to cow's milk protein will occur (Tainio and Savilahti, 1990). Jejunal biopsies usually are not necessary to diagnose CMPA in newborns (Sumithran and Lyngkaran, 1977). If biopsy specimens are obtained, however, they demonstrate partial or total villus atrophy or an increase in the presence of eosinophils in the lamina propria, epithelial mucosa, or muscularis mucosae (Savilahti and Verkasalo, 1984). Biopsies may be useful to demonstrate the absence of parasites, ova, or crypt architectural abnormalities (Odze et al, 1995).

### Management

The management of CMPA is the removal of cow's milk protein from the diet. Some clinicians advocate the use of soy protein-based formulas as an initial therapeutic approach (Businco et al, 1992). As many as 30% of infants who have CMPA, however, exhibit allergy to soy protein (Kleinman, 1992; Powell, 1978). Thus, it is currently recommended that soy-based formulas not be used in treatment of CMPA (American Academy of Pediatrics, 1983, 2000; Joint Statement of ESPACI and ESPGHAN, 1999).

*Hypoallergenic formulas* contain hydrolyzed protein to decrease their allergenic potential. Casein hydrolysate formulas are more extensively hydrolyzed and cause less allergic reactions (Businco et al, 1989; Wahn et al, 1992). On rare occasions, infants may remain allergic to these formulas, and an elemental diet consisting of free amino acids as the protein source may be needed (Odze et al, 1995).

Breast-fed infants with CMPA usually improve when dairy products are removed from the mother's diet (Barau and Dupont, 1994). If severe colitis persists in breast-fed infants, however, hypoallergenic or elemental formulas may be necessary. Sensitivity to cow's milk protein decreases with age. As many as 28% of children with CMPA are tolerant of milk protein by 2 years of age and 78% by 6 years of age (Bishop et al, 1990).

## PANCREAS-RELATED DISORDERS

### Shwachman Syndrome

Shwachman syndrome is characterized by pancreatic insufficiency, bone marrow dysfunction, and poor growth (Aggett et al, 1980; Mack, 1996). The defect appears to be with enzyme secretion and acinar function, not bicarbonate secretion and duct function (Hill et al, 1982). Thus, serum trypsinogen concentrations are low, resulting in steatorrhea (Ginzberg et al, 1999). The presence of neutropenia is almost universal, although the presence of neutropenia may be intermittent (Ginzberg et al, 1999). Infants also may have thrombocytopenia or anemia, and approximately 20% will have pancytopenia (Ginzberg et al, 1999). Skeletal anomalies often are present, especially of the rib cage. The cause of Shwachman syndrome is genetic, but the mode of

inheritance is unknown. Clinically, affected infants present with neutropenia and failure to thrive. Although pancreatic enzyme replacement improves nutrition, most will have short stature. The mortality rate is high (30%) because of recurrent infections (Mack, 1996) and the risk for leukemia (Woods et al, 1981).

### Persistent Hyperinsulinemic Hypoglycemia of Infancy

Persistent hyperinsulinemic hypoglycemia of infancy (PHHI), or nesidioblastosis, typically manifests in a macrosomic infant who develops recurrent episodes of hypoglycemia. Aggressive glucose administration is required to maintain normoglycemia (Aynsley-Green et al, 1981). The diagnosis is made by confirming the presence of hyperinsulinemia when hypoglycemia is present. The diagnosis of PHHI requires the presence of an elevated insulin concentration concurrent with glucose less than 40 mg/dL on at least two or more occasions. (See Chapter 93 for a full discussion of this condition.)

## Abdominal Wall Problems

Carol Lynn Berseth and Dan Poenaru

### DISORDERS OF THE UMBILICAL REGION

The umbilical region is the site of intricate, complex activity during embryonic life. Early in gestation, a widely open communication exists between the yolk sac and primitive gut. Later, the entire midgut passes through this communication to form a large physiologic umbilical hernia that persists in utero for several weeks. Thereafter, the gut returns to its position in the abdominal cavity. By the third trimester, the aperture around the vessels, omphalomesenteric (vitelline) duct, and urachus begins to narrow. After birth, the umbilical arteries contract, blood flow ceases, their intimal and medial layers undergo aseptic necrosis, and the stump separates. Alterations in this orderly but complex sequence of events result in serious congenital anomalies.

### UMBILICAL CORD LESIONS

#### Noncoiled Umbilical Blood Vessels

The three vessels within the cord are coiled to form a helical structure. The number of twists can vary greatly (ranging from 0 to 40) and, rarely, reaches 380 per cord. Left-twisted vessels outnumber right-twisted vessels 7 to 1. Absence of any twists occurs in about 4% to 5% of pregnancies (Edmonds, 1954). The helical structure is identifiable by ultrasound examination by the end of the first trimester. Although how the vessels come to have this geometric arrangement has not been established, such a configuration—like that of a telephone cord—is more able to resist external compression, stretch or torsion, and the cord remains flexible (Strong et al, 1993). The absence of coils is associated with increased abnormalities that include single umbilical artery, trisomy 21, and coarctation of the aorta. Approximately 10% of infants without coils are stillborn, and the incidence of preterm birth is greater than expected.

#### Single Umbilical Artery

Normally the umbilical cord is composed of two arteries and a vein. A single umbilical artery occurs in 1% of single births and in 7% of twin births. In approximately a third of these infants, gastrointestinal obstructive lesions and urogenital abnormalities are present. The presence of single umbilical artery is higher among aborted fetuses and thus is thought to be a marker for increased fetal risk (Persutte and Hobbins, 1995; Pierce, 2001). Among newborns with single umbilical artery, there is a higher incidence of poor fetal growth (Leung and Robinson, 1989) and a slightly

increased risk for renal anomalies (Thummala et al, 1998). Therefore, the presence of a single umbilical artery warrants careful physical examination for other anomalies and consideration of further imaging after birth.

### Granuloma of the Umbilicus

If the separation of the umbilical stump is delayed beyond 5 to 8 days after birth, granulation tissue may be produced, delaying epithelialization. Granulomas must be differentiated from everted gastric or intestinal mucosa, which permits the entrance of a fine probe. Treatment for both is judicious desiccation with silver nitrate.

### Delay in Separation of the Cord

If the umbilical cord fails to separate after more than 14 days, investigation for a possible defect in neutrophil function and chemotaxis should be undertaken.

## ABDOMINAL WALL DEFECTS

### Umbilical Hernia

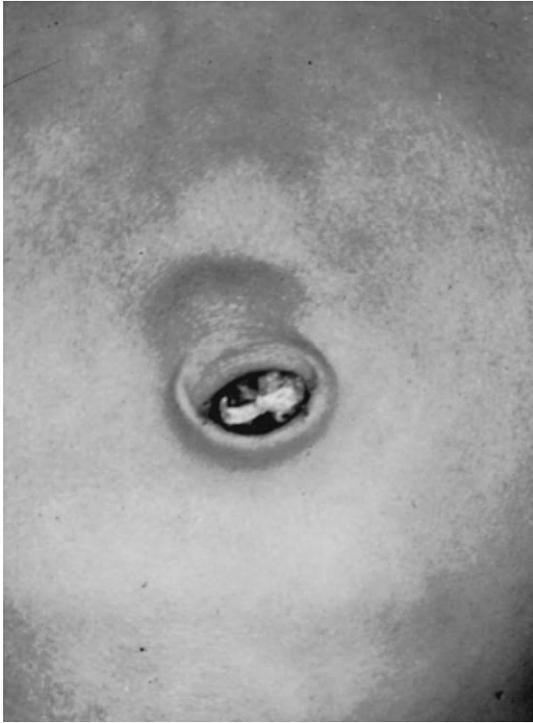

The umbilical ring is formed when the mesoderm of the muscle and fascia around the umbilical vessels and urachus contracts. Umbilical hernias are caused by failure of closure of the umbilical ring; unlike with omphaloceles, skin and subcutaneous tissue cover the defect. These lesions are found in 30% of African-American infants and in 4% of white infants; there is a high familial incidence. The condition is more common in low-birth-weight babies and in infants with Down syndrome.

The actual fascial defect varies in size, ranging from 1 to 4 cm in diameter. The sac may contain a loop of bowel that is easily pushed back into the abdomen, or some preperitoneal fat. Approximately 80% of these hernias close spontaneously by 3 to 4 years, and the risk of incarceration is exceedingly low (Fig. 73-1). Spontaneous closure is less likely in hernias with fascial defects greater than 1.5 cm. Surgical correction is therefore only indicated in large-defect hernias, in children over 4 to 6 years of age, or if symptoms occur (Poenaru et al, 2001) (Fig. 73-2).

### Omphalocele

#### Definition and Epidemiology

*Omphalocele* refers to a congenital defect in the formation of the umbilical portion of the abdominal wall that is larger than 4 cm in diameter (Table 73-1; Figs. 73-3, 73-4, and 73-5). The defect occurs in 1 in 6000 to 1 in 10,000 live births. Although many are isolated defects, some are part of a constellation of malformations (such as Beckwith-Wiedemann syndrome or trisomy 18), and a few cases are associated with maternal ingestion of valproic acid for seizure control (Boussemart et al, 1995). Omphalocele is also present in infants who have the OEIS complex, a constellation of anomalies that includes omphalocele, bladder exstrophy, imperforate anus, and spinal defects

**FIGURE 73-1.** Two definite bulges are seen cephalad to the umbilicus, one above the other. Two distinct apertures could be felt in the midline. This finding represents a minor defect of the abdominal wall.

(Keppler-Noreuil, 2001.) Because of the nature of the developmental defect, all infants with omphalocele have malrotation.

### Etiology

Early in fetal life, the small intestine lies outside of the abdominal cavity. By the 10th week, the midgut returns to the abdomen, and the somatic layers of the cephalic,

**FIGURE 73-2.** Large triangular herniation at and above the umbilicus. The bulge contained easily reducible bowel. A large aperture could be felt just above the umbilicus and a second, smaller one several centimeters above. Between them the rectus muscles were diastatic. This is a large defect of the abdominal wall demanding surgical closure.

**TABLE 73-1**

### Characteristics of Gastroschisis and Omphalocele

Defect	Gastroschisis	Omphalocele
Covering sac	Absent	Present, but may be torn
Fascial defect	Small	Small or large
Cord attachment	Onto the abdominal wall	Onto the sac
Herniated bowel	Edematous	Normal
Prematurity (%)	50-60	10-20
Associated anomalies (%)	10-15	45-55
Gastrointestinal	18	37
Cardiac	2	20
Trisomy syndromes	—	30
Necrotizing enterocolitis (%)	18	Only if sac is ruptured
Malabsorption	Common	Only if sac is ruptured

caudal, and lateral folds join to close the defect in the abdominal wall. For unknown reasons, this closure may not occur. Several types of omphalocele are recognized, based on the fold that fails to close. *Epigastric omphalocele* occurs when there is abnormal closure of the cephalic fold. Because these somites form the lower thoracic wall, failure of closure results in the Cantrell pentalogy, which includes cleft sternum, diaphragmatic defects, pericardial defects, cardiac anomalies, and omphalocele. *Classic omphalocele* occurs when there is an interruption in lateral fold development, resulting in an abdominal wall defect that lies between the epigastric and hypogastric regions. In addition to loops of bowel, liver also may herniate through the abdominal wall defect. The umbilicus arises from an anterior position on the omphalocele, and the muscular abdominal wall is normal. Failure in closure of the caudal fold results in a *hypogastric omphalocele*. Associated defects include bladder exstrophy and imperforate anus (Fig. 73-6).

### Diagnosis

Alpha-fetoprotein (AFP) is synthesized in the fetal liver and is excreted by the fetal kidneys. It also crosses the placenta and appears in the maternal circulation by 12 weeks of gestation. Maternal plasma levels of AFP are elevated when fetuses have neural tube defects, abdominal wall defects, or atresia of the duodenum or esophagus. Maternal serum AFP is used as a screening test although there is a 40% rate of false-positive results. Analysis of amniotic AFP and acetylcholinesterase-pseudocholinesterase can be sensitive in detecting abdominal wall defects, especially gastroschisis (Saleh et al, 1993; Saller et al, 1994). Human chorionic gonadotropin levels have shown promise in small series to detect abdominal wall defects (Schmidt et al, 1993).

Ultrasound evaluation is not useful during the first trimester because the midgut normally is herniated.

**FIGURE 73-3.** A mass is seen protruding from the umbilical region. No specific structure can be identified. It is covered by whitish, glistening membrane and obviously is an omphalocele.

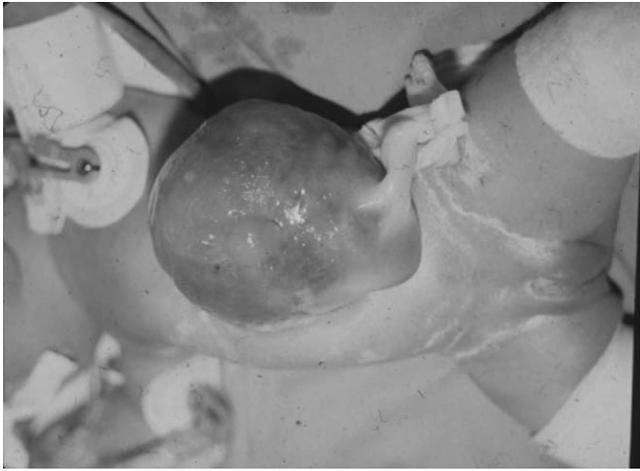

Therefore, current recommendations are for use of this modality beyond 14 weeks (Cyr et al, 1986). The combined use of maternal serum AFP and ultrasound examination at 19 weeks has been shown in a series of 8000 patients to have excellent sensitivity in identifying abdominal wall defects (Luck, 1992). Once an abdominal wall defect has been identified, ultrasound examination often can distinguish omphalocele from gastroschisis. Because the association of cardiac anomalies and chromosomal disorders is high, fetal echocardiography and amniocentesis should also be performed. Vaginal delivery does not adversely affect outcome; therefore, the need for cesarean section should be based on obstetric indications alone (Lewis et al, 1990; Sipes et al, 1990). If not discovered prenatally, the diagnosis is obvious at birth. If the sac ruptures, the bowel loops may become edematous and matted together, mimicking gastroschisis.

#### Treatment

The presence of exteriorized bowel results in heat loss and extravasation of fluid and provides a major portal of entry for bacteria. When the omphalocele is first seen, the sac should be kept moist by wrapping it with gauze sponges that have been soaked in warmed normal saline. A plastic covering is then wrapped around the defect to limit water and heat loss. Care should be taken to place the contents above the abdomen if the patient is prone, to prevent kinking of mesenteric vessels. Alternatively, the infant can be positioned on the side, with the exteriorized bowel in an anterior position. A nasogastric tube is passed to decrease the accumulation of air in the bowel. The infant should be given 1.5 times the maintenance intravenous fluid volume and broad-spectrum antibiotics. Thereafter, any inspection and manipulation of the abdominal contents should be done with sterile gloves.

**FIGURE 73-4.** Omphalocele in which the containing amniotic-peritoneal membrane must have been torn away during the delivery. Loops of bowel lie free on the abdominal wall. (Courtesy of Dr. Arnold Tramer, Baltimore, Maryland.)

**FIGURE 73-5.** (See also Color Plate 73-5.) Male newborn with omphalocele. The fascial defect is large, situated at the base of the umbilical cord, covered by a glistening membrane and containing both liver and bowel.

Operative repair should be done as soon as possible, ideally within 2 to 4 hours of birth. Small defects can be closed with a single-stage repair. For larger defects, primary repair may cause respiratory failure and abdominal compartment syndrome because the abdominal cavity is too small to accommodate the bowel. Complications of compartment syndrome include renal failure, hypotension from vena cava compression, hepatic ischemia, and intestinal ischemia. In affected infants, a staged repair is performed using a prosthetic device called a *silo* to cover the defect. After the bowel is gradually pushed into the abdominal cavity over 7 to 10 days, finally closure can be achieved (Schuster, 1979).

Postoperatively, protracted ileus may occur, necessitating prolonged parenteral nutrition. Attention also must be directed to the diagnosis and management of associated anomalies.

### Prognosis

The mortality rate with associated heart disease is 80%. In the absence of heart disease, 70% to 90% of infants with omphalocele survive (Forrester and Merz, 1999; Kitchanan et al, 2000).

**FIGURE 73-6.** A combination of omphalocele and ectopia vesicae. The bright structure below the omphalocele is an everted, extrophic bladder.

### Cord Hernia

A small omphalocele is called a *cord hernia*. By definition, the defect in the abdominal wall is less than 4 cm in diameter, and the exteriorized sac contains only loops of bowel (Figs. 73-7 and 73-8). This defect arises between the 8th and 10th weeks as a result of failure of closure of the umbilical ring. Cord hernias can be missed at birth, and the intestine can be injured by careless application of the cord clamp. Otherwise, these defects are easily managed by primary closure at birth and have an excellent outcome.

### Gastroschisis

#### Definition and Epidemiology

Gastroschisis is the herniation of abdominal contents through an abdominal wall defect, usually occurring on the right side of a normally positioned umbilical cord (Fig. 73-9; see also Table 73-1). This lesion was traditionally less frequent than omphalocele, but its incidence appears to be increasing worldwide (Penman et al, 1998). The defect appears most common among young mothers and those of low gravidity (Yang et al, 1992). Associated anomalies are found in only 15% of patients, the vast majority being intestinal atresias (Snyder et al, 2001). Infants with gastroschisis tend to have intrauterine growth restriction (Forrester and Merz, 1999; Tan et al, 1996).

#### Etiology

Although the cause of these lesions is not known, many investigators speculate that they may be of vascular origin. Intrauterine interruption of the omphalomesenteric artery has been proposed, an explanation that accounts for many of the clinically observed differences between this lesion and omphalocele (Hoyme et al, 1981).

**FIGURE 73-7.** A comparatively small mass protrudes from the umbilical region, and a loop of bowel can be readily recognized running around its lower margin. The mass is completely covered by shiny transparent membrane—clearly an umbilical cord hernia.

**FIGURE 73-8.** (See also Color Plate 73-8.) Hernia of the umbilical cord. This is in fact a small omphalocele, containing only bowel loops in a small sac within the umbilical cord.

#### Diagnosis and Treatment

As described for omphalocele, gastroschisis can be correctly diagnosed prenatally. Because the peritoneal sac is absent, the fetal bowel is continuously bathed in amniotic fluid, which results in a significant intestinal “peel,”

**FIGURE 73-9.** (See also Color Plate 73-9.) Female newborn with gastroschisis. The fascial defect is relatively small and situated to the right of the umbilical cord and contains exposed bowel (as well as an ovary in this instance).

causing poor intestinal motility. As with omphalocele, the need for cesarean section should be restricted to obstetric indications only, despite some isolated evidence that prelabor cesarean section results in better outcome because of the resulting absence of the fibrous peel (Moore et al, 1999).

The diagnosis is readily made at birth. The entire gastrointestinal tract usually is eviscerated, but unlike with omphalocele, the liver is not exteriorized. The intestinal loops usually are covered by a thick fibrous “peel,” which makes them firm, often with a cauliflower-like appearance. Intestinal atresias may be apparent as well. Rare complications include intrapartum mesenteric disruption, prenatal volvulus, and closure of the abdominal wall defect around the exteriorized gut. All of these events can cause catastrophic intestinal loss.

As described for omphalocele, the bowel contents should be kept moist and relatively sterile at birth. A nasogastric tube is passed for decompression, and 1.5 times the maintenance intravenous fluid volume is given. Broad-spectrum antibiotics also should be started. Because the abdominal wall defect often is small, vascular compromise occurs more readily, and great care should be taken to position the infant and the exteriorized bowel to prevent kinking of mesenteric vessels. Unlike with omphalocele, primary closure is possible in 90% of patients, but larger defects may require staged repair. Postoperatively, prolonged ileus often occurs because of intestinal dysmorphism, which often includes the myenteric plexus. Affected infants are at increased risk for necrotizing enterocolitis (Oldham et al, 1988). Intestinal atresias usually are not repaired at the initial procedure because of the fibrous peel and therefore require repair at 3 to 4 weeks of age (Snyder et al, 2001).

#### Prognosis

Mortality rates have decreased to 5% to 10% (Forrester and Merz, 1999; Kitchanan et al, 2000; Snyder, 1999). Postoperative recovery may be longer in infants undergoing repair of gastroschisis than in those undergoing repair of omphalocele. Enteral feedings may not be established until 2 months after operation, and some infants will require home parenteral nutrition (Molik et al, 2001). In spite of these initial feeding difficulties, most gastroschisis survivors maintain normal growth during infancy and childhood (Davies and Stringer, 1997).

#### Prune-Belly Syndrome

*Prune-belly syndrome* refers to a triad of anomalies consisting of a deficiency of abdominal musculature, cryptorchidism, and urinary tract abnormalities. The most common urinary tract anomalies seen in this triad are megaloureter, cystic renal dysplasia, urethral obstruction, and megacystis (Lattimer, 1958). Malrotation occurs in 30% of the cases, and cardiac anomalies in 20%. The syndrome rarely occurs in females, and its exact cause is unknown. Theories include failure in the development of the abdominal wall between the sixth and eighth weeks of gestation and primary urethral obstruction with early bladder distention (Moerman et al, 1984). At birth, the defect is obvious on inspection. The abdomen is shapeless, and

the skin hangs in wrinkled folds. There may be an open patent urachus, which by itself signals a poor prognosis. Of immediate concern is evaluation for and relief of urinary tract obstruction. Approximately 20% of patients with prune-belly syndrome die in the neonatal period from renal dysplasia or pulmonary hypoplasia, but of those who survive, 30% develop renal failure during childhood (Burbige et al, 1987). Surgical management of the genitourinary tract remains controversial, with advocates of both watchful waiting and major reconstruction. The latter should be performed only where specialized surgical and anesthesia expertise are available, as the surgery is challenging and postoperative complications are frequent (Snow and Duckett, 1987). The undescended testes are corrected in childhood for monitoring and psychological reasons.

### Inguinal Hernia

The gonads are formed during weeks 5 to 12 of gestation. The testes descend through the internal ring at 28 weeks. In the general population, inguinal hernias occur in 1% of all live births. The incidence of inguinal hernia in low-birth-weight and very low-birth-weight infants is as follows: with birth weights of 500 to 1000 g, 42%; with birth weights of 1000 to 1500 g, 10%; and with birth weights of 1500 to 2000 g, 3% (Peevy et al, 1986). With preterm delivery and the accompanying increase in intra-abdominal pressure, testicular descent and inguinal canal closure do not take place, thus explaining the increased incidence of inguinal hernia (Fig. 73–10).

Additional risk factors for inguinal hernias are cystic fibrosis, congenital dislocation of the hip, presence of a ventriculoperitoneal shunt, and abdominal wall defects. Incarceration and strangulation are common in infant hernias. The combined incidence of these complications appears to be as high as 30% (Rowe and Clatworthy, 1970), although it appears to be lower in preterm infants. Therefore, repeated examinations may be necessary, particularly if the infant's clinical status becomes unstable or if a tense, fluctuant scrotal mass or vomiting develops. Most of these incarcerated hernias may be reduced

**FIGURE 73–10.** (See also Color Plate 73–10.) Large bilateral inguinal hernias in a previously premature infant.

nonoperatively by placing the infant in the Trendelenburg position with sedation and application of an ice pack to the inguinal-scrotal area (Scherer and Grosfeld, 1993). Successful reduction should be followed by surgical repair in 24 to 48 hours (allowing for resolution of local edema). Failure of reduction necessitates immediate surgical repair.

Nonincarcerated hernias in infants require repair as soon as convenient, preferably within 1 to 2 weeks of diagnosis. Premature babies are best served with repair just before their discharge from the neonatal intensive care unit, or very soon afterward. Postoperative apnea is common in preterm infants, and postoperative overnight admission for apnea monitoring is therefore indicated for outpatients until 48 weeks of postconceptional age. The lowest incidence of apneas occurs with surgery performed using spinal block without sedation (Somri et al, 1998). Other specific postoperative complications include persistent scrotal swelling, recurrence, testicular atrophy, and injury to the vas deferens. Contralateral exploration is probably not indicated in most cases, as the actual risk of a metachronous hernia has been estimated at only 5% to 15% (Surana and Puri, 1993). The most common complication of operative repair is postoperative apnea.

### Hydrocele

A *hydrocele* is a collection of fluid in the scrotum without an obvious inguinal hernia. The typical hydrocele is noted at or shortly after birth as a unilateral or bilateral swelling in the scrotum, which may fluctuate in size.

The scrotum is enlarged, may be very tense with fluid, and usually is nontender, often with a bluish appearance; the inguinal canal is normal. Differentiation between hydrocele and hernia is critical and may be difficult in the infant. Transillumination is useful, but findings must be interpreted cautiously, as fluid or gas-filled bowel may transilluminate in small infants. An irreducible nontender groin or scrotal mass probably is a hydrocele.

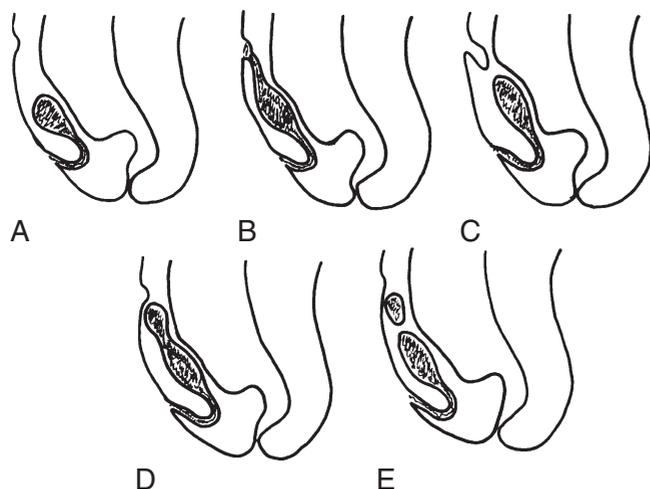

The recommended management of a hydrocele is observation during the first 1 or 2 years of life, unless a hernia cannot be excluded. Hydroceles that persist or appear beyond that age are unlikely to resolve spontaneously, and affected infants should therefore undergo elective surgical repair.

### URACHAL LESIONS

The urachus is the remnant of the allantois that extends from the bladder portion of the cloaca to the umbilicus. The urachus may remain completely patent throughout its length or fail to obliterate (Fig. 73–11). All varieties of this defect are rare, and treatment is customized to each (Ney and Friedenber, 1968).

#### Completely Patent Urachus

A completely patent urachus manifests with the passage of urine from the umbilicus. Radiopaque contrast material injected into the orifice outlines the urachal tract and fills

**FIGURE 73-11.** Urachal anomalies. **A**, Normal anatomy. **B**, Completely patent urachus. **C**, Blind external tract: urachal sinus. **D**, Blind internal tract: Bladder diverticulum. **E**, Urachal cyst.

the bladder. Treatment consists of surgical excision of the umbilicus along with the entire urachus and a small portion of the bladder. Results usually are good.

#### **Blind External Type**

When only the distal end of the urachus fails to obliterate, a draining sinus results. Drainage of urine begins sometime after the cord separates. Treatment consists of surgical excision of the sinus tract.

#### **Blind Internal Type**

Failure of obliteration of the proximal end of the urachus results in a bladder diverticulum. It produces no symptoms and may be coincidentally discovered on cystogram. Nothing needs to be done surgically.

#### **Urachal Cyst**

Incomplete obliteration of the midportion of the urachus leads to the development of a urachal cyst. Cysts may present at birth or may grow slowly and become obvious at any time during infancy or childhood. The cysts frequently become infected. Ultrasound examination is diagnostic. Treatment involves surgical resection, which may be preceded by incision and drainage of the superimposed abscess.

### **MALFORMATIONS OF THE OMPHALOMESENTERIC DUCT**

In the developing embryo, the omphalomesenteric (vitelline) duct connects the yolk sac to the primitive midgut through the umbilical cord. In the normal course of ontogeny, the duct becomes obliterated and disappears. Under certain circumstances, all or portions of the duct may persist (Fig. 73-12). They may cause symptoms

through drainage, infection, and intestinal obstruction. As with urachal remnants, presentation and management vary with each type (Moore, 1996).

#### **Patent Omphalomesenteric Duct**

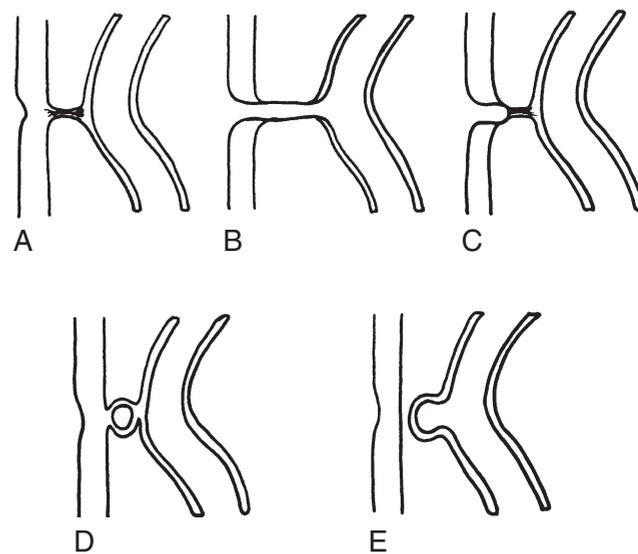

Patent omphalomesenteric duct is an enteroumbilical fistula, manifesting with the passage of meconium or fecal matter through the umbilicus. The condition may begin at birth or occur within 1 to 2 weeks. The most significant danger with this lesion is evagination (prolapse) of the small bowel through the umbilical orifice, with a significant increase in mortality. Once this lesion is diagnosed, it should be corrected by surgical excision of the umbilicus and the duct.

#### **Omphalomesenteric Sinus**

Failure of distal closure of the omphalomesenteric duct leads to the formation of a sinus. Persistent watery discharge from the umbilical cord is the initial presentation. Examination of the umbilicus reveals a red nodule projecting from the base. Gentle massage results in the extrusion of mucus, which differentiates this lesion from an umbilical granuloma. Injection of radiopaque contrast material outlines the sinus tract. Treatment consists of surgical excision.

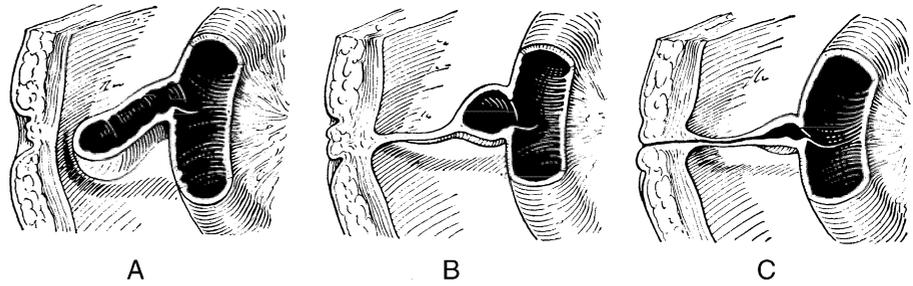

#### **Omphalomesenteric Duct Cyst**

When the middle portion of the omphalomesenteric duct persists and eventually fills with secretions, a cyst forms. This lesion may be detected as an enlarging umbilical mass. Treatment consists of surgical excision.

**FIGURE 73-12.** Omphalomesenteric (vitelline) duct anomalies. **A**, Normal anatomy. **B**, Patent omphalomesenteric duct. **C**, Blind external tract: umbilical sinus. **D**, Omphalomesenteric duct cyst. **E**, Blind internal tract: Meckel diverticulum.

**FIGURE 73-13.** Meckel diverticulum of the ileum. **A**, Ordinary blind sac. **B**, Diverticulum continued to umbilicus as a cord. **C**, Diverticulum with fistulous opening of umbilicus. (From Arey *LB: Developmental Anatomy*, 7th ed. Philadelphia, WB Saunders, 1974.)

### Meckel Diverticulum

When the proximal, or intestinal, end of the omphalomesenteric duct fails to become obliterated completely, an outpouching of the ileum persists. The diverticulum may vary in size, shape, and point of attachment, although the junction usually lies at some point in the ileum. It must arise from the antimesenteric side of the bowel, a feature that distinguishes Meckel diverticulum from duplications. Its distal end usually lies free in the peritoneal cavity, but in some cases it is attached to the umbilicus by a fibrous cord and in a small minority remains patent to the umbilicus (omphalomesenteric fistula) (Fig. 73-13). Twenty percent of diverticula contain ectopic pancreatic or gastric tissue.

Meckel diverticulum manifests clinically with bowel obstruction, intestinal bleeding, inflammation, or perforation (St.-Vil et al, 1991). A pancreatic or gastric mass may act as a leading point to produce intussusception. Gastric mucosa may cause peptic ulceration and bleeding; the latter is almost always the presenting sign if Meckel diverticulum becomes symptomatic. The fibrous cord, if present, may produce intestinal obstruction. Rarely, inflammation of the diverticulum may lead to peritonitis.

The diagnostic test of choice for Meckel diverticulum is a technetium 99m pertechnetate scan ("Meckel scan"), which detects the ectopic gastric mucosa (Fig. 73-14).

This test is most useful in patients presenting with rectal bleeding—the false-negative rate is high in patients with other symptoms. Treatment is reserved for symptomatic diverticula and those thought to contain ectopic tissue (Moore, 1996). Diverticulectomy can be performed by either laparotomy or laparoscopy (Huang and Lin, 1993).

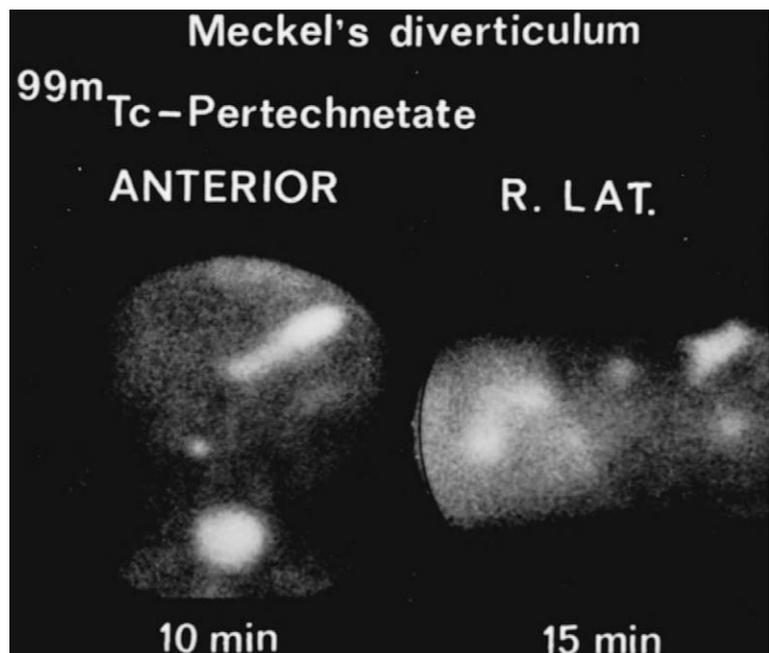

### Incidence

A Meckel diverticulum can be discovered in 1.5% to 2% of all persons. Only a small proportion of these diverticula ever become symptomatic, and when they do, this usually happens beyond the age of 4 months. Only exceptionally do they cause illness in the neonatal period. Affected males outnumber females in a ratio of 3:1 to 5:1.

### Diagnosis

Hemorrhage from the bowel is the definitive sign of Meckel diverticulum. A few cases in older children and adults may produce the signs and symptoms of diverticulitis, but this condition has never been described in young infants. Hemorrhage is often sudden and catastrophic, causing a precipitous fall in the hematocrit and a shock-like state within a few hours. The first few stools passed may be composed almost entirely of unchanged blood; later, they become burgundy colored and then tarry. In other instances, bleeding is constant and occult. About

**FIGURE 73-14.** Anterior gamma camera view of the abdomen of a 2-year-old infant. Note the small, well-defined area of increased uptake located in the right lower quadrant. The stomach and bladder also are visualized. On the lateral view, some radioactivity is evident on the diaper as well. (Courtesy of Dr. S. Treves, Children's Hospital, Boston, Massachusetts.)

25% of persons with Meckel diverticulum present with intussusception.

Meckel diverticulum must be differentiated from other disorders that produce gross bleeding from the bowel: peptic ulcer, duplication, intestinal polyp, intussusception, and intestinal hemangioma. Fissure in ano, proctitis, and ulcerative colitis ordinarily do not lead to gross hemorrhage, blood loss being confined to the passage of bloody mucus or of stools containing a surface accumulation of blood. The most useful point in the differential diagnosis is that hematemesis usually coexists with rectal bleeding when peptic ulcer is present, whereas hematemesis rarely occurs with Meckel diverticulum. The mass of duplication is sometimes palpable.

Scans after intravenous injection of technetium-99 m pertechnetate are often, but not always, diagnostic of Meckel diverticulum because the technetium is concentrated in gastric mucosa. Pentagastrin or cimetidine is useful in enhancing the image of gastric mucosa on subsequent technetium scans (see Fig. 73-14).

### Treatment

Resuscitation and blood replacement therapy is the initial treatment regardless of the cause of bleeding. If bleeding ceases, careful observation for recurrence of bleeding is often all that is indicated, because peptic ulcer rarely recurs. A second episode of bleeding, however, strongly suggests that other diagnostic procedures may be needed, including endoscopy, laparoscopy, and laparotomy. If a diverticulum is discovered, it must be excised.

# Necrotizing Enterocolitis and Short Bowel Syndrome

Carol Lynn Berseth and Dan Poenaru

## NECROTIZING ENTEROCOLITIS

Necrotizing enterocolitis (NEC) is the most commonly occurring gastrointestinal emergency in preterm infants. With the advent of modern neonatology, its incidence has ranged from 10% to 25% over the past 3 decades or so. Signs or symptoms suggestive of NEC develop in approximately one third to one half of all very low-birth-weight infants; of these, approximately one third to one half eventually are given a diagnosis of NEC. Of the infants in whom NEC develops, approximately half require surgery. The mortality rate ranges from 25% to 30%. Of those who survive, approximately 25% experience long-term sequelae related to the gastrointestinal tract. In addition, these infants require longer hospitalizations than infants of similar maturity who do not have NEC (Bisquera et al, 2002) and have impaired neurodevelopmental outcomes (Sonntag et al, 2000). In the National Institute of Child Health and Human Development studies, NEC was a significant and independent predictor of neurodevelopmental morbidity (Vohr et al, 2000).

### Epidemiology and Pathogenesis

The incidence of NEC varies geographically and temporally. It typically occurs in a pattern of clustered cases. Although 10% of all cases of NEC occur in term infants, it is more commonly seen in preterm infants, particularly those with birth weights less than 1000 g. The incidence appears to be similar among male and female infants, but it is more common among black infants (Mizrahi et al, 1965; Wilson et al, 1983).

The age at onset of NEC is inversely related to gestational age, with a mean age of 3 to 4 days for term infants and 3 to 4 weeks for infants born at less than 28 weeks of gestation. NEC is 10 times more common in infants who have been fed than in those who have not received enteral nutrition, and it occurs more commonly among infants fed formula than among those fed breast milk. NEC, however, does occur in infants who have never been fed and in those who have received breast milk feedings.

NEC occurs in epidemics. Most neonatal intensive care units (NICUs) experience a low endemic incidence of NEC that is periodically punctuated by sporadic epidemics. A wide variety of organisms have been associated with these outbreaks, including *Klebsiella pneumoniae*, *Escherichia coli*, clostridia, coagulase-negative staphylococci,

and rotavirus. Most typically, these outbreaks occur during times of nursery crowding, but it is not clear that NEC is caused by infectious agents. Although a single, clear-cut cause for NEC has not been identified, several contributing risk factors have been identified: bowel ischemia, immaturity of host defense, and enteral feedings.

### Bowel Ischemia

The role of ischemia in the pathogenesis of NEC has been supported by reports of increased occurrences of NEC among infants who have low Apgar scores, umbilical vessel catheterization, polycythemia, and reduced aortic blood flow. It has been postulated that when the preterm infant is stressed by periods of hypoxia or hypotension, blood flow is redistributed via input from the adrenergic system away from the splanchnic bed. More recent evidence, however, suggests that these neurogenic events are transient and are reversed within 1 to 2 minutes by local vascular events called the *autoregulatory escape mechanism*, which restores intestinal tissue oxygenation. In fact, case-control studies have failed to confirm that hypoxic events occur any more frequently among infants in whom NEC develops than among those in whom it does not (Wilson et al, 1983).

Despite the lack of a direct causal relationship of hypoxia and NEC, regulation of vascular bed flow differs in preterm infants and in adults, and these unique differences may make the preterm intestine more vulnerable to hypoxia during the period of reperfusion that typically follows a period of ischemia. During reperfusion, oxygen free radicals are generated; these free radicals can cause the tissue damage that is typically seen in reperfusion injuries. These free radicals result from the enzymatic breakdown of hypoxanthine that accumulates during ischemia and from activated neutrophils that adhere to the gut microvasculature after ischemic injury.

The high tissue levels of xanthine that result from episodes of ischemia may contribute in part to NEC, but the occurrence of NEC also appears to be related to other vascular events that are related to the use of centrally placed vascular catheters. Vascular access in most preterm infants is achieved by the use of umbilical arterial or venous catheters. NEC also is seen among infants who have had umbilical catheters inserted to perform an exchange transfusion for hyperbilirubinemia or polycythemia. Increases in portal venous pressure that may occur during an exchange transfusion in term infants can result in a decrease in ileal and colonic blood flow (Touloukian et al, 1973). It is not clear whether this myogenic vasoconstriction occurs in preterm infants (Crissinger and Granger, 1989). Exchange transfusions, however, are no longer a common procedure in this population.

Umbilical arterial catheters may pose more serious risk to the intestinal vasculature. It has been suggested that embolization of catheters may result in embolization of mesenteric arteries.

Infusion of medications such as calcium may cause vasospasm in humans and frank intestinal necrosis in rabbits (Book and Herbst, 1980). Emboli, however, cannot be demonstrated to be present in the intestinal circulation of infants who have NEC (Tyson et al, 1976).

NEC also has been described among infants who have a patent ductus arteriosus (Ryder et al, 1980). In a randomized, control trial in infants whose birth weights were less than 1000 g, prophylactic closure of the ductus arteriosus by surgical ligation reduced the rate of NEC from 30% in the control group, compared with 8% in the early-closure group (Cassady et al, 1989). Meyers and colleagues (1991) have shown in a near-term fetal lamb model that the presence of a patent ductus arteriosus results in diminished intestinal blood flow. In spite of this observation, autoregulation prevented a decrease in intestinal oxygen consumption.

Other investigators have suggested that treatment for patent ductus arteriosus and not the presence of the patent ductus per se increases the risk for NEC (Grosfeld et al, 1996). NEC has been described to occur among infants who received indomethacin for treatment of a patent ductus arteriosus. It is speculated that indomethacin causes a generalized decrease in splanchnic bed flow that may compromise vascular supply to the distal ileum and colon. In a small descriptive study, administration of indomethacin caused a decrease in mean flow velocity in the superior mesenteric artery that was sustained for 12 hours after treatment (Van Bel et al, 1990). See also Chapter 56, Patent Ductus Arteriosus in the Preterm Infant.

As techniques for treatment for infants with cyanotic heart disease have improved, concerns regarding an increased risk for NEC among these infants have emerged (Martinez-Tallo et al, 1997; Polin et al, 1976). In a recent case-control analysis, McElhinney and associates (2000) showed that the risk of NEC among neonates with congenital heart disease was substantial, and it was highest among infants with hypoplastic left heart syndrome and truncus arteriosus or aortopulmonary window.

NEC also has an increased incidence among infants who are polycythemic (Leake et al, 1975). Polycythemia has been shown to cause a reduction in intestinal perfusion in swine (Nowicki et al, 1984) and intestinal necrosis in puppies (LeBlanc et al, 1984). It also has been shown that antenatal exposure to cocaine is associated with postnatal development of NEC. Cocaine may cause a generalized fetal hypoxia as a result of impaired uterine blood flow. It also can cause selective intestinal ischemia that is not reversed by the autoregulatory escape mechanism. Thus, cocaine-related NEC may be vascular in origin.

### *Host Defense Factors*

As reviewed in Chapter 70, host defenses in the preterm gastrointestinal tract are either absent or functionally immature. Because of the variety of agents that have been identified with outbreaks of NEC, it is unclear whether these organisms actually cause NEC or are agents of secondary infection. Although specific bacteria have been reported during some outbreaks of NEC, these same bacteria frequently can be cultured from unaffected infants.

Nevertheless, several immunologically based strategies have been employed to treat or prevent NEC. Several small studies have shown that the administration of oral antibiotics can reduce the incidence of NEC (Egan et al, 1976); however, there are concerns that liberal use of these medications may permit the overgrowth of resistant organisms. Other investigators have shown that the

administration of oral immune globulin reduces the occurrence of NEC (Eibl et al, 1988), but this practice has not been validated by additional studies.

Other investigations have assessed whether mediators of inflammation contribute to the tissue damage of NEC. Platelet-activating factor, which is synthesized by white cells, stimulates the release of complement, oxygen radicals, catecholamines, prostaglandins, thromboxane, and leukotrienes. In animal models, the administration of exogenous platelet-activating factor causes neutrophil aggregation, platelet aggregation, systemic hypotension, and ischemic bowel necrosis. During artificially created episodes of ischemia/reperfusion of mesenteric circulation in animals, plasma platelet-activating factor levels increase, and severe bowel necrosis occurs. This sequence of events can be prevented if platelet-activating factor antagonists are administered (Kubes et al, 1990). Plasma platelet-activating factor concentrations are higher among infants who have NEC than in age-matched control infants (Caplan et al, 1990). Furthermore, providing enteral feedings results in increased levels of platelet-activating factor (MacKendrick et al, 1993b). The action of platelet-activating factor may be inhibited by the release of endogenous nitric oxide (MacKendrick, 1993a). Inducible nitric oxide messenger RNA (mRNA) expression is increased in stressed neonatal rats (Nadler, 2000).

In other recent studies, erythropoietin receptors have been identified on intestinal epithelium. Erythropoietin protects against programmed cell death in the intestinal epithelium (Juul, 1999), and the incidence of NEC is lower among preterm infants given recombinant erythropoietin for anemia of prematurity (4.6% versus 10.8% in age-matched controls) (Ledbetter and Juul, 2000). Using interleukin-8 (IL-8) as a marker for proinflammatory cytokine activation, Nanthakumar and colleagues (2000) showed that fetal intestinal epithelial cells and tissue make significantly more IL-8 in response to challenges by endotoxin and IL-1 than that made by more mature cells and tissues. These authors speculate that NEC may occur among preterm infants because their “over-response” triggers a brisk release of inflammatory mediators.

Nitric oxide also has been proposed to function as a mediator in NEC. Messenger RNA expression of intestinal trefoil factor, a small peptide that is secreted by goblet cells as a component of the mucosal barrier, does not emerge in the fetal rat until late gestation, and neonatal levels are lower than those seen in mature animals (Lin et al, 1999). Other mediators that are currently under investigation are tumor necrosis factor, endothelin-1, and prostaglandins.

Because NEC occurs less frequently among infants fed breast milk, and because breast-feeding appears to protect infants from a number of diseases (Schanler, 1999a), numerous investigators have attempted to delineate the factors in breast milk that contribute to neonatal host defense. As detailed in Chapter 68, breast milk contains immunoglobulins, leukocytes, and antibacterial agents. When neonatal rats were fed maternal milk, the incidence of NEC was significantly lower than that seen in neonatal rats fed artificial formula (Barlow et al, 1974). For breast milk to confer this protection from NEC, intact leukocytes had to be present in the milk. The protective effects conferred by the ingestion of breast milk also were reproduced

by feeding the immunoglobulin fraction of breast milk alone. In a large prospective trial, infants fed formula had a 2.5-fold greater risk of developing NEC than that in infants fed breast milk. Furthermore, infants fed artificial formula supplemented by a preparation of human serum gamma immunoglobulin A (IgA) and IgG demonstrated a significant reduction in the incidence of NEC (Eibl et al, 1988). Thus, it appears that host defense conferred by feeding breast milk may provide some protection against the development of NEC (Schanler et al, 1999b). Additional research in this area is still needed, however, to elucidate the component(s) that confer this protection and the mechanism(s) whereby this protection is conferred.

### Enteral Feeding

Although NEC occurs in infants who have never been fed, its incidence is much higher among infants who have been fed than among those who have not. Earlier studies suggested that delaying the onset of the initiation of enteral feeding reduced the incidence of NEC (Lucas and Cole, 1990); however, more recent studies have not confirmed this observation. In fact, several randomized prospective studies have failed to show an increase in the occurrence of NEC among infants fed early (within the first postnatal week) compared with those whose feedings are initiated late (at 2 to 3 weeks of postnatal age) (Berseth, 1992; Dunn et al, 1988; La Gamma et al, 1985; Meetze et al, 1992). A retrospective study demonstrated that preterm infants who developed NEC had had their feeding volumes increased daily by 25 mL/kg per day or more (McKeown et al, 1992). However, a recent prospective trial failed to show a relationship between the incidence of NEC and two different increments of daily increase in feeding volume (Rayyis et al, 1999). Indeed, Owens and Berseth (1995) showed that the onset of NEC most commonly occurs when infants reach larger feeding volumes (i.e., those that exceed 100 mL/kg/day), regardless of the day of initiation of feeding or the rate of increasing feeding volume. On the other hand, the prolonged use of small enteral feeding volumes for the first 10 feeding days reduced the incidence of NEC compared with that in infants whose feeding volumes were increased daily by 20 mL/kg/day increments (Berseth et al, 2003). Because of the apparent protective effect of breast milk on the incidence of NEC, several studies have evaluated the use of additives for artificial formulas. Carlson and colleagues (1998), for example have shown that the addition of egg phospholipids to preterm formula reduced the incidence of NEC from 17.6% in a control group to 2.9%. In another trial, the addition of *Lactobacillus acidophilus* and *Bifidobacterium* significantly reduced the incidence of NEC in a treatment group compared with that in a historical control group (Hoyos, 1999). However, a prospective, randomized trial has not yet confirmed these findings. Other additives that have not been shown to be effective consistently include human IgA and IgG (Lawrence et al, 2001) and enteral antibiotics (Bury and Tudehope, 2001). See also Chapter 68, Enteral Nutrition for the High-Risk Neonate.

NEC has been linked to the use of hyperosmolar formulas (Abrams et al, 1975), and it is also important for the clinician to realize that the addition of medications such as theophylline, sodium bicarbonate, and calcium supple-

ments as well as vitamins may significantly raise the osmotic loads of formulas (Ernst et al, 1983).

### Clinical Presentation

The clinical signs and symptoms of NEC are highly variable. In general, infants demonstrate gastrointestinal dysfunction, as reflected in the presence of abdominal distention, vomiting, bilious drainage from enteral feeding tubes, or hematochezia, and systemic illness, as reflected in temperature instability, apnea, lethargy, or hypotension (Fig. 74-1). Abdominal signs initially may be limited to distention and tenderness and then may progress to include palpable loops of bowel, fixed mass, abdominal wall erythema, and/or crepitus. The presentation of these signs and symptoms may be acute or insidious. Although a number of infants develop NEC within the first week of life, it also is a disease seen in the NICU graduate who has been transferred to the intermediate care nursery. Because the age at onset of NEC is inversely related to gestational age, clinicians must be exceedingly vigilant in assessing very preterm infants for a protracted postnatal period that may extend to 10 to 12 weeks. In addition, Owens and Berseth (1996) have noted that the clinical presentation in infants with birth weights less than 1500 g may differ from that in infants whose birth weights are 1501 to 2499 g (Table 74-1).

The initial evaluation of an infant who exhibits the signs or symptoms of NEC should include a radiographic examination of the abdomen, collection of body fluids for culture, a metabolic evaluation including electrolytes, and a complete blood count. As is the case in sepsis, white blood counts may be depressed or elevated, and thrombocytopenia commonly occurs in NEC. Hyponatremia and acidosis also commonly occur in NEC. The intestinal inflammatory process often causes shifts in body fluid distribution,

**FIGURE 74-1.** Clinical presentation of a preterm infant with necrotizing enterocolitis. This infant was born at 28 weeks of gestation and had been receiving enteral feedings for 1 week, when he developed acute abdominal distention, hematochezia, and vomiting. Note the discoloration of the skin overlying the abdomen. Also, this infant required endotracheal intubation because of respiratory compromise that occurred as a result of the upward pressure of the abdominal contents on the diaphragm. resulting in hypotension and acid-base imbalance. In addition, inflammation and swelling of the abdominal contents can cause upward compression against the diaphragm, resulting in respiratory embarrassment. Thus, infants who are acutely ill may also require evaluation of respiratory status by laboratory and radiographic testing.

The severity of NEC is staged using criteria proposed by Bell and colleagues (1978) and later modified by Kliegman and associates (1982). These criteria are based on systemic signs, intestinal signs, and radiologic signs. As shown in Table 74-2, radiographic findings must be present to confirm a diagnosis of NEC.

TABLE 74-2

**Modified Bell's Staging Criteria for Necrotizing Enterocolitis**

Stage	Systemic Signs	Intestinal Signs	Radiologic Signs	Treatment
I: Suspected				
A	Temperature instability, apnea, bradycardia	Elevated pre-gavage residuals, mild abdominal distention, occult blood in stool	Normal or mild ileus	NPO, antibiotics × 3 days
B	Same as for IA	Same as for IA, plus gross blood in stool	Same as for IA	Same as for IA
II: Definite				
A: Mildly ill	Same as for IA	Same as for I, plus absent bowel sounds, abdominal tenderness	Ileus, intestinal pneumatosis	NPO, antibiotics × 7-10 days
B: Moderately ill	Same as for I, plus mild metabolic acidosis, mild thrombocytopenia	Same as for I, plus absent bowel sounds, definite abdominal tenderness, abdominal cellulitis, right lower quadrant mass	Same as for IIA, plus portal vein gas, with or without ascites	NPO, antibiotics × 14 days
III: Advanced				
A: Severely ill, bowel intact	Same as for IIB, plus hypotension, bradycardia, respiratory acidosis, metabolic acidosis, disseminated intravascular coagulation, neutropenia	Same as for I and II, plus signs of generalized peritonitis, marked tenderness, and distention of abdomen	Same as for IIB, plus definite ascites	NPO, antibiotics × 14 days, fluid resuscitation, inotropic support, ventilator therapy, paracentesis
B: Severely ill, bowel perforated	Same as for IIIA	Same as for IIIA	Same as for IIB, plus pneumoperitoneum	Same as for IIA, plus surgery

NPO, nulla per os (nothing by mouth).

Nonspecific radiographic findings in suspected but unproven NEC are dilated bowel loops, bowel wall thickening, and increased peritoneal fluid. The diagnostic radiographic finding in NEC is the presence of intestinal pneumatosis. However, this radiographic feature is seen only in approximately 85% of infants subsequently proved to have NEC (Kliegman et al, 1982; Foglia, 1995). Intestinal pneumatosis is caused by the presence of hydrogen in the bowel wall as a byproduct of bacterial metabolism (Fig. 74-2A). Two radiographic patterns are commonly observed. More typically, there is a linear streak of gas within the bowel wall. This streaking may be visualized in a single discrete subserosal portion of the small intestine or may extend throughout the entire small and large intestine. The other pattern seen in NEC is a “bubbly gas” pattern in the submucosa similar to that seen in newborn infants who retain meconium in the intestine (see Fig. 74-2B). Because this pattern can be confused with that of retained meconium, it is less specific for NEC than is the linear streaking pattern. If gas is seen in the colon alone, the infant has a better prognosis than if the gas is seen in small bowel and colon (Leonidas et al, 1976). Portal venous gas may be an indicator of more severe disease because there is a 38% incidence of severe bowel necrosis, with mortality rates as high as 70%, associated with this finding (Grosfeld et al, 1991; Molik et al, 2001). If intestinal pneumatosis extends into the portal venous circulation, linear branching areas of radiolucency may appear overlying the liver (Fig. 74-3). Intraperitoneal fluid, with the associated displacement of intestinal loops to the central abdomen, usually is a sign of significant loss of integrity of the bowel wall, with impending or recent perforation (Foglia, 1995). If NEC progresses to bowel perforation, pneumoperitoneum may be identified. Most typically, free air is visualized on a cross-table lateral or right lateral decubitus film (Fig. 74-4A). Occasionally, free air can be visualized as a central periumbilical

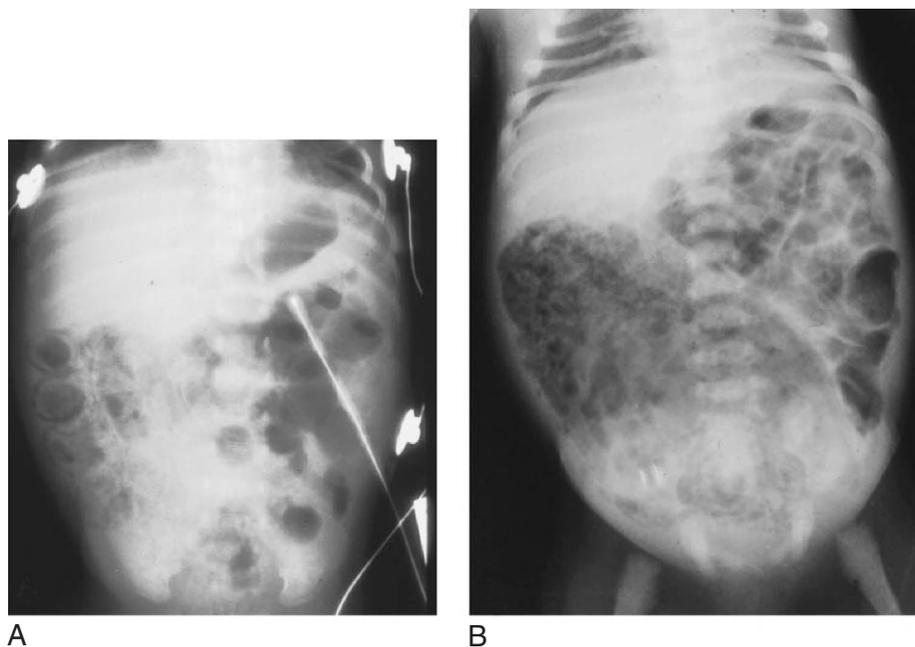

collection on an anteroposterior film—the “football sign” (see Fig. 74-4B).

## Treatment

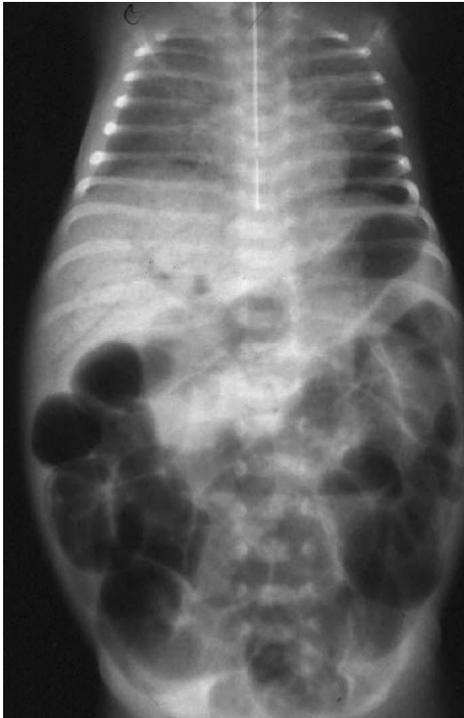

### Medical Management

The medical management of NEC requires attention to acute care as well as long-term care. Acute care is focused on providing aggressive supportive care while attempting to limit the progression of disease. If the infant is receiving enteral nutrition, feedings should be discontinued and the stomach should be decompressed. Body fluids should be collected for culturing, and broad-spectrum antibiotic therapy should be initiated. Although NICUs may choose specific coverage based on their specific nursery flora, antibiotic coverage usually includes ampicillin or a cephalosporin and an aminoglycoside. In some nurseries, additional antistaphylococcal antibiotics may be given. In the event of bowel perforation, anaerobic coverage may be added by using clindamycin or metronidazole.

Because enteral nutrients generally are discontinued for 10 to 14 days, placement of central vascular lines often is necessary to deliver parenteral nutrition. Because NEC is an inflammatory process that results in substantial third space fluid loss, substantial volume support may be needed during the first 48 to 72 hours of treatment. In addition to the aggressive use of fluids and volume expanders such as albumin, pressor agents such as dopamine may be required to maintain the infant's blood pressure and peripheral perfusion. Because many infants with NEC develop apnea or respiratory compromise owing to abdominal distention and upward compression on the diaphragm, intubation and ventilatory support may be required. Frequent monitoring of blood gases assists in management decisions concerning ventilator support as well as fluid management.

**FIGURE 74-2.** **A**, Typical abdominal radiographic appearance of intestinal pneumatosis seen in necrotizing enterocolitis: dark concentric rings around the bowel loops in the right upper quadrant. **B**, This radiograph displays the *bubbly gas* pattern occasionally seen in necrotizing enterocolitis. (Courtesy of Dr. Lalo Cabrera-Meza, Baylor College of Medicine, Houston, Texas.)

**FIGURE 74-3.** This radiograph displays the presence of portal gas, which is seen as linear dark streaks within the hepatic density. (Courtesy of Dr. Lalo Cabrera-Meza, Baylor College of Medicine, Houston, Texas.)

Radiographic evaluations should be repeated every 6 to 8 hours during the first 48 to 72 hours of the disease to assess whether the disease is progressing or to determine if pneumoperitoneum is present (Bisquera et al, 2002). Approximately one fourth to one half of infants with NEC

require surgical intervention (Foglia, 1995; Janik and Ein, 1980; Kosloske, 1985).

NEC usually lessens in severity in 48 to 72 hours. Thereafter, infants typically are given antibiotics and parenteral nutrition for 10 to 14 days. Then enteral nutrition may be slowly reintroduced.

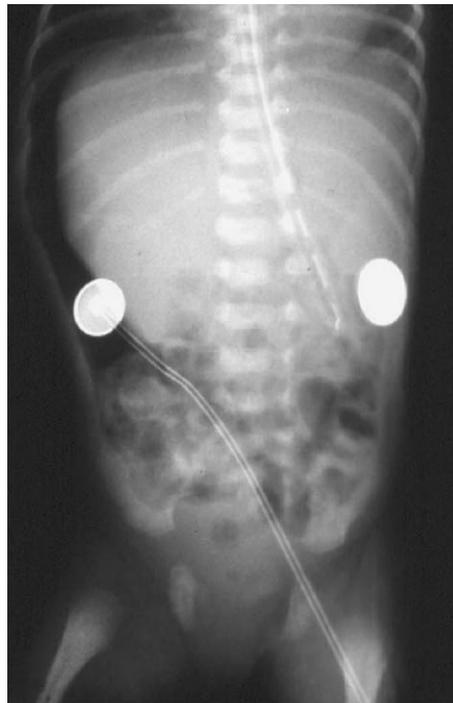

#### **Surgical Management**

The most common indication for surgery is the presence of pneumoperitoneum. Other indications may be the presence of clinical deterioration despite aggressive medical therapy, the presence of portal vein gas, the presence of a fixed dilated loop of bowel on serial radiographs, and evidence of peritonitis and gangrenous bowel obtained by paracentesis (Koloske, 1994). In a study evaluating various clinical and radiologic criteria, Koloske found that pneumoperitoneum, portal vein gas, positive paracentesis, fixed loop, abdominal wall erythema, and palpable mass all are good indicators of intestinal gangrene. Preoperatively, the infant should undergo expeditious optimization of the clinical status, which may include bedside needle decompression of a tense pneumoperitoneum.

The goals of surgery are to resect necrotic bowel, to decompress the intestine, and to preserve as much bowel length as possible. The choice of procedures is based on the operative findings. The findings at surgery can be grouped into three general categories: (1) isolated perforation or localized NEC, (2) multiple localized areas of necrosis (with over 50% of gut viable), and (3) pan-necrosis (with less than 25% viable).

Isolated disease with limited necrosis or perforation is treated with resection of the affected area. The resected ends are brought out as stomas, usually at the ends of the abdominal incision. Occasionally, very limited NEC, with otherwise healthy-appearing bowel in a stable infant,

**FIGURE 74-4. A,** This radiograph demonstrates intestinal perforation as displayed by the presence of a gas lucency that lies between the hepatic density and the outer abdominal wall. **B,** This radiograph is from another infant whose bowel is perforated. In **B**, air lies anterior to the loops of intestine as well as along the right abdominal wall, where it is displacing loops of bowel medially. (Courtesy of Dr. Lalo Cabrera-Meza, Baylor College of Medicine, Houston, Texas.)

**A**

**B**

may be treated with resection and primary anastomosis (Griffiths et al, 1989).

With multiple areas of necrosis, there are several operative approaches, depending on the overall condition of the infant and the extent of disease. If two or three isolated areas can be resected, the most proximal area of resection can be brought out as two stomas and the distal areas of resection anastomosed. In the case of more extensive disease, options include the “patch, drain, and wait” approach (Moore, 1989) and the “clip and drop-back” method (Vaughan et al, 1996).

Surgical options in the case of pan-necrosis include proximal diversion only, resection of all necrotic bowel, or simple abdominal closure and compassionate care. The last option is supported by the high mortality rate and uniform occurrence of short bowel syndrome associated with pan-necrosis.

In the unstable or very small newborn, another alternative is that of bedside peritoneal drainage. This procedure, originally advocated by Ein and colleagues (1990), consists of the placement of drains in the right lower quadrant (and sometimes the left). Peritoneal drainage appears to be a useful temporizing procedure in selected patients, with a majority still requiring an open surgical intervention. A recent meta-analysis of existing studies comparing peritoneal drainage and laparotomy showed no clear benefit for either approach, as well as a strong treatment bias for smaller infants to undergo drainage (Moss et al, 2001).

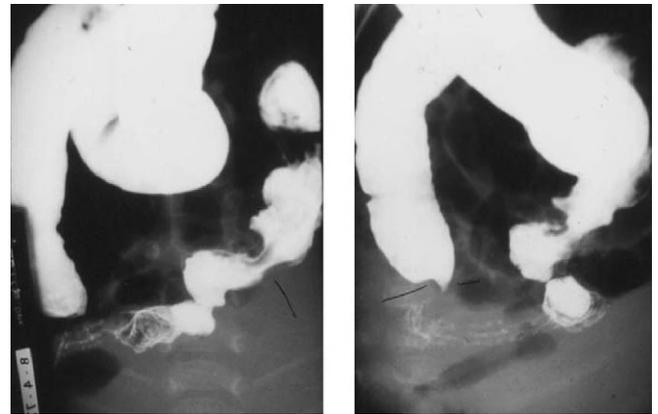

### Long-Term Complications

Approximately 75% of infants who develop NEC survive. Half of surviving infants incur a long-term complication. The two most common complications are intestinal strictures and short bowel syndrome.

Because NEC is an inflammatory process that involves all layers of the bowel, development of fibrosis is common during the healing phase. Strictures occur in infants who have been managed medically or surgically, with an incidence from 10% to 35% (Horowitz et al, 1995). Although NEC occurs most commonly in the distal ileum, strictures occur most commonly in the large bowel (Fig. 74–5), most often on the left side. These infants typically develop recurrent abdominal distention 2 to 3 weeks after recovery from NEC. The areas of stricture can be identified by barium enema examination. Surgical resection of the strictured areas is necessary. Because infants who have had surgical resection may also develop strictures, contrast studies are routinely performed in these patients before definitive reanastomosis of the bowel is performed so that areas of stricture can be resected at the time of surgery. Infants who have had conservatively treated NEC are often followed clinically without routine radiological studies.

Recurrent NEC occurs in about 5% of infants, usually a month after the initial episode. There are no identified risk factors for recurrence, and a nonoperative treatment is successful in most cases (Stringer et al, 1993).

Although the bowel may hypertrophy postoperatively after resection, infants may develop malabsorption owing to shortened bowel length. It is estimated that infants require a minimum of 25 to 40 cm of small intestine (Galea et al, 1992). As outlined in the next section, medical

**FIGURE 74–5.** This barium study was obtained in an infant who had recovered from necrotizing enterocolitis and was experiencing intermittent episodes of abdominal distention when enteral feedings were given. Note that multiple areas of stricture are present. (Courtesy of Dr. Lalo Cabrera-Meza, Baylor College of Medicine, Houston, Texas.)

and surgical management must address issues related to malabsorption, bacterial overgrowth, and alterations in intestinal transit.

## SHORT BOWEL SYNDROME

The normal small intestine length in the term infant is 200 to 300 cm. The most common cause of short gut in the newborn is resection performed to treat NEC, midgut volvulus, or congenital anomalies such as jejunal or ileal atresia and gastroschisis. Thus, newborns most typically have a short gut characterized by losses of ileum and the ileocecal valve (ICV).

Reduction in bowel length results in loss of surface area for absorption of nutrients; thus, malnutrition and fluid electrolyte loss occur. Loss of the ICV results in greater disease because the absence of the valve permits colonic bacteria to reflux into the distal ileum and colonize it. Thus, outcome from intestinal resection depends on two factors: the length of bowel remaining and whether the ICV is intact. Despite many advances in neonatal care, the “traditional” limits of intestinal length as suggested by Wilmore (1972)—15 cm of intestine when the ileocecal valve is intact and 38 cm when it is absent—have not significantly changed. A more contemporary review identifies 25 cm of bowel with an intact ICV and 42 cm without an ICV as the minimum for successful survival and adaptation in full-term neonates (Galea et al, 1992). Premature neonates are capable of better adaptation, and lengths of 22 cm and 30 cm, respectively, apply. Instances of successful adaptation with shorter intestinal lengths have been reported, but constitute the exception rather than the rule (Dorney et al, 1985). As a result, the diagnosis of short bowel syndrome has become a functional one rather than an anatomic one based on gut length. Hence, patients are often identified as having short bowel syndrome if they require parenteral nutrition for more than 6 weeks (Sigalet, 2001; Vanderhoof and Langnas, 1997).

Intestinal adaptation after intestinal resection depends on several factors. First, the remaining bowel dilates, the mucosa hypertrophies, and functional absorptive capacity per length increases. These responses result in an increased absorption area per unit length of intestine. Second, as the infant grows in body length, the intestine elongates, increasing absorptive area. Third, adaptation occurs differently in ileum and jejunum. Ileal mucosa increases in size and function much more effectively than does jejunal mucosa (Dowling, 1982). Although ileal structures can perform jejunal functions, jejunal structures cannot perform ileal functions. Complete adaptation of all four of these aspects may not be completed for 2 years (Cooper et al, 1984; Grosfeld et al, 1986; Purdum and Kirby, 1991). Therefore, many neonatologists may be responsible for managing the care in only early stages of adaptation in an infant who develops short gut syndrome, and they must exercise restrained patience in caring for infants with this disease.

### Treatment

The first priority of treatment must be the provision of adequate calories for growth. This first must be achieved by using parenteral nutrition to establish positive nitrogen balance. Thereafter, clinical care for the newborn must address four issues: (1) malabsorption of nutrients and fluids, (2) gastric hypersecretion, (3) bacterial overgrowth, and (4) difficulties with intestinal adaptation.

Because bile salts and fat-soluble vitamins and trace minerals are absorbed in the distal ileum, infants with short bowel syndrome develop steatorrhea and specific vitamin and mineral deficiencies. Cholestyramine, an ion-exchange resin that binds bile salts, often is used to reduce steatorrhea. Although cholestyramine reduces steatorrhea, it does not reduce fat malabsorption, and attention should still be given to nutritional needs for fat. Fat can be given either parenterally or enterally. Deficiencies of vitamins A, D, E, K, and B<sub>12</sub> as well as zinc and magnesium all have been described in infants with short gut. Therefore, levels of all of these substrates should be monitored and supplemented appropriately.

Gastric acid hypersecretion occurs after intestinal resection in adults and children (Clark, 1984). Infants have limited gastric acid secretion, and it has not been confirmed that gastric acid hypersecretion occurs in preterm infants following resection. H<sub>2</sub> blockers and proton pump inhibitors, however, commonly are used to suppress acid secretion, to prevent low pH in the duodenum, which can inactivate pancreatic enzymes or impair micelle formation. Occasionally, somatostatin or its synthetic analogue octreotide may be used to reduce acid secretion (Schwartz and Kuenzler, 2001).

Bacterial overgrowth can occur intermittently as a result of reflux of colonic contents into the distal ileum in the absence of an ileocecal valve. Bacterial overgrowth also can occur as the result of the presence of hypotonic, dilated bowel segments or the presence of fistulas. Bacterial overgrowth can impair fat and vitamin B<sub>12</sub> absorption and depress mucosal levels of maltase, sucrose, lactase, and enterokinase (Gianella et al, 1974), resulting in malabsorption and profound diarrhea. Patients may require intermit-

tent cyclic treatment with double-antibiotic regimens, such as metronidazole and trimethoprim-sulfamethoxazole or oral vancomycin and gentamicin, to suppress bacterial overgrowth and its attendant complications.

Finally, these patients require adequate long-term nutritional support. Most infants initially are supported by parenteral nutrition supplemented by additional fluid and electrolytes to overcome losses caused by malabsorption and those occurring via ostomy sites. Enteral feedings are exceedingly important in providing stimulation for intestinal growth and adaptation. In a recent retrospective review of patients with short bowel syndrome, Andorsky and colleagues (2001) showed that although remaining bowel length was the greatest predictor of required duration of parenteral nutrition, early enteral feeding also was associated with reduced duration of parenteral nutrition and a lower incidence of cholestasis. The physical presence of luminal nutrients stimulates mucosal growth. In addition, enteral nutrients stimulate the release of hormones and pancreatic biliary secretions, which also stimulate intestinal growth. Recently, investigators have studied the use of additives such as glutamine and insulin-like growth factor (IGF-1) to enhance mucosal growth, but results of these studies have been equivocal (Schwartz and Kuenzler, 2001). Enteral nutrients also may cause diarrhea, because mucosal hypoplasia may result in inadequate processing of enteral nutrients. Therefore, most infants initially are fed small volumes of elemental formulas that are lactose-free and contain medium-chain triglycerides. As adaptation occurs, more complex standard formulas can be used to stimulate mucosal hyperplasia better (Purdum and Kirby, 1991). Fluid and electrolyte losses via ostomy sites should be replaced, and reinfusion of ostomy losses into noncontiguous distal bowel segments prevents bowel atrophy while the patient is awaiting reanastomosis (Purdum and Kirby, 1991). The stool pH may be acidic if malabsorption, bacterial overgrowth, or both are present. Because acidic fecal material has a more rapid transit, the addition of sodium bicarbonate to feedings may be needed to maintain the stool pH above 6.

Although most infants can be managed medically until intestinal adaptation occurs, approximately 10% to 15% are dependent on total parenteral nutrition. Several surgical options are available for this group of patients. Techniques include reversal of a small segment of bowel to slow transit, tapering or plicating dilated loops of intestine to improve motility, and intestinal lengthening procedures such as Bianchi's isoperistaltic doubling (Bianchi, 1980) and Kimura's isolated segments technique (Vernon and Georgeson, 2001). Experience with these procedures remains limited, and their associated complication and failure rates are high; still, they constitute a less invasive option than intestinal transplantation.

Intestinal transplantation is becoming an increasingly viable option for selected patients. A recent review by one center reported a 3-year survival rate of 60% (Vennarecci et al, 2001). A significant shortage of appropriate donors has created long waiting lists, resulting in the death of many patients from complications of total parenteral nutrition-induced cholestasis while waiting for a donor. It is not surprising, therefore, that significant disagreement exists among neonatologists and pediatric gastroenterologists

concerning the outcomes of various treatment options for patients and concerning the subspecialist who should discuss treatment options with families (Cooper et al, 1999). Thus, the care of these infants must be multidisciplinary in nature and should occur in an environment that fosters broad communication among subspecialists, nursing staff, and families.

# HEMATOLOGIC SYSTEM AND DISORDERS OF BILIRUBIN METABOLISM

Editor: CHRISTINE A. GLEASON

CHAPTER  
**75**

## Developmental Biology of the Hematologic System

Sandra E. Juul

### OVERVIEW OF EMBRYONIC HEMATOPOIESIS

*Hematopoiesis* is the overall process by which self-renewing stem cells give rise to the multiple lineages of differentiated blood cells (Fig. 75-1). This complex process is the result of the coordinated expression and interaction of many growth factors, some of which act on primitive progenitor cells that can give rise to multiple cell lineages and others of which support lineage-committed multipotential hematopoietic stem cells. Hematopoiesis begins early in embryonic life, with the first hematopoietic cells appearing in the human yolk sac at embryonic day 7.5. By day 10 of gestation, hematopoietic stem cells are present in the aorto-gonado-mesonephron (AGM), and from there activity shifts to the liver and finally to the bone marrow (Huss, 2000). Each cell line undergoes developmental changes that are unique and specific. The developmental peculiarities of each of these systems and the resulting clinical impact of these changes are reviewed individually in the rest of the chapters in Part XV.

### STEM CELL BIOLOGY

Pluripotent stem cells can sustain marrow function throughout a person's lifetime. A unique characteristic of these cells is that their direct offspring include at least one identical daughter cell, thus perpetuating the population. This is in contrast to progenitor cells, which are more differentiated and give rise only to cells more differentiated than themselves. It was long believed that pluripotent stem cells were specific to the bone marrow and gave rise only to hematopoietic tissue and the associated supporting stroma. Recent evidence has demonstrated a more unrestricted potential for these cells. Indeed, progenitor cells

have been found in a variety of postnatal tissues with apparently "unorthodox" potential for differentiating into unrelated tissues. For example, bone marrow cells, when placed in a conducive environment, can generate neural cells, and conversely, neural stem cells can reestablish hematopoiesis in irradiated mice (Bjornson et al, 1999; Mezey et al, 2000). This ability of stem cells from one tissue type to differentiate into cells of another tissue type is dependent on the microenvironment.

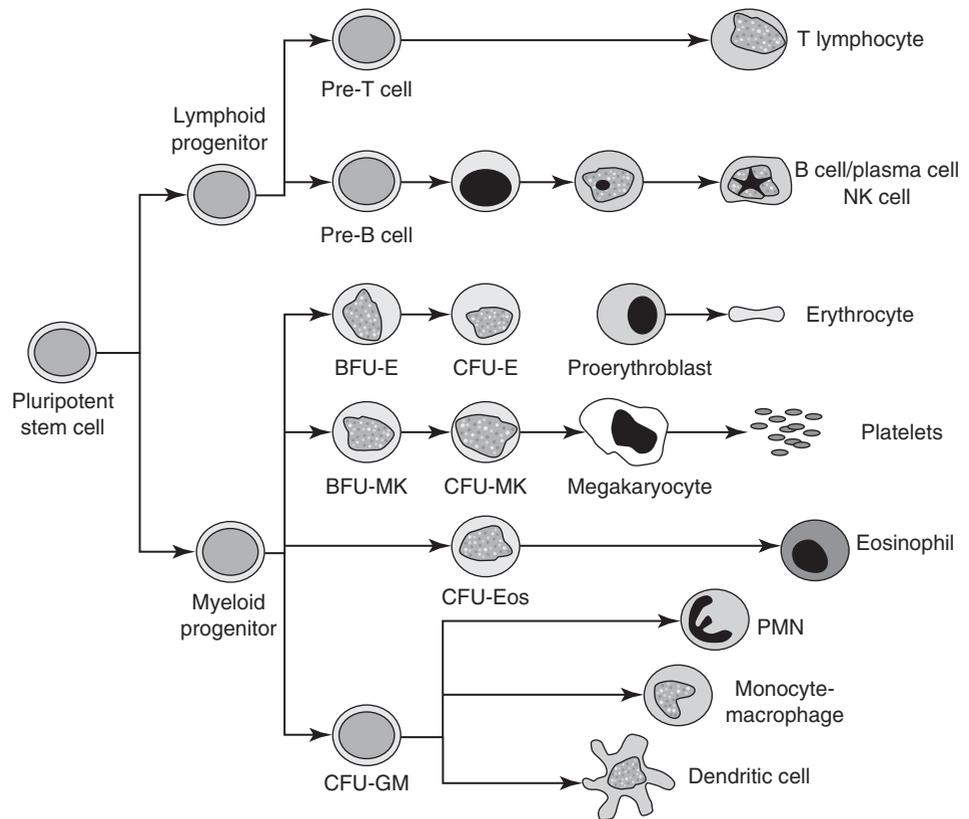

The developmental changes in the number, function, and location of hematopoietic stem cells are of great interest to transplantation biologists and gene therapists. The cycling potential and proliferative capacity of hematopoietic stem cells vary with the anatomic source of the cells, and with the age at which the cells are harvested. The sensitivity of these cells to recombinant cytokines also changes with age. Thus, improving the understanding of the ontogeny of these cells will be helpful in optimizing their clinical use.

Embryonic and fetal hematopoietic stem cells are capable of repopulating an adult organism (Fleischmann et al, 1984). In contrast, transplanted adult stem cells have a lower capacity for self-renewal, often resulting in late graft failure. This limitation may be because the adult stem cells continue to express the adult differentiation program despite the fetal environment, indicating an irreversible change in gene expression (Fleischmann et al, 1984). Another explanation for the decrease in proliferative potential may have to do with the loss of telomere repeats with each stem cell division, limiting the replicative potential of stem cells (Lansdorp, 1997; Notaro et al, 1997; Vaziri et al, 1994). Mean telomere lengths in donor-recipient pairs have been measured, with a decrease roughly equivalent to 15 years of aging controls noted in the transplant recipients (Wynn et al, 1998). Thus, the increase in cell replication required after engraftment may impose replicative stress on the hematopoietic stem cells, resulting in a pronounced aging effect.

A focus of ongoing research is optimization of techniques by which to harvest stem cells. Cell surface markers, which are dependent on cell maturity and gestational age, are often used to identify and separate hematopoietic stem cells using monoclonal antibodies and fluorescence-activated cell sorter (FACS) analysis. For example, CD34, a cell-surface sialomucin, is a commonly used antigen to select hematopoietic stem cells and early erythropoietic progenitor cells. Combining CD34 positivity with the absence of lineage-specific markers ( $lin^{-}$ ) allows selection of a cell population highly enriched for the cells desired for transplantation or research purposes. The search is ongoing for still earlier cell populations by a

This chapter is based on work supported by grants RR-00083 and 38782-01A2 from the National Institutes of Health.

**FIGURE 75-1.** Overview of hematopoiesis. Hematopoietic lineages are outlined in this simplified overview of hematopoiesis. (BFU, burst forming unit; CFU, colony forming unit; E, erythroid; MK, megakaryocyte; GM, granulocyte-macrophage; Eos, eosinophil; NK, non-killer; PMN, polymorphonuclear).

combination of their physical characteristics, growth factor response, and the presence and absence of certain cell markers (Huss, 1997). Similarly, research focused on optimizing various harvest sites is ongoing. Bone marrow and cord blood are rich in stem cells and have long been used as progenitor cell pools. The collection of stem cells from peripheral blood by stimulated apheresis, with ex vivo expansion of select populations, is now also a viable option (Brugger et al, 2000; Pettengell et al, 1994a, 1994b).

This new appreciation for the vast potential of these pluripotent cells has raised political and ethical issues, which are currently being debated. It also has raised interesting new questions about the balance of hematopoiesis in the adult organism. That is, if pluripotent and multipotent cells are common throughout the body, what are the mechanisms by which they are kept in check?

## DEVELOPMENTAL ASPECTS OF ERYTHROPOIESIS

Erythropoiesis is the process of perpetual production of red blood cells. This process undergoes serial adaptations throughout development in order to meet the changing oxygen demands of the embryo, fetus, and neonate. The type of cells produced, the locations in which they are produced, and even the microenvironments present in these locations change as development proceeds. The molecular mechanisms involved in instituting, regulating, and maintaining these adaptations are complex and not yet fully understood. They are still the focus of active investigation.

## Primitive and Definitive Erythropoiesis

The earliest form of erythropoiesis is called *primitive erythropoiesis*. Primitive erythropoiesis takes place at several sites including the yolk sac, the ventral aspect of the aorta, the liver, and bone marrow. It is characterized by large CD34-negative (CD34<sup>-</sup>) erythroblasts (>20 μm in diameter) that differentiate within blood vessels, remain nucleated, and contain predominantly embryonic hemoglobin. As development proceeds, a transition to definitive erythropoiesis occurs. Definitive erythropoiesis is characterized by smaller (<20 μm) CD34<sup>+</sup> erythroblasts, which produce fetal and adult hemoglobins and extrude their nuclei when mature. Unlike primitive erythropoiesis, this process is dependent on Janus kinase (JAK) signal transduction and erythropoietin (Epo) stimulation (Neubauer et al, 1998; Tavassoli, 1991; Wu et al, 1995). Primitive erythroblasts normally undergo apoptosis, becoming extinct during fetal life, whereas definitive erythroblasts are able to self-renew (Dieterlen-Lievre, 1997).

## Switch of the Primary Site of Erythropoiesis

Humans have four main sites of embryonic and fetal erythropoiesis: yolk sac, ventral aspect of the aorta, liver, and bone marrow. In rodents, the spleen also is an important site of hematopoiesis, but there is no evidence for this in healthy humans (Calhoun et al, 1996; Wolf et al, 1983). Studies using an in vitro embryonic stem cell differentiation system have shown that primitive and definitive erythroblasts arise from a common multipotential precursor,

which is transiently responsive to specific cytokines such as vascular endothelial growth factor (VEGF) and *c-kit* ligand (Kennedy et al, 1997). Primitive progenitor cells first develop exclusively in the yolk sac, followed by the rise of definitive progenitors, also in the yolk sac (Palis et al, 1999). Another source of the early definitive progenitors is along the ventral aspect of the embryonic aorta (Tavian et al, 1996). Once circulation is established, progenitors from all lineages are detected in the blood, then in the fetal liver, and finally in the marrow (Palis et al, 1999).

### Yolk Sac

The yolk sac is an extraembryonic structure that can be subdivided into the primary and the secondary yolk sac. The primary yolk sac is transient and has no known hematopoietic function. It forms by proliferation and differentiation of primitive endodermal cells 7 to 8 days after conception. These endodermal cells give rise to mesodermal precursors (intermediate cells). The primary yolk sac then collapses into small vesicles, and the secondary yolk sac is formed from its remnants at 12 to 15 days post conception. By 16 to 19 days post conception, primitive erythropoiesis is found in the human yolk sac (Kelemen et al, 1979; Kennedy et al, 1997; Tavassoli, 1991). The secondary yolk sac is an active site of protein synthesis, nutrient transport, and hematopoiesis (Enders and King, 1993). Primitive hematopoietic cells, adherent to surrounding endothelial cells, are first observed at day 16 in the mesodermal layer. These hematopoietic-endothelial cell masses have been described as blood islands (Zon, 1995). As maturation proceeds, these blood islands migrate toward each other, merging to form a network of capillaries. Small clusters of undifferentiated cells, the hemangioblasts, and clusters of primitive erythroblasts are observed in the small vessels present at this developmental stage (Enders and King, 1993). As differentiation proceeds, endothelial and hematopoietic cell lineages emerge. These cell lines share common molecular markers and responsiveness to a cohort of growth factors, and, depending on the microenvironment, can be derived from a common stem cell in culture (Choi, 1998; Choi et al, 1998; Eichmann et al, 1997; Munoz-Chapuli et al, 1999; Robb and Elefanty, 1998; Robertson et al, 1999). Hematopoietic cell antigen is an adhesion molecule that is thought to be a crucial element of the hematopoietic microenvironment present in the yolk sac, essential for both embryonic hematopoiesis and vasculogenesis (Ohneda et al, 2001).

After the sixth week post conception, definitive erythroblasts are found in the yolk sac. A decline in yolk sac hematopoiesis is observed after the eighth week of gestation (Enders and King, 1993). *In vivo* differences in hematopoietic potential have been observed between yolk sac cells and progenitor cells in the liver. Yolk sac-derived hematopoietic cells have more restricted potential *in vivo*, as only red cells and macrophages are present in the yolk sac (Enzan, 1986), whereas progenitor cells in the liver develop into the full spectrum of hematopoietic lineages (Palis et al, 1999). However, when yolk sac-derived stem cells are cultured *in vitro*, or are transplanted, they are multipotent, illustrating the importance of the microenvironment in the development of committed cell lineages (Tavassoli, 1991).

### Aorto-Gonado-Mesonephron

Another site of early erythropoietic activity in the developing human embryo is the ventral aspect of the aorta, in the periumbilical region (Huyhn et al, 1995; Tavian et al, 1996). At around the 23rd postconceptional day in humans, the multipotent hematopoietic progenitor cells in this region are more numerous than in the yolk sac or the liver (Huyhn et al, 1995). It remains unclear whether this is the primary source of definitive hematopoietic stem cells in humans (Zon, 1995) or whether these cells are first derived from the yolk sac and then migrate into this region, the liver, and the bone marrow. By day 40 of gestation, hematopoiesis in the AGM is concluded.

### Liver

A short time after the onset of the circulation (weeks 4 to 5 of gestation), erythropoiesis begins in the liver (Kelemen et al, 1979). As in the yolk sac, primitive erythroblasts predominate in early erythropoiesis. However, over the next 4 weeks, definitive erythrocytes become the predominant red cell form. During this time, the liver mass increases 40-fold, with hematopoietic cells constituting 60% of the liver by weeks 11 to 12 (Thomas and Yoffey, 1964). Meanwhile, other hematopoietic cell lineages also are produced in the liver. Early in this process (5 weeks), the macrophage predominates, with approximately one granulocyte to every nine macrophages (Slayton et al, 1998a). In contrast with the yolk sac, during the period of peak hepatic hematopoiesis (weeks 6 to 18), production of all hematopoietic cell lines—erythrocytes, macrophages, megakaryocytes, granulocytes, and lymphocytes—occurs. Between 18 and 21 weeks of gestation, hematopoiesis in the liver diminishes but the liver continues as an erythropoietic organ until term.

### Bone Marrow

As hepatic hematopoiesis diminishes, the bone marrow becomes the primary site of erythropoiesis and remains so throughout postnatal life. The process of erythropoiesis in marrow begins at about 8 weeks, again, with primitive erythrocytosis (Kelemen et al, 1979). Over the next weeks, a switch to definitive erythropoiesis occurs, and by 14 weeks, only definitive erythroblasts are present. As with the liver, production of all hematopoietic cells occurs in bone marrow. Erythropoietic cells constitute a maximum of 35% of total bone marrow cells at week 12 of gestation, falling to between 20% and 30% thereafter (Charbord et al, 1996; Thomas and Yoffey, 1962).

### Factors Influencing the Sites of Erythropoiesis

The microenvironment at each site of hematopoiesis influences the type and timing of hematopoietic development. The microenvironment includes hematopoietic growth factors and cytokines, as well as the extracellular matrix in which the cells proliferate.

Growth factors are thought to act mainly as permissive and/or selective signals, allowing specific, already committed, cell types to proliferate and differentiate. Growth

factors important for definitive erythropoiesis include Epo, stem cell factor (SCF) *c-kit*, interleukin-3 (IL-3), thrombopoietin (TPO), and possibly insulin and insulin-like growth factor I (IGF-1), both of which act as nonessential survival factors for CD34<sup>+</sup> cells (Muta et al, 1994; Ratajczak et al, 1998). The foregoing growth factors work in concert to promote erythropoiesis; however, Epo can be considered the primary growth factor in the process of erythropoiesis, as in its absence, definitive erythropoiesis does not occur. Similarly, the absence of the Epo receptor also eliminates definitive erythropoiesis. Null mutations of either Epo or its receptor are therefore lethal at 13 days of gestation in the mouse (Wu et al, 1995).

### Extramedullary Hematopoiesis

After the bone marrow has been established as the primary site of erythropoiesis, extramedullary hematopoiesis occasionally occurs as a pathologic process. This can occur with severe bone marrow failure of any etiology, but common causes include congenital rubella and cytomegalovirus (CMV) or parvovirus B19 infection. Extramedullary hematopoiesis has been documented in many tissues, including the liver, spleen, adrenal glands, pancreas, thyroid gland, endocardium, testes, uterus, skin, and brain. Involvement of the skin results in the classic “blueberry muffin” rash seen in newborns with congenital rubella or CMV infection.

### Ontogeny of Erythrocytes

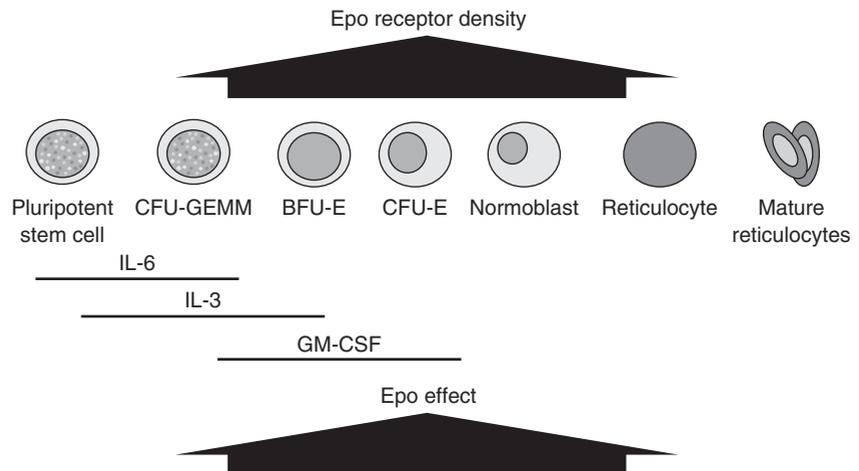

The earliest precursor cells specific to the erythroid lineage are the burst-forming unit–erythroid (BFU-E) cells. BFU-Es have low numbers of Epo receptors (Sawada et al, 1988, 1990) and respond to Epo, as well as to granulocyte-macrophage colony stimulating factor (GM-CSF) and IL-3. As these cells mature into colony-forming unit–erythroid (CFU-E) cells and proerythroblasts, they become highly dependent on Epo, which is reflected by the high density of Epo receptors on the cell membrane (up to 1000 per cell) (Broudy et al, 1991). Mature erythroblasts have fewer Epo receptors and therefore are less sensitive to Epo stimulation, whereas reticulocytes and erythrocytes have no

Epo receptors and are unresponsive to Epo (Fig. 75–2). These mature cells are unique in that they do not have a nucleus, DNA, RNA, ribosomes, or mitochondria. The principal functions of mature erythrocyte metabolism are to maintain adequate adenosine triphosphate (ATP) stores, to produce reducing substances to act as antioxidants, and to produce 2,3-diphosphoglycerate (2,3-DPG), which modifies the oxygen affinity of hemoglobin.

Important developmental changes occur in hematocrit, reticulocyte count, and red cell morphology, membrane content, deformability, life span, and metabolism. Over the course of gestation, there is a rise in expected hematocrit, from 36% ± 3% at 18 to 20 weeks of gestation (fetal samples) to 61% ± 7% expected at term birth. In order to maintain the increase in blood volume and hematocrit associated with fetal growth (up to 7 mL/day during the last trimester), the production of approximately 50 × 10<sup>9</sup> erythrocytes per day is required, based on animal experiments (Bell and Wintour, 1985). During this same period of fetal development, erythrocyte size (the mean cell volume) decreases from 134 ± 9 fL to 119 ± 9 fL (Forestier et al, 1986; McIntosh et al, 1988; Zaizov and Matoth, 1976). Mean cell volume continues to drop postnatally, reaching a nadir at 4 to 6 months of life. It then increases until it reaches adult values (88 ± 8 fL) at approximately 1 year of life.

Reticulocytes are erythrocytes that have been recently released from the bone marrow into the circulation. Although the nucleus has been extruded, they retain cytoplasmic organelles such as ribosomes, mitochondria, and Golgi bodies for approximately 24 hours. These newly released cells can be differentiated from mature red blood cells by staining with new methylene blue or brilliant cresyl blue, both of which stain the nucleic acid within the cells. Evaluation of a patient’s reticulocyte count can be used to assess the level of erythrocyte production, as high values indicate active erythropoiesis and depressed levels indicate low levels of erythropoiesis. At birth, reticulocyte counts in preterm infants tend to be higher than in term infants (400,000 to 550,000 versus 200,000 to 400,000) (Christensen, 2000). Absolute reticulocyte counts, reticulocyte percentage of total red cells, and corrected reticulocyte counts can be obtained. In general, in evaluating neonates, the corrected reticulocyte count is the most helpful, as this reflects the reticulocyte

**FIGURE 75–2.** Simplified scheme of erythropoiesis. The timing of cytokine effects during erythropoiesis are delineated. (CFU, colony forming unit; GEMM, granulocyte erythroid monocyte macrophage; BFU, burst forming unit; E, erythroid; IL, interleukin; GM-CSF, granulocyte macrophage-colony stimulating factor; Epo, erythropoietin).

response relative to the hematocrit. This corrected value is obtained as follows: reticulocyte percentage (%)  $\times$  hematocrit (L/L)  $\div$  desired or optimal hematocrit (L/L).

Red cell morphology is quite heterogeneous in preterm and term infants as compared with that in adults. Irregularly shaped cells such as poikilocytes, acanthocytes, schizocytes and burr cells are common in the blood smears of neonates. This finding reflects developmental changes in membrane deformability and flexibility. The neonatal red blood cell membrane has decreased deformability, which contributes to its decreased life span of approximately 70 days, compared with 120 days for the adult red blood cell. Membrane characteristics become more adult-like by 4 to 6 weeks of age.

## Developmental Changes in the Regulation of Erythropoiesis

### Erythropoietin

The principal growth factor that regulates erythropoiesis is Epo. This 30.4-kDa glycoprotein contains 165 amino acids and is extensively glycosylated, with a 40% carbohydrate content. Epo maintains red cell production during fetal, neonatal, and adult life by inhibiting apoptosis of erythroid progenitors and by stimulating their proliferation and differentiation into normoblasts (Jelkmann, 1992; Muta et al, 1994; Moritz et al, 1997; Palis and Segel, 1998). Because erythropoietin does not cross the placenta, the Epo concentrations measured in the fetus reflect fetal synthesis (Widness et al, 1989, 1991). Epo production begins early in fetal life, and it has been identified in extraembryonic coelomic fluid and amniotic fluid (Campbell et al, 1992). The primary site of Epo production during fetal life is the liver, but this changes to the kidney postnatally (Koury and Koury, 1993). The liver is less sensitive to hypoxic stimuli than the kidney, so in utero, Epo is thought to work synergistically with other growth factors such as hepatic growth factor, TPO, and IGF-1 (Iguchi et al, 1999; Ikehara, 1996; Kaushansky et al, 1995; Migliaccio and Migliaccio, 1988; Okajima et al, 1998). During human development the kidneys contribute less than 9% of total Epo mRNA expression until the 30th week of gestation, increasing to 27% later in gestation. This increase of renal Epo production after the 30th week of gestation may be a consequence of the growth and maturation of the kidney and the developmental increase in Epo-expressing interstitial cells (Avner, 1992). These data suggest that the switch of Epo production would be complete by several months of life. This switch from liver to kidney as the primary site of Epo production and the relative insensitivity of the liver Epo production to tissue hypoxia may contribute to anemia of prematurity.

During fetal development, circulating Epo concentrations increase from 4 mU/mL at 16 weeks of gestation to 40 mU/mL at term (Fahnenstich et al, 1996; Ireland et al, 1992; Ruth et al, 1988; Widness et al, 1984). After birth in healthy term infants, serum Epo concentrations decrease from between 15 to 40 mU/mL at birth to reach a nadir between weeks 4 to 6 after birth (Brown et al, 1983; Ruth et al, 1990). By 10 to 12 weeks of age they reach adult concentrations (approximately 15 mU/mL) (Kling et al, 1996).

These changes in Epo concentrations are consistent with the changes in hemoglobin and hematocrit seen following term birth (physiologic anemia). In premature infants, the anemia is more severe and persists longer, leading to the anemia of prematurity described previously. Epo concentrations in these infants are inappropriately low, forming the rationale for recombinant human Epo therapy.

## Ontogeny of Hemoglobin Chains

### Organization and Structure of the Hemoglobins

Hemoglobin is a tetrameric molecule composed of two pairs of polypeptide subunits. As development proceeds, various hemoglobins are constructed by combining two  $\alpha$ -like globins ( $\zeta$  or  $\alpha$ ) with two  $\beta$ -like globins ( $\epsilon$ ,  $\gamma$ ,  $\delta$ , or  $\beta$ ) to form a hemoglobin tetramer. These tetramers include the embryonic hemoglobins Hb Gower 1 ( $\zeta_2\epsilon_2$ ), Hb Gower 2 ( $\alpha_2\epsilon_2$ ), and Hb Portland 1 ( $\zeta_2\gamma_2$ ); fetal hemoglobin (HbF) ( $\alpha_2\gamma_2$ ); and the adult hemoglobins HbA ( $\alpha_2\beta_2$ ) and HbA<sub>2</sub> ( $\alpha_2\delta_2$ ). Their expression and proportion depend on gestational age but can be modified in part by external mechanisms. The basic function of the various hemoglobins is similar, but their oxygen affinity differs. As the hemoglobins switch from embryonic to fetal to adult forms, oxygen affinity decreases. Thus, the switch from embryonic to fetal to adult hemoglobin synthesis is a major mechanism by which the developing fetus adapts from the intrauterine to the extrauterine environment (Bard, 2000).

### Changes in Hemoglobin Synthesis with Development

The genes within the  $\alpha$ -globin as well as the  $\beta$ -globin families are expressed according to a strict ontogenetic schedule, and the quantitative expression of the genes from each of these families is strictly balanced and coordinated (Bard, 2000). Hemoglobin synthesis begins around 14 days post conception, with synthesis of  $\zeta$ -globin and  $\epsilon$ -globin chains. These are replaced by the synthesis of  $\alpha$ -globin and  $\gamma$ -globin chains by the fifth to seventh week of gestation (Hb Gower 2, Hb Portland 1, and HbF become predominant) (Gale et al, 1979). By 12 weeks of gestation, HbF ( $\alpha_2\gamma_2$ ) accounts for almost all of the hemoglobin (Cividalli et al, 1974). After the 20th week of gestation, no  $\epsilon$ -globin chains are produced, but the production of the  $\zeta$ -globin chains can persist through the last trimester in pathologic conditions such as homozygous alpha-thalassemia. The expression of the  $\gamma$ -globin gene peaks during midgestation and declines rapidly during the last month of fetal gestation. Beta-globin synthesis, required for HbA, starts at the sixth week of gestation, increasing as  $\gamma$ -globin synthesis declines, a transition that continues to the sixth month of life (Bard, 1975; Kazazian and Woodhead, 1973). Thus, HbA synthesis quantitatively increases first after the 30th week of gestation. At the end of the last trimester, a rapid switch from the synthesis of fetal hemoglobin to adult hemoglobin occurs, falling from 85% at 34 weeks of gestation to 60% to 80% at birth (Peri et al, 1998). The synthesis of  $\delta$ -globin chains, required for HbA<sub>2</sub> ( $\alpha_2\delta_2$ ), begins at weeks 34 to 35 of gestation. After birth, a rapid increase in HbA and HbA<sub>2</sub> occurs.

## BILIRUBIN METABOLISM

The primary source of bilirubin in the fetus and newborn is from the breakdown of heme derived from hemoglobin in circulating erythrocytes. Heme is a porphyrin ring surrounding a ferric ion ( $\text{Fe}^{3+}$ ). The rate-limiting step in the breakdown of this molecule is the formation of biliverdin, a process controlled by heme oxygenase (Beri and Chandra, 1993; Rodgers and Stevenson, 1990). The iron molecule is recycled, and biliverdin is then reduced to bilirubin IX $\alpha$  by biliverdin reductase. In utero, unconjugated bilirubin is processed by the mother after placental transfer. Thus, under normal circumstances, the fetal liver plays only a minor role in bilirubin excretion. Unconjugated bilirubin is lipophilic and is tightly bound to albumin in the circulation. The conjugation of bilirubin results in a relatively polar, water-soluble molecule, bilirubin diglucuronide, which can be excreted. This process occurs in the liver and is dependent on ligandin, a transfer protein, and uridine diphosphoglucuronyltransferase. The conjugating ability of the fetus and newborn is impaired relative to older cohorts as a result of reduced transferase activity and low levels of uridine diphosphoglucuronic acid (Denery et al, 2001). Conjugation can be induced in the fetus, however, as during circumstances of increased hemolysis, with its associated increase in bilirubin load, increased conjugated bilirubin can be detected at birth. After birth, the neonate must metabolize the increased load of bilirubin without the assistance of the mother.

### DEVELOPMENTAL ASPECTS OF MEGAKARYOCYTOPOIESIS

Platelets are small (average volume of 7.5 fL), anucleate fragments of megakaryocytes, which circulate as smooth disks when unactivated. The normal circulating lifespan of a platelet is 10 days. Platelets provide the first line of defense in hemostasis. When a breach of the vascular endothelial lining occurs, platelets are activated and adhere to the exposed subendothelium. These activated platelets generate various mediators, including the potent vasoconstrictor thromboxane A<sub>2</sub> and adenosine diphosphate (ADP), both of which further contribute to hemostatic plug formation.

### Sites of Megakaryocyte Production

*Megakaryocytopoiesis* is the process by which megakaryocytes and ultimately platelets develop. As with erythropoiesis, the sites of megakaryocytopoiesis change during embryonic and fetal development. In mouse development, megakaryocytes have been identified in the early yolk sac. These cells, when cultured in the presence of SCF, IL-3, IL-6, Epo, TPO, and granulocyte colony-stimulating factor (G-CSF), can produce not only erythroid bursts but also megakaryocyte colonies. The megakaryocyte progenitors share a common progenitor with primitive hematopoietic cells (Xu et al, 2001). In humans, electron micrographic studies have shown megakaryocytes present in the liver and circulatory system as early as 8 weeks post conception (Hesseldahl and Falck Larsen, 1971).

## Megakaryocyte Precursors

Megakaryocytopoiesis begins with the pluripotent hematopoietic stem cells, which give rise to myeloid progenitor cells (CFU-S) and then burst-forming unit–megakaryocyte (BFU-MK) cells, followed by colony-forming unit–megakaryocyte (CFU-MK) cells (see Fig. 75–1). Further maturation brings these small mononuclear cells, which are largely indistinguishable from monocytes, to large polyploid cells that are easily recognized on the basis of their phenotype. The process of megakaryocyte differentiation has been separated into four stages. Stage I cells, or megakaryoblasts, are the smallest and most immature. As cells mature through stage II (promegakaryocytes), stage III (granular megakaryocytes), and stage IV (mature megakaryocytes), the nucleus becomes multilobed, the cytoplasm becomes increasingly eosinophilic by Wright-Giemsa staining, and cellular size increases from 6 to 24  $\mu\text{m}$  up to as great as 50  $\mu\text{m}$ . The presence of granules increases steadily until in the mature cells they become organized into “platelet fields.” Unlike in other cell lines, as the nucleus of megakaryocytes matures, it undergoes endomitosis or endoreduplication, a process by which cell ploidy is increased in the absence of cell division. Megakaryocytes from adults typically have a modal ploidy of 16N, while comparable samples from preterm or term infants have a significantly lower ploidy of less than 8N (Ma et al, 1996). Megakaryocytes from newborns are also typically smaller than in adults, although they manifest features of mature megakaryocytes. Adult-size megakaryocytes appear by 2 years of age. Typically, smaller cells with lower ploidy produce less platelets than do larger cells with higher ploidy. Nevertheless, the platelet count in fetuses and newborns is within the normal adult range. This is thought to reflect an increased proliferative rate in fetal megakaryocyte progenitors.

### Control of Megakaryocytopoiesis

Multiple cytokines participate in the process of megakaryocytopoiesis; however, TPO is the principal one. IL-3, IL-6, and SCF increase ploidy and size of megakaryocytes. IL-11 also stimulates the proliferation of megakaryocyte progenitors and induces megakaryocyte maturation. Still other growth factors such as Epo, kit ligand, GM-CSF, IL-1, basic fibroblast growth factor, platelet-derived growth factor, and interferon- $\gamma$  have a less clearly defined role. Some cytokines inhibit thrombopoiesis, including transforming growth factor- $\beta$  (TGF- $\beta$ ) and platelet factor-4 (Gewirtz et al, 1995). The magnitude of the influence of these growth factors changes with development (Deutsch et al, 1995).

### Thrombopoietin

The presence of a growth factor to regulate platelet formation was first hypothesized in 1958 by Kelemen, but it was not actually realized until 1994, when the protein was isolated by five independent laboratories. TPO is composed of 332 amino acids and contains two domains. The amino terminus is the active domain (153 amino acids) and bears marked homology to Epo. TPO is produced primarily by the liver and kidney, although other tissues

express small amounts. TPO acts as a potent stimulator of all stages of megakaryocyte growth and development by binding to its specific cell surface receptor, c-mpl. In TPO and c-mpl knockout models, platelet production is 10% to 15% of controls, confirming that TPO is the primary regulator of platelet production but also indicating that alternative pathways exist for megakaryocytopoiesis. Serum TPO concentrations tend to be lower in preterm infants than in older infants and children, and the TPO response to thrombocytopenia is less robust as gestational age decreases. This diminished response is counterbalanced by an increased sensitivity of megakaryocyte precursors to TPO (Sola et al, 1999, 2000).

### Developmental Changes in Platelet Count

Fetal platelet counts increase linearly with gestation. At 15 weeks of gestation, average platelet counts are 187,000/ $\mu$ L, increasing to 274,000/ $\mu$ L at term (Van den Hof, 1990). Although platelet counts in preterm infants are somewhat lower than those in adults, they remain within the same range (150,000 to 400,000/ $\mu$ L). Thus, a platelet count of less than 150,000/ $\mu$ L is considered abnormal, even in a premature infant.

### DEVELOPMENTAL ASPECTS OF GRANULOCYTOPOIESIS

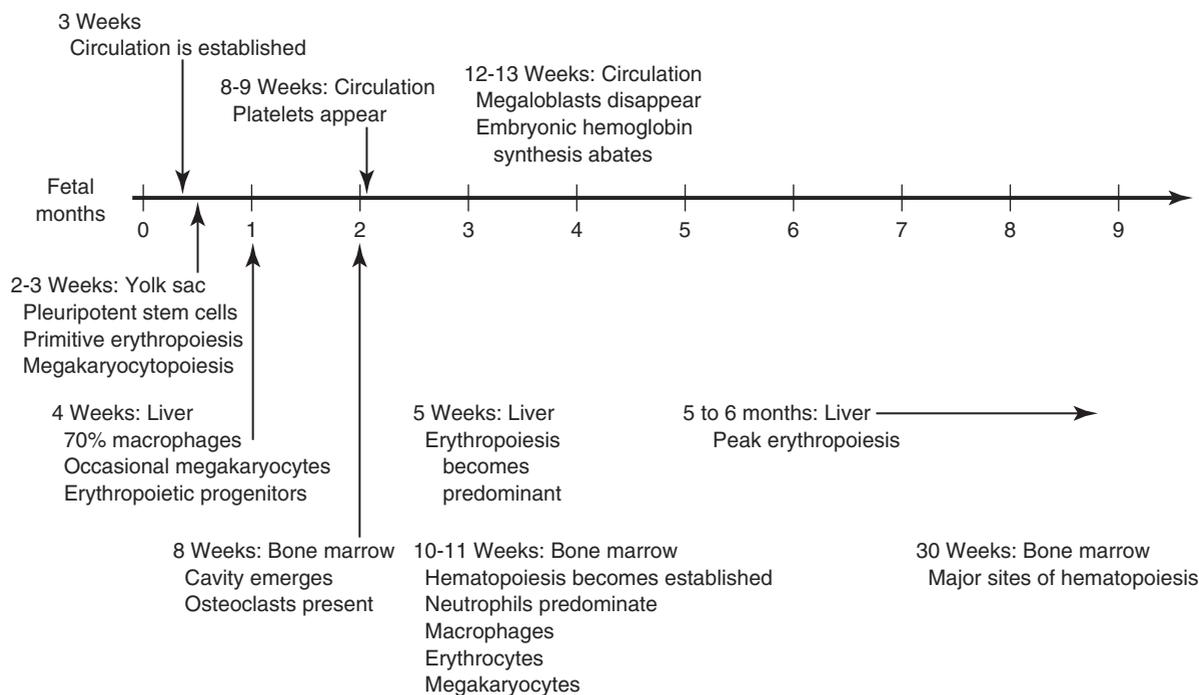

Early hematopoiesis is characterized almost exclusively by erythropoiesis, although a small number of macrophages are produced in the yolk sac. After circulation begins in

the fourth to fifth week of gestation, macrophages appear in the liver, brain, and lungs. During the fifth week, hematopoiesis begins in the liver, and the first hematopoietic cells to appear are macrophages (Kelemen and Janossa, 1980). Whether Kupffer cells originate in the yolk sac and migrate to the liver or rise *de novo* in the liver is unknown. The marrow space begins to develop around the eighth week after conception, and as is true in the liver, the first hematopoietic cells to appear in the bones are phagocytes (Kelemen et al, 1979; Slayton et al, 1998a). These phagocytic osteoclasts seem to “core out” the marrow space. When hematopoiesis is established in the marrow at 10 to 11 weeks post conception, primarily neutrophils are produced, in contrast to the liver, where primarily macrophages are present (Slayton et al, 1998a, 1998b).

The thymus appears around 8 weeks post conception. T cell progenitors are thought to migrate from the fetal liver to the thymus at 8 to 9 weeks following conception (Haynes et al, 1989), and by the 10th week, lymphoid cells constitute 95% of this organ, with granulocyte precursors and macrophages making up the remainder. B-cell precursors first appear in the omentum and the fetal liver at 8 weeks post conception. B-cell production in the omentum occurs transiently from 8 to 10 weeks, while production continues in the fetal liver.

The spleen is an important secondary lymphatic organ in humans, and lymphocytes begin to appear in the spleen around 11 weeks following conception. By the 22nd week, 70% of the cells are lymphocytes (Kelemen et al, 1979).

The events of erythropoiesis are summarized in Fig. 75–3.

**FIGURE 75-3.** Change sites of hematopoiesis during human gestation. Fetal gestation is shown in months along the central horizontal arrow. The timing of significant events during hematopoiesis are shown from primitive erythropoiesis and megakaryocytopoiesis in the yolk sac, to mature hematopoiesis in the bone marrow during late gestation.

## OVERVIEW OF HEMATOPOIETIC CYTOKINES

Hematopoietic growth factors can be classified into two groups: those responsible for the regulation of myeloid and erythroid growth and differentiation, called *colony-stimulating factors* (CSFs), and those concerned with immunity, called *lymphokines*. Once sequenced, lymphokines are assigned interleukin (IL) numbers. There is a great deal of functional overlap between hematopoietic growth factors (redundancy), and each growth factor has a multiplicity of biologic actions (pleiotropy). Thus, more than one cytokine controls cells in any cell lineage, and most factors affect cells in more than one lineage (Metcalf, 1994; Nicola, 1994; Nicola and Metcalf, 1991).

Epo, GM-CSF, and G-CSF belong to a family of hematopoietic cytokines that includes growth hormone, prolactin, and IL-2 through IL-7 (Bazan, 1989). These cytokines share a predicted tertiary structure and function by binding to specific cell surface receptors. Specific ligand binding results in allosteric changes in the receptor molecules, which, depending on the type of receptor, results either in protein kinase activation, as with macrophage colony-stimulating factor (M-CSF) (Nicola et al, 1997), or in a cascade of intracellular signaling via the JAK-2 mechanism, as is characterized by Epo (Watowich et al, 1996).

The receptors for most of these cytokines belong to a receptor superfamily. Family members include receptors for GM-CSF, G-CSF, IL-3 through IL-7, growth hormone, prolactin, neurociliary trophic factor, and TPO. Members of this family share structural similarities and an absence of a tyrosine kinase domain in the cytoplasmic domain (Bazan, 1990; Watowich et al, 1996). These cytokine receptors often are assembled as multisubunit complexes and have been grouped into subfamilies on the basis of the pattern subunit formation. In some cases (e.g., GM-CSF receptor [GM-CSF-R]), an accessory protein contributes to the stability of the receptor complex (Brizzi et al, 1991).

Many of the hematopoietic cytokines were discovered by virtue of their growth-promoting effects on hematopoietic cell lines or their specific immune functions. It initially was assumed that the effects of these cytokines were specific to the hematopoietic system. This view has now been challenged, as evidence has accumulated that many of these growth factors have other important roles that are not hematopoietic (Juul, 2000). Indeed, this is an area of active research, as some of these cytokines have potential as protective agents in the brain, gut, and elsewhere (Cerami, 2001; Juul et al, 2001; Ledbetter and Juul, 2000).

## Hemostatic Disorders of the Newborn

Stefan Kuhle, Lesley Mitchell, Patricia Massicotte, and Maureen Andrew\*

The diagnosis and management of acquired and hereditary hemostatic disorders in newborns differ from those of such disorders in older patients, owing to the presence at birth of a unique hemostatic system and to the age specificity of many pathologic conditions. For example, physiologic levels of many coagulation proteins are decreased compared with those in adults, making the diagnosis of most inherited and acquired hemostatic problems challenging. The hemostatic system is dynamic and age dependent; therefore, multiple reference ranges reflecting both gestational and postnatal ages of infants are necessary (Andrew et al, 1987b, 1988). Because most severe deficiencies manifest in the neonatal period, the index of suspicion for detection of these disorders must be increased.

After confirming the presence of a hemostatic problem, the clinician is faced with the challenge of providing both safe and effective treatment. The efficacy and safety of therapeutic interventions require testing in randomized, controlled trials, whenever feasible. However, in dealing with rare or consistently life-threatening events, alternative study designs can be useful. Guidelines for the classification of study design allowing an estimation of the strength of the findings have been established (Hirsh et al, 2001). Conclusions from studies with strong designs are necessarily given greater weight than that assigned to conclusions from studies with weaker designs.

This chapter provides a brief review of developmental hemostasis and the diagnosis and management of both bleeding and thromboembolic disorders in newborns.

### PHYSIOLOGY OF HEMOSTASIS

#### Coagulation System

Physiologically, blood is maintained in a fluid phase. In response to a damaged vessel wall, platelets, plasma coagulation proteins, and the damaged vessel contribute to the formation of a hemostatic plug. Figure 76-1 provides a scheme of the current concepts of the coagulation system as discussed in a recent review (Dahlback, 2000). The central purpose of coagulant proteins is to generate thrombin from prothrombin. Thrombin is a serine protease with potent coagulant functions: (1) it activates factor V (FV), FVIII, and FXI, thereby enhancing its own generation;

(2) it cleaves fibrinopeptide A (FPA) and FPB from fibrinogen, resulting in fibrin formation; (3) it promotes fibrin cross-linking by activating FXIII; and (4) it is a potent physiologic activator of platelets.

#### Coagulant Proteins

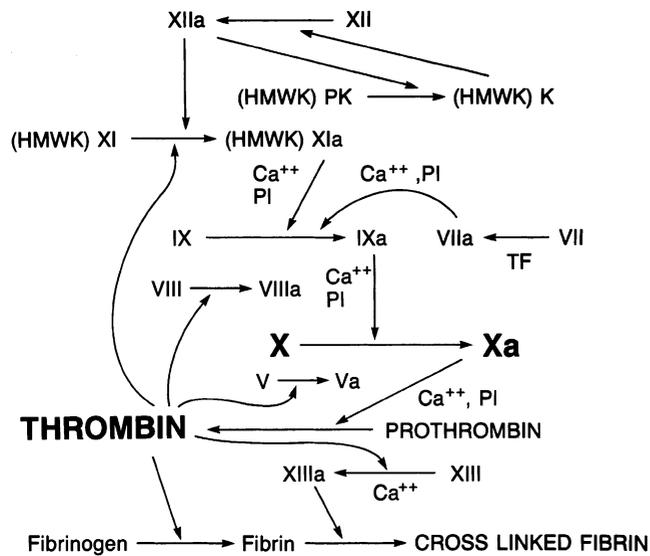

Components of the coagulation system do not cross the placenta but are synthesized by the fetus, with detectable levels at the end of the first trimester (Heikinheimo, 1964). Plasma concentrations of coagulant proteins in healthy fetuses and preterm and full-term newborns are available (Andrew et al, 1988; Reverdiau-Moalic et al, 1996) and are summarized in Tables 76-1, 76-2, and 76-3. Those fetal reference values may potentially provide a good assessment of the coagulation system of the very premature infant. Plasma concentrations of most coagulant proteins in newborns differ significantly from those in adults (see Tables 76-2 and 76-3). Plasma levels of the vitamin K-dependent coagulant proteins—FII, FVII, FIX, FX—and the contact factors—FXI, FXII, prekallikrein, and high-molecular-weight kininogen—are approximately 50% of adult values at birth. In contrast, plasma concentrations of fibrinogen, FV, and FVIII are not decreased at birth or during infancy (Andrew et al, 1987b, 1988). Plasma concentrations of von Willebrand factor (vWF), vWF high-molecular-weight multimers, and vWF collagen-binding activity are increased during the first weeks of life (Katz et al, 1989; Thomas et al, 1995). By 6 months of age, plasma concentrations of most coagulant proteins are in the lower part of the adult normal range (see Tables 76-2 and 76-3).

#### Inhibitors of Coagulation

Several proteins are involved in regulation of the coagulation system. The direct plasma inhibitors of thrombin include antithrombin (AT),  $\alpha_2$ -macroglobulin ( $\alpha_2$ M), and heparin cofactor II (HCII). AT-mediated inhibition of thrombin is potentiated by certain glycosaminoglycans, most important of which is heparin. At birth, plasma concentrations of the direct inhibitors AT and HCII are approximately 50% of adult values, whereas  $\alpha_2$ M levels are increased, compensating in large part for the decreased plasma concentrations of AT (Schmidt et al, 1989a). By 6 months of age, plasma concentrations of AT and HCII reach adult levels, whereas  $\alpha_2$ M levels are nearly twice the adult values (see Tables 76-2 and 76-3).

The indirect inhibitors of thrombin include protein C, protein S, and tissue factor pathway inhibitor (TFPI). When thrombin is generated in vivo, it binds to an endothelial cell receptor, thrombomodulin (TM), and can no longer cleave fibrinogen, FV, and FVIII, nor can it activate platelets. However, thrombin can activate protein C to its activated form (aPC). Activated protein C, a VK-dependent serine protease, enzymatically inactivates FVa and FVIIIa by limited proteolytic cleavage. The enzymatic activity of aPC is enhanced by another VK-dependent protein, protein S, which acts as a cofactor. Plasma concentrations of protein C and protein S are reduced at birth by 60% and remain decreased during the first weeks of life

\*Deceased.

**FIGURE 76-1.** Physiology of normal hemostasis.

(see Tables 76-2 and 76-3). Protein C circulates in a fetal form that differs from the adult form by a twofold increase in single-chain protein C (Greffé et al, 1989). Protein S circulates only in the free, active form in newborn plasma, because C4b-binding protein is absent in newborns (Schwarz et al, 1988). In contrast with proteins C and S, plasma concentrations of TM are increased in fetuses, newborns, and infants (Menashi et al, 1999). Whether this reflects increased endothelial expression of TM in the young is unknown. A second, indirect mechanism for regulating thrombin generation is via TFPI, an inhibitor of the FVIIa/tissue factor pathway. TFPI forms a complex with FXa, and the TFPI/FXa complex inhibits FVIIa, thereby inhibiting the generation of thrombin. Information on the influence of age on TFPI is limited. Plasma concentrations of TFPI in fetuses and neonates at birth are decreased compared with those in adults (Reverdiu-Moalic et al, 1996; Weissbach et al, 1994).

## Thrombin Regulation of Plasma

### Thrombin Generation

Values for the prothrombin time (PT) and the activated partial thromboplastin time (APTT) are prolonged in newborns. More sensitive assays show that thrombin generation is delayed and decreased by approximately 50% in plasmas from newborns compared with adult values (Schmidt et al, 1989b). The plasma concentration of prothrombin is directly related to the amount of thrombin generated in newborn plasma (Andrew et al, 1990c).

### Thrombin Inhibition

The inhibition of iodine-125-labeled thrombin in newborn plasma is slower than in adult plasma, probably reflecting the low plasma concentrations of AT (Schmidt et al, 1989a). However, the total capacity to inhibit thrombin is similar for

newborns and for adults owing to the increased binding of thrombin by  $\alpha_2$ M in newborns (Schmidt et al, 1989a). In addition to the increased binding of thrombin to  $\alpha_2$ M in newborn plasma, the amount of thrombin complexing to HCII is increased owing to a circulating dermatan sulfate proteoglycan (DSPG) that specifically catalyzes thrombin inhibition by HCII (Andrew et al, 1992b). DSPG also is present in plasmas from pregnant women and probably is released from the placenta (Delorme et al, 1998). The length of time DSPG circulates in newborns is not known, except that it is still present during the first week of life in sick infants with respiratory distress syndrome (RDS) (Shah et al, 1992).

## Conversion of Fibrinogen to Fibrin

### Fibrinogen

At birth, plasma concentrations of fibrinogen are similar to adult levels. Fibrinogen is present in a fetal form that has an increased sialic acid content compared with adult fibrinogen (Francis and Armstrong, 1982). The thrombin clotting time (TCT), if the determination is performed without calcium in the system, is prolonged in newborns, reflecting the presence of fetal fibrinogen. If sialic acid is removed, fetal fibrinogen appears indistinguishable from adult fibrinogen (Francis and Armstrong, 1982). The physiologic significance of fetal fibrinogen is unknown.

### Fibrin Clots

The capacity of newborn fibrin clots to bind thrombin has been assessed by measuring FPA production by fibrin clots prepared from adult and from cord plasma (Patel et al, 1996). Cord plasma clots generate significantly less FPA compared with clots formed in adult plasma, owing to decreased concentrations of prothrombin (Patel et al, 1996). Increasing cord plasma concentrations of prothrombin increase FPA production by cord clots. This observation suggests that thrombi in newborns with low plasma concentrations of prothrombin may have a decreased propensity to propagate.

## Fibrinolysis

Once a fibrin clot has formed *in vivo*, it is modified by the fibrinolytic system (Fig. 76-2). Activities of the fibrinolytic system are localized to the fibrin clot through specific lysine-binding sites. Plasminogen is converted to plasmin by tissue plasminogen activator (tPA) and urokinase. Analogous to thrombin, plasmin is the critical enzyme in fibrinolysis. Plasmin is a serine proteinase that cleaves fibrin in sequential steps, resulting in fibrin degradation products and the specific fibrin fragment, D-dimer. The fibrinolytic system is regulated by both the direct inhibitors of plasmin and inhibitors of plasminogen activators. Plasmin is inhibited primarily by  $\alpha_2$ -antiplasmin ( $\alpha_2$ AP). However, when bound to the fibrin surface, plasmin is relatively protected from

TABLE 76-1

## Reference Values for Coagulation Parameters in Fetuses and Full-Term Infants versus Adults

Parameter	Fetus: Weeks of Gestation			Newborn (n = 60)	Adult (n = 40)
	19-23 (n = 20)	24-29 (n = 22)	30-38 (n = 22)		
<b>A. Coagulation Screening Tests and Coagulation Factors*</b>					
<i>Coagulation Tests</i>

\*All values are means, followed in parentheses by the lower and upper boundaries including 95% of the population. The significant differences between any two groups are denoted by *P* values, using Dunnett multiple regression.

<sup>†</sup>*P* < .01.

<sup>‡</sup>*P* < .05.

<sup>§</sup>For TFPI, 20 samples were assayed for each group, but only 10 for 19- to 23-week-old fetuses.

Ag, antigen; APTT, activated partial thromboplastin time; AT, antithrombin; BP, binding protein; c, coagulant activity; HCII, heparin cofactor II; HMWK, high-molecular-weight kininogen; INR, international normalized ratio; PC, protein C; PK, prekallikrein; PS, protein S; PT, prothrombin time; TCT, thrombin clotting time; TFPI, tissue factor pathway inhibitor.

Data from Reverdiau-Moalic et al, (1996).

inhibition by  $\alpha_2$ AP. The activators of plasminogen are inhibited by plasminogen activator inhibitors (PAIs), of which PAI-1 is the most important during infancy and childhood.

blood (Astedt and Lindoff, 1997) and neonatal blood (Andrew et al, 1990b) are significantly increased over adult values.

## The Fibrinolytic System in Newborns

### Plasma Concentrations

Plasma concentrations of components of the fibrinolytic system are age dependent (Table 76-4). At birth, plasminogen levels are about 60% to 70% of adult values;  $\alpha_2$ AP levels are approximately 85% of adult values (Andrew et al, 1990b). Plasma concentrations of PAI-1 and tPA in cord

### Fetal Plasminogen

At birth, plasminogen is present in a "fetal" form characterized by increased amounts of mannose and sialic acid. Fetal plasminogen may have mildly decreased enzymatic activity as well as decreased binding to cellular receptors for plasminogen (Edelberg et al, 1990). The physiologic significance of fetal plasminogen is unknown.

\*Born at 30 to 36 weeks of gestation, with measurements at given intervals during first 6 months of life.

†All values except those for fibrinogen are expressed in U/mL, where pooled plasma contains 1.0 U/mL. Values are given as means, followed by the lower and upper boundaries encompassing 95% of the population. Some measurements were skewed owing to a disproportionate number of high values. The lower limit excludes the lower 2.5% of the population. *Coagulation Tests*: Between 40 and 96 samples were assayed for each value for the entire period of time. *Inhibitors of Coagulation*: Between 40 and 75 samples were assayed for each value for the entire period of time.

‡Values not statistically different from adults.

§Values different from those in full-term infant.

APTT, activated partial thromboplastin time; AT, antithrombin; α<sub>1</sub>AT, α<sub>1</sub>-antitrypsin; C<sub>1</sub>E-INH, C<sub>1</sub>-esterase inhibitor; HClI, heparin cofactor II; HK, high-molecular-weight kininogen; INR, international normalized ratio; α<sub>2</sub>M, α<sub>2</sub>-macroglobulin PK, prekallikrein; PT, prothrombin time; TCT, thrombin clotting time; VIII, factor VIII procogulant; vWF, von Willebrand factor.Data for **A** from (Andrew et al (1988)) data for **B** from (Andrew et al (1990b)).

Values are means, followed in parentheses by the lower and upper boundaries encompassing 95% of the population. Some measurements were skewed owing to a disproportionate number of high values. The lower limit excludes the lower 2.5% of the population. *Coagulation Tests:* Between 40 and 77 samples were assayed for each value for newborn. *Inhibitors of Coagulation:* Between 40 and 75 samples were assayed for each value for newborn.

†Values not statistically different from adults.

APTT, activated partial thromboplastin time; AT, antithrombin; α<sub>1</sub>AT, α<sub>1</sub>-antitrypsin; C<sub>1</sub>E-INH, C<sub>1</sub>-esterase inhibitor; F, factor; HCI, heparin cofactor II; HMWK, high-molecular-weight kininogen; INR, international normalized ratio; α<sub>2</sub>M, α<sub>2</sub>-macroglobulin; PK, prekallikrein; PT, prothrombin time; TCT, thrombin clotting time; von Willebrand factor (vWF).

Data for **A** from Andrew et al, 1987a; data for **B** from Andrew et al (1990b).

**FIGURE 76-2.** Physiology of fibrinolysis.

### Activation of the Fibrinolytic System at Birth

The fibrinolytic system is transiently activated at birth, as evidenced by increased plasma concentrations of plasmin- $\alpha_2$ AP, D-dimer, and B $\beta$ 15-42-related peptides (Ekelund et al, 1970; Knofler et al, 1998a; Suarez et al, 1985). The clinical significance of an activated fibrinolytic system at birth is uncertain.

### Regulation of Plasmin

The capacity to generate plasmin is reduced in cord blood, probably as a result of reduced plasma concentrations of plasminogen (Corrigan et al, 1989). The contribution of "fetal" plasminogen to impaired fibrinolysis is uncertain (Edelberg et al, 1990).

## Platelets

### General Information

Platelets are disk-shaped cells produced by megakaryocytes in the bone marrow and released into the circulation. The plasma membrane of platelets contains several glycoproteins that bind specific adhesive proteins to facilitate platelet-to-surface interactions (adhesion) and platelet-to-platelet interactions (aggregation). Under normal circumstances, platelets circulate without adhering to vessel walls or to other cells. When the endothelial lining of blood vessels is damaged or removed, platelets adhere to subendothelial molecules, are activated, undergo shape change, spread over the surface, and bind to each other. Adhesion initiates the secretion of platelet granule contents. These substances promote adhesion and formation of aggregates. Activated platelets also participate in coagulation by providing a lipoprotein surface on which the soluble coagulation factor complexes can assemble, resulting in the generation of thrombin and the formation of fibrin. As discussed previously, thrombin itself is a potent stimulus of platelet aggregation. Occupation of platelet surface receptors by a variety of extracellular molecules (such as thrombin, collagen, and

adenosine diphosphate [ADP]) activates membrane-associated enzymes that, in turn, generate intracellular second messengers that promote platelet activation and secretion. Platelet secretion is a process whereby platelet granules form a cluster and fuse with the membranes of other granules and the surface-connected open canalicular system. The process of platelet adhesion is mediated by glycoprotein Ib/IX/V (GPIb/IX/V), an integral membrane protein specific to the platelet membrane. It serves as a binding site for subendothelial vWF, an adhesive protein. Von Willebrand factor is secreted by endothelial cells and platelets and is present in the subendothelium and in plasma. Both the plasma concentrations of vWF and the proportion of high-molecular-weight multimers of vWF are important for adhesive function. Following activation of platelets, the GPIIb/IIIa complex on the platelet surface exposes a binding site for fibrinogen and, to a lesser extent, vWF, fibronectin, and thrombospondin. Platelet-to-platelet adherence or aggregation is mediated by fibrinogen bound to GPIIb/IIIa. GPIIb/IIIa is the most abundant platelet surface glycoprotein, with approximately 50,000 molecules per platelet.

### Platelets in the Newborn

Platelet counts in newborns are similar to adult values, ranging between 150 and 400  $\times 10^9/L$ , with mean volumes of 7 to 9 fL. Values in fetuses between 18 and 30 weeks of gestation are also within this range, with average values of 250  $\times 10^9/L$  (Forestier et al, 1986). The life span of platelets in healthy infants probably is similar to that in adults at approximately 7 to 10 days, at which time platelets are removed from the circulation by macrophages in the reticuloendothelial system. In a rabbit model, platelet survival times were comparable for rabbit pups and adults (Castle et al, 1988).

### Platelet Function

Until recently, little information was available on the function of platelets taken directly from infants because of the volume of blood required and the technical difficulty of obtaining an adequate sample. With the advent of flow cytometry, recent studies using that technique have provided new insights into platelet function of the newborn. However, the limited availability of flow cytometry has hindered its use in routine clinical practice.

Most studies show that cord and newborn platelets function differently from adult platelets. Neonatal platelets have been demonstrated to have fewer pseudopods, smaller glycogen deposits, less visible microtubular structures, and markedly fewer alpha granules (Saving et al, 1994). Flow cytometry studies show that, without added agonists, expression of GPIb or GPIIb/IIIa in newborn platelets does not differ from that in adult platelets.

**Adhesion.** The components required for platelet adhesion, GP Ib and vWF, are present early in fetal life (Gruel et al, 1986). Both plasma concentrations and the proportion of high-molecular-weight multimers of vWF are increased in newborns (Katz et al, 1989) and these changes may be

TABLE 76-4

## Reference Values for Components of Fibrinolytic System in Full-Term and Premature Infants\* versus Adults

Parameter	Infant					Adult
	Day 1	Day 5	Day 30	Day 90	Day 180	
<b>A. Healthy Full-Term Infants<sup>†</sup></b>						
Plasminogen (U/mL)	1.95 (1.25-2.65)	2.17 (1.41-2.93)	1.98 (1.26-2.70)	2.48 (1.74-3.22)	3.01 (2.21-3.81)	3.36 (2.48-4.24)
TPA (ng/mL)	9.6 (5.0-18.9)	5.6 (4.0-10.0) <sup>‡</sup>	4.1 (1.0-6.0) <sup>‡</sup>	2.1 (1.0-5.0) <sup>‡</sup>	2.8 (1.0-6.0) <sup>‡</sup>	4.9 (1.4-8.4)
$\alpha_2$ AP (U/mL)	0.85 (0.55-1.15)	1.00 (0.70-1.30) <sup>‡</sup>	1.00 (0.76-1.24) <sup>‡</sup>	1.08 (0.76-1.40) <sup>‡</sup>	1.11 (0.83-1.39) <sup>‡</sup>	1.02 (0.68-1.36)

\*Measurements at given intervals during first 6 months of life.

<sup>†</sup>For  $\alpha_2$ AP, values are expressed as U/mL, where pooled plasma contains 1.0 U/mL. Plasminogen units are those recommended by the Committee on Thrombolytic Agents. Values for tPA are given as ng/mL. Values for PAI-1 are given as U/mL, where 1 unit of PAI-1 activity is defined as the amount of PAI-1 that inhibits 1 international unit (IU) of human single-chain tPA. All values are means, followed in parentheses by the lower and upper boundaries encompassing 95% of the population.

<sup>‡</sup>Values not statistically different from adults.

<sup>§</sup>Values different from those in full-term infant.

$\alpha_2$ AP,  $\alpha_2$ -antiplasmin; PAI-1, plasminogen activator inhibitor-1; tPA, tissue plasminogen activator.

Data from Andrew et al (1990b).

responsible for enhanced cord platelet aggregation by low concentrations of ristocetin (Ts'ao et al, 1976). The multimeric forms of vWF appear similar to those released by endothelial cells, suggesting that mechanisms for processing the multimers may not be fully developed at birth.

**Activation and Secretion.** Recent studies, using whole-blood flow cytometry, show that platelets of preterm and term neonates are hyporeactive to thrombin, a combination of ADP and epinephrine, and a thromboxane A<sub>2</sub> analogue (Rajasekhar et al, 1994, 1997). The reason for this hyporeactivity is not completely understood. Agonist receptors, with the exception of the  $\alpha$ -adrenergic receptor (Corby and O'Barr, 1981a), do not appear to be decreased in number. Studies of activation pathways showed that inositol phosphate production and protein phosphorylation, as well as production of arachidonic acid and its metabolites, are normal (Israels et al, 1990). A more recent study linked the transient platelet hyporeactivity to a defect in the thromboxane A<sub>2</sub> postreceptor signal transduction pathway (Israels et al, 1999).

On the basis of evidence from studies using cord blood, platelets of newborns formerly were thought to be in a state of transient dysfunction secondary to platelet activation during the birth process (Suarez et al, 1988). More recent studies using flow cytometry, however, suggest that hyporeactivity of newborn platelets is not caused by preactivation during birth (Grosshaupt et al, 1997) but is rather a developmental phenomenon that resolves around day 10 of life (Gatti et al, 1996). The clinical significance of these findings remains unknown.

**Aggregation.** Platelet GPIIb/IIIa is present on fetal platelet membranes from early gestation (Gruel et al, 1986). Although the collagen receptor GPIa/IIa is found in adult concentrations on neonatal platelets, the platelet aggregation response to collagen is markedly reduced, probably owing to an impaired intracellular signal transduction (Israels et al, 1999). Collagen-induced aggregation normalizes between the fifth and ninth days of life (Tanindi et al, 1995). Platelet aggregation in response to epinephrine is diminished owing to decreased numbers or occupation of  $\alpha$ -adrenergic receptors (Corby and O'Barr, 1981a).

Some studies show that the capacity of cord and neonatal platelets to aggregate following exposure to ADP, thrombin, and arachidonic acid may be similar to that of adult platelets (Corby and O'Barr, 1981b; Israels et al, 1990; Knofler et al, 1998b).

### **Platelet Function Testing**

For many years, the bleeding time has been the most commonly used test of primary hemostasis in infants and children. However, poor reproducibility, operator dependence, and poor predictability of bleeding risk have limited its usefulness. The Platelet Function Analyzer (PFA-100) provides a promising alternative to the bleeding time. The PFA-100 is a high-shear system for the *in vitro* evaluation of primary hemostasis in anticoagulated whole blood, simulating injury to a small vessel

(Kundu et al, 1995). As with the bleeding time (Andrew et al, 1990a), PFA-100 closure times in newborns are shorter than in adults (Carcao et al, 1998). Increased plasma concentrations of vWF and enhanced function of vWF due to increased amounts of high-molecular-weight multimers partly account for this finding in newborns. The contribution of a higher hematocrit to the shortening of PFA-100 closure times in newborns is controversial (Israels et al, 2001; Roschitz et al, 2001). The clinical significance of mild platelet aggregation defects or platelet hyporeactivity in newborns is uncertain when BT and PFA-100 closure time in newborns are shorter than in adults.

## **HEMORRHAGIC DISORDERS**

All infants with clinically significant bleeding should be evaluated for a hemostatic deficit. Although acquired problems are more frequent, severe forms of hereditary factor deficiencies often first manifest in early infancy and should be seriously considered in otherwise healthy infants. Clinical presentation, diagnosis, and management of hemorrhagic disorders in newborns differ considerably from those in older infants and children.

### **Approach to the Newborn with Bleeding**

#### **History and Physical Examination**

Evaluation of any newborn with hemorrhagic complications includes a careful history of familial bleeding problems, maternal illnesses (e.g., infections, immune thrombocytopenia), outcome of previous pregnancies, drug administration (maternal and neonatal), and documentation that vitamin K was given at birth. Simple observations on physical examination, such as localized versus diffuse bleeding and healthy or sick appearance of the newborn, have tremendous importance for the classification of hemorrhagic disorders. Whereas vitamin K deficiency or inherited coagulation defects characteristically manifest with large ecchymoses or localized bleeding in apparently healthy newborns, bleeding due to disseminated intravascular coagulation (DIC) or liver injury generally is seen in sick infants with diffuse bleeding from several sites. Infants with isolated platelet disorders generally appear healthy except for progressive petechiae, ecchymoses, and/or mucosal bleeding. Common bleeding sites in the newborn include the umbilicus, mucous membranes, circumcision wounds, the scalp, and the skin. Hemarthrosis, a common presentation of severe hemophilia in older children, is rarely seen in newborns. In a small but important proportion of infants, intracranial hemorrhage (ICH) is the initial manifestation of a bleeding tendency. In sick newborns, bleeding from the lungs, the gastrointestinal tract, the urinary tract, or peripheral blood sampling sites may be the first sign of a coagulopathy. In otherwise healthy infants, the most common causes of bleeding are thrombocytopenia secondary to transplacental passage of a maternal antiplatelet antibody, vitamin K deficiency, and, less commonly, a hereditary coagulation factor deficiency. Although sick infants may have an underlying hereditary defect, acquired disorders such as DIC and liver failure are more common.

### Laboratory Evaluation

In a majority of newborns with a hemorrhagic disorder, history and physical examination alone will point to the correct diagnosis, with laboratory tests providing confirmation. The initial workup usually includes a PT, APTT, TCT, fibrinogen level, platelet count, and on rare occasion, a bleeding time or PFA-100 assay. Abnormalities in these tests will usually guide the selection of additional tests such as specific factor assays (Fig. 76–3). Deficiencies of FXIII,  $\alpha_2$ AP, and PAI do not alter the results of the screening tests, and these must be measured directly if deficiencies are suspected.

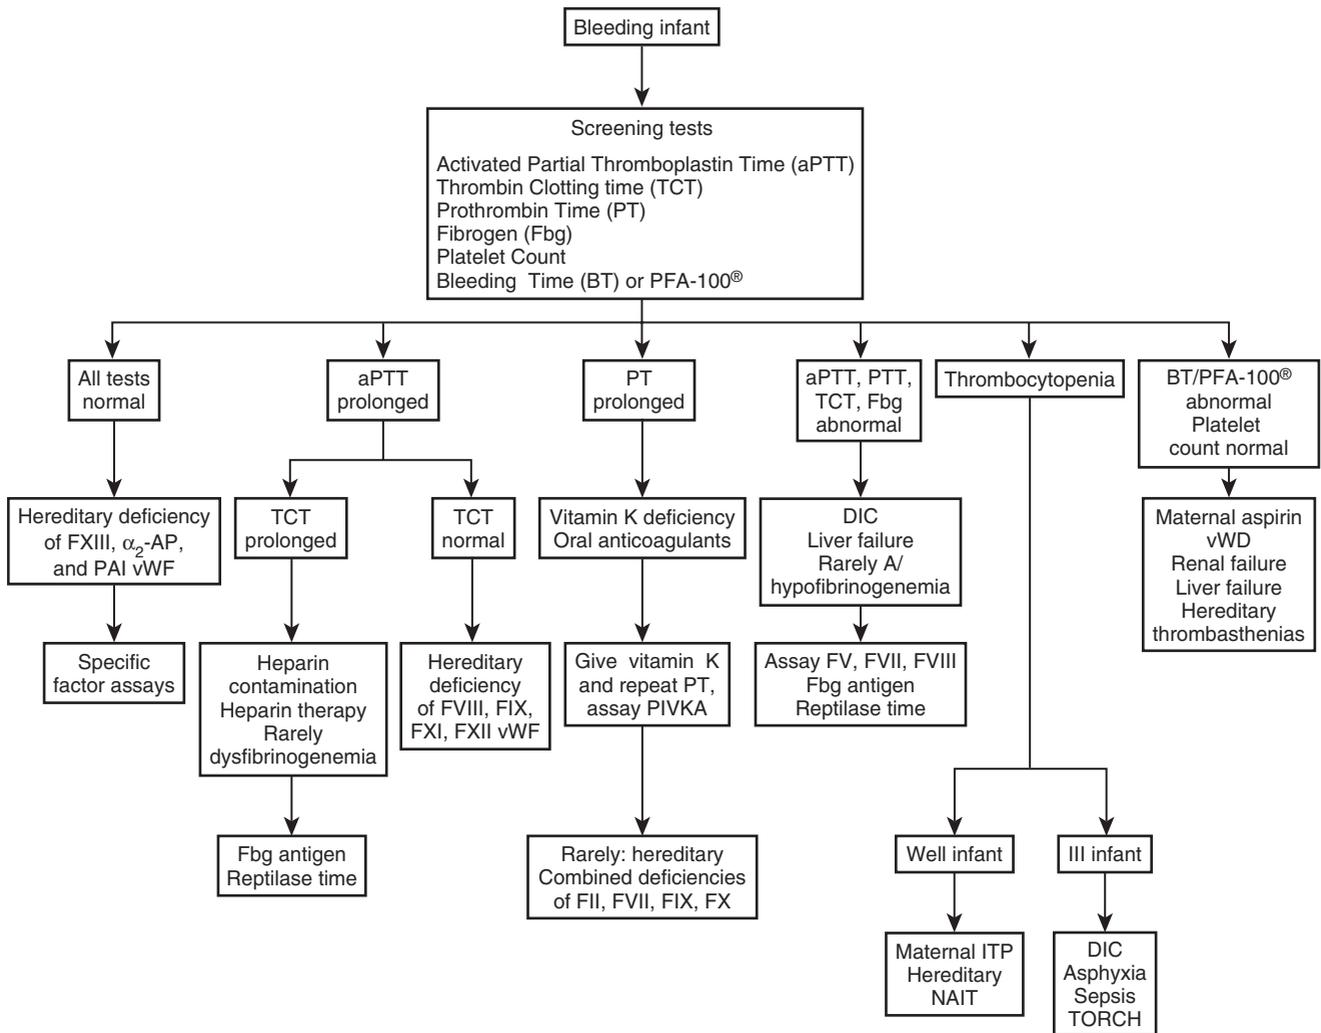

Ideally, samples should be taken from a peripheral vein. This approach often is not feasible in small preterm infants or in infants with difficult venous access after repeated sampling. If samples are drawn from central lines, even minute contamination with heparin may give erroneous

results. In these instances, preanalysis incubation of the sample with protamine or heparinase may be used to eliminate heparin contamination (Ellis, 1993; Keller et al, 1998).

All laboratory results must be considered in the context of age-related reference values. Differentiation of hereditary and acquired deficiencies from physiologic values can be difficult for most coagulation proteins, a problem unique to newborns.

### Management

The appropriate management of an infant with a hemorrhagic disorder is dependent on the current identification of the hemostatic defect. Options for replacement therapy include specific factor concentrates, fresh frozen plasma (FFP), platelet concentrates, and cryoprecipitate. Other therapeutic considerations are related to whether venous access can be maintained, particularly if an exchange

**FIGURE 76-3.** Flow diagram for the evaluation of a bleeding newborn.  $\alpha_2$ AP,  $\alpha_2$ -antiplasmin; APTT, activated partial thromboplastin time; BT, bleeding time; DIC, disseminated intravascular coagulation; F, factor; Fbg, fibrinogen; FSPs, fibrin split products; ITP, idiopathic thrombocytopenic purpura; NAIT, neonatal alloimmune thrombocytopenia; PAI, plasminogen activator inhibitor; PIVKA, protein induced in the absence of vitamin K; PT, prothrombin time; TCT, thrombin clotting time; TORCH, toxoplasmosis, other infections, rubella, cytomegalovirus infection, herpes simplex; vWD, von Willebrand disease; vWF, von Willebrand factor.
