The terms *hemophilia A* and *hemophilia B* designate hereditary deficiencies of FVIII and FIX, respectively. On the basis of the factor levels, the hemophilias are classified as severe (<1% of the normal level), moderate (1% to 5%), or mild (>5% to <40%). Severe hemophilia is the most common hereditary coagulation defect to manifest in newborns. Hemophilia is inherited as an X-linked recessive trait. About 20% to 30% of cases are from spontaneous mutations. Hemophilia occurs in 1/5000 male births, with approximately 80% to 85% of cases accounting for hemophilia A and 15% to 20% for hemophilia B. Both forms are clinically indistinguishable but differ in laboratory and management aspects. A positive family history is usually present in about two thirds of cases. Very rarely, hemophilia may occur in females and manifest at birth.

### Pregnancy and Perinatal Management

In affected families, early genetic diagnosis in the fetus can be made by chorionic villus sampling at 11 to 13 weeks of gestation or by amniocentesis around 16 weeks. Cordocentesis for fetal blood sampling for FVIII or FIX is possible after 18 to 20 weeks of gestation (Ljung, 1999). Controversy exists concerning the safest delivery mode of newborns with suspected or proven hemophilia. As yet, no firm evidence-based recommendations can be given. Vaginal delivery appears to be reasonably safe (Ljung et al, 1994) and is used by most centers (Kulkarni et al, 1999). Delivery by cesarean section does not completely eliminate the risk of ICH (Michaud et al, 1991). Vacuum extraction should strictly be avoided as it carries a significant bleeding risk (Ljung et al, 1994). Close communication among hematologist, neonatologist, and obstetrician is of utmost importance. After birth, a cord blood sample for the appropriate clotting factor assay should be taken. Heel sticks or venipunctures in a newborn with hemophilia should be performed only when absolutely necessary. After puncture, local pressure should be applied for 5 to 10 minutes, and the site should be closely observed for 24 hours. Vitamin K may be given intramuscularly, but the same precautions as for venipunctures apply (Kulkarni and Lusher, 2001).

### Clinical Presentation

Recent studies indicate that 40% to 70% of children with severe hemophilia are diagnosed in the neonatal period (Conway and Hilgartner, 1994; Pollmann et al, 1999), and the vast majority present with bleeding symptoms. The most common presentations are ICH, cephalohematoma, and bleeding from the umbilical stump or following venipuncture, heel prick, or circumcision (Kulkarni and Lusher, 2001).

### Diagnosis

Severe and moderate hemophilia A as well as severe hemophilia B can be reliably diagnosed in the neonatal period, as factor levels in affected newborns are well below physiologic values. Infants with moderate hemophilia B or with mild forms of hemophilia A or B, however, may have normal PT and APTT values. Therefore, if hemophilia is suspected, specific factor assays should be performed regardless of the PT or APTT value.

### Treatment

Currently, administration of FVIII and FIX concentrates (highly purified or recombinant) is the treatment of choice for hemophilia. In cases of severe bleeding with pending factor assay results, FFP may be used. Dosage of replacement factor strongly depends on the site and severity of the bleed. Target levels of FVIII/IX range from 40% to 50% in muscular bleeds to 100% in ICH (DiMichele and Neufeld, 1998). In newborns with hemophilia and ICH, treatment with factor concentrates should be continued for at least 2 weeks, and early prophylactic treatment should be considered (Kulkarni and Lusher, 2001). Insufficient data are available to support the benefit of prophylactic doses of FVIII given while the baby is still in the intrauterine environment or shortly after birth to offset the trauma of labor in newborns suspected or confirmed to have hemophilia (Buchanan, 1999). In neonates with severe hemophilia undergoing circumcision, use of local fibrin glue has reduced the need for postoperative factor replacement (Kavakli, 1999).

## Other Hereditary Coagulation Factor Deficiencies

### Overview

Von Willebrand disease (vWD), the most common hereditary bleeding disorder, found in up to 1% of the general population (Rodeghiero et al, 1987), only rarely manifests during infancy, because of elevated levels of vWF after birth with an increased proportion of high-molecular-weight multimers.

Severe deficiencies of prothrombin, FV, FVII, FX, FXI, fibrinogen, FXIII,  $\alpha_2$ AP, and PAI all can manifest with bleeding in the first days of life in otherwise healthy infants. However, the severe forms of these disorders are rare, and their prevalence ranges from 1/500,000 to 1/1,000,000 (Peyvandi and Mannucci, 1999). Deficiencies of FXII, high-molecular-weight kallikrein (HMWK), and prekallikrein generally are not associated with bleeding.

Inheritance of vWD usually follows an autosomal dominant pattern, although autosomal recessive cases have been reported. Hereditary deficiencies of prothrombin, FV, FVII, FX, FXI, FXIII, fibrinogen, and  $\alpha_2$ AP are inherited in an autosomal recessive fashion, and consanguinity often is found in affected families.

### Clinical Presentation

Von Willebrand disease does not usually present in the neonatal period. However, there are rare reports of ICH, thrombocytopenia, and soft tissue bleeds in newborns with

vWD type II or III (Bignell et al, 1990; Donner et al, 1987; Gazengel et al, 1988).

Bleeding symptoms in hereditary deficiencies of prothrombin, FV, FVII, FX, FXI, FXIII, fibrinogen, and  $\alpha_2$ AP generally appear to be less severe than those of hemophilia A and B. There are no specific bleeding manifestations typical for a single disorder. Bleeding from the umbilical stump, previously thought to be typical of inherited defects of fibrin formation (FXIII deficiency and afibrinogenemia), has recently also been described in deficiencies of prothrombin, FV, and FX (Peyvandi and Mannucci, 1999).

### Diagnosis

Diagnosis of vWD in newborns may be difficult owing to the increased proportion of high-molecular-weight multimers. However, those forms of vWD that may manifest in the neonatal period, such as type IIB or type III, should not pose any diagnostic difficulties, as vWF levels and multimeric structure are clearly departed from normal. In cases with known mutations, DNA analysis may be used to ascertain the diagnosis (Mannhalter et al, 1991).

Homozygous forms of FV, FVII, and FXIII deficiency result in factor levels that are easily distinguishable from normal values for newborns. By contrast, in homozygous deficiencies of prothrombin, FX, and FXI, there may be an overlap between the plasma concentrations of the respective factors and neonatal physiologic values.

### Treatment

Treatment of hereditary hemorrhagic disorders is aimed at increasing plasma concentrations of the deficient coagulation protein to a minimal hemostatic level when a newborn is bleeding or a hemostatic challenge is planned. The minimal hemostatic plasma concentration of a particular coagulation protein varies and is dependent on the protein and the nature of the hemostatic challenge. Specific replacement therapy is available for deficiencies of FVII, FXI, FXIII, and fibrinogen and for vWD. Nonspecific treatment modalities comprise FFP, cryoprecipitate, and antifibrinolytics.

## Acquired Hemorrhagic Disorders

### Vitamin K Deficiency

The discovery of vitamin K and its important role in hemostasis was intertwined with the role of vitamin K in the treatment and subsequent prevention of hemorrhagic disease of the newborn (HDN). This term was coined in 1894 by Townsend, who first described the picture of bleeding from multiple sites in otherwise healthy infants in the absence of trauma, asphyxia, or infection on days 1 to 5 of life. The link between vitamin K deficiency and spontaneous hemorrhage was first reported in 1929. Recognition of the association between vitamin K deficiency and HDN quickly followed, with subsequent treatment of infants with HDN. Replacement of the original term *hemorrhagic disease of the newborn* with *vitamin K deficiency bleeding* (VKDB) has been suggested, because the former entity included many infants with bleeding from other causes (Sutor et al, 1999).

### Clinical Presentation

Generally, infants are at greater risk for VKDB than are similarly affected adults, because plasma concentrations of vitamin K–dependent factors are physiologically decreased. Breast-fed infants are at higher risk owing to the low vitamin K content of breast milk. The clinical presentation of VKDB can be classified into three patterns—early, classic, late—based on the timing and type of complications.

The *early* form of VKDB manifests in the first 24 hours of life and is almost exclusively linked to maternal use of specific medications that interfere with vitamin K stores or function. These medications include anticonvulsants (carbamazepine, phenytoin, and barbiturates), antibiotics (cephalosporins), tuberculostatic agents (rifampicin, isoniazid), and vitamin K antagonists (Sutor et al, 1999). The *classic* form of VKDB manifests on days 2 to 7 of life in breast-fed, healthy full-term infants. Etiologic factors include poor placental transfer of vitamin K, marginal vitamin K content in breast milk, delayed or inadequate feeding, malabsorption, and a sterile gut. VKDB rarely occurs in formula-fed infants because formula has a higher content of vitamin K ( $>50 \mu\text{g/L}$ ) than that of breast milk ( $<5 \mu\text{g/L}$ ) (Greer et al, 1991). In the absence of prophylactic vitamin K, the frequency of classic VKDB ranges from 0.25% to 1.7% (American Academy of Pediatrics, 1993). Common bleeding sites are the gastrointestinal tract, the umbilical stump, venipuncture or heel prick sites, and circumcision wounds. Intracranial hemorrhage is infrequent in classic VKDB but can cause significant morbidity or death. The *late* form of VKDB manifests between weeks 2 and 8 of life and rarely after 3 months of life. It occurs almost exclusively in breast-fed infants, and boys are affected twice as often as girls (Sutor et al, 1995). A clustering of cases in warmer months has been described (McNinch and Tripp, 1991). The incidence ranges between 4.4/100,000 and 10.5/100,000 births (Von Kries and Hanawa, 1993). Late VKDB is mostly secondary to disorders that compromise the supply of vitamin K, such as biliary atresia or other hepatobiliary diseases (Loughnan and McDougall, 1993). Warning signs are rare in the idiopathic forms, but infants with underlying hepatobiliary diseases may show prolonged jaundice, minor bleedings, failure to thrive, and vomiting.

On rare occasions, deficiency of vitamin K–dependent coagulation factors is due to a genetic defect of vitamin K metabolism (Oldenburg et al, 2000). Affected patients may present with bleeding in the intrauterine or early neonatal period.

### Laboratory Diagnosis

Deficiency of vitamin K leads to decreased activity of vitamin K–dependent coagulation factors (II, VII, IX, X); vitamin K–independent factors are in the normal range. Accordingly, a clearly prolonged PT (international normalized ratio [INR]  $>3.5$ ) in the presence of normal fibrinogen concentration and platelet count is highly suggestive of vitamin K deficiency. Rapid normalization of these values within 30 to 120 min after parenteral vitamin K administration is diagnostic of vitamin K deficiency (Sutor et al, 1999). Patients with vitamin K deficiency produce decarboxylated forms of the vitamin K–dependent factors (PIVKAs [proteins induced in vitamin K absence]). PIVKA-II has

a half-life of up to 70 hours (Shapiro et al, 1986) and thus can be measured even after vitamin K therapy and normalization of the PT. The most common conditions that need to be excluded are liver disease and DIC. Children with liver disease usually also have deficiencies of vitamin K-independent coagulation factors, such as fibrinogen, FV, FVIII, or AT. Infants with DIC generally are severely ill and show deficiencies of all coagulation factors, a low platelet count, and elevated levels of fibrin degradation products. Hereditary coagulation factor deficiencies can be excluded by single factor analysis. Common to all these conditions is the lack of normalization of the PT after vitamin K administration.

### Prophylactic Vitamin K Administration

Several studies have unequivocally demonstrated that prophylactic administration of vitamin K to newborns is effective in reducing the incidence of VKDB. Two major randomized controlled trials that assessed the benefits of vitamin K prophylaxis using clinical bleeding as the outcome measure showed a significantly positive result for prophylactic (intramuscular) vitamin K administration (Sutherland and Glueck, 1967; Vietti et al, 1960). In addition, biochemical evidence of vitamin K deficiency has been found in infants who did not receive vitamin K at birth (Motohara et al, 1985). Population-based studies show that VKDB rarely occurs when vitamin K prophylaxis is used, but it does occur when prophylactic vitamin K is withdrawn (McNinch and Tripp, 1991). Methods for prophylaxis of vitamin K deficiency vary in different parts of the world; regimens consist of either a single intramuscular dose of 1 mg or an oral dose of 2 to 4 mg at birth, with two or multiple subsequent doses during the first 6 to 12 weeks of life. Both routes are effective in preventing classic VKDB (Von Kries and Hanawa, 1993). However, no randomized clinical trial has assessed the efficacy of these regimens for the prevention of late VKDB. Available evidence suggests that a single dose (1.0 mg) of vitamin K given intramuscularly after birth appears to be effective in preventing virtually all cases of late VKDB (Von Kries and Hanawa, 1993). Disadvantages of intramuscular vitamin K prophylaxis are local trauma (such as nerve or vessel injury, osteomyelitis, or abscesses), poor acceptance by parents, and relatively high cost. Other concerns are the high blood levels of vitamin K after intramuscular injection (McNinch et al, 1985) and the potentially elevated risk of cancer (see later on). Use of the oral route of administration of vitamin K is less expensive and less traumatic than use of the intramuscular route. A disadvantage is the unreliable intake due to regurgitation or malabsorption. As oral vitamin K lacks the depot effect of the intramuscular preparation, the duration of effect of a single dose is comparatively short. Accordingly, oral vitamin K is not as effective as intramuscular vitamin K in the prevention of late vitamin K deficiency. Strategies to improve the efficacy of oral vitamin K and to prevent late VKDB include the use of a new mixed-micellar water-soluble vitamin K formulation, repeated administration of oral vitamin K at single doses of 2 mg, and continuous low-dose vitamin K supplementation (1 mg weekly or 25 µg daily) (Cornelissen et al,

1993; Hansen and Ebbesen, 1996; Schubiger et al, 1999; Von Kries et al, 1999). The last regimen seems to be as effective as the intramuscular preparation in the prevention of late VKDB but requires appropriate compliance and may not protect infants with cholestatic liver disease from late VKDB.

In small preterm infants, the first dose of vitamin K often is given as an intravenous bolus. No evidence-based recommendations on the appropriate dose are available. A recent study showed that the intravenous administration of 0.2-0.4 mg/kg vitamin K results in vitamin K plasma levels comparable to those after intramuscular injection (Raith et al, 2000). Vitamin K plasma concentrations remained well above the critical level below which bleeding manifestations can be anticipated (Stoekel et al, 1996) for at least 1 week. As a single dose of intravenous vitamin K provides no protection from late VKDB (Loughnan et al, 1996), subsequent oral or intravenous doses must be given. In preterm infants who received a single intramuscular injection of vitamin K at birth, plasma concentrations of vitamin K at 2 and 6 weeks of life were higher than those in formula-fed term infants, probably as a result of a high vitamin K intake through parenteral nutrition (Kumar et al, 2001).

Pregnant women receiving oral anticonvulsant therapy should be given about 10 to 20 mg/day of vitamin K orally for 15 to 30 days before delivery to prevent overt vitamin K deficiency in their infants at birth (Cornelissen et al, 1993).

### Vitamin K and Childhood Cancer

In 1990, an unexpected association between childhood cancer and prophylactic vitamin K was reported by Golding and colleagues (1990). A case-control study by the same investigators found a significant association between intramuscular vitamin K and cancer when compared with no vitamin K or oral vitamin K (Golding et al, 1992). Subsequently, several studies have investigated that association. Although taken as a whole these studies failed to establish a significant link between intramuscular vitamin K and childhood cancer (Ross and Davies, 2000), a minimal residual risk cannot be excluded (Parker et al, 1998).

### Treatment of Vitamin K Deficiency

An infant suspected of having VKDB should be treated immediately with vitamin K pending laboratory confirmation. Vitamin K should not be given intramuscularly to infants with VKDB, because large hematomas may form at the site of the injection. The absorption of subcutaneous vitamin K is rapid, and its effect is only slightly slower than systematically administered vitamin K. Intravenous vitamin K should be given slowly because it may induce an anaphylactoid reaction. Infants with major bleeding secondary to vitamin K deficiency also should be treated with plasma products to rapidly increase levels of vitamin K-dependent proteins. Plasma is the product of choice for treatment of a non-life-threatening hemorrhagic event; prothrombin complex concentrate (PCC) at a minimum dose of 50 U/kg should be given for life-threatening bleeding.

## Disseminated Intravascular Coagulation

### Etiology

DIC is not a primary diagnosis but a secondary process related to a variety of primary disease states. Common etiologic disorders in the neonatal period include asphyxia, shock, infection, RDS, necrotizing enterocolitis (NEC), and meconium aspiration syndrome. Rare causes are hypothermia, hemolytic disorders, and hemangiomas. The pathogenic mechanism of DIC is an inappropriate, systemic activation of coagulation with the resultant generation of excess thrombin and decreased generation of anticoagulant factors such as AT, protein C, and protein S. These changes lead to diffuse intravascular thrombus formation (from which the term *disseminated intravascular coagulation* historically originated) and consumption of coagulation factors and platelets. The simultaneous inhibition of the fibrinolytic pathway due to increased concentrations of PAI-1 prevents removal of fibrin from small vessels, leading to extensive thrombosis and organ failure. The consumption of platelets and coagulation factors may in turn cause severe, diffuse hemorrhage (Levi and ten Cate, 1999).

### Clinical Presentation

Unlike bleeding due to vitamin K deficiency or inherited factor deficiencies, DIC occurs in sick infants, most commonly premature infants. Intensity and duration of activation of the hemostatic system, degree of impaired blood flow, and liver function all influence the clinical severity of DIC. Some infants with laboratory evidence of DIC may show little or no clinical signs, whereas those clinically affected usually present with multiorgan failure and/or bleeding from multiple sites. Common bleeding manifestations include oozing from mucous membranes or sites of invasive procedures, hematuria, pulmonary hemorrhage, bruising, and in some cases ICH.

### Laboratory Diagnosis

The diagnosis of DIC is based on compatible clinical features in conjunction with abnormalities of specific coagulation tests. Laboratory findings in severe DIC are characterized by prolonged PT and APTT, depletion of certain coagulation factors (fibrinogen, FV, FVIII), increased fibrin degradation products, thrombocytopenia, and a microangiopathic hemolytic anemia with schistocyte formation. Yet diagnosis of DIC in the newborn is difficult, and no clear-cut diagnostic criteria are available. The diagnostic difficulties are due to an overlap of physiologic and pathologic values for several procoagulant and anticoagulant factors, physiologically elevated markers of thrombin formation and fibrinolysis, and the limited blood volume available for diagnostic workup. In practice, no single laboratory test can be used to confirm or exclude DIC. Although abnormal global coagulation tests strongly support the diagnosis of DIC, normal results do not rule out activation of the coagulation and fibrinolytic system (Schmidt et al, 1993). The availability of sensitive markers for endogenous thrombin and plasmin generation has complicated the diagnosis of DIC in newborns. For example, plasma concentrations of thrombin-AT complexes are increased in the first hours of postnatal life in

healthy infants (Knofler et al, 1998a), reflecting activation of the coagulation system during birth. Positive results for these sensitive paracoagulation tests thus do not necessarily indicate the presence of DIC or the need to intervene. On the other hand, D-dimer levels may be normal if fibrinolytic activity is suppressed by elevated PAI-1 levels, a common finding in newborns, even in the absence of sepsis (Andrew et al, 1990b).

### Treatment

The cornerstone of management of DIC remains the successful treatment of the underlying problem. The decision to treat the hemostatic disorder is often difficult to make. In the absence of clinical manifestations, newborns probably do not require therapy for the hemostatic disorder itself. In the presence of clinically significant bleeding, therapeutic intervention with plasma products is indicated and often improves hemostasis. For infants between these two ends of the spectrum, treatment is dictated by the severity of the hemostatic impairment and the underlying problem. In general, the more pronounced the laboratory abnormalities, the greater the risk of bleeding or thrombotic complications. The argument that replacement therapy may “fuel the fire” is theoretical, and this association has not been proved. Therapeutic interventions in neonates with DIC include administration of FFP, cryoprecipitate, factor concentrates, and anticoagulants and exchange transfusions. Unfortunately, no recent clinical studies on replacement therapy in newborns with DIC are available to permit strong recommendations to be made. The following discussion provides a brief overview of the currently used treatment modalities for neonatal DIC.

The most extensively used treatment is administration of FFP, which contains adult concentrations of all the coagulation proteins. The major drawback is that the large volumes of FFP required to achieve sufficient concentrations of coagulation factors may result in fluid overload. Potential adverse effects include viral transmission and graft-versus-host disease. Cryoprecipitate provides high concentrations of fibrinogen and FVIII, two proteins that are frequently depleted in DIC. Prothrombin complex concentrates have been used in newborns but generally are not recommended because of the potential thrombotic and infectious side effects (Roddie et al, 1999). Exchange transfusions occasionally are used in severe DIC, but their effects are transient unless the underlying problem resolves.

The rationale for use of heparin in the treatment of DIC is to reduce the generation of excess thrombin in the early stages of DIC. Heparin treatment has to be initiated prior to microthrombus formation to provide at least a theoretical benefit. Efficacy of heparin treatment also depends on the AT-prothrombin ratio, which may be low in neonatal sepsis, resulting in a reduced heparin sensitivity. To date, no evidence is available to support the use of heparin for infants with DIC.

The observation that plasma concentrations of the coagulation inhibitors AT and protein C are decreased during DIC provides the rationale for the use of AT and protein C concentrates in these patients. So far, only two small uncontrolled studies have investigated the use of AT and/or protein C concentrates in newborns with DIC (Kreuz et al, 1999; Nowak-Gottl et al, 1992). Both studies

showed 100% survival, effective treatment of purpura fulminans, and marked improvement in laboratory parameters. However, a carefully designed randomized controlled trial of AT substitution in newborns with RDS reported a trend toward higher bleeding rates and increased mortality in the AT-treated group (Schmidt et al, 1998). On the basis of the data available, treatment with AT and protein C concentrates currently cannot be recommended for routine use. Well-designed controlled trials are required to determine the safety and efficacy of AT and protein C concentrates in neonatal DIC. In the absence of definitive clinical trials, reasonable goals in the treatment of DIC are to maintain platelet counts above  $50 \times 10^9$  /L, fibrinogen concentrations over 1.0 g/L, and PT values at normal levels for postnatal and gestational ages.

### Liver Disease

The coagulopathies of liver disease in newborns are similar to those in adults and reflect the failure of hepatic synthetic functions superimposed on a physiologic immaturity, activation of the coagulation and fibrinolytic systems, poor clearance of activated coagulation factors, loss of hemostatic proteins into ascitic fluid, and splenic sequestration of platelets. Some of the common pathologic causes of hepatic dysfunction in newborns are viral hepatitis, hypoxia, total parenteral nutrition, biliary atresia, congenital heart disease with low cardiac output, inherited metabolic disorders, shock, and fetal hydrops. The clinical presentation is variable and usually depends on the underlying disorder. Symptoms include ecchymosis and petechiae, mucous membrane bleeding, hemorrhage from gastrointestinal varices or into the abdomen, and ICH. Laboratory abnormalities in newborns with liver failure include prolongation of PT and APTT, thrombocytopenia, and a prolonged bleeding time. Plasma concentrations of FV, FVII, fibrinogen, AT, and plasminogen are decreased; fibrin degradation products and D-dimer are frequently increased. Normal levels of FVIII, reflecting significant extrahepatic synthesis, can help distinguish severe liver disease from DIC. The etiology of thrombocytopenia and platelet dysfunction is multifactorial and includes impaired platelet production, inappropriate platelet activation and degranulation, splenic sequestration, and accelerated clearance. Patients with clinical bleeding may benefit temporarily from replacement of coagulation proteins with FFP, cryoprecipitate, and platelet transfusion. However, without recovery of hepatic function, replacement therapy is futile. Vitamin K should be administered to infants in whom cholestatic liver disease is suspected. Prothrombin complex concentrate should be avoided in newborns owing to the high risk of transmitting hepatitis and the risk of thrombotic disease, especially in patients with liver disease (Roddie et al, 1999). No data are available to support a role for AT concentrates in treatment of neonatal liver disease.

### Intraventricular Hemorrhage

Intraventricular hemorrhage (IVH) is most commonly seen in premature infants and is characterized by bleeding from the fragile microvasculature of the subependymal

germinal matrix, which may extend into the lateral ventricles. Intraventricular hemorrhage is found in about 20% of premature infants with birth weights less than 1500 g and is the major risk factor for long-term neurologic morbidity in this group. A combination of vascular, intravascular, and extravascular factors is operative in the pathogenesis of IVH (Volpe, 2001). The role of hemostasis in this context is controversial. Proposed mechanisms include decreased activities of coagulation factors, thrombocytopenia, platelet dysfunction, and enhanced local fibrinolytic activity (Andrew et al, 1987a; Beverley et al, 1984; Chen and Lorch, 1996; Setzer et al, 1982; Van de Bor et al, 1986). However, lack of uniformity in the results obtained on this topic suggests that its role is merely contributory, if it has any at all. Two studies on the influence of prothrombotic conditions on the incidence of IVH showed conflicting results (Gopel et al, 2001; Petaja et al, 2001).

A number of clinical trials have assessed various hemostatic prevention strategies for IVH and are summarized next.

### Antenatal Vitamin K

Five clinical trials have investigated the effect of antenatal vitamin K (with or without addition of phenobarbital) on plasma activities of vitamin K–dependent coagulation proteins and IVH in premature infants. (Kazzi et al, 1989; Morales et al, 1988; Pomerance et al, 1987; Thorp et al, 1994; Yang et al, 1989). Two reported a benefit, and three did not. The inconsistencies in results and methodologic problems prevent a recommendation for antenatal vitamin K.

### Coagulation Factor/Platelet Replacement

Since 1980, five clinical trials have assessed coagulation factor and platelet replacement in newborns at risk for IVH. Three trials assessed FFP because of the potential contribution to IVH of low plasma concentrations of many coagulation proteins at birth. Two trials failed to show a benefit (Northern Neonatal Nursing Initiative Trial Group, 1996; Wright, 1995), whereas a positive effect was reported in the third but without a placebo control (Beverley et al, 1985). It is possible that the observed beneficial effect was the result not of the increase in plasma concentrations of coagulation proteins but of volume expansion. One trial assessed the effects of FXIII concentrates because of the potential benefit of enhanced fibrin cross-linking (Shirahata et al, 1990). Although this study reported a significant effect, the analysis was performed only on a small subset of infants. In addition, there is no strong biologic rationale for this approach because FXIII levels are well within the adult range at birth. Another trial investigated the effects of platelet concentrates administered to thrombocytopenic premature infants because of the association of thrombocytopenia and IVH (Andrew et al, 1993). No beneficial effect on IVH was shown in this study, which was designed to detect a 25% effect or greater.

### Fibrinolytic or Antifibrinolytic Therapy

One trial assessed the effects of an antifibrinolytic agent, tranexamic acid, because fibrinolytic activity is increased at birth and could contribute to IVH (Hensey et al, 1984). No significant effect was demonstrated.

## Conclusion

At this time, no firm recommendations can be made for any of the intervention modalities discussed because of inconsistent results. Ongoing clinical studies are necessary to test potentially beneficial therapeutic agents within the context of improving clinical care.

## Extracorporeal Membrane Oxygenation

Extracorporeal membrane oxygenation (ECMO) is an increasingly used technique for the treatment of respiratory and/or cardiac failure refractory to conventional forms of therapy. The most common indications for the use of ECMO are meconium aspiration syndrome, congenital diaphragmatic hernia, RDS, pulmonary hypertension, sepsis, and pneumonia. Survival rates depend on the primary diagnosis and range from 55% in congenital heart disease to almost 100% in meconium aspiration syndrome (Bartlett, 1997; Rais-Bahrami and Short, 2000).

During ECMO, gas exchange occurs through a semi-permeable membrane in an extracorporeal circuit driven by a servo-regulated pump. To combat the activation and consumption of platelets and clotting factors by the extracorporeal surfaces, the patient must be systemically heparinized during the ECMO session. Therapeutic heparin levels are usually achieved by using a bolus of 100 U/kg of unfractionated heparin (UFH) followed by a continuous infusion of UFH at a rate of about 25 to 50 U/kg/h. Most centers use the activated clotting time (ACT) to monitor anticoagulation, targeting an ACT two to three times the baseline value (180 to 220 seconds) in noncomplicated cases. The correlation between the ACT and heparin levels in children on extracorporeal circuits is poor, probably as a result of concurrent hemodilution of hemostatic factors and activation of the hemostatic system and platelets (Chan et al, 1997).

The most common reported complication of ECMO with major impact on mortality and long-term morbidity is ICH. The increased risk of bleeding is mostly due to the use of heparin in association with contact-induced platelet and clotting factor consumption (Urlesberger et al, 1996) and platelet dysfunction (Cheung et al, 2000). The alteration of physiologic pulsatile blood flow during venoarterial ECMO impairs cerebral autoregulation (Short et al, 1993), which may further contribute to the development of ICH. The overall incidence of ICH in neonatal ECMO patients is reported at 10% to 20%, with an overall mortality rate of 50% (Bulas et al, 1996; Hardart and Fackler, 1999; Upp et al, 1994). The incidence of ICH is increased in neonates less than 35 weeks of gestational age. Other recognized risk factors for ICH include acidosis, sepsis, coagulopathy, and treatment with epinephrine (Hardart and Fackler, 1999).

## THROMBOEMBOLIC DISORDERS

Improvements in pediatric tertiary care during the last decade have led to a significant increase in the incidence of thromboembolic events (TEs) during childhood. Both the rise in survival rates for previously fatal conditions and the increased use of thrombogenic surfaces such as catheters, ECMO circuits, and cardiopulmonary bypass

circuits account for this phenomenon. Based on the results of national and international pediatric thrombosis registries, it is estimated that more than 50% of TEs in children occur during the neonatal period (Andrew et al, 1994a; Schmidt and Andrew, 1995; van Ommen et al, 2001). The incidence of TE in newborns is approximately 2.4/1000 admissions to the neonatal intensive care unit (NICU) (Schmidt and Andrew, 1995), which is about the same as the incidence of TE in the general adult population (Heit et al, 2001). The single most common risk factor for TE is the presence of a central catheter—a finding in about 80% of affected neonates (Schmidt and Andrew, 1995; van Ommen et al, 2001). Historically, neonatal hemostasis has focused on bleeding disorders only. Clinicians should now be aware of the increased frequency and importance of neonatal thrombosis.

## Hereditary Prothrombotic Disorders

An ever-growing number of established or candidate hereditary risk factors for venous and/or arterial TE have been described. It cannot be stressed enough, however, that acquired risk factors (e.g., central catheters) are significantly more important in relation to neonatal TE than hereditary prothrombotic disorders alone. Hereditary prothrombotic disorders rarely manifest with TE during the neonatal period unless a significant acquired risk factor is present (Martinelli et al, 2000; Sanson et al, 1999; Schmidt and Andrew, 1995; van Ommen et al, 2001). Furthermore, sufficient evidence currently is available for only a few hereditary prothrombotic disorders to link them to neonatal TE. Assessing the attributable risk of a single prothrombotic abnormality for a specific neonatal thromboembolic disorder requires a large case-control study. To date, most studies assessing prothrombotic risk factors in children did not differentiate between neonates and older children, owing to the low incidence of childhood TE. Sometimes it is difficult to ascertain whether a patient has a true hereditary deficiency of an inhibitor protein and not an acquired transient deficiency due to the underlying disorder or the TE itself. Difficulty in diagnosis of a potential inhibitor deficiency may be further compounded by an overlap of neonatal physiologic values and deficiency states. Therefore, testing for prothrombotic conditions should be delayed until the infant reaches 3 months of age, unless the presentation is unusually severe (e.g., purpura fulminans). If a rare hereditary prothrombotic condition such as AT or protein C deficiency is suspected, familial testing may assist in confirmation of the diagnosis. Routine screening for hereditary prothrombotic conditions is not cost effective and probably is not indicated, as TEs develop in only a small minority of neonates with hereditary prothrombotic disorders. In a majority of cases, the risks of long-term continuous prophylaxis starting in the neonatal period probably outweigh the benefits.

### Activated Protein C Resistance/Factor V Leiden Mutation

Activated protein C is a natural anticoagulant that proteolyzes FVa and FVIIIa, thereby inhibiting conversion of prothrombin to thrombin and of FX to FXa, respectively.

In 95% of cases, aPC resistance (aPCR) is caused by a mutation in the FV gene, the FV Leiden mutation. Activated protein C resistance is the single most common hereditary prothrombotic disorder in Caucasians, found in about 5% of the population (Rees et al, 1995). In heterozygous adult carriers, the relative risk for TE is increased sevenfold (van der Meer et al, 1997). This increases to 80-fold in homozygous persons (Rosendaal et al, 1995). Despite its relative frequency, heterozygous or homozygous FV Leiden mutation rarely manifests in the neonatal period (Simioni et al, 1999). When a TE occurs in newborns with the FV Leiden mutation, another prothrombotic disorder or a significant acquired risk factor usually is present (Nowak-Gottl et al, 1996). An increased frequency of FV Leiden has been reported in children with porencephaly (Debus et al, 1998) and with cerebral palsy (Nelson et al, 1998). Testing for aPCR in newborns and infants is hampered by elevated levels of FV and FVIII and a reduced capacity to generate thrombin (Andrew et al, 1990c), which strongly interferes with the test result (Montaruli et al, 1997; Nowak-Gottl et al, 1996). Diagnosis of the FV Leiden mutation by DNA testing is preferable and necessary for definitive diagnosis.

### **Prothrombin Gene Mutation G20210A**

A mutation of the prothrombin gene at position 20210 was recently found to be associated with an increased risk of venous TE in adults (Poort et al, 1996). To date, there is no evidence that either a homozygous or a heterozygous prothrombin gene mutation is a risk factor for neonatal TE.

### **Antithrombin Deficiency**

AT is the major inhibitor of thrombin and other serine proteases such as FXa, FIXa, FXIa, and FXIIa. Persons with heterozygous AT deficiency usually present with venous TE in early adulthood, occurring either spontaneously or in association with relatively minor acquired risk factors for TE (Thaler and Lechner, 1981). The prevalence of AT deficiency in the general population is estimated at 1/600 (Tait et al, 1994).

Several publications have reported on newborns with heterozygous AT deficiency and severe TE. The clinical presentation was variable, reflecting the site of the thrombi. In these case reports, the TEs often were spontaneous, occurred in venous or arterial vessels, and included unusual locations like the brain (Brenner et al, 1988), pulmonary artery (Martin Montaner et al, 1987), aorta (Sanchez et al, 1998), and coronary arteries (Jochmans et al, 1994). Larger cohort studies on childhood TE, however, have failed to identify significant numbers of neonates with AT deficiency (Aschka et al, 1996; Heller et al, 2000). Therefore, the attributable risk of AT deficiency in neonatal TE is likely to be small. Homozygous or compound heterozygous AT deficiency type I manifesting with purpura fulminans and extensive thrombosis has been reported in two siblings born to consanguineous parents (Hakten et al, 1989). Both children died in the neonatal period. Homozygous AT deficiency type II has been described in four newborns and infants

(Chowdhury et al, 1994; Kuhle et al, 2001), all of whom shared the same mutation. Presentation included deep venous thrombosis (DVT) of the leg, pulmonary artery thrombosis, and arterial ischemic stroke in two children. Treatment of newborns and infants with AT deficiency and TE includes anticoagulation with UFH or low-molecular-weight heparin (LMWH) and transfusion of AT concentrates. In the absence of firm data, recommendations on dose and duration of AT replacement cannot be given at this time.

### **Protein C Deficiency**

Protein C is a vitamin K-dependent serine protease produced in the liver. Following activation by thrombin and thrombomodulin, aPC proteolyzes FVa and FVIIIa. Heterozygous deficiency of protein C results in a 10-fold increased risk for TE in adults (Allaart et al, 1993). The prevalence of protein C deficiency in the general population is estimated at 1/200 to 1/300 (Miletich et al, 1987).

### **Heterozygous Protein C Deficiency**

Heterozygous protein C deficiency does not usually manifest with TE during childhood (De Stefano et al, 1994). Some cohort studies, however, suggest that the attributable risk for cerebral TE in children is slightly elevated (Debus et al, 1998; deVeber et al, 1998b; Vielhaber et al, 1998). Two studies in neonates found an elevated attributable risk for abdominal venous thrombosis and arterial ischemic stroke in newborns with protein C deficiency (Gunther et al, 2000; Heller et al, 2000). However, a majority of children had additional, acquired clinical risk factors for TE that unmasked the defect.

### **Homozygous Protein C Deficiency**

Homozygous deficiency of protein C is a rare and life-threatening disorder that usually manifests within hours after birth, but presentation later in childhood has been described.

### **Clinical Presentation**

The classic clinical presentation of homozygous protein C deficiency consists of cerebral and ophthalmic damage that occurred in utero, purpura fulminans within hours or days of birth, and, in rare cases, large-vessel thrombosis. Purpura fulminans is an acute, lethal syndrome of DIC with rapidly progressive hemorrhagic necrosis of the skin due to dermal vascular thrombosis. The skin lesions start as small ecchymotic sites that increase in a radial fashion and become purplish black with bullae and then necrotic and gangrenous. The lesions occur mainly on the extremities but can occur on the buttocks, abdomen, scrotum, and scalp. They also occur at pressure points, at sites of previous punctures, and at previously affected sites (Marlar and Neumann, 1990).

### Diagnosis

The diagnosis of homozygous protein C deficiency usually is unanticipated and is made at the time of the clinical presentation. Prerequisites are the appropriate clinical picture, a protein C level that is usually undetectable, a heterozygous state in the parents, and, ideally, the identification of the molecular defect. The presence of very low levels of protein C in the absence of clinical manifestations and family history cannot be considered diagnostic because physiologic plasma levels can be as low as 0.12 U/mL (Andrew et al, 1988).

### Treatment

Although numerous forms of initial therapy have been used, administration of 10 to 20 mL/kg of FFP every 6 to 12 hours is usually the form of therapy immediately available. Plasma levels of protein C achieved with 10 mL/kg of FFP vary from 15% to 32% at 30 minutes after the infusion and from 4% to 10% at 12 hours (Marlar et al, 1989). If available, protein C concentrates are preferable to FFP, as they are more concentrated and safer in terms of risk of viral transmission. Doses of protein C concentrate have ranged from 20 to 60 U/kg. In one study, a dose of 60 U/kg resulted in peak protein C levels above 0.60 U/mL (Dreyfus et al, 1991). Replacement therapy was continued until all of the clinical lesions resolved, which was usually 6 to 8 weeks. In addition to the clinical course, plasma D-dimer concentrations were useful for monitoring the effectiveness of protein C replacement. Following resolution of skin lesions, long-term oral anticoagulation should be instituted. To avoid skin necrosis when oral anticoagulation therapy is initiated, replacement therapy should be continued until the INR is therapeutic. The therapeutic range for the INR can be individualized to some extent but is usually between 3.0 and 4.5 (Monagle et al, 2001). The risk with oral anticoagulation therapy includes bleeding with high INRs and recurrent purpuric lesions with low INRs. Frequent monitoring of INR values is required to avoid these complications. Recurrence of skin lesions should be treated with FFP or protein C concentrates. Bone development should also be monitored, as long-term warfarin therapy may have a negative effect on bone mineral density (Cheung et al, 2001). Two case reports have described the successful use of subcutaneous protein C administrations at a dose of 250 to 350 U/kg every third day (Minford et al, 1996; Sanz-Rodriguez et al, 1999) in children with homozygous protein C deficiency. Successful prophylactic long-term treatment with LMWH has been described in two sisters with homozygous protein C deficiency and measurable plasma concentrations of protein C (Monagle et al, 1998). Liver transplantation has been performed successfully in one patient with homozygous protein C deficiency (Marlar et al, 1989).

### Protein S Deficiency

Protein S is a vitamin K–dependent protein that functions as a cofactor of aPC by enhancing its proteolytic activity against FVa and FVIIIa. The prevalence of protein S deficiency in the general population is unknown. In persons with heterozygous protein S deficiency, TE usually does not occur before puberty (De Stefano et al, 1994).

To date, there have been no reports of newborns with heterozygous protein S deficiency and TE. Homozygous protein S deficiency and compound heterozygous protein S deficiency have been described in a small number of newborns (Mahasandana et al, 1990b; Marlar and Neumann, 1990; Pegelow et al, 1988). A majority of these presented with purpura fulminans similar to that seen in homozygous protein C deficiency. The plasma concentrations of protein S in those infants who presented with purpura fulminans were less than 1%. Because no protein S concentrates are available, treatment of purpura fulminans secondary to homozygous protein S deficiency requires FFP or cryoprecipitate. A pharmacokinetic study following administration of 10 mL/kg FFP found protein S levels of 23% and 14% at 2 and 24 hours, respectively (Mahasandana et al, 1990a). Long-term treatment strategies are similar to those in homozygous protein C deficiency.

## Acquired Prothrombotic Disorders

### Central Venous Lines

Presence of a central venous line (CVL) is the single most common risk factor associated with TE in newborns (Schmidt and Andrew, 1995; van Ommen et al, 2001). CVLs in newborns are placed either in the upper venous system (jugular or subclavian vein), in the lower venous system (femoral vein), or through peripheral veins into the inferior vena cava (“long lines”). A number of studies have investigated the incidence of CVL-related TE in neonates. The incidence reported ranged from 1% to up to 47% (Abdulla et al, 1990; Hruszkewycz et al, 1991; Mehta et al 1992; Neubauer, 1995; Salonvaara et al, 1999; Tanke et al, 1994), depending on the criterion used for diagnosis (loss of CVL patency versus objective tests), the radiographic test used, the study design, the duration of use, and the patient group studied.

### Clinical Presentation and Diagnosis

Presenting symptoms and signs of CVL-related thrombosis include loss of CVL patency, swelling and discoloration of the affected limb, swelling of the face, pulmonary embolism (PE), chylothorax, and superior vena cava syndrome. In the lower venous system, ultrasound examination is an appropriate first choice for the diagnosis of DVT. In the upper venous system, ultrasound examination has been shown to have poor sensitivity for the diagnosis of DVT because of the lack of compressibility of intrathoracic vessels, obstruction of view by the clavicle, and inability to distinguish flow through large collaterals from the normal venous system (Male et al, 2002). Ultrasound examination may be used to screen for DVT in the upper venous system. However, if findings on the ultrasound study are negative and the infant is symptomatic, venography should be used. Injection of contrast material through the CVL (“lineogram”) enables visualization of thrombi only at the tip of the catheter, not on the vessel wall along the course of the CVL (Chait et al, 2001).

### Prophylaxis of Central Venous Line–Related TE

A recent meta-analysis has shown that prophylactic use of heparin (UFH and LMWH) or heparin-bonded catheters significantly reduces catheter-related DVT and may also

decrease the rate of bacterial colonization (Randolph et al, 1998). However, studies included in this meta-analysis were done mainly in adults and used varying concentrations of UFH and LMWH. Further studies are needed assess the efficacy in children and to determine the most cost-effective regimen.

### Therapy

In the absence of sufficient data, the following options exist for treatment of CVL-related DVT in neonates: (1) short-term anticoagulation, (2) conventional anticoagulation therapy, and (3) close monitoring of the thrombus with objective tests. If anticoagulation is used, the current guidelines (Monagle et al, 2001) recommend a short course (10 to 14 days) of therapeutic doses of UFH or LMWH. Depending on the location and extension of the thrombus, longer courses (3 months) of therapy may be required. The decision to remove a CVL associated with a large-vessel DVT should be individualized. Consideration should be given to anticoagulation therapy before CVL removal, especially in patients with right-to-left shunts.

### Clinical Impact of CVL-Related DVT

Even clinically silent CVL-related DVTs are of clinical importance and require treatment, for a number of reasons. First, evidence suggests that CVL-related DVT is associated with recurrent CVL-related infection (Randolph et al, 1998). Second, CVL-related DVT may cause PE, with potentially fatal results (Monagle et al, 2001). Third, many newborns with CVL have right-to-left shunting, which puts them at risk for embolic stroke. Finally, post-thrombotic syndrome (PTS) is increasingly recognized as a complication of childhood DVT, occurring in about 10% of patients (Monagle et al, 2001).

### Umbilical Venous Catheters

Umbilical venous catheters (UVCs) are placed through the umbilical vein into the inferior vena cava. With appropriate positioning of UVC above the diaphragm, the incidence of portal vein thrombosis was 1.3% in an ultrasound study (Schwartz et al, 1997) and 30% when venography was used (Roy et al, 1997). Comprehensive long-term follow-up data are not available, but case reports have described the development of portal hypertension, splenomegaly, and gastric and esophageal varices following UVC placement (Junker et al, 1976).

### Umbilical Artery Catheters

Umbilical artery catheters (UACs) are used in critically ill newborns for performing arterial blood gas analyses and for continuous monitoring of blood pressure, and to facilitate repeated blood sampling. The tip of the catheter is placed either “high” (between T6 and T10) or “low” (at L3 to L5). A recent meta-analysis found that high positioning of the UAC tip results in longer usability and less complications than with low positioning (Barrington, 2000b). However, there is currently no convincing evidence that the position of the UAC tip influences the incidence of TE. The

incidence for UAC-related TE is reported at about 30% when objective radiographic tests are used for the diagnosis (Boo et al, 1999; Seibert et al, 1987). A majority of UAC-related TEs cause minimal or no symptoms, but up to 5% of patients present with major symptoms of ischemia or organ dysfunction (Caeton and Goetzman, 1985). Ultrasound examination and angiography are used for the diagnosis of UAC-related TE. However, the sensitivity of ultrasonography for the diagnosis of aortic TE remains to be proved.

A continuous infusion of low-dose UFH significantly prolongs the patency of the UAC (Barrington, 2000a). However, a reduction in incidence of TE could not be shown. The effective concentration of UFH in the infusate may be as low as 0.25 U/mL. The association of heparin with intraventricular hemorrhage (IVH) has been assessed in four studies. Two randomized trials showed no difference in rate of IVH between patients receiving UFH and those receiving no UFH (Ankola and Atakent, 1993; Chang et al, 1997). However, both studies lacked sufficient power (i.e., did not have adequate patient numbers) to answer the question. The remaining case-control study and retrospective cohort study reported an increased risk of IVH in association with heparin, with an odds ratio of 3.9 (95% confidence interval [CI] 1.4-11) (Lesko et al, 1986) and 1.96 (95% CI 1.32-2.91) (Malloy and Cutter, 1995), respectively. The limitations of the designs of these two studies make it impossible to determine whether heparin is associated with IVH or is simply a marker of disease severity. Therefore, the evidence associating heparin use and IVH is inconclusive.

## Thromboembolic Complications in Specific Organ Sites

### Pulmonary Embolism

Most reported studies on PE group newborns, infants, and older children together, which necessitates a joint analysis and limits the information available specifically on newborns. Given the fact that in the pediatric population DVT is most prevalent among newborns, there is no reason to assume that PE is less common in this age group. Therefore, data on PE in the following section are extrapolated from children. PE represents the major cause of DVT-associated mortality in children (Monagle et al, 2000). A prospective cohort study reported an incidence of PE of 8.6 cases per 100,000 hospital admissions (Andrew et al, 1994a). However, clinical studies probably underestimate the true incidence of PE in children owing to a decreased index of suspicion and absence of standardized diagnostic techniques. CVL-related thrombi in the upper venous system are the major source for PE in children (Monagle et al, 2000). The incidence of PE in children with CVL was found to be as high as 15% to 30% when objective radiographic tests were used for the diagnosis (Dollery et al, 1994; Massicotte et al, 1998a).

PE often is not diagnosed during life in newborns owing to the subtlety of symptoms, the inability to verbalize symptoms, and the presence of underlying cardiorespiratory problems that may mask PE. Respiratory distress, hemoptysis or bloody tracheal aspirate, cyanosis, acute right-sided heart failure, hypotension, increasing oxygen requirements,

arrhythmias, and pallor all may be linked to neonatal PE. Any unexplained deterioration in a newborn with a CVL should raise the suspicion of PE.

Performance of pulmonary angiography, the gold standard radiographic test for diagnosis of PE, and the more commonly used ventilation-perfusion scan is not always feasible in critically ill neonates. Pulmonary angiography is difficult to perform in neonates, carries a higher rate of complications in critically ill patients, and requires an experienced radiologist. Ventilation-perfusion scans may be difficult to interpret in neonates with underlying cardiorespiratory disorders because of to imbalances in pulmonary blood flow between the right and left lungs, or even within each lung. Accordingly, both tests have not been validated for the diagnosis of PE in neonates. Echocardiography may be used at the bedside for direct imaging of PE in the central pulmonary arteries. Increased right ventricular volume or pressure may provide an indirect index of more peripheral PE (Pollard et al, 1995). If none of these radiographic tests is feasible, searching for the source of the PE by ultrasound examination and venography may give indirect clues to the diagnosis of PE.

Insufficient data are available to make firm recommendations on the treatment of neonatal PE. Current guidelines recommend intravenous treatment with therapeutic doses of UFH (Monagle et al, 2001). In life-threatening situations or after failure of UFH therapy, thrombolytic therapy or embolectomy might be considered.

### Renal Vein Thrombosis

About 80% of childhood cases of renal vein thrombosis (RVT) occur during the neonatal period (Andrew and Brooker, 1996). RVT accounts for approximately 20% to 40% of neonatal TEs, with about half of the patients being preterm infants (Nowak-Gottl et al, 1997; Schmidt and Andrew, 1995). In up to 20% of cases, RVT is bilateral; in 30%, RVT extends into the inferior vena cava (Bokenkamp et al, 2000). Typically, RVT manifests with hematuria, flank mass, and thrombocytopenia. Occasionally, a transient hypertension is observed. In about 10% of cases, an associated adrenal hemorrhage is found on ultrasound examination. Risk factors for RVT in the newborn include asphyxia, shock, congenital heart disease, dehydration, polycythemia (predominantly infants of diabetic mothers), and sepsis. Diagnosis is usually made by ultrasound studies. Mortality and long-term morbidity associated with RVT are considerable (Bokenkamp et al, 2000). The role of antithrombotic therapy in RVT and its impact on outcome remain uncertain (Nuss et al, 1994). In the absence of clinical trials, one approach is to use supportive therapy for unilateral RVT without uremia or extension into the inferior vena cava (IVC). Anticoagulation should be considered for unilateral RVT extending into the IVC or for bilateral RVT because of the risk of PE and renal failure. Thrombolytic therapy should be considered in cases of bilateral RVT and pending renal failure.

### Arterial Ischemic Stroke

About 25% of cases of arterial ischemic stroke during childhood occur in neonates and young infants (deVeber et al,

2000). The incidence of neonatal arterial ischemic stroke based on clinical data is estimated at 1/4000 live births (Estan and Hope, 1997). However, this figure probably is an underestimate, as the diagnosis of arterial ischemic stroke is frequently delayed owing to the subtlety or lack of symptoms, or may be made only at autopsy (Barmada et al, 1979). Arterial ischemic stroke is most commonly found in full-term newborns but has also been described in preterm infants (de Vries et al, 1997). All three major cerebral arteries and their branches may be affected. However, most lesions are diagnosed in the territory of the middle cerebral artery. Some authors have reported a predominance of left-sided lesions. The vascular anatomy of the aortic arch favoring blood flow to the left common carotid artery or regional differences in cerebral metabolism associated with a higher susceptibility to ischemic injury may explain this predilection (Levy et al, 1985; Trauner et al, 1993).

The typical clinical presentation of neonatal arterial ischemic stroke is focal or generalized seizures. A prospective magnetic resonance imaging (MRI) study in a cohort of term newborns with seizures found an arterial ischemic stroke in 50% of the cases (Mercuri et al, 1995). Abnormalities in muscular tone, lethargy, jitteriness, and feeding problems also have been reported as presenting signs.

Acquired risk factors that have been described in association with neonatal arterial ischemic stroke include asphyxia, sepsis, pulmonary hypertension, congenital heart disease, dehydration, and meningitis (deVeber et al, 1997; Klesh et al, 1987; Ment et al, 1986; Pellicer et al, 1992). However, in a majority of cases, no acquired risk factor can be identified (deVeber et al, 1997). The incidence of hereditary prothrombotic disorders reported in neonates with arterial ischemic stroke varies widely, ranging from 10% to 60% of cases (deVeber et al, 1997; Gunther et al, 2000; Mercuri et al, 2001). The strength of the association and the etiologic role of these conditions in arterial ischemic stroke, however, are not well established.

Cranial ultrasound examination in conjunction with transcranial Doppler techniques may be used for bedside screening for neonatal arterial ischemic stroke. However, the sensitivity of ultrasonography is low, and definitive diagnosis should be made by computed tomography (CT) or MRI with angiography (MRA). MRI is preferred to CT, as it has a higher sensitivity for hypoxic-ischemic brain injury in the neonate (Barkovich, 1997).

The role of anticoagulant therapy in neonatal arterial ischemic stroke is uncertain, as there are no controlled trials assessing the benefits and risks of such treatment. In the absence of studies on neonates with arterial ischemic stroke, treatment guidelines are extrapolated from adult studies. The optimal duration of therapy is unknown. Current guidelines recommend a short course (10 to 14 days) of UFH or LMWH at therapeutic doses (Monagle et al, 2001). Because neonates have a low risk of recurrence of arterial ischemic stroke, subsequent long-term treatment with aspirin usually is not necessary.

Published data on the long-term prognosis with neonatal arterial ischemic stroke show a wide range of outcomes, probably reflecting differences in patient population and study design. Large prospective studies have reported a normal outcome in about 30% to 50% of survivors;

the remaining 50% to 70% develop hemiplegia, cerebral palsy, seizures, visual impairment, and/or mental disability (deVeber et al, 2000; Mercuri et al, 2001; Sreenan et al, 2000).

### Sinovenous Thrombosis

A large population-based study has estimated the incidence of childhood sinovenous thrombosis (SVT) at 0.67 case per 100,000 children, with about 50% cases manifesting during the neonatal period (deVeber and Andrew, 2001).

The clinical presentation is subtle and diffuse, includes seizures, lethargy and jitteriness, and may develop gradually over many hours or days. Physical findings comprise a tense fontanel, dilated scalp veins, and, rarely, swelling of the eyelids. Owing to the frequency of diffuse neurologic signs and seizures, a high index of suspicion for SVT is necessary.

Most neonates have one or two risk factors associated with SVT, among which perinatal asphyxia, dehydration, and sepsis are the most frequently encountered. Hereditary prothrombotic disorders are found in about 20% of affected neonates (deVeber and Andrew, 2001; deVeber et al, 1998b).

Doppler ultrasound examination may be used to screen for abnormalities in sinovenous blood flow (Bezinque et al, 1995). However, MRI and MR venography, if available, are the radiographic methods of choice for the definitive diagnosis of SVT and follow-up evaluation. Alternatively, cranial CT can be used, but sensitivity and specificity in neonates are lower than for MRI (deVeber and Andrew, 2001).

Results from adult studies and a cohort study in children suggest that anticoagulant therapy may be useful in neonates with SVT (deVeber et al, 1998a). However, owing to the lack of clinical studies in neonates with SVT, no firm recommendations on treatment can be made. One approach is to treat neonates for 10 to 14 days with therapeutic doses of UFH or LMWH and then reassess the situation (Monagle et al, 2001).

The long-term prognosis for SVT in neonates is not known. The mortality rate has been reported at about 4%. At the age of 2 years, 77% of survivors were found to be neurologically normal. Among those with neurologic defects, motor impairment was present in 80%. The presence of cortical infarctions was a predictor for adverse neurologic outcome. Recurrence of thrombosis occurs in about 8% of neonates (deVeber and Andrew, 2001).

### Anticoagulant and Thrombolytic Therapy

The lack of consensus regarding prophylaxis and treatment of TE in newborns reflects the lack of controlled trials in this area. Recommendations for adult patients provide useful guidelines but may not reflect optimal therapy for newborns due to marked differences in the coagulation system and the distinct etiology and pathogenesis of neonatal TE. Current therapeutic options for TE in newborns include supportive care alone with close observation of the thrombus, UFH or LMWH, oral anticoagulants (OAs), and thrombolytic therapy.

### Unfractionated Heparin

UFH is the most widely used anticoagulant drug in children. The anticoagulant activities of UFH are mediated by catalysis of AT inhibition of thrombin and FXa. Some observations suggest that heparin requirements in newborns will be decreased compared with those in adults. For example, (1) the capacity of plasma from healthy newborns to generate thrombin is both delayed and decreased compared with adults and is similar to that of plasma from adults receiving therapeutic amounts of UFH (Schmidt et al, 1989b); (2) at UFH concentrations in the therapeutic range, the capacity of plasmas from healthy newborns to generate thrombin is barely measurable (Schmidt et al, 1989b); and (3) the amount of clot-bound thrombin is decreased in newborns owing to low plasma concentrations of prothrombin, which probably decreases heparin requirements (Ansell et al, 1995). Other observations suggest that heparin requirements will be increased compared with adults. For example, (1) the clearance of UFH is accelerated in newborns (McDonald et al, 1981); (2) plasma concentrations of AT are decreased to levels frequently less than 0.40 U/mL in premature infants, which may limit the antithrombotic activities of UFH (Vieira et al, 1991); and (3) studies in a newborn piglet model of venous thrombosis have shown that low AT levels limit the anticoagulant and antithrombotic effectiveness of heparin (Schmidt et al, 1988). These findings suggest that the optimal dosing of UFH therapy in newborns probably will differ from that in adults.

### Therapeutic Range

Therapeutic ranges reflect the optimal risk-benefit ratio of anticoagulant therapy with regard to recurrent thrombotic events and bleeding complications. In the absence of clinical trials in newborns, these ranges are extrapolated from adult studies. The therapeutic range for adults is an APTT between 60 and 85 seconds. The APTT should reflect a heparin level by protamine titration of 0.2 to 0.4 U/mL or an anti-Xa level of 0.3 to 0.7 U/mL (Hirsh, 1991). The APTT correctly predicts the heparin level in about 70% of pediatric patients (Andrew et al, 1994b). However, recent data show that this relationship has changed, with about 70% of APTT values not corresponding to anti-Xa levels (unpublished data). The reasons for this finding are unclear. Most likely it reflects a change in the patient populations receiving UFH.

### Dosing

Average doses of heparin required in newborns to achieve adult therapeutic APTT values are bolus doses of 75 to 100 U/kg and maintenance doses of 28 U/kg/hour (Monagle et al, 2001). The duration of heparin therapy required for the treatment of neonatal TE is uncertain. One approach is to treat for 10 to 14 days with UFH alone (Monagle et al, 2001). The thrombus size should be carefully monitored using an objective test to detect any changes. If extension of the thrombus occurs despite anticoagulation therapy, further treatment with heparin (preferably LMWH) or OA should be considered. A nomogram to facilitate appropriate dosing of UFH in newborns is provided in Table 76-5.

TABLE 76-5

**Protocol for Systemic Heparin Administration and Adjustment for Pediatric Patients**

- I. Loading dose: heparin 75 units/kg given IV over 10 minutes.
- II. Initial maintenance dose: 28 units/kg/hour for infants younger than 1 year; 20 units/kg/hour for children older than 1 year.
- III. Adjust heparin to maintain APTT at 60-85 seconds (assuming this reflects an anti-factor Xa level of 0.30-0.70 unit/mL):

APTT (sec)	Bolus (u/kg)	Hold (min)	Rate Change, (%)	Repeat
<50	50	0	+10%	After 4 hr
50-59	0	0	+10%	After 4 hr
60-85	0	0	0	Next day
86-95	0	0	-10%	After 4 hr
96-120	0	30	-10%	After 4 hr
>120	0	60	-15%	After 4 hr

- IV. Obtain blood for APTT 4 hours after administration of the heparin loading dose and 4 hours after every change in the infusion rate.
- V. When APTT values are therapeutic, perform a daily CBC and APTT determination.

APTT, activated partial thromboplastin time; CBC, complete blood count.  
Data from Monagle et al (2001).

**Adverse Effects**

There are three clinically important adverse effects of heparin therapy: major bleeding, osteoporosis, and heparin-induced thrombocytopenia (HIT).

Data from a pediatric cohort study (Andrew et al, 1994b) suggest that major bleeding is an infrequent event in children receiving UFH for the treatment of DVT. However, doses used in this study were lower than those used today and case reports have reported major bleeding events secondary to UFH therapy in children. A recent retrospective study found major bleeding events in 18% of children receiving therapeutic UFH (unpublished data).

Heparin-induced osteoporosis is a known complication of long-term therapy with UFH in adults. There are only three case reports describing heparin-induced osteoporosis in children (Monagle et al, 2001). Long-term data on UFH therapy in a larger group of pediatric patients are not available yet, however. Given the clear association between heparin and osteoporosis in adults, long-term use of heparin in newborns and children should be avoided when possible.

HIT is a serious and relatively common complication of heparin therapy in adults. In the only published case series of newborns with HIT, this complication developed in about 1% of newborns admitted to the NICU during the study period (Spadone, 1996). UFH had been given prophylactically to maintain UAC patency. About 85% of newborns with HIT suffered aortic TE with a mortality rate of 21% (Spadone, 1996). A high index of suspicion is

needed for the diagnosis of neonatal HIT in the setting of low-dose prophylactic UFH and multiple coexisting disorders that can cause thrombocytopenia in critically ill neonates. In the absence of an alternative cause for thrombocytopenia, UFH should be discontinued, and the patient should be evaluated for HIT. Danaparoid may be used if anticoagulation is required (Monagle et al, 2001).

**Low-Molecular-Weight Heparin**

In adults, LMWH has consistently been shown to be as efficacious and safe as UFH for the prevention and treatment of thrombotic complications. In contrast with UFH, the LMWH-AT complex is too small to inhibit thrombin but does retain its activity against FXa. The advantages of LMWH include predictable pharmacokinetics, minimal monitoring, ease of administration, equivalent or decreased risk of bleeding, equal or increased efficacy, and potentially less risk of osteoporosis with long-term use. Although LMWHs are more expensive than UFH, reduction in laboratory testing, nursing hours, intravenous starts, and phlebotomy time results in lower total costs (Massicotte et al, 1996).

**Therapeutic Range**

Therapeutic ranges for LMWH therapy as monitored by the anti-Xa level are extrapolated from adults. The target range is an anti-Xa level of 0.10 to 0.30 U/mL for prophylaxis and 0.50 to 1.0 U/mL for therapy (Monagle et al, 2001). Anti-Xa level determinations are performed 4 hours after a subcutaneous injection.

**Dosing**

Two clinical trials have established doses required to achieve adult therapeutic anti-Xa levels for two LMWHs: enoxaparin (Lovenox, Aventis Pharma, Bridgewater, NJ) and reviparin (Clivarin, Knoll Pharmaceuticals, Germany) (Massicotte et al, 1996, 1999). Peak anti-Xa levels for both preparations occur 4 hours after subcutaneous injection. Newborns have increased dose requirements compared with older children, probably owing to altered pharmacokinetics (Andrew et al, 1989). Dosing requirements and a nomogram to facilitate appropriate dosing of LMWH in newborns are provided in Tables 76-6 and 76-7. The optimal duration of LMWH therapy in the treatment of neonatal TE is uncertain. As with UFH, an initial short course (10 to 14 days) may be used; this may be extended to 3 months if the thrombus size increases (Monagle et al, 2001). If LMWH is used for longer than 3 months, bone density should be monitored to detect heparin-induced osteoporosis.

**Adverse Effects**

The important adverse effects of LMWH are similar to those of UFH but usually are less frequent and less severe. However, in one large study, major bleeding events occurred in 5% of children receiving therapeutic doses of LMWH (Dix et al, 2000). Other studies did not report major bleeds during LMWH treatment in children (Hofmann et al, 2001; Nohe et al, 1999). In addition, there are no reports of heparin-induced osteoporosis or HIT in newborns and infants who received LMWH therapy.

**TABLE 76-6****Dosing for Low-Molecular-Weight Heparins**

<b>Revisparin: Weight-Dependent Dosing</b>	<b>&lt;5 kg</b>	<b>&gt;5 kg</b>
Initial treatment dose	150 u/kg/dose q12h	100 u/kg/dose q12h
Initial prophylactic dose	50 u/kg/dose q12h	30 u/kg/dose q12h
<b>Enoxaparin: Age-Dependent Dosing</b>	<b>&lt;2 mo</b>	<b>&gt;2 mo</b>
Initial treatment dose	1.5 mg/kg/dose q12h	1.0 mg/kg/dose q12h
Initial prophylactic dose	0.75 mg/kg/dose q12h	0.5 mg/kg/dose q12h

Enoxaparin contains 100 anti-factor Xa units/mg.

Data from Monagle et al (2001).

### Oral Anticoagulation

OAs function by reducing plasma concentrations of the vitamin K–dependent proteins. At birth, levels of the vitamin K–dependent proteins are similar to those found in adults receiving therapeutic amounts of OAs. In keeping with this observation, the pattern of thrombin generation in healthy newborns is similar to that in adults receiving warfarin (Massicotte et al, 1998b). In addition, stores of vitamin K are low, and a small number of newborns have evidence of a functional vitamin K deficiency state (Bovill et al, 1993). Therefore, there is a potential risk of hemorrhage from further anticoagulation. OA therapy in newborns and infants is extremely difficult to perform and should be avoided, when possible, during the first year of life. There are, however, exceptions to this rule, such as homozygous protein C and protein S deficiency and presence of prosthetic heart valves.

#### Therapeutic Range and Dose

The optimal therapeutic INR range for newborns is unknown and almost certainly differs from that for adults. Recommendations for OA therapy in adults can be used as

a guideline, with the goal of using the lowest effective dose, which can be individualized to some extent. Maintenance doses for therapeutic amounts of OA are age dependent, with infants having the highest requirements per unit of body weight (0.33 mg/kg) (Streif et al, 1999).

#### Monitoring

Close monitoring of oral anticoagulation in newborns is required to prevent hemorrhagic and recurrent thrombotic complications. Unfortunately, infants have poor venous access as well as poor venous access and frequently complicated medical problems. Weekly or twice-weekly measurements of the INR are often required with frequent dose adjustments (Streif et al, 1999). Reducing or removing vitamin K supplementation of total parenteral nutrition significantly reduces the dose requirements. Most infants requiring OA also require other medications on an intermittent and long-term basis. The effects of dosage changes and the introduction of new medications must be closely supervised. A whole blood monitor has been used with success in the monitoring of OA in infants (Marzinotto et al, 2000). However, these infants were managed in a pediatric anticoagulation clinic with expert staff available at all times.

#### Adverse Effects

The most important adverse effect of OA therapy is bleeding. A large cohort study on warfarin therapy in children found an overall incidence of major bleeding of 0.5% per patient year, which is comparable to that in adults (Streif et al, 1999). The rate of serious bleeding in children who receive OA for prosthetic heart valves is less than 3.2% (Solymar et al, 1991). A recent study suggests that long-term warfarin therapy in young patients may negatively influence bone mineral density (Cheung et al, 2001). Further studies are required to determine the mechanism, impact, and possible prevention of this side effect.

### Thrombolytic Therapy

The action of thrombolytic agents is mediated by converting endogenous plasminogen to plasmin. In the newborn, plasminogen concentrations are reduced to about 50% of adult values (Andrew et al, 1987b). Low plasminogen levels

**TABLE 76-7****Nomogram for Monitoring Revisparin/Enoxaparin Therapy in Pediatric Patients**

<b>Anti-Factor Xa Level</b>	<b>Hold Next Dose?</b>	<b>Dose Change?</b>	<b>Repeat Anti-Factor Xa Level?</b>
<0.35 unit/mL	No	Increase by 25%	4 hours after next dose
0.35-0.49 unit/mL	No	Increase by 10%	4 hours after next dose
0.5-1.0 unit/mL	No	No	Next day, then 1 week later and monthly thereafter while receiving Revisparin-Na treatment (at 4 hours after AM dose)
1.1-1.5 units/mL	No	Decrease by 20%	Before next dose
1.6-2.0 units/mL	3 hours	Decrease by 30%	Before next dose; then 4 hours after next dose
>2.0 units/mL	Until anti-Xa 0.5 unit/mL	Decrease by 40%	Before next dose; if not <0.5 unit/mL, repeat every 12 hours

Data from Monagle et al (2001).

result in an impaired capacity to generate plasmin (Corrigan et al, 1989) and a decreased capacity to lyse fibrin clots in response to thrombolytic drugs (Andrew et al, 1992a). Increasing plasma concentrations of plasminogen with purified plasminogen resulted in fibrin clot lysis that was greater than for adult plasma, probably owing to the decreased levels of  $\alpha_2$ -antiplasmin in newborns' plasma (Andrew et al, 1992a).

### Indications

There are two classes of thrombolytic agents: (1) the nonselective plasminogen activators such as streptokinase (SK) and urokinase (UK) and (2) the more specific fibrin-bound plasminogen activators such as tissue plasminogen activator (tPA) and its recombinant variants. No studies are available comparing the efficacy and safety of these agents *in vivo*. SK is not used in neonates and children because of its potential for allergic reactions and its reduced efficacy at low plasminogen concentrations (Andrew et al, 1992b). UK was widely used in pediatric patients until the Food and Drug Administration (FDA) warning about a potential risk for viral transmission issued in 1999 substantially diminished its popularity (Food and experimental evidence of Drug Administration, 1999). Tissue plasminogen activator has become the thrombolytic agent of choice in newborns and infants for its fibrin specificity, low immunogenicity and experimental evidence of improved clot lysis compared with that achieved with SK and UK (Andrew et al, 1992a). However, the costs for tPA are considerably higher, and no controlled clinical trial has proved its superiority to other thrombolytic agents.

Indications for the use of thrombolytic therapy in infants are (1) to restore patency of blocked central venous or arterial lines and (2) to treat serious thrombotic complications, defined by severe organ or limb impairment. The clinical objective in the latter situation is to remove the clot as quickly and safely as possible. The surgical removal of a clot in a major vessel in infants can be curative; however, it is technically difficult owing to the small size of neonatal vessels and poses a considerable life-threatening risk to affected infants, who often are premature. In the absence of contraindications, the use of thrombolytic agents for these infants is a preferred approach. Contraindications to the use of thrombolytic therapy in newborns include general surgery within the previous 10 days, neurosurgery within the previous 3 weeks, recent history of major bleeding (intracranial, gastrointestinal, or pulmonary), perinatal asphyxia, arterial hypertension, and severe thrombocytopenia.

### Therapeutic Range and Monitoring

There is no therapeutic range for thrombolytic agents. However, a variety of coagulation tests are used to monitor the activities of thrombolytic agents to ensure that a fibrinolytic effect is present. These tests include determination of fibrinogen concentrations, thrombin clotting time, and fibrin/fibrinogen degradation products and D-dimer assay. The clinically most useful test is the fibrinogen level. A commonly used lower limit for fibrinogen level below which FFP or cryoprecipitate should be administered is 100 mg/dL. The APTT is not helpful in the setting of low fibrinogen levels, concomitant heparin use, and fibrin split products (Bovill et al, 1992). Measurement of fibrin degradation products is helpful to determine whether a

fibrinolytic effect is present. When thrombolytic therapy is used, it is advisable, when possible, to correct other concurrent hemostatic problems such as thrombocytopenia and vitamin K deficiency.

### Low-Dose Therapy for Restoring Catheter Patency

SK should not be used to reestablish CVL patency because of the possibility of allergic reactions with repeated doses. UK is no longer used for restoration of CVL patency following the FDA warning about potential infectious hazards with its use. Alteplase (recombinant tPA) appears to be a safe and effective alternative to UK (Choi et al, 2001). The commonly used low-dose guideline for newborns and infants weighing less than 10 kg is to instill 0.5 mg of alteplase diluted in normal saline to a volume required to fill the line and let it dwell for 2 to 4 hours (Monagle et al, 2001).

### Systemic Thrombolytic Therapy

Although more information is available on the use of SK and UK, this section deals with tPA only, which is currently the treatment of choice for systemic thrombolytic therapy in newborns. The recommended regimen is to administer tPA as a continuous infusion (no bolus) at a rate of 0.1 to 0.6 mg/kg/hour for 6 hours (Monagle et al, 2001). Currently, no evidence exists for an advantage of catheter-directed over systemic lysis in terms of efficacy and safety. During or immediately after completion of thrombolytic therapy, UFH at a rate of 10 to 20 U/kg/hour may be administered to prevent reocclusion of the vessel (Monagle et al, 2001). However, currently no data are available showing a beneficial effect of such adjuvant therapy. If an infant does not respond to thrombolytic therapy, replacement of plasminogen through administration of FFP at a dose of 10 to 20 mL/kg may be considered.

### Adverse Effects

The most important adverse effect of thrombolytic therapy is bleeding. Bleeding from sites of invasive procedures is reported in about 10% of newborns and infants receiving thrombolytic therapy. The incidence of major bleeding in this patient group is about 4% (Nowak-Gottl et al, 1999). The incidence of ICH secondary to thrombolytic therapy is age dependent and is highest in preterm infants during the first week of life (Zenz et al, 1997). However, three recent cohort studies with a total number of 37 newborns (10 of whom were younger than 34 weeks of gestational age) receiving tPA did report one case of ICH in a neonate with severe thrombocytopenia (Farnoux et al, 1998; Hartmann et al, 2001; Weiner et al, 1998). In the absence of controlled trials, these data should be regarded with caution, as different protocols for thrombolysis and adjuvant therapy were used in the different studies.

Treatment of mild bleeding secondary to thrombolytic therapy consists of local measures (pressure, topical thrombin preparations), and transfusion of packed red blood cells when necessary. Treatment of major bleeding consists of stopping the thrombolytic therapy and administration of FFP, with consideration of an antifibrinolytic agent.

## PLATELET DISORDERS

### Thrombocytopenia

Healthy newborns and fetuses have platelet counts in the same range as for adults; therefore, a platelet count less than  $150 \times 10^9/L$  is the accepted definition of thrombocytopenia for all infants. Thrombocytopenia is classified as mild ( $100$  to  $150 \times 10^9$  platelets/L), moderate ( $50$  to  $100 \times 10^9/L$ ), or severe ( $<50 \times 10^9/L$ ). The clinical significance of mild thrombocytopenia is unclear. However, it may be indicative of an underlying pathologic process and should be investigated. The reported overall incidence of neonatal thrombocytopenia ranges from 0.7% (Uhrynowska et al, 1997) to 4% (Burrows and Kelton, 1988), depending on the population studied, the definition of thrombocytopenia, and the timing of blood sampling (immediately postnatally versus during the first week of life). This relatively low overall frequency contrasts with a high incidence of thrombocytopenia in infants admitted to the NICU. About 20% to 40% of sick neonates develop thrombocytopenia (Castle et al, 1986; Mehta et al, 1980; Murray and Roberts, 1995). In more than 50% of affected neonates, platelet counts fall below  $100 \times 10^9/L$ , and 20% of neonates have platelet counts less than  $50 \times 10^9/L$  (Castle et al, 1986). The natural history of thrombocytopenia in sick newborns is remarkably consistent. It is present by day 2 of life in 75% of affected infants, reaches a nadir by day 4, and resolves with recovery of the platelet count to more than  $150 \times 10^9/L$  by day 10 of life in nearly 90% of infants (Castle et al, 1986).

### Causes of Thrombocytopenia in the Newborn

A large number of conditions have been associated with thrombocytopenia in the newborn (Table 76–8). A detailed description of each disorder is beyond the scope of this discussion. This section focuses on those conditions that are most frequently encountered.

**Infections.** Thrombocytopenia is a common finding in septic neonates. About 60% of newborns with proven infection become thrombocytopenic, with platelet counts of less than  $100 \times 10^9/L$  (Modanlou and Ortiz, 1981). Responsible mechanisms include immune-mediated platelet destruction, decreased production, and DIC (Murray et al, 1994; Tate et al, 1981). Thrombocytopenia may be found in up to 90% of newborns with NEC, with platelet counts of less than  $50 \times 10^9/L$  in about half of the cases (Hutter et al, 1976). Congenital intrauterine infections of the TORCH group (toxoplasmosis, other infections, rubella, cytomegalovirus infection, herpes simplex) as well as parvovirus B19 infection also may result in neonatal thrombocytopenia (Hohlfeld et al, 1994; Srivastava et al, 1990). The underlying mechanism is probably a mix of diminished production, increased destruction, and sequestration in an enlarged spleen.

**Asphyxia.** Asphyxia has been identified as a major risk factor for neonatal thrombocytopenia (Castle et al, 1986). The most important mechanism responsible is DIC caused by

**TABLE 76–8**

### Causes of Neonatal Thrombocytopenia

#### Decreased Platelet Production

Congenital thrombocytopenias  
 Amegakaryocytic thrombocytopenia  
 Thrombocytopenia-absent radius (TAR) syndrome  
 Amegakaryocytic thrombocytopenia without limb abnormalities  
 Wiskott-Aldrich syndrome  
 Chédiak-Higashi syndrome  
 May-Hegglin anomaly  
 Alport syndrome  
 Fechtner syndrome  
 Trousseau syndrome  
 Mediterranean macrothrombocytopenia  
 Bernard-Soulier syndrome  
 Marrow-infiltrative disorders  
 Congenital leukemia  
 Congenital neuroblastoma  
 Letterer-Siwe disease  
 Osteopetrosis

#### Increased Platelet Destruction

Intravascular coagulation  
 Disseminated (e.g., DIC associated with severe birth asphyxia)  
 Localized (e.g., renal vein thrombosis, necrotizing enterocolitis, maternal eclampsia, HELLP syndrome, Kasabach-Merritt syndrome)

Systemic infections (bacterial, viral, fungal, protozoal)  
 Congenital  
 Acquired  
 Immune-mediated  
 Neonatal alloimmune thrombocytopenia  
 Neonatal autoimmune thrombocytopenia  
 Drug-induced thrombocytopenia (e.g., quinine)  
 Von Willebrand disease (type IIB)

#### Combination of Decreased Production and Increased Destruction

Infection  
 Congenital (e.g., TORCH association)  
 Acquired (e.g., bacterial sepsis)  
 Erythroblastosis fetalis

#### Miscellaneous

Exchange transfusion  
 Extracorporeal membrane oxygenation  
 Polycythemia  
 Chromosomal abnormalities (e.g., Down syndrome)  
 Neonatal cold injury  
 Mechanical ventilation  
 Pulmonary hypertension

DIC, disseminated intravascular coagulation; HELLP, hemolysis, elevated liver enzymes, low platelets; TORCH, toxoplasmosis, other infections, rubella, cytomegalovirus infection, herpes simplex.

Data from Blanchette and Rand ML (1997).

activation of the extrinsic coagulation pathway secondary to the release of tissue factor from damaged tissues.

**Intrauterine Growth Restriction and Pregnancy-Induced Hypertension.** Thrombocytopenia is a common finding in small-for-gestational-age preterm infants and preterm infants born to hypertensive mothers (Burrows and Andrew, 1990; Philip and Tito, 1989). Neutropenia and an increased nucleated red cell count frequently accompany the thrombocytopenia in these patients. The platelet count rarely drops below  $50 \times 10^9/L$  and normalizes by 7 to 10 days of life (Burrows and Andrew, 1990; Murray et al, 1998). The underlying mechanism is not known.

**Hemangiomas.** The presence of giant hemangiomas, or Kasabach-Merritt syndrome, is associated with a local consumptive coagulopathy characterized by hypofibrinogenemia, elevated fibrin degradation products, microangiopathic fragmentation of red blood cells, and thrombocytopenia. The thrombocytopenia is usually severe, with platelet counts less than  $50 \times 10^9/L$ . Treatment options include steroids, surgery, embolization, irradiation, and  $\alpha$ -interferon (IFN) therapy. The last treatment option is relatively contraindicated in the first months of life owing to reports of spastic diplegia in infants who had received IFN (Barlow et al, 1998).

**Chromosomal Abnormalities.** Thrombocytopenia may be a feature of chromosomal abnormalities such as trisomies 13, 18, and 21 and monosomy X (Turner syndrome). A retrospective study of fetal blood samples found thrombocytopenia in 54% of fetuses with trisomy 13, in 87% of fetuses with trisomy 18, and in 7% of fetuses with trisomy 21 (Hohlfeld et al, 1994). With trisomy 21, a transient moderate thrombocytopenia lasting 2 to 3 weeks may be found in 5% to 30% of newborns (Hord et al, 1995; Miller and Cosgriff, 1983).

### Diagnostic Approach to the Thrombocytopenic Newborn

In evaluation of a thrombocytopenic newborn, the general clinical condition of the infant, maternal and perinatal history, age at onset of thrombocytopenia, severity of thrombocytopenia, and the presence of abnormal findings on physical examination are important considerations. A cranial ultrasound examination should be performed in every neonate with severe thrombocytopenia to rule out intracranial bleeding.

#### History and Physical Examination

Simple observation of the clinical appearance of the newborn can have a tremendous impact on further management of thrombocytopenic infants. Whereas infections, asphyxia, and placental insufficiency account for a majority of thrombocytopenias in sick neonates, thrombocytopenia in the apparently healthy neonate is mainly due to transmission of maternal antiplatelet antibodies. An onset during fetal life or in the early neonatal period (i.e., during the first 72 hours) is most often due to maternal factors or perinatal events. A careful history including family bleeding problems, maternal illnesses and medication use, platelet count, outcome of

previous pregnancies, and perinatal events may provide clues to enable correct diagnosis. Common conditions causing early thrombocytopenia are immune thrombocytopenia, preeclampsia, placental insufficiency, congenital infections, asphyxia, and maternal medications. Thrombocytopenia beyond the first 3 days of life is most commonly due to sepsis or NEC. On physical examination, particular attention should be given to the presence of conditions associated with neonatal thrombocytopenia such as dysmorphic features and skeletal abnormalities (thrombocytopenia-absent radii or other dysmorphic syndromes), hemangiomas (Kasabach-Merritt syndrome), and hepatosplenomegaly (congenital infections).

#### Laboratory Evaluation

The first step in the laboratory evaluation of a thrombocytopenic newborn should include a complete blood count with examination of a peripheral blood smear and a coagulation screen. These tests can help to diagnose potentially life-threatening conditions such as infections, DIC, or NEC. The presence of giant platelets, leukocyte inclusions, or very small platelets in the blood smear may indicate the presence of a hereditary hematologic disorder. A platelet count should also be performed on the infant's mother. Other laboratory tests for the evaluation of thrombocytopenic neonates include mean platelet volume determination, reticulated platelet counts, platelet survival study, platelet-associated immunoglobulin G (IgG) assay, and measurement of thrombopoietin levels (Castle et al, 1986; Peterec et al, 1996; Sola et al, 1999a). Although these tests may be helpful in determining the underlying mechanism of the thrombocytopenia (decreased production, increased destruction, or splenic sequestration), they are relatively nonspecific and not readily available and therefore are rarely used in routine clinical practice. Bone marrow biopsies should be performed in cases of persistent thrombocytopenia of unknown origin. A bone marrow biopsy technique suitable for neonates has recently been described (Sola et al, 1999b).

#### Treatment

Currently, platelet transfusions remain the only treatment option for most sick thrombocytopenic infants. In the future, megakaryocytopoietic cytokines such as interleukin-11 or thrombopoietin may provide an alternative form of management for some forms of neonatal thrombocytopenia.

Evidence-based recommendations on what platelet count constitutes an indication for intervention are lacking. However, there is general agreement that in sick preterm infants, the platelet count should be maintained well above  $50 \times 10^9/L$ , especially during the first week of life to reduce the risk of intraventricular hemorrhage (IVH) (Andrew et al, 1987a, 1993; Blanchette and Rand, 1997; Calhoun et al, 2000). The importance of moderate thrombocytopenia in sick premature infants is unclear (Andrew et al, 1993). In one study, maintaining a platelet count over  $150 \times 10^9/L$  with platelet concentrates did not have a beneficial effect on incidence of IVH, although it did reduce requirements for red blood cell transfusions and FFP (Andrew et al, 1993).

Platelet concentrates for newborns should be ideally leukocyte depleted and CMV negative (Blanchette et al, 1995). Usually, 10 to 20 mL/kg is administered. The routine

use of volume-reducing procedures should be avoided when possible because of the potentially negative effects on the platelets (Hume et al, 1997). However, a recent study failed to show an effect of volume reduction on *in vitro* platelet function and *in vivo* platelet recovery (Rand et al, 2001). At 1 hour following transfusion, a platelet count should be performed to assess the response to the platelet concentrate. The life span of transfused platelets varies with the underlying mechanism of thrombocytopenia. Adult studies have shown a mean platelet survival of 5.4 days in patients with decreased platelet production, compared with 2.7 days in patients with increased platelet destruction (Tomer et al, 1991).

### Immune Thrombocytopenia in the Newborn

Immune thrombocytopenia should always be suspected in otherwise healthy infants with isolated severe thrombocytopenia. An IgG antiplatelet autoantibody or alloantibody is produced in mothers and crosses the placenta, causing fetal thrombocytopenia. Because the antibody is not autologous, the thrombocytopenia persists only as long as the maternal IgG antibody remains in the infant's circulation. Normally, this would be several months, because the half-life of IgG is approximately 21 days. Because the antibody binds to platelets, however, its life span is dependent on the life span of the sensitized platelets and therefore may be very short. As a result, neonatal immune thrombocytopenic disorders are usually short-lived but can cause serious bleeding, making the correct diagnosis and management of these disorders all the more important. The differentiation of autoimmune from alloimmune thrombocytopenia is critical, because the management and severity of these disorders are quite different.

### Neonatal Alloimmune Thrombocytopenia

Neonatal alloimmune thrombocytopenia (NAIT) is similar to hemolytic disease of the newborn and neonatal alloimmune neutropenia. All three disorders are caused by maternal IgG alloantibodies that cross the placenta into the fetal circulation, bind to specific cell antigens, and accelerate the removal of the cell type in question from the circulation. Unlike hemolytic disease of the newborn, NAIT may occur with the first pregnancy, as fetal platelets may leak into the maternal circulation, causing sensitization and subsequent production and transmission of antibodies directed against fetal platelets. Mothers of infants with NAIT have normal platelet counts and no bleeding history, although they may have previously delivered thrombocytopenic newborns. Maternal IgG alloantibodies are directed against specific paternally derived antigens on the infant's platelets, which are absent from the mother's platelets. The most frequently implicated alloantigen in the white population is the HPA-1a (PIA<sup>1</sup>) antigen (found in >80% of cases), which is present on the platelets of 98% of the general population. The second most common alloantigen is HPA-5b (Br<sup>a</sup>) (Mueller-Eckhardt et al, 1989). The frequency of platelet antigens differs between ethnic groups. The HPA-1b (PIA<sup>2</sup>) antigen usually is not found in African American and Oriental populations (Mueller-Eckhardt et al, 1994; Ramsey

and Salamon, 1986). Accordingly, NAIT due to HPA-1b incompatibility is virtually unknown in these populations. ABO and human leukocyte antigen (HLA) alloantibodies are infrequent causes of NAIT (Mueller-Eckhardt et al, 1989). One potential explanation is that maternal HLA alloantibodies do not enter the fetal circulation in sufficient quantities because they are absorbed by foreign HLA antigens on the placenta.

### Incidence

The pooled incidence of NAIT derived from five large studies including a total of 40,027 newborns is 0.18% (Blanchette et al, 2000). This incidence is considerably lower than the actual risk based on the frequency of the alloantigens, which is estimated to be about 2.5% for the most prevalent maternal antigen (HPA-1b) implicated (Williamson et al, 1998). There is evidence that one or more immune response genes determine the formation of alloantibodies. For example, women possessing the HLA-DR3 alloantigen have a 140-fold increased risk of forming anti-HPA-1a alloantibodies (Williamson et al, 1998). Alloimmunization against HPA-5b antigen is associated with HLA-DRw6 (Mueller-Eckhardt and Kiefel, 1989).

### Clinical Presentation

The clinical presentation of NAIT is usually severe, isolated thrombocytopenia in a healthy, full-term infant. First-born infants are affected as often as subsequent infants. However, subsequent siblings are invariably as affected as or more affected than the previous sibling. Minor bleeding in the form of petechiae, gastrointestinal tract hemorrhage, hematuria, or hemoptysis is a frequent finding. Of great concern and associated with serious morbidity is the occurrence of ICH in as many as 15% of infants who have symptoms of thrombocytopenia (Mueller-Eckhardt et al, 1989). ICH may occur prenatally as well as postnatally. The severity of bleeding in infants with NAIT may reflect not only the severe thrombocytopenia but also an additional platelet dysfunction caused by antiplatelet alloantibody impairing aggregation through binding to GPIIb/IIIa (van Leeuwen et al, 1984).

### Diagnosis

The diagnosis of NAIT is based on the clinical presentation and the presence of severe thrombocytopenia with a platelet count frequently less than  $10 \times 10^9/L$ . Neonatal alloimmune thrombocytopenia should be confirmed by serologic and/or DNA testing; however, specific therapy should be instituted immediately. Testing can be performed in almost all cases on only the parents of the newborn (Bussel et al, 1991). Serologic testing includes typing of the parents' platelet antigens and testing for the presence of antiplatelet alloantibody in the maternal serum. DNA-based platelet typing, although more expensive, offers several advantages over serologic testing (Bussel, 2001). Determining the paternal zygosity for the implicated alloantigen is important for predicting the risk of recurrence in future pregnancies. Not infrequently, alloantibodies are undetectable in the maternal serum (Mueller-Eckhardt et al, 1989). In such cases, the antibodies may be detected a few weeks or months after delivery (Schabel et al, 1996).

### Prevention

In women who have had a previously affected infant, there is a high probability that all subsequent infants will be affected (Bussel et al, 1997). Because of the risk of ICH in utero, it is important that monitoring for the presence of ICH and therapeutic interventions commence prenatally. However, general agreement on the optimal management strategy is lacking (Bussel et al, 1996). In some centers, cordocentesis with regular platelet transfusions is performed (Murphy et al, 1994). This strategy effectively increases the fetal platelet count but entails a significant risk of complications due to repeated cordocenteses. An alternative, less invasive approach is the intravenous administration of IgG with or without corticosteroids to the mother in the latter part of the pregnancy (Bussel et al, 2001). The relative safety and efficacy of these differing approaches require further clarification. Elective delivery is recommended at the time of fetal maturity to facilitate the postnatal management of the infant (Blanchette et al, 2000). The necessity of cesarean section to prevent ICH has not been proved.

### Treatment

The choice of treatment depends on the severity of the thrombocytopenia. In an affected newborn with a platelet count below  $30 \times 10^9/L$ , transfusion of platelet antigen-negative platelets from the mother or an antigen-negative donor should be given as soon as possible (Blanchette et al, 2000). These platelets can be prepared before delivery if a planned cesarean section is the mode of delivery. Maternal platelets are preferred to matched platelets from an unrelated donor because of their certain compatibility, availability, and safety. Maternal platelets must be washed and centrifuged to remove maternal alloantibody and irradiated to prevent graft-versus-host disease caused by maternal lymphocytes. Random donor platelets should be used in an infant with significant hemorrhage while awaiting maternal platelets. The infusion of random donor platelets may transiently help the bleeding infant, and the lack of a sustained increase in platelet number confirms the diagnosis of NAIT. In those infants with platelet counts between 30 and  $50 \times 10^9/L$ , intravenous IgG in a dose of 1 g/kg/day on two consecutive days may be used to effectively raise the platelet count (Blanchette et al, 2000). IgG is not as rapidly effective as compatible platelets, however. No convincing evidence is available to support the use of corticosteroids or exchange transfusions. Data on the safety of breast-feeding affected infants are sparse, and thus no recommendations can be made (Reese et al, 1994).

### ***Autoimmune Neonatal Thrombocytopenia***

Newborns with thrombocytopenia secondary to maternal autoimmune disorders present with a milder clinical course than that of newborns affected with alloimmune disorders. Usually, the mother has idiopathic thrombocytopenic purpura (ITP), but autoimmune platelet consumption also can be associated with other maternal disorders such as systemic lupus erythematosus, lymphoproliferative disorders, and hyperthyroidism. Serologically, the antibody is directed against antigens common to maternal and neonatal platelets.

Maternal ITP must be distinguished from the mild thrombocytopenia that frequently occurs in healthy pregnant women at term. The latter, referred to as gestational thrombocytopenia, appears to have no adverse effect on either the mothers or their infants and does not necessitate any specific treatment or delivery by cesarean section (Burrows and Kelton, 1993). The overall incidence of thrombocytopenia in the offspring of mothers with ITP is about 15% to 45%. Severe thrombocytopenia is found in about 5% to 15% of newborns of affected mothers (al Mofada et al, 1994; Burrows and Kelton, 1990). The varying results are explained by differing definitions of thrombocytopenia and by differential timing of the blood sampling. The platelet count nadir in neonates born to mothers with ITP occurs not at birth but a few days after birth (Burrows and Kelton, 1990). Therefore, the platelet count should be monitored closely for the first week of life. Maternal platelet counts in mothers with ITP do not predict which infants will be thrombocytopenic. Some women who are “cured” of ITP by splenectomy can still deliver thrombocytopenic babies, whereas other women who are severely thrombocytopenic will not necessarily deliver thrombocytopenic infants. There are no reliable clinical or laboratory predictors of severe thrombocytopenia in the infant except for direct determination of the fetal platelet count by cordocentesis. However, this procedure entails risks (Pielet et al, 1988) that outweigh the relatively infrequent risk of significant bleeding complications in this disorder. A review of 474 cases reported in the literature until 1991 found a 3% incidence for ICH in newborns with moderate to severe thrombocytopenia (Cook et al, 1991). More recent cohort studies did not report any cases of significant bleeding—in particular, no ICH—in affected newborns (al Mofada et al, 1994; Burrows and Kelton, 1990; Sainio et al, 1998).

Given the low risk for the newborn, the pregnant mother should be managed according to her own platelet count and not the hemostatic risk to the infant (Cook et al, 1991). If the woman has had previous uncomplicated deliveries and the obstetrician anticipates no problems, spontaneous vaginal delivery is appropriate. Infants for whom a difficult procedure is anticipated can be delivered by cesarean section, but the evidence indicating that this approach is safer for the fetus is lacking.

Clinically, affected infants present as full term and healthy appearing, with at most mild clinical manifestations of thrombocytopenia in the form of petechiae. These infants usually do not have clinical or laboratory evidence of any other neonatal problems, such as DIC, hepatosplenomegaly, and prematurity. The diagnosis of autoimmune thrombocytopenia in newborns is made predominantly by the clinical presentation of mother and infant as well as the exclusion of other known causes of thrombocytopenia.

Possible therapeutic interventions for affected newborns with autoimmune thrombocytopenia include platelet transfusions, high-dose IgG, and corticosteroids. The effect of platelet transfusions can be anticipated to be very short-lived. Intravenous IgG has been used after delivery and is safe and effective, with in an 80% response rate in the infant when it is used alone or in combination with steroids (Ballin et al, 1988). It is unclear whether the addition of steroids to intravenous IgG is beneficial. Clearly, prospective studies are required to confirm the high rate of

response to intravenous IgG and the beneficial effects of intravenous IgG over other forms of therapy. If the infant is bleeding, platelet transfusions should also be given at doses of 10 to 20 mL/kg. A poor response in platelet count as well as a rapid fall in platelet number supports the diagnosis of autoimmune thrombocytopenia. If the infant does not respond and has evidence of bleeding, adjunctive steroids should be given and intravenous IgG therapy repeated.

### Qualitative Platelet Disorders

Qualitative platelet disorders may be hereditary or acquired. Hereditary disorders of platelet function such as Glanzmann thrombasthenia or Bernard-Soulier syndrome rarely manifest with bleeding in the neonatal period.

Acquired impairment of platelet function in the newborn has been reported to occur in response to maternal and neonatal drugs. Aspirin crosses the placenta and can be detected in fetuses following maternal ingestion. However, the evidence linking maternal analgesic doses of aspirin to clinically important bleeding in newborns is weak (Corby, 1978). Low-dose aspirin appears to be safe for the fetus (Dasari et al, 1998).

Ex vivo studies from newborns receiving inhaled nitric oxide (NO) for the treatment of pulmonary hypertension show a prolonged bleeding time and inhibition of platelet aggregation (Cheung et al, 1998; George et al, 1998). The clinical significance of these findings is uncertain.

Platelet dysfunction also has been reported in infants undergoing ECMO, as well as in infants with congenital heart disease, hyperbilirubinemia, renal failure, or hepatic failure. The extent to which the platelet function defect contributes to clinical bleeding manifestations in these conditions is not known.

### Acknowledgments

Our friend and colleague Dr. Maureen Andrew, who passed away in 2001, was instrumental in completion of the work reported here, and we respectfully dedicate this chapter to her memory.

We thank Dr. Anthony Chan, Dr. Margaret Rand, and Dr. Manuel Carcao for critical review of the manuscript. We also are indebted to Lu Ann Brooker for editing of the manuscript.

Dr. Kuhle gratefully acknowledges the support of the Austrian Science Foundation (FWF), Vienna, Austria, in the form of an Erwin Schrödinger scholarship for his work contributing to this chapter (Project J-2038/2001).

CHAPTER  
 77

## Erythrocyte Disorders in Infancy

William C. Mentzer and Bertil E. Glader

### NORMAL ERYTHROCYTE PHYSIOLOGY IN THE FETUS AND NEWBORN

#### Fetal Erythropoiesis

Fetal erythropoiesis occurs sequentially during embryonic development in three different sites: yolk sac, liver, and bone marrow. The growth factors and cytokines that regulate embryonic hematopoiesis in humans are not yet defined, but animal work suggests that they are different from those that regulate proliferation and differentiation of stem cells in later life (Zon, 1995). Yolk sac formation of red blood cells (RBCs) is maximal between 2 and 10 weeks of gestation. Myeloid, or bone marrow, production of RBCs begins around week 18, and by the 30th week of fetal life, bone marrow is the major erythropoietic organ. At birth, almost all RBCs are produced in the bone marrow, although a low level of hepatic erythropoiesis persists through the first few days of life. Sites of fetal erythropoiesis occasionally are reactivated in older patients with hematologic disorders such as myelofibrosis, aplastic anemia, and severe hemolytic anemia.

RBC production in extrauterine life is controlled in part by erythropoietin, a humoral erythropoietic-stimulating factor (ESF) produced by the kidney. The role of erythropoietin in the developing fetus has not been completely defined. Current thought is that ESF does not influence yolk sac or hepatic erythropoiesis but may partially regulate myeloid RBC production (Finne and Halvorsen, 1972). ESF is detected in fetal blood and amniotic fluid during the last trimester of pregnancy. The concentration of this hormone increases directly with the period of gestation, and thus, erythropoietin levels in term newborns are significantly higher than in premature infants. This difference may reflect some degree of fetal hypoxia during late intrauterine life. Increased ESF titers also are seen in placental dysfunction, fetal anemia, and maternal hypoxia (Finne, 1966). Fetal RBC formation is not influenced by maternal erythropoietin, because transfusion-induced maternal polycythemia (decreased maternal ESF levels) has no effect on fetal erythropoiesis (Jacobson et al, 1959). Maternal nutritional status also is not a significant factor in the regulation of fetal erythropoiesis, because iron, folate, and vitamin B<sub>12</sub> are trapped by the fetus irrespective of maternal stores. Most studies have demonstrated that women with severe iron deficiency bear children with normal total body hemoglobin content (Lanzkowsky, 1961).

Hemoglobin, hematocrit, and RBC count increase throughout fetal life (Table 77-1). Extremely large RBCs (mean corpuscular volume [MCV] of 180 fL) with an increased hemoglobin content (mean corpuscular hemoglobin [MCH] of 60 pg/cell) are produced early in fetal life. The size and hemoglobin content of these cells decrease throughout gestation, but the mean corpuscular hemoglobin concentration (MCHC) does not change significantly. Even at birth, the MCV and MCH are greater than those in older children and adults. Many nucleated RBCs and reticulocytes are present early in gestation, and the percentage of these cells also decreases as the fetus ages.

Hemoglobin production increases markedly during the last trimester of pregnancy. The actual hemoglobin concentration increases, but, more important, body weight, blood volume, and total body hemoglobin triple during this period. Fetal iron accumulation parallels the increase in total body hemoglobin content. The neonatal iron endowment at birth, therefore, is directly related to total body hemoglobin content and length of gestation. Term infants have more iron than premature infants.

#### RBC Physiology at Birth

In utero, the PO<sub>2</sub> in blood delivered to the tissues is only one-third to one-fourth the value in adults. This relative hypoxia may be responsible for the increased content of erythropoietin and signs of active erythropoiesis (nucleated RBCs, increased reticulocytes) seen in newborns at birth. When lungs become the source of oxygen, hemoglobin-oxygen saturation increases to 95% and erythropoiesis decreases. Within 72 hours after birth, erythropoietin is undetectable, nucleated RBCs disappear, and reticulocytes decrease to less than 1%.

The concentration of hemoglobin during the first few hours of life increases to values greater than those in cord blood. This is both a relative increase caused by a reduction in plasma volume (Gairdner et al, 1958) and an absolute increase caused by placental blood transfusion (Usher et al, 1963). The umbilical vein remains patent long after umbilical arteries have constricted, and thus transfusion of placental blood occurs when newborns are placed at a level below the placenta. The placenta contains approximately 100 mL of fetal blood (30% of the infant's blood volume). Approximately 25% of placental blood enters the newborn within 15 seconds of birth, and by 1 minute, 50% is transfused. The time of cord clamping is thus a direct determinant of neonatal blood volume. The blood volume in term infants (mean of 85 mL/kg) varies considerably (50 to 100 mL/kg) because of different degrees of placental transfusion (Usher et al, 1963). These differences are readily apparent when the effects of early versus delayed cord clamping are compared at 72 hours of age: 82.3 mL/kg (early clamping) versus 92.6 mL/kg (delayed clamping). These changes are largely the result of differences in RBC mass (early clamping, 31 mL/kg; delayed clamping, 49 mL/kg). The blood volume in premature infants (89 to 105 mL/kg) is slightly greater than that in term infants, but this difference is due in large part to an increased plasma volume (Usher and Lind, 1965).

TABLE 77-1

## Mean Red Blood Cell (RBC) Values During Gestation

Age (wk)	Hb (g/dL)	Hematocrit (%)	RBC ( $10^6/\text{mm}^3$ )	Mean Corpuscular Volume (fL)	Mean Corpuscular Hb (pg)	Mean Corpuscular Hb Concentration (g/dL)	Nucleated RBCs (% of RBCs)	Reticulocytes (%)	Diameter ( $\mu\text{m}$ )
12	8.0-10.0	33	1.5	180	60	34	5.0-8.0	40	10.5
16	10.0	35	2.0	140	45	33	2.0-4.0	10-25	9.5
20	11.0	37	2.5	135	44	33	1.0	10-20	9.0
24	14.0	40	3.5	123	38	31	1.0	5-10	8.8
28	14.5	45	4.0	120	40	31	0.5	5-10	8.7
34	15.0	47	4.4	118	38	32	0.2	3-10	8.5

Hb, hemoglobin.

Data from Oski FA, Naiman JL: Hematologic Problems in the Newborn, 3rd ed. Philadelphia, WB Saunders, 1982.

The RBC mass in premature infants, expressed in milliliters per kilogram, is the same as in term newborns.

### Fetal and Neonatal Hemoglobin Function

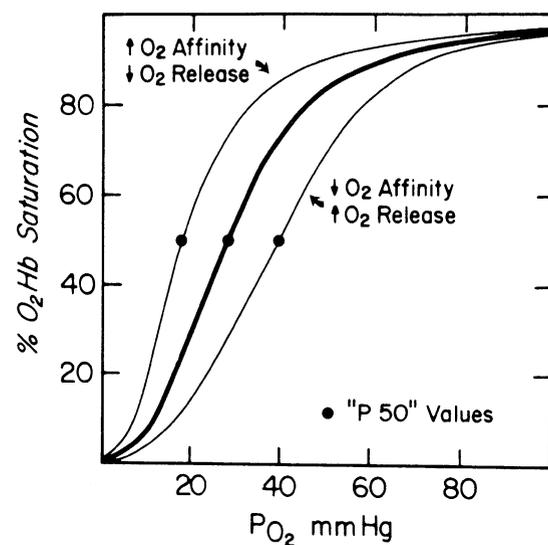

A variety of hemoglobins are present during fetal and neonatal life (see Hemolysis Due to Hemoglobin Disorders). Fetal hemoglobin is the major hemoglobin in utero, whereas hemoglobin A is the normal hemoglobin of extrauterine life. A single RBC may contain both hemoglobin F and hemoglobin A in varying proportions, depending on gestational and postnatal age. One major difference between hemoglobins A and F is related to oxygen transport.

The transport of oxygen to peripheral tissues is regulated by several factors, including blood oxygen capacity, cardiac output, and hemoglobin-oxygen affinity. (1) Oxygen capacity is a direct function of hemoglobin concentration (1 g hemoglobin combines with 1.34 mL oxygen). (2) Compensatory changes in cardiac output can maintain normal  $\text{O}_2$  delivery under conditions in which oxygen capacity is significantly reduced. (3) The oxygen affinity of hemoglobin also influences oxygen delivery to tissues. Hemoglobin A is 95% saturated at arterial oxygen tensions (100 mm Hg), but this decreases to 70% to 75% saturation at a venous  $\text{PO}_2$  of 40 mm Hg. The difference in  $\text{O}_2$  content at arterial and venous oxygen tensions reflects the amount of oxygen that can be released. Changes in hemoglobin affinity for oxygen can influence oxygen delivery (Oski and Delivoria-Papadopoulos, 1970) (Fig. 77-1). At any given  $\text{PO}_2$ , more oxygen is bound to hemoglobin when oxygen affinity is increased. Stated in physiologic terms, increased hemoglobin-oxygen affinity reduces oxygen delivery, whereas decreased hemoglobin-oxygen affinity increases oxygen release to peripheral tissues.

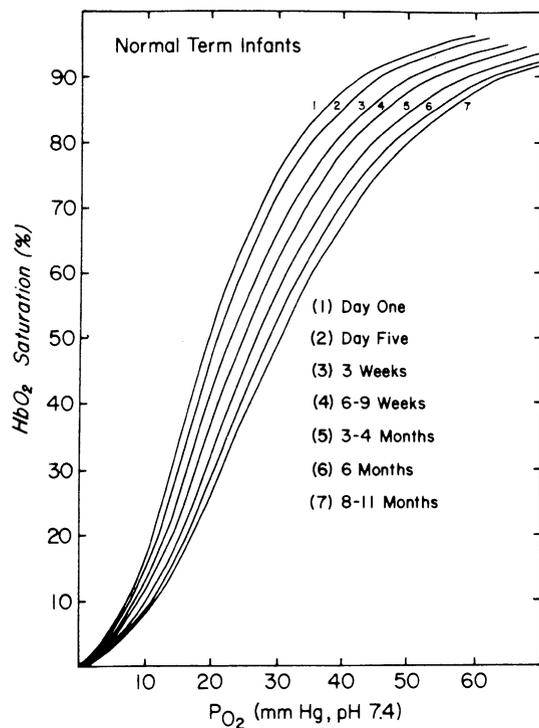

The oxygen affinity of hemoglobin A in solution is greater than that of hemoglobin F. Paradoxically, however, whole blood from normal children (hemoglobin A) has a lower oxygen affinity than that of neonatal blood (hemoglobin F) (Allen et al, 1953). This difference is related to an intermediate of RBC metabolism, 2,3-diphosphoglycerate (2,3-DPG). This organic phosphate compound interacts with hemoglobin A to decrease its affinity for oxygen, thereby enhancing  $\text{O}_2$  release. Fetal hemoglobin does not

interact with 2,3-DPG to any significant extent (Bauer et al, 1968); consequently, cells containing hemoglobin F have a higher oxygen affinity than those containing hemoglobin A.

The increased oxygen affinity of fetal RBCs is advantageous for extracting oxygen from maternal blood within the placenta. A few months after birth, however, infant blood acquires the same oxygen affinity as that of older children (Fig. 77-2). The postnatal decrease in oxygen affinity is due to a reduction in hemoglobin F and an increase in hemoglobin A (which interacts with 2,3-DPG). Oxygen delivery (the difference in arterial and venous  $\text{O}_2$  content) actually increases while oxygen

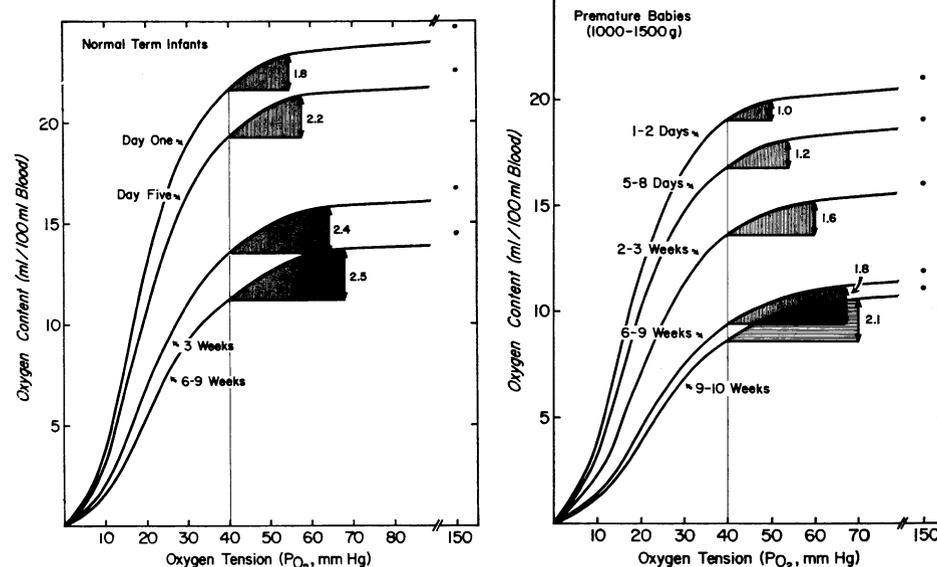

**FIGURE 77-1.** The oxygen dissociation curve for normal adult hemoglobin (dark line). The percent oxygen saturation (ordinate) is plotted for arterial oxygen tensions between 0 and 100 mm Hg (abscissa). As the curve shifts to the right, more oxygen is released at any given  $\text{PO}_2$ . Conversely, as the curve shifts to the left, more oxygen is retained on hemoglobin at any given  $\text{PO}_2$ . The "P 50" refers to that  $\text{PO}_2$  in which hemoglobin is 50% saturated with oxygen. This term is useful in comparing the oxygen affinities of different hemoglobins. (From Oski FA, Delivoria-Papadopoulos M: The red cell, 2,3-diphosphoglycerate, and tissue oxygen release. *J Pediatr* 77:941, 1970.)

**FIGURE 77-2.** The oxygen affinity of blood from term infants at birth and at different postnatal ages. The gradual rightward shift of the oxygen saturation curve indicates increased oxygen release from hemoglobin as infants get older. This decreased oxygen affinity is due to a decrease in hemoglobin F and an increase in hemoglobin A. (From Oski FA, Delivoria-Papadopoulos M: *The red cell, 2,3-diphosphoglycerate, and tissue oxygen release.* *J Pediatr* 77:941, 1970.)

capacity (hemoglobin concentration) decreases during the 1st week of life (Fig. 77-3). This enhanced delivery is largely a reflection of the decreased oxygen affinity of infant blood (Delivoria-Papadopoulos et al, 1971). The oxygen affinity of blood from premature infants is higher

**FIGURE 77-3.** Oxygen delivery in normal term and premature infants. Oxygen content (a function of total hemoglobin) is on the ordinate. Oxygen tension is on the abscissa. Oxygen delivery is measured by the difference in oxygen content at arterial (100 mm Hg) and venous (40 mm Hg) oxygen tensions. For both term and premature infants, oxygen delivery (shaded areas) increases with age. This occurs despite a decrease in oxygen content. (From Delivoria-Papadopoulos M, Roncevic NP, Oski FA: *Postnatal changes in oxygen transport of term, premature, and sick infants: The role of red cell 2,3-diphosphoglycerate and adult hemoglobin.* *Pediatr Res* 5:235, 1971.)

than that of term infants, and the normal postnatal changes (decrease in oxygen affinity, increase in oxygen delivery) occur much more gradually in premature infants (see Fig. 77-3).

## GENERAL APPROACH TO ANEMIC INFANTS

### Medical History and Physical Examination

The cause of anemia frequently can be ascertained by medical history and physical examination. Particular importance is given to family history (anemia, cholelithiasis, unexplained jaundice, splenomegaly), maternal medical history (especially infections), and obstetric history (previous pregnancies, length of gestation, method and difficulty of delivery). The age at which anemia becomes manifest also is of diagnostic importance. Significant anemia at birth invariably is due to blood loss or alloimmune hemolysis. After 24 hours, internal hemorrhages and other causes of hemolysis become evident. Anemia that appears several weeks after birth can be caused by a variety of conditions, including abnormalities in the synthesis of hemoglobin beta chains, hypoplastic RBC disorders, and the physiologic anemia of infancy or prematurity.

Infants with anemia resulting from chronic blood loss may appear pale, without other evidence of clinical distress. Acute blood loss can produce hypovolemic shock and a clinical state similar to severe neonatal asphyxia. Newborns with hemolytic anemia frequently show a greater-than-expected degree of icterus. In addition, hemolysis often is associated with hepatosplenomegaly, and in cases resulting from congenital infection, other stigmata may be present.

### Laboratory Evaluation of Anemia

A simple classification of neonatal anemia based on physical examination and simple laboratory tests is presented in Table 77-2. More esoteric RBC tests are described elsewhere (Alter, 1989).

TABLE 77-2

**Differential Approach to Anemia in the Newborn Period**

Hemoglobin	Reticulocytes	Bilirubin	Coombs Test	Clinical Considerations
Decreased	Normal/decreased	Normal	Negative	Physiologic anemia of infancy and prematurity Hypoplastic anemia
Decreased	Normal/increased	Normal	Negative	Hemorrhagic anemia
Decreased	Normal/increased	Increased	Positive	Immune-mediated hemolysis
Decreased	Normal/increased	Increased	Negative	Acquired or hereditary red blood cell defects Enclosed hemorrhage with resorption of blood Coombs-negative ABO incompatibility

**Red Blood Cell Count, Hemoglobin, Hematocrit, and Red Blood Cell Indices**

RBC values during the neonatal period are more variable than at any other time of life. The diagnosis of anemia must therefore be made in terms of “normal” values appropriate for gestational and postnatal ages. The mean cord blood hemoglobin of healthy term infants ranges between 14 and 20 g/100 mL (Table 77-3). Shortly after birth, however, hemoglobin concentration increases. This increase is both relative (owing to a reduction of plasma volume) and absolute (owing to placental RBC transfusion). Failure of hemoglobin to increase during the first few hours of life may be the initial sign of hemorrhagic anemia. RBC values at the end of the first week are virtually identical with those seen at birth. Anemia during the first week of life is thus defined as any hemoglobin value less than 14 g/100 mL. A significant hemoglobin decrease during this time, although within the normal range, is suggestive of hemorrhage or hemolysis. For example, 14.5 g hemoglobin at 7 days of age is abnormal for a term infant whose hemoglobin was 18.5 g at birth. A slight hemoglobin reduction normally occurs in premature infants during the first week of life. Beyond the first week, however, the hemoglobin concentration decreases in both term and premature infants (see later section, Physiologic Anemia of Infancy and Prematurity).

The electronic equipment currently used for blood counts also gives statistical information regarding erythrocyte size (MCV) and hemoglobin content (MCH). The normal MCV in older children ranges from 75 to 90 fL. MCV values of less than 75 fL are considered microcytic, whereas those over 100 fL indicate macrocytosis. Normal infant RBCs are large (MCV 105 to 125 fL), and not until 8 to 10 weeks of age does cell size approach that in older children. Neonatal microcytosis is defined as an MCV of less than 95 fL at birth. The RBC hemoglobin content of neonatal cells (MCH 35 to 38 pg/cell) is greater than that seen in older children (MCH 30 to 33 pg/cell). Neonatal hypochromia is defined as an MCH of less than 34 pg/cell. Hypochromia and microcytosis generally occur together, and invariably these abnormalities are due to hemoglobin production defects. Neonatal hypochromic microcytosis is seen with iron deficiency (chronic blood loss) and thalassemia disorders (alpha- and gamma-thalassemias).

The site at which blood is obtained is important, because hemoglobin and hematocrit are higher in capillary blood than in simultaneously obtained central venous samples (up to 20%). This difference can be minimized by warming an extremity to obtain “arterialized capillary blood” (Oh and Lind, 1966). In the face of acute hemorrhage, however, central venous samples must be obtained because of marked peripheral vasoconstriction.

TABLE 77-3

**RBC Values in Term and Premature Infants During the First Week of Life**

	Hb (g/100 mL)	Hct (%)	Reticulocytes (%)	Nucleated RBCs (cells/1000 RBCs)
<b>Term</b>				
Cord blood	17.0 (14-20)	53.0 (45-61)	<7	<1.00
Day 1	18.4	58.0	<7	<0.40
Day 3	17.8	55.0	<3	<0.01
Day 7	17.0	54.0	<1	0
<b>Premature (birth weight &lt;1500 g)</b>				
Cord blood	16.0 (13.0-18.5)	49	<10	<3.00
Day 7	14.8	45	<3	<0.01

Hct, hematocrit; Hb, hemoglobin; RBCs, red blood cells.

### Reticulocyte Count

The normal reticulocyte count in children and older infants is 1% to 2% of the circulating red cells. The reticulocyte count in term infants ranges between 3% and 7% at birth, but this decreases to 1% to 3% by 4 days and to less than 1% by 7 days of age (see Table 77-3). In premature infants, reticulocyte values at birth are higher (6% to 10%) and may remain elevated for a longer period of time. Nucleated RBCs are seen in newborn infants, but they generally disappear by the third day of life in term infants and in 7 to 10 days in premature infants. The persistence of reticulocytosis or nucleated RBCs suggests the possibility of hemorrhage or hemolysis. Hypoxia, in the absence of anemia, also can be associated with increased release of reticulocytes and nucleated RBCs.

### Peripheral Blood Smear

Examination of the peripheral blood smear is an invaluable aid in the diagnosis of anemia. In particular, the smear is evaluated for alterations in the size and shape of RBCs as well as abnormalities in leukocytes and platelets. Erythrocytes of older children are approximately the size of a small lymphocyte nucleus, whereas those of newborns are slightly larger. RBC hemoglobinization (e.g., hypochromia) is estimated by observing the area of central pallor, which is one-third the diameter of normal RBCs and more than one-half the diameter of hypochromic cells. Spherocytes are detected by the complete absence of central pallor. The degree of reticulocytosis can be estimated, because these cells are larger and have a bluish coloration.

### Direct Antiglobulin Test

Most cases of neonatal hemolytic anemia are due to isoimmunization. The direct antiglobulin test (DAT), also known as the direct Coombs test, detects the presence of antibody on RBCs or in the plasma (indirect Coombs test). The clinician must search diligently to rule out an alloimmune disorder before embarking on a more wide-ranging (and expensive) workup of hemolysis.

### Blood Transfusions in the Treatment of Anemia

A hemoglobin of 14 g/100 mL corresponds to an RBC mass of 31 mL/kg. Thus, an RBC transfusion of 2 mL/kg will increase the hemoglobin concentration by approximately 1 g/100 mL. Packed RBCs (hematocrit approximately 67%) contain 2 mL of RBCs/3 mL of packed RBCs. Whole blood (hematocrit approximately 33%) contains 2 mL of RBCs/6 mL whole blood. Thus, the transfusion of 3 mL of packed RBCs/kg or 6 mL of whole blood/kg increases hemoglobin concentration by approximately 1 g/100 mL.

Packed RBCs are the product of choice when transfusion is necessary for simple anemia, as occurs in hemolysis. If anemia is accompanied by hypovolemia from acute blood loss, volume expansion must be achieved promptly, using either whole blood or packed RBCs and a colloid

such as 5% serum albumin or plasma protein fraction (infused separately). Because of the reduced availability of whole blood, owing to the demand for its components, the usual choice is packed RBCs and colloid. The previously common practice of reconstituting RBCs with fresh frozen plasma to make "whole blood" is no longer acceptable, because the increased donor exposure increases the risk of transmitting infectious disease. When packed RBCs need to be diluted to facilitate nonurgent transfusion, isotonic saline is the preferred diluent. If exchange transfusion is needed to treat hyperbilirubinemia, the capability of albumin to improve bilirubin binding and removal is ample reason to request whole blood. Although fresh blood less than 2 days old is ideal because there is a reduced risk of hyperkalemia, this is not usually available. An acceptable substitute is packed RBCs less than 4 to 5 days old. These packed RBCs provide adequate oxygen delivery; hyperkalemia can be prevented by washing the RBCs once in saline and then reconstituting with normal saline. Washing is not required for the usually small, simple transfusions of packed RBCs, because the small volume of plasma minimizes any toxic effect of increased concentration of potassium in the plasma.

Blood currently available in most blood banks is anticoagulated with citrate-phosphate-dextrose (CPD), CPD-adenine (CPDA-1), or adenine-saline (AS-3), with a shelf life of 21, 35, or 42 days, respectively. Hematocrit usually ranges between 65% and 80% for packed RBCs. Near-normal 2,3-DPG levels are maintained for up to 12 to 14 days, which is advantageous in transfusing infants with acute hypoxia or those receiving large volumes of blood. Hematocrits range from 55% to 65%, thus facilitating flow during infusion. The newest of these preparations, AS-3, is well tolerated by newborns even after up to 42 days of storage, so long as only small-volume transfusions are given at any one time (Strauss, 2000). Designation of a single AS-3-preserved red cell donation for use by one neonate is an effective way to limit donor exposures and reduce the risk of transfusion-associated infections (Goldman, 2001).

Preterm infants born weighing less than 1250 g are uniquely susceptible to potentially serious cytomegalovirus (CMV) infection from transfused blood, particularly if they lack immunity because their mothers are seronegative. CMV infection can be prevented by using blood products only from seronegative donors (Yeager et al, 1981). Because approximately 40% to 60% of adults are seropositive, this limits the availability of seronegative donors. Reserving seronegative blood for the minority of infants who are seronegative can reduce the demand for such donors. Alternatively, because CMV resides mainly in leukocytes, removal of such cells also can prevent transmission of the virus. Transfusion of frozen thawed, deglycerolized RBCs (Brady et al, 1984) and use of high-efficiency leukocyte depletion filters (Gilbert et al, 1989) have proved effective. Transfusion of conventional saline-washed RBCs is not adequate for prevention of infection, presumably because they contain greater numbers of residual leukocytes (Demmler et al, 1986). A potential disadvantage of using CMV-seronegative blood in CMV-positive infants receiving large amounts of blood is dilution of infant's antibody level, resulting in increased susceptibility

to nursery-acquired CMV infection. Currently, a majority of neonatal services utilize leukocyte-reduced red cell products rather than relying on CMV-negative products to prevent CMV infection (Engelfreit and Reesink, 2001).

Graft-versus-host (GVH) reaction rarely follows transfusion and occurs mainly in certain newborns at risk. For this to occur, viable lymphocytes in cellular blood products must be able to engraft and react against foreign antigens on tissues of the recipient. Infants at risk include those with congenital or acquired defects of cellular immunity, those who as fetuses received intrauterine transfusion of RBCs or platelets, newborns receiving exchange transfusion following intrauterine transfusion (Naiman et al, 1969; Parkman et al, 1974), and infants receiving directed blood donations from first-degree relatives (whose genetic similarity may increase the likelihood of engraftment). Irradiation of RBCs, whole blood, platelets, and granulocytes with a minimum of 1500 rads has proved effective in preventing GVH reaction. Reports of GVH reaction after RBC transfusion in very premature infants without known risk factors (Enoki et al, 1985; Sanders et al, 1989) have prompted most neonatal services to irradiate all RBC blood products (Engelfreit and Reesink, 2001).

### HEMORRHAGIC ANEMIA

Anemia frequently follows fetal blood loss, bleeding from obstetric complications, and internal hemorrhages associated with birth trauma (Table 77-4). Iatrogenic anemia due to repeated removal of blood for laboratory testing is common in premature infants. The clinical presentation of anemia depends on the magnitude and acuteness of blood loss.

Infants with anemia subsequent to moderate hemorrhage or chronic blood loss are generally asymptomatic. The only physical finding is pallor of the skin and mucous membranes. Laboratory studies can range from a mild

normochromic normocytic anemia (hemoglobin 9 to 12 g/100 mL) to a more severe hypochromic microcytic anemia (hemoglobin 5 to 7 g/100 mL). The only therapy required for asymptomatic children is iron (2 mg elemental iron/kg three times a day for 3 months). RBC replacement is indicated only if there is evidence of clinical distress (tachycardia, tachypnea, irritability, feeding difficulties). In most cases, increasing the hemoglobin to 10 to 12 g/100 mL removes all signs and symptoms associated with anemia. Because severely anemic infants are frequently in incipient heart failure, however, these children should be transfused very slowly (2 mL/kg/hour). If signs of congestive heart failure appear, a rapid-acting diuretic (furosemide, 1 mg/kg intravenously) should be given before proceeding with the transfusion. An alternative approach is to administer a partial exchange transfusion with packed RBCs to severely anemic infants. This approach increases the hemoglobin concentration without the danger of increasing blood volume and precipitating congestive heart failure.

A simple formula for the volume of RBCs needed in a partial exchange transfusion to correct severe anemia has been described by Nieburg and Stockman (1977):

$$\begin{aligned} \text{Packed RBC volume needed (mL)} &= \text{body weight (kg)} \\ &\times 75 \text{ mL/kg} \times \text{desired hemoglobin change} \\ &\div [22 \text{ g/dL} - \text{Hb}_w] \end{aligned}$$

where 75 mL/kg approximates the average blood volume and 22 g/dL represents the hemoglobin concentration of packed RBCs. The term  $\text{Hb}_w$  is a reflection of the hemoglobin removed during the exchange transfusion, approximated by  $(\text{initial hemoglobin} + \text{desired hemoglobin})/2$ . For each infusion and withdrawal, syringe volumes up to 5% of the blood volume are well tolerated. For example, in the case of a 3-kg newborn with a hemoglobin of 3 g/dL that needs to be raised to a hemoglobin of 10 g/dL, approximately 100 mL of packed RBCs is needed for the procedure; syringe volumes of 15 mL can be used for each cycle of infusion and withdrawal of blood.

Infants who rapidly lose large volumes of blood appear to be in acute distress (pallor, tachycardia, tachypnea, weak pulses, hypotension, and shock). This presentation is distinct from that seen in neonatal respiratory asphyxia (slow respirations with intercostal retractions, bradycardia, and pallor with cyanosis) (Table 77-5). The clinical response to assisted ventilation and oxygen also is different: Infants with respiratory problems demonstrate a marked improvement, whereas there is little change in anemic newborns. Cyanosis is not a feature of severe anemia because the hemoglobin concentration is too low (clinical cyanosis indicates at least 5 g/100 mL of deoxygenated hemoglobin). The hemoglobin concentration immediately after an acute hemorrhage may be normal, because the initial response to acute volume depletion is vasoconstriction. A decreased hemoglobin may not be seen until the plasma volume has reexpanded several hours later. In view of these hemodynamic considerations, it is apparent that the diagnosis of acute hemorrhagic anemia is based largely on physical findings and evidence of blood loss. It is important to recognize these clinical features because immediate therapy is required. Treatment is directed at rapid expansion of the vascular space (20 mL fluid/kg). This is most quickly

**TABLE 77-4**

#### **Causes of Hemorrhagic Anemia in Newborns**

Fetal hemorrhage
Spontaneous fetomaternal hemorrhage
Hemorrhage following amniocentesis
Twin-twin transfusion
Nuchal cord

Hepatic rupture, splenic rupture
Retroperitoneal hemorrhages

TABLE 77-5

**Comparative Clinical Findings in Neonatal Asphyxia and Acute Hemorrhage**

	Neonatal Asphyxia	Acute Blood Loss
Heart rate	Decreased	Increased
Respiratory rate	Decreased	Increased
Intercostal retractions	Present	Absent
Skin color	Pallor with cyanosis	Pallor without cyanosis
Response to oxygen and assisted ventilation	Marked improvement	No significant change

accomplished by rapid infusion of either isotonic saline or 5% albumin, followed by either type-specific, cross-matched whole blood or packed RBCs resuspended with saline, depending on availability. Fresh frozen plasma, formerly used for reconstituting RBCs, is no longer acceptable because of the risk of transfusion-transmissible infection. In infants in whom anemia and hypoxia are severe, non-cross-matched group O, Rh-negative RBCs are an acceptable alternative to cross-matched RBCs. Infants with hypovolemic shock caused by acute external blood loss usually show marked clinical improvement after this treatment. A poor response is seen in newborns with severe internal hemorrhage.

**Fetal Hemorrhage****Fetomaternal Hemorrhage**

Significant bleeding into the maternal circulation occurs in approximately 8% of all pregnancies and thus represents one of the most common forms of fetal bleeding. Small amounts of fetal blood are lost in most cases, but in 1% of pregnancies, fetal blood loss may exceed 40 mL (Cohen et al, 1964). Fetomaternal hemorrhage occasionally follows amniocentesis and placental injury (Zipursky et al, 1963), although anemia is seen only after unsuccessful amniocentesis or when there is evidence of a bloody tap (Woo Wang et al, 1967). For this reason, infants born to mothers who have had amniocentesis should be observed closely for signs of anemia. The effects of anemia resulting from fetomaternal hemorrhage are variable. Large acute hemorrhages can produce hypovolemic shock (Raye et al, 1970), whereas slower, more chronic blood loss results in hypochromic microcytic anemia resulting from iron deficiency (Pearson and Diamond, 1959). Some infants with severe chronic anemia (hemoglobin as low as 4 to 6 g/100 mL) may have minimal symptoms.

An examination of maternal blood for the presence of fetal cells is necessary in any infant with suspected fetomaternal hemorrhage. Two techniques are available. The Kleihauer-Betke preparation involves examination of a stained specimen of maternal blood by microscopy following differential elution of hemoglobin A but not hemo-

globin F from the red cells. Alternative, flow cytometry-based techniques are probably more accurate but are less widely available and require blood group antigen incompatibility between fetus and mother (Chapman et al, 1999, Fong et al, 2000).

Approximately 50 mL of fetal blood must be lost to produce significant neonatal anemia. This volume is greater than 1% of the maternal blood volume, and therefore fetal cells within the maternal circulation may be detected readily. Tests that depend on the presence of fetal hemoglobin are not valid when a maternal hemoglobinopathy with increased hemoglobin F levels coexists. In addition, fetomaternal ABO incompatibility may cause rapid removal of fetal RBCs, thus obscuring any significant hemorrhage. For this reason, it is important to examine maternal blood as soon as anemia from fetal hemorrhage is suspected. An unusual form of fetal blood loss is presumed to occur in infants born with a nuchal cord. In these cases, anemia is caused by compression of the umbilical vein, preventing placental blood from returning to the fetus (Shepherd et al, 1985).

**Twin-Twin Transfusion**

Transfusion of blood from one monozygous twin to another can result in anemia in the donor twin and polycythemia in the recipient. Significant hemorrhage is seen only in monochorionic monozygous twins (approximately 70% of all monozygous twins). In approximately 15% to 35% of these pregnancies, there is a twin-to-twin transfusion (Rausen et al, 1965; van Gemert et al, 2001). Bleeding occurs because of vascular anastomosis in monochorionic placentas. The anemic donor twin is usually smaller than the polycythemic recipient, with a greater than 20% difference in birth weight. Polyhydramnios is frequently seen in the recipient twin and oligohydramnios is seen in the donor. The high rate of intrauterine mortality (approximately 63% with conservative management) has spurred attempts at fetal therapy, including decompression amniocentesis, laser coagulation of vascular anastomoses, interfetal septal disruptions, and selective feticide (Seng and Rajadurai, 2000; van Gemert et al, 2001). Twin-twin transfusions should be suspected when the hemoglobin concentration of identical twins differs by more than 5 g/100 mL; however, such a difference in hemoglobin concentration does not prove there has been a twin-twin transfusion. Recent studies indicate that this major hemoglobin difference can exist in some dichorionic twins, in whom there are no vascular anastomoses and therefore no possibility for twin-twin transfusion (Danskin and Neilson, 1989).

**Placental Blood Loss**

Placental bleeding during pregnancy is common, but in most cases hemorrhage is from the maternal aspect of the placenta. In placenta previa, however, the thinness of the placenta overlying the cervical os frequently results in fetal blood loss. The vascular communications between multilobular placental lobes also are very fragile and are easily subjected to trauma during delivery. *Vasa previa* is the condition in which one of these connecting vessels

overlies the cervical os and thus is prone to rupture during delivery. *Abruptio placentae* generally causes fetal anoxia and death, although some infants survive but can be severely anemic. Bleeding also follows inadvertent placental incision during cesarean section (Montague and Krevans, 1966), and thus the placenta should be inspected for injury following all cesarean sections.

### Umbilical Cord Bleeding

The normal umbilical cord is resistant to minor trauma and does not bleed. The umbilical cord of dysmature infants, however, is weak and liable to rupture and hemorrhage (Raye et al, 1970). In cases of precipitous delivery, a rapid increase in cord tension can rupture the fetal aspect of the cord, causing serious acute blood loss. Short or entangled umbilical cords and abnormalities of umbilical blood vessels (velamentous insertions into the placenta) are also liable to rupture and hemorrhage. Bleeding from injured umbilical cords is rapid but generally ceases after a short period of time, owing to arterial constriction. The umbilical cord should always be inspected for abnormalities or signs of injury, particularly after unattended, precipitous deliveries.

### Hemorrhage after Delivery

Hemorrhagic anemia due to internal bleeding is occasionally associated with birth trauma. Characteristically, internal hemorrhages are asymptomatic during the first 24 to 48 hours of life, with signs and symptoms of anemia developing after this time. Cephalhematomas can be sufficiently large to cause anemia and hyperbilirubinemia, secondary to the resorption of blood (Leonard and Anthony, 1961). Subgaleal hemorrhages are seen infrequently, sometimes after vacuum extraction used during delivery. These hemorrhages may be extensive because bleeding is not limited by periosteum. Adrenal and kidney hemorrhages occasionally follow difficult breech deliveries. Splenic rupture and hemorrhage occur most commonly in association with splenomegaly, as in erythroblastosis fetalis. Hepatic hemorrhages are generally subcapsular and may be asymptomatic. Rupture of the hepatic capsule results in hemo-peritoneum and hypovolemic shock. Hepatic hemorrhages are suspected when a previously healthy infant goes into shock with clinical manifestations of an increasing right upper quadrant abdominal mass, shifting dullness on percussion, and evidence of free fluid on abdominal radiographs. In contrast with newborns with acute blood loss from fetomaternal or umbilical vessel bleeding, infants with hepatic hemorrhage generally demonstrate a poor clinical response to blood replacement.

### HEMOLYTIC ANEMIA

RBCs from children and adults normally circulate for 100 to 120 days. Erythrocyte survival in newborns is somewhat shorter: 70 to 90 days in term infants, 50 to 80 days in premature infants (Pearson, 1967). Hemolytic anemia, which further shortens RBC survival, may arise for many reasons (Table 77-6). The precise mechanism of cell destruction is

**TABLE 77-6**

#### Causes of Hemolytic Anemia During the Newborn Period

##### Immune Disorders

- Isoimmune: Rh and ABO incompatibility
- Maternal immune disease: autoimmune hemolytic anemia, systemic lupus erythematosus
- Drug-induced: penicillin

##### Acquired Red Blood Cell (RBC) Disorders

- Infection: cytomegalovirus toxoplasmosis, syphilis, bacterial sepsis
- Disseminated and localized intravascular coagulation, respiratory distress syndrome

##### Hereditary RBC Disorders

- Membrane defects: hereditary spherocytosis, hereditary elliptocytosis
- Enzyme abnormalities: glucose-6-phosphate dehydrogenase pyruvate kinase
- Hemoglobinopathies: alpha-thalassemia syndromes, gamma/beta-thalassemia

not always known, although membrane deformability is thought to be an important determinant (LaCelle, 1970). Erythrocytes are 7 to 8  $\mu\text{m}$  wide, whereas the vascular diameter in some areas of the microcirculation may be less than 3  $\mu\text{m}$ . Consequently, RBCs must deform their membranes and intracellular contents in order to pass through these narrow channels. This requirement is no problem for normal RBCs. Abnormalities in RBC metabolism, hemoglobin, or cell shape, however, all lead to decreased RBC membrane deformability. The consequence of this decreased membrane flexibility is RBC sequestration and removal by reticuloendothelial cells of the spleen and liver.

In older infants and children, the usual response to increased RBC destruction is enhanced erythropoiesis, and there may be little or no anemia if the rate of production matches the accelerated rate of destruction. In these cases of well-compensated hemolysis, the major manifestations are due to increased erythrocyte destruction (hyperbilirubinemia) and augmented erythropoiesis (reticulocytosis). During the early neonatal period, however, the increased oxygen-carrying capacity of blood (see later section, Physiologic Anemia of Infancy and Prematurity) may blunt any compensatory erythropoietic activity in cases of mild hemolysis. Consequently, hyperbilirubinemia in excess of normal neonatal levels may be the only apparent manifestation of hemolysis. In most cases of significant hemolysis, however, some degree of reticulocytosis is usually present. The degree of hyperbilirubinemia and reticulocytosis must be interpreted in terms of values appropriate for gestational and postgestational ages.

### Immune Hemolysis

Placental transfer of maternal antibodies directed against fetal RBC antigens is the most common cause of neonatal hemolysis. This phenomenon is a consequence of maternal sensitization to fetal RBC antigens inherited from the

father. Hemolysis occurs only in the fetus. The spectrum of clinical problems ranges from minimal anemia and hyperbilirubinemia to severe anemia with hydrops fetalis. At one time, before effective prevention of Rh sensitization was available, hemolytic disease of the newborn was responsible for more than 10,000 deaths annually in the United States (Freda et al, 1975). Since the development of immunoprophylaxis against Rh(D) sensitization, the overall incidence of alloimmune hemolysis has decreased dramatically. Nevertheless, a majority of *serious* alloimmune hemolysis cases are still due to Rh(D) incompatibility, although ABO maternal-fetal incompatibility is much more common. A much smaller fraction of neonatal hemolytic disease is due to sensitization to Kell, Duffy, Kidd, and other Rh antigens such as c and E.

### Rh Hemolytic Disease: Erythroblastosis Fetalis

The role of Rh antibody in classic erythroblastosis fetalis was first elucidated by Levine and Katzin in 1941. Several Rh antigens are recognized, each of which is detected by specific antibodies. It is known that Rh blood group antigens are determined by at least two homologous but distinct membrane-associated proteins. Two of these membrane proteins have separate isoforms (C and c; E and e), which are detected by specific antibodies (anti-C and anti-c; anti-E and anti-e). The most important of the membrane Rh proteins is the D antigen. Rh-positive RBCs are those that possess this antigen. A lowercase d is used to denote the absence of D, or Rh-negative status; it is not related to a specific antigen—no “anti-d” serum has been identified. Rh proteins are encoded by two separate genes located on chromosome 1; they are designated *RHCE* and *RHD* (Mouro et al, 1993). The *RHCE* gene encodes both the C/c and E/e proteins. The *RHD* gene encodes the Rh D proteins. The Rh-negative phenotype results from deletion of the *RHD* gene on both chromosomes. In most cases, the Rh-negative phenotype also is associated with Rh c and Rh e (i.e., Rh cde). The frequency of Rh negativity varies in different racial groups. It is high in whites (15%), lower in blacks (5%), and virtually nonexistent in Asians. The Rh-positive phenotype may result from homozygosity (DD) or heterozygosity (Dd) for the D antigen. In Rh-positive whites, approximately 44% are homozygous (DD) and 56% are heterozygous (Dd). Knowledge of differences in *RHD* genotype is important because approximately 25% of fetuses of couples with an Rh(D)-negative mother and an Rh(D)-positive father will be Rh(D)-negative.

Current understanding of the natural history of Rh sensitization is derived largely from clinical experience gained before the immunologic prevention of neonatal hemolysis was readily available. The pathophysiology of alloimmune hemolysis resulting from Rh incompatibility includes the following: an Rh-negative mother, an Rh-positive fetus, leakage of fetal RBCs into maternal circulation, maternal sensitization to D antigen on fetal RBCs, production and transplacental passage of maternal anti-D antibodies into fetal circulation, attachment of maternal antibodies to Rh-positive fetal RBCs, and destruction of antibody-coated fetal RBCs. Historically, Rh hemolytic disease was rare (occurring in 1% of cases) during the first

pregnancy involving an Rh-positive fetus but increased significantly with each subsequent pregnancy. Small volumes of fetal RBCs enter the maternal circulation throughout gestation, although the major fetomaternal bleeding responsible for sensitization occurs during delivery (Zipursky et al, 1963). Once sensitization has occurred, reexposure to Rh(D) RBCs in subsequent pregnancies leads to an anamnestic response, with an increase in the maternal anti-D titer. Currently, significant hemolysis occurring in the first pregnancy indicates prior maternal exposure to Rh-positive RBCs, a consequence of fetal bleeding associated with a previous spontaneous or therapeutic abortion, ectopic pregnancy, or a variety of different prenatal procedures. On occasion the sensitization may be a consequence of an earlier transfusion in which Rh-positive RBCs were administered by mistake or in which some other blood component (e.g., platelets) containing Rh(D) RBCs was transfused.

The major factor responsible for the reduced death rate is the development of Rh immune globulin to prevent maternal sensitization. Important early observations were that fetomaternal RBC transfer (and thereby sensitization) occurs primarily during delivery and that the frequency of Rh immune hemolytic disease was much lower in ABO-incompatible pregnancies (maternal RBC type O, fetal RBC type A or B). The apparent beneficial effect of ABO incompatibility is due to the fact that maternal anti-A and anti-B antibodies recognize the corresponding A and B fetal RBCs, leading to their destruction before sensitization can occur. As a result of these early observations, it became standard practice for unsensitized Rh-negative mothers to receive a single intramuscular dose of Rh immune globulin (300  $\mu$ g) within 72 hours of delivering of an Rh-positive infant (Freda et al, 1975). The results of this therapy were remarkable, with the virtual elimination of Rh(D) sensitization as a major cause of hemolytic disease in newborns. The few treatment failures seen were attributed to fetomaternal bleeding of greater than 30 mL at delivery or bleeding that occurred antenatally. The current standard of practice is to administer a full dose of Rh immune globulin to all unsensitized Rh-negative women at 28 weeks of gestation, with an additional dose given at birth if the infant is Rh-positive. Moreover, the dose of Rh immune globulin should be increased proportionately when there is evidence of larger-than-normal fetomaternal bleeding at delivery. All newborns should be screened using the rosette test to screen for fetal red cells (Brecher, 2002). Positive results should be followed by a quantitative test such as the Kleihauer-Betke test (Judd, 2001). In suspicious cases (e.g., with placental abruption or neonatal anemia), the volume of fetal hemorrhage can be quantified using the Kleihauer-Betke procedure. Rh immune globulin also should be administered to unsensitized Rh-negative women after any event known to be associated with increased risk of fetomaternal hemorrhage (e.g., spontaneous or therapeutic abortion, amniocentesis, chorionic villus biopsy). The risk of anti-Rh desensitization ranges from 0.6% to 5.4% when nonsensitized Rh-negative women undergo amniocentesis (Spinnato, 1992).

In pregnant Rh-negative women previously sensitized to Rh(D), the transplacental passage of maternal anti-D leads to a positive DAT on Rh(D) fetal RBCs. Depending

on the amount of anti-D absorbed, a variable degree of fetal hemolysis occurs, thereby leading to anemia, hepatosplenomegaly, and increased bilirubin formation. In utero, bilirubin is removed by transfer across the placenta into the maternal circulation; therefore, hyperbilirubinemia is not a problem until after delivery, when levels may increase because of immaturity of hepatic conjugating enzymes. The major threat to the fetus is severe anemia leading to hydrops fetalis and intrauterine death. The clinical severity of neonatal hemolytic disease varies.

*Mild hemolytic disease* is most common, manifested by a positive DAT with minimal hemolysis, little or no anemia (cord blood hemoglobin greater than 14 g/dL), and minimal hyperbilirubinemia (cord blood bilirubin less than 4 mg/dL). Aside from early phototherapy, these newborns generally require no therapy unless the postnatal rate of rise in bilirubin is greater than expected. Infants who do not become sufficiently jaundiced to require exchange transfusion are at risk of development of severe late anemia associated with a low reticulocyte count, usually at 3 to 6 weeks of age; thus, it is important to closely monitor hemoglobin levels after hospital discharge.

*Moderate hemolytic disease* is found in a smaller fraction of affected infants. This form is characterized by hemolysis, moderate anemia (cord blood hemoglobin less than 14 g/dL), and increased cord blood bilirubin levels (greater than 4 mg/dL). The peripheral blood may reveal numerous nucleated RBCs, decreased numbers of platelets, and occasionally a leukemoid reaction with large numbers of immature granulocytes. The cause of thrombocytopenia is not understood, but it is unlikely to be an immune reaction, because platelets lack Rh antigens. Similarly, the cause of the leukemoid reaction is not defined, although rarely it may be confused with congenital leukemia. Infants with Rh disease also may exhibit marked hepatosplenomegaly, a consequence of extramedullary hematopoiesis and sequestration of antibody-coated RBCs. The risk of development of bilirubin encephalopathy is high if these neonates do not receive treatment. Thus, early exchange transfusion with type O Rh-negative fresh RBCs (less than 5 days old) is usually necessary, in conjunction with intensive phototherapy. This approach has been responsible for the favorable outcome for most infants with moderate alloimmune hemolysis. It is common for newborns who receive exchange transfusion to demonstrate a lower-than-normal hemoglobin concentration at the nadir of their "physiologic" anemia. Therefore, follow-up evaluation of hemoglobin for at least 2 months is important. The decrease in hemoglobin may be due in part to persistence of some anti-D antibody and destruction of the patient's own Rh(D)-positive RBCs. Also, this low hemoglobin measurement may reflect the decreased oxygen affinity and enhanced oxygen delivery of adult RBCs used for the exchange process, thereby blunting the expected erythropoietic response to hypoxia. Preliminary data suggest that the administration of recombinant human erythropoietin (rHuEPO) may minimize this late anemia of Rh hemolytic disease (Scaradavou et al, 1993; Ovali et al, 1996).

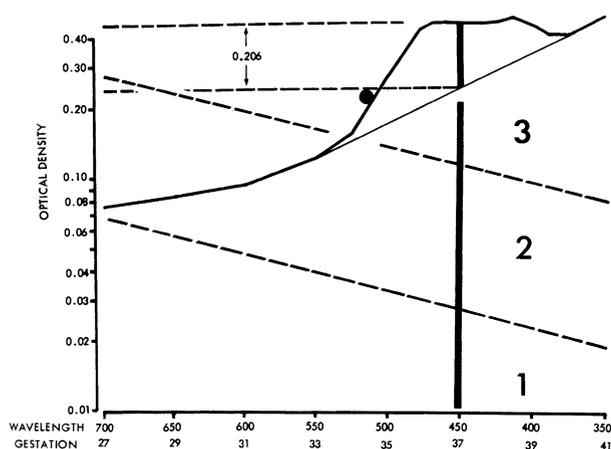

*Severe hemolytic disease* is seen in approximately 25% of affected infants, who are either stillborn or hydropic at birth. Understanding of hydrops fetalis, originally attributed

to high-output cardiac failure secondary to severe anemia, is incomplete. Two other consequences of anemia also may contribute to the edema of hydrops. One of these is low colloid osmotic pressure resulting from hypoalbuminemia, a consequence of hepatic dysfunction. The second is a capillary leak syndrome secondary to tissue hypoxia. Management of seriously affected fetuses is directed at the prevention of severe anemia and death. To accomplish this, it first is necessary to identify those fetuses at risk. An increase in the maternal anti-D titer in a previously sensitized Rh-negative woman is a good serologic measure of a fetus in potential jeopardy. Moreover, a previous history of neonatal hemolytic disease resulting from anti-D antibodies suggests that the current fetus also may be at risk. In this regard it may be useful to know the fetal Rh blood type because this identifies those Rh-negative infants who are not at risk. In many cases this can be accomplished by direct Rh typing of fetal RBCs obtained via cordocentesis. Alternatively, molecular biologic techniques can be used to determine the Rh genotype in DNA obtained from amniocytes or chorionic villus samples (Bennett et al, 1993; Fisk et al, 1994). When the fetus is found to be Rh-negative, no further maternal monitoring or fetal blood studies are necessary.

An increase in the maternal titer of immunoglobulin G (IgG) anti-D indicates maternal sensitization but does not accurately predict the potential severity of fetal hemolysis. A better correlation is obtained by spectrophotometric estimation of bile pigment in amniotic fluid as measured by the deviation in optical density (OD) at 450 nm (Fig. 77-4). Amniocentesis should be done when the indirect anti-globulin test exceeds a critical threshold level (1:16 to 1:32). Plotting the "delta OD 450 nm" against fetal age provides a good correlation with the severity of fetal hemolysis during the third trimester, and the trend of two or more values is a more reliable predictor of severity of fetal disease (Liley, 1961). Fetuses with amniotic fluid delta OD values in zone 3 (see Fig. 77-4) or increasing toward zone 3 are at greatest risk of intrauterine death from severe anemia and hydrops fetalis.

In earlier studies, at-risk fetuses greater than 32 weeks of gestation with evidence of mature lung function were delivered early. However, for those fetuses less than 32 weeks of gestation with immature lung function, early delivery was not possible and fetal RBC transfusions were given. Initially, intrauterine RBC transfusions were administered through the peritoneal cavity, and this procedure ameliorated the anemia sufficiently to save many otherwise doomed fetuses (Liley, 1963). However, in some of these cases in which hydrops was already present, the success rate was much lower because RBC absorption from the peritoneal cavity (complicated by ascites) was too slow to reverse the effects of severe anemia and hypoxia.

In severely affected fetuses, hydrops may occur as early as 20 to 22 weeks of gestation. Moreover, in these instances, the Liley amniocentesis curves (which were derived from studies of fetuses after 27 weeks of gestation) do not accurately predict severe disease (Nicolaidis et al, 1988). However, the development of high-resolution ultrasound techniques has been a major advance that facilitates detection of early hydrops (ascites and edema)

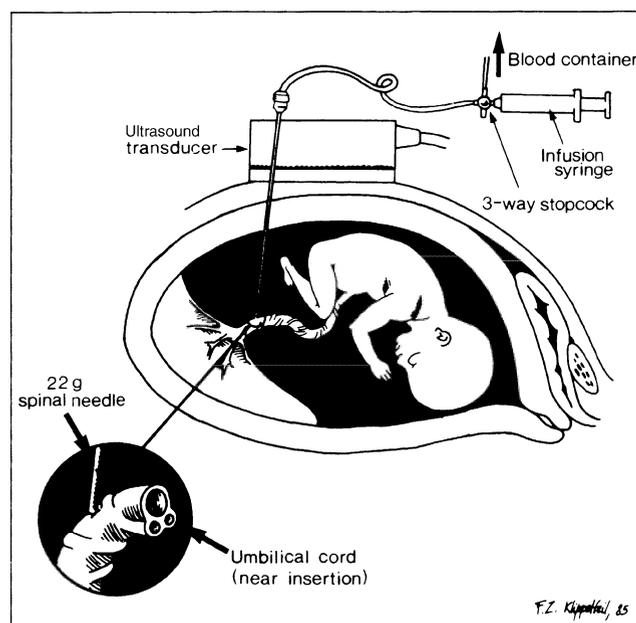

**FIGURE 77-4.** This composite graph depicts how spectrophotometric estimation of amniotic fluid bilirubin levels can be used as an indicator of fetal jeopardy from hemolytic disease. To begin, the optical density of amniotic fluid (ordinate) is measured from 700 to 350 nm (abscissa—top). This absorption curve is depicted as the *heavy solid line*. Next, the contribution of bilirubin to this absorption is calculated by subtracting the optical density of the projected baseline (*fine solid line*) from the measured optical density at 450 nm. In this case, the calculated value is 0.206. This calculated contribution of bilirubin is then plotted as a function of gestational age (abscissa—bottom). In this particular patient, the gestational age of 34.5 weeks and the bilirubin absorption of 0.206 determine the point indicated by the *solid dot*. The *dashed lines* demarcate three zones: Zone 1 indicates an unsensitized infant or one with very mild hemolytic disease. Zone 2 indicates mild to moderate hemolytic disease. Zone 3 represents severe hemolytic disease with impending fetal death. Because the bilirubin concentration of amniotic fluid decreases with gestational age, the absolute optical density that places a fetus in zone 3 decreases as the length of gestation increases. In the case depicted here, an absorption of 0.206 at 34.5 weeks of gestation indicated severe (zone 3) disease, placing the fetus at serious risk. (From Bowman JM, Pollock JM: *Amniotic fluid spectrophotometry and early delivery in the management of erythroblastosis fetalis*. *Pediatrics* 35:815, 1965. Reproduced with permission from *Pediatrics*.)

and enables direct percutaneous umbilical blood sampling (PUBS) (cordocentesis) for determination of red cell antigen typing and measurement of fetal hematocrit or hemoglobin levels (Fig. 77-5). Fetal hydrops does not occur until hemoglobin concentration of the fetus decreases below approximately about 4 g/dL (or hematocrit below approximately 15%). However, the hemoglobin concentration of normal fetuses increases gradually during the latter part of pregnancy; thus, hemoglobin values in affected fetuses must be interpreted relative to those in normal subjects for the same stage of gestation (Nicolaidis et al, 1988). A reference range for normal fetuses and fetuses with varying degrees of hemolysis is seen in Figure 77-6. Expressing the degree of anemia as “hemoglobin deficit” (grams per deciliter below the normal mean hemoglobin value for age), three zones of severity have been defined:

Zone I (mild): deficit less than 2 g/dL

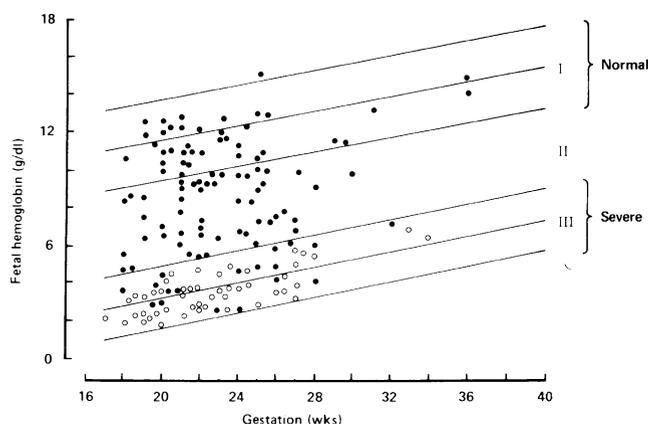

Zone II (moderate): deficit 2 to 7 g/dL

Zone III (severe, hydropic): deficit 7 to 10 g/dL

**FIGURE 77-5.** Diagrammatic view of in utero direct intravascular transfusion. U/S, ultrasound. (From Grannum PA, Copel JA, Plaxe SC, et al: *In utero exchange transfusion by direct intravascular injection in severe erythroblastosis fetalis*. *N Engl J Med* 314:1431, 1986. Reprinted by permission of the *New England Journal of Medicine*.)

The use of ultrasound examination, which allows fetal blood sampling through a 22-gauge spinal needle, has reduced the rate of fetal trauma and morbidity associated with cordocentesis to less than 2% (Parer, 1988). Cordocentesis also has facilitated direct intravascular RBC

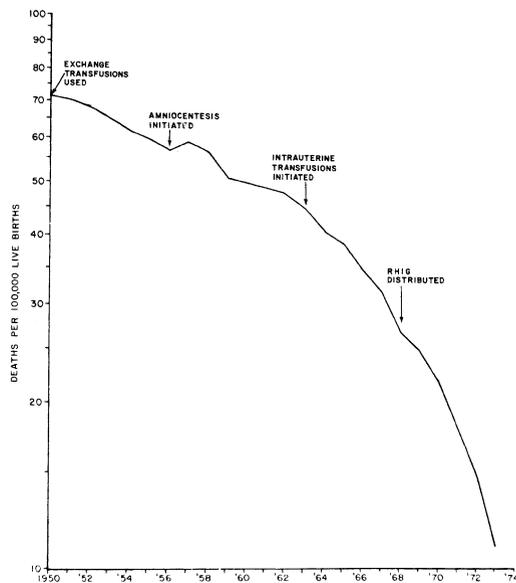

**FIGURE 77-6.** Fetal hemoglobin concentration of 48 hydropic (*open circles*) and 106 nonhydropic (*solid circles*) fetuses from red blood cell isoimmunized pregnancies at time of first fetal blood sampling. Values are plotted on the reference range of fetal hemoglobin for gestation. The individual 95% confidence intervals of the normal hemoglobin for gestation define zone I, and the individual 95% confidence intervals of the hemoglobin for gestation define zone III. Zone II indicates moderate anemia. (From Nicolaidis JH, Soothill PW, Clewell WH, et al: *Fetal hemoglobin measurement in the assessment of red cell isoimmunization*. *Lancet* 1:1073, 1988.)

transfusion to correct severe life-threatening anemia, with the reversal of established hydrops in most cases (Grannum et al, 1988; Rodeck et al, 1984). Depending on the age of the fetus and severity of anemia, the desired volume of RBCs transfused generally is that which will achieve a post-transfusion hematocrit of approximately 35% to 45%. When RBC transfusion induces a reversal of hydrops, the serum albumin also increases; this finding supports the role of anemia in the pathogenesis of the low albumin levels. Both simple transfusions and exchange transfusions have been performed in a number of fetuses (Grannum et al, 1986). Most perinatologists prefer simple RBC transfusion because of its shorter duration, aiming for a post-transfusion hematocrit no greater than 45% to avert circulatory overload (Weiner et al, 1991).

Hyperbilirubinemia (with elevation of the conjugated fraction) often develops in newborns who have received intrauterine RBC transfusions and often predicts the need for exchange transfusions. This hyperbilirubinemia reflects the severity of hemolysis and its effects on the fetal liver. In some cases, anemia may be minimal or absent, and the DAT may be negative if the Rh-negative RBCs transfused prenatally still predominate. In such cases the infant may not require exchange transfusion. Neonatal exchange transfusion, amniocentesis, selective early induction of delivery, and intrauterine fetal blood transfusions all have contributed to the declining neonatal death rate from Rh incompatibility (Fig. 77-7).

### ABO Incompatibility

Hemolysis associated with ABO incompatibility is similar to Rh hemolytic disease in that maternal anti-A or anti-B antibodies enter the fetal circulation and react with A or B antigens on the erythrocyte surface (Table 77-7). In persons

### Clinical and Laboratory Features of Immune Hemolysis Due to Rh Disease and ABO Incompatibility

	Rh Disease	ABO Incompatibility
<b>Clinical Features</b>		
Frequency	Unusual	Common
Pallor	Marked	Minimal
Jaundice	Marked	Minimal to moderate
Hydrops	Common	Rare
Hepatosplenomegaly	Marked	Minimal
<b>Laboratory Features</b>		
Blood type		
Mother	Rh(-)	O
Infant	Rh(+)	A or B
Anemia	Marked	Minimal
Direct Coombs test	Positive	Frequently negative
Indirect Coombs test	Positive	Usually positive
Hyperbilirubinemia	Marked	Variable
RBC morphology	Nucleated RBCs	Spherocytes

RBC, red blood cell.

with type A and type B blood, naturally occurring anti-B and anti-A isoantibodies largely are IgM molecules that do not cross the placenta. In contrast, the alloantibodies present in persons with type O blood are predominantly IgG molecules (Abelson and Rawson, 1961). For this reason, ABO incompatibility is largely limited to type O mothers with type A or B fetuses. The presence of IgG anti-A or anti-B antibodies in type O mothers also explains why hemolysis caused by ABO incompatibility frequently occurs during the first pregnancy without prior “sensitization.” ABO incompatibility is present in approximately 12% of pregnancies, although evidence of fetal RBC sensitization (i.e., positive result on DAT) is found in only 3% of births, and less than 1% of live births are associated with significant hemolysis (Kaplan et al, 1976; Zipursky et al, 1963). The relative mildness of neonatal ABO hemolytic disease contrasts sharply with the findings in Rh incompatibility. In large part, this is because A and B antigens are present in many tissues besides RBCs; consequently, only a small fraction of anti-A or anti-B antibody that crosses the placenta actually binds to erythrocytes, the remainder being absorbed by other tissues and soluble A and B substances in plasma.

Although hemolytic disease resulting from ABO incompatibility is clinically milder than Rh disease, severe hemolysis occasionally occurs, and hydrops fetalis has been reported. In such cases it is essential to exclude other antibodies and nonimmune causes of hemolysis such as glucose-6-phosphate dehydrogenase (G6PD) deficiency or hereditary spherocytosis. In most cases, pallor and jaundice are minimal (see Table 77-7). Hepatosplenomegaly is uncommon. Laboratory features include evidence of minimal to moderate hyperbilirubinemia and, occasionally, some degree of anemia. The DAT frequently is negative,

although the indirect antiglobulin test (neonatal serum plus adult group A or B RBCs) more commonly is positive. This paradox is related to the fact that fetal RBCs, compared with adult erythrocytes, have less type-specific antigen on their surface (Voak and Williams, 1971). Heat elution is the most sensitive test for anti-A or anti-B antibodies on infant red cells, but like the antiglobulin tests, it has poor predictive value for hemolysis. Studies of the subclass of the IgG anti-A and anti-B in maternal serum and on red cells of ABO-incompatible infants point to a possible explanation (Brouwers et al, 1988). The most common subclass is IgG2, which crosses the placenta but does not bind to Fc receptors of phagocytic cells and therefore is incapable of causing cell lysis. This finding accounts for the frequent observation of positive indirect and direct antiglobulin tests with little or no hemolysis. On the other hand, IgG3 antibodies and, to a lesser extent, IgG1 antibodies, although present in lower concentrations on fetal RBCs, do bind to Fc receptors and have strong lytic activity. This seems to account for cases of hemolysis associated with a negative or only weakly positive DAT.

The peripheral blood smear is characterized by marked spherocytosis, which is thought to be due to the reduced RBC surface area that results as antibody and membrane are removed by splenic macrophages. Autoimmune hemolytic anemia in older children is associated with antibodies directed against the Rh locus, and these cases also are characterized by spherocytosis. For unknown reasons, spherocytes are not a prominent feature of neonatal hemolysis resulting from Rh incompatibility.

Hemolysis in ABO incompatibility is usually mild, presenting with some degree of hyperbilirubinemia. Of major concern in the current cost-conscious health care environment is that some infants with ABO incompatibility may be discharged home from medical establishments before significant clinical jaundice is evident. *It is critical that infants with ABO incompatibility be monitored closely for evolving jaundice and hyperbilirubinemia in the first few days of life.* In most cases, hyperbilirubinemia is readily controlled by phototherapy (Osborn et al, 1984). When hyperbilirubinemia is not controlled by phototherapy, exchange transfusion is necessary using group O Rh-compatible RBCs. Tin-protoporphyrin, an inhibitor of heme catabolism to bilirubin, may help prevent hyperbilirubinemia in ABO-incompatible infants (Kappas et al, 1988). Additional follow-up at 2 to 3 weeks of age to check for anemia in these infants is essential.

### Minor Blood Group Incompatibility

With the sharp decline of hemolytic disease caused by Rh incompatibility, the proportion of cases caused by Rh c, Rh E, Kell, Duff, and Kidd incompatibility has increased from the previous estimates of 1% to 3%, to as high as 20% (for Kell sensitization). The pathophysiology of these disorders is similar to that of Rh and ABO incompatibility. The infrequency of minor group incompatibility is primarily a reflection of the lower antigenicity of these RBC antigens. Diagnosis of minor group incompatibility is suggested by hemolytic anemia with a positive DAT in the absence of ABO or Rh incompatibility and with a negative

maternal DAT. Definitive diagnosis requires identification of the specific antibody in neonatal serum or an eluate from neonatal RBCs. This is readily accomplished by testing maternal serum against a variety of known RBC antigens. With some antibodies such as Kell, antibody titer and amniocentesis findings may underestimate the severity of fetal hemolysis. Therefore, frequent ultrasound monitoring may be necessary, with performance of fetal blood sampling in worrisome cases. Fetal blood sampling also is useful in determining whether the fetus of a heterozygous father has inherited the offending RBC antigen. This test identifies those fetuses that need further serial evaluations.

### Immune Hemolytic Anemia Due to Maternal Disease

Maternal autoimmune hemolytic anemia or lupus erythematosus during pregnancy may be associated with passive transfer of IgG antibody to the fetus. The diagnosis is suggested by the presence of neonatal hemolytic disease, a positive DAT, absence of Rh or ABO incompatibility, and antiglobulin-positive hemolysis in the mother. Treatment with prednisone in the mother may reduce both maternal hemolysis and the risk of neonatal morbidity. As in other cases of neonatal hemolysis, attempts are made to prevent hyperbilirubinemia and kernicterus.

### Drug-Induced Immune Hemolysis

The classic example of drug-induced immune hemolysis is seen following administration of penicillin and appears when an antibody is directed to a complex of penicillin bound to the RBC membrane. No hemolysis occurs in the absence of penicillin, even though antibody persists in the circulation. This type of drug-mediated immune hemolysis is seen rarely in newborn infants. Cephalosporin drugs also have been implicated to cause immune-mediated hemolysis by a similar mechanism. In all of these cases, the DAT may be positive only when the test is done in the presence of the drug in question. Moreover, hemolysis ceases once the drug is withdrawn.

### Nonimmune Acquired Hemolytic Disease

#### Infection

Cytomegalic inclusion disease, toxoplasmosis, syphilis, and bacterial sepsis all can be associated with hemolytic anemia. In most of these conditions, some degree of thrombocytopenia also exists. Generally, hepatosplenomegaly is present. In cases of bacterial sepsis, both the direct and indirect bilirubin levels may be elevated. The mechanism of hemolysis is not clearly defined, but it may be related to RBC sequestration in the presence of marked reticuloendothelial hyperplasia associated with infection. Documentation of infection as the cause of hemolysis is made by the presence of other clinical and laboratory evidence of neonatal infections. Hemolysis caused by infections may be exhibited early in the neonatal period, or it can be delayed for several weeks.

### Schistocytic Anemias

Disseminated intravascular coagulation (DIC) is discussed in Chapter 76. The hemolytic component of this disorder is secondary to the deposition of fibrin within the vascular walls. When erythrocytes interact with fibrin, fragments of RBCs are broken off, producing fragile, deformed RBCs, or schistocytes. These cells are relatively rigid and thus incapable of normal deformation within the microcirculation. The hemolytic-uremic syndrome represents a localized form of intravascular coagulation that is characterized by thrombocytopenia, renal disease, and hemolytic anemia. Hemolysis is characterized by RBC fragmentation, presumably for the aforementioned reasons. Abnormalities of the placental microcirculation or macrovascular anomalies such as an umbilical vein varix are rare causes of congenital schistocytic anemia (Batton et al, 2000).

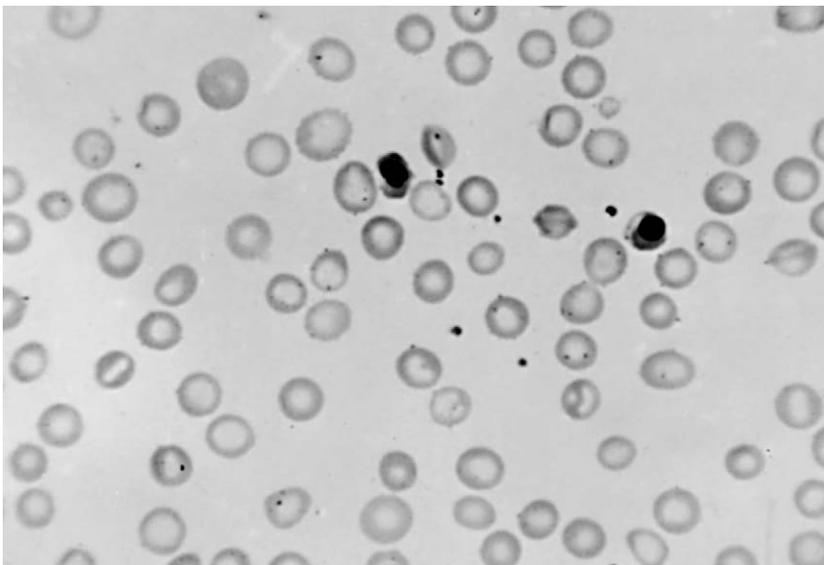

### Hereditary Red Blood Cell Disorders

#### Membrane Defects

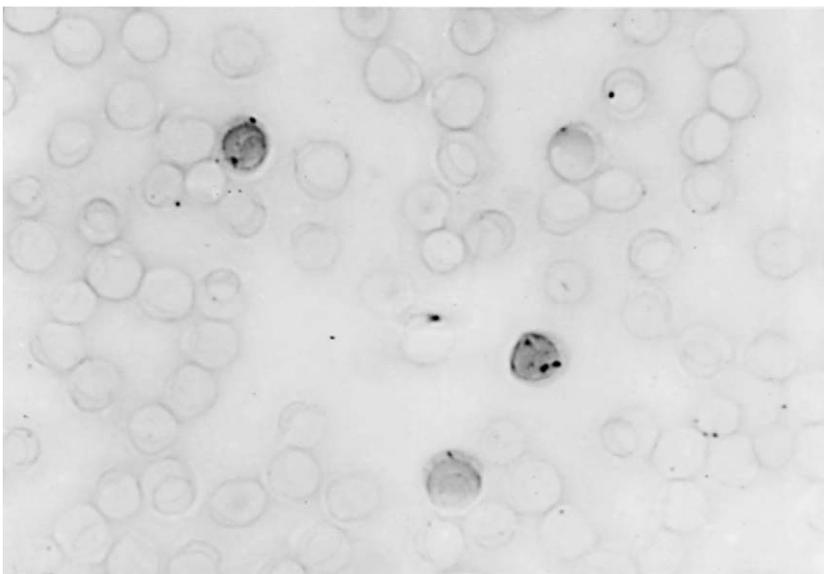

The customary findings in RBC membrane disorders are the presence of dominant inheritance, abnormal RBC morphology (Fig. 77-8), and either increased or decreased osmotic fragility. Aside from hereditary spherocytosis, these disorders are uncommon.

#### Hereditary Spherocytosis

The hallmark of hereditary spherocytosis is the presence in the circulation of spherocytes, cells that have become spheroid because of a loss of membrane surface with no concomitant loss in volume. Inherited mutations in components of the membrane cytoskeleton (spectrin, ankyrin,

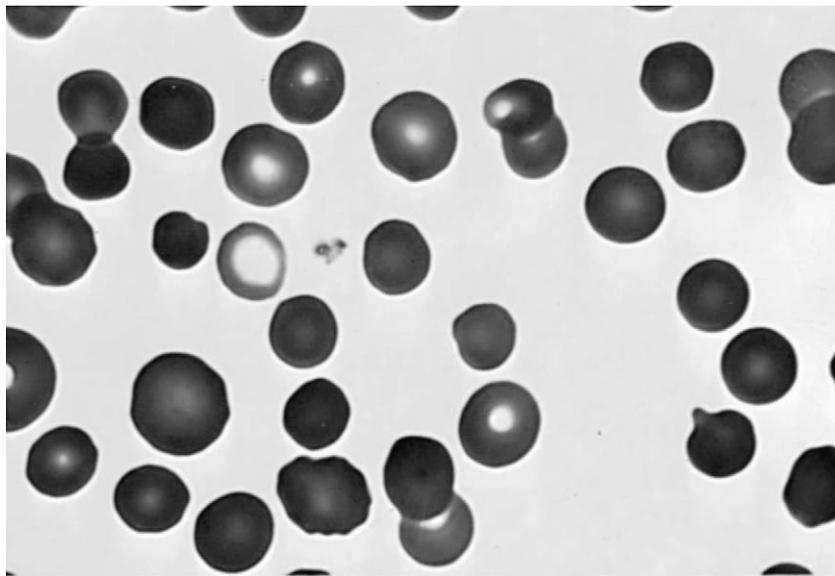

A

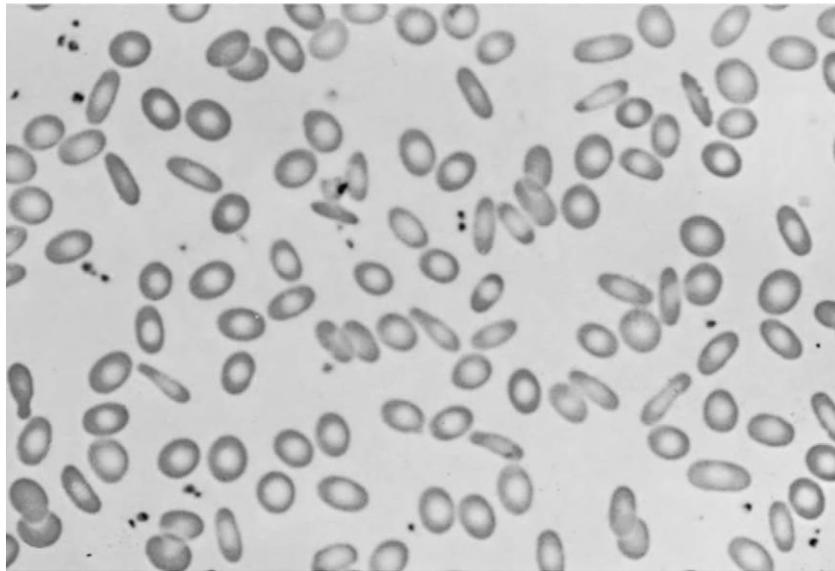

B

*Continued*

or band 3) weaken the stability of the interactions between the cytoskeleton and the membrane lipid bilayer, promoting vesiculation and loss of bits of the bilayer, thus leading to progressive loss of membrane surface area (Palek and Jarolim, 1993). As the RBC becomes more spherical, it loses flexibility and becomes vulnerable to entrapment in the spleen, where metabolic depletion and attack by the reticuloendothelial system lead to hemolysis. Removal of the spleen allows the spherocytes to have a near-normal life span despite their cytoskeletal defects and abnormal shape.

The clinical manifestations of hereditary spherocytosis range from hydrops fetalis with fetal death (Gallagher et al, 1997) to fully compensated, lifelong hemolysis marked by reticulocytosis but no anemia (Mentzer et al, 2004). Neonatal hemolysis or hyperbilirubinemia appears in approximately half of all affected infants (Stamey and

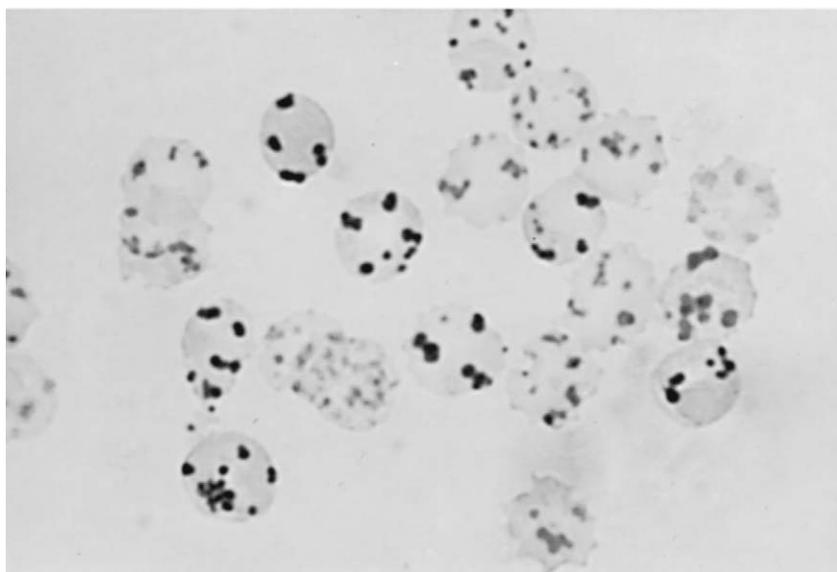

Diamond, 1957). In most cases, other family members are affected in a pattern consistent with autosomal dominant inheritance. In 20% to 30% of cases, recessive inheritance is noted, and only homozygotes express the clinical features of spherocytosis. Occasionally, the appearance of a new case of spherocytosis in a previously unaffected family is due to spontaneous mutation.

The diagnosis of spherocytosis is suspected when spherocytes are seen on the blood smear and the RBC osmotic fragility is increased in a patient with laboratory evidence of hemolysis. In the newborn, morphologic assessment of the RBCs is sometimes difficult because even normal newborns may possess a minor population of spherocytes; conversely, in hereditary spherocytosis, fewer spherocytes may be evident than will be the case later in life. Furthermore, interpretation of the osmotic fragility curve has to take into account the relative osmotic resistance of normal

E

F

neonatal RBCs. If this is done by using newborns rather than normal adults as controls, the fragile RBCs of infants who have hereditary spherocytosis can easily be identified (Schröter and Kahsnitz, 1983). Immune hemolysis, which also generates spherocytes, must always be ruled out in the workup of a suspected case of hereditary spherocytosis. In the newborn, maternal antibody rather than autoantibody must be suspected if immune hemolysis is present. Spherocytes are commonly observed in ABO incompatibility but not in Rh disease. Blood typing and a Coombs test usually confirm a diagnosis of ABO incompatibility, but the Coombs test result may occasionally be negative and thus misleading. In this situation, evaluation of the family for other persons affected with spherocytosis may point to a hereditary rather than an acquired cause. Sometimes it is necessary to wait until the infant is

3 months of age or so to obtain a definitive laboratory diagnosis of hereditary spherocytosis, because, by this age, the confounding effects of maternal antibody and fetal RBCs are no longer present.

Treatment during the newborn period is directed toward management of hyperbilirubinemia, which often is present. Occasionally, RBC transfusions may be required at birth for management of symptomatic anemia (Gallagher et al, 1997). A common occurrence is the appearance of a transient but severe anemia during the first 20 days of life due to underproduction of erythropoietin in the face of continuing hemolysis (Delhommeau et al, 2000). Careful monitoring of affected infants after discharge from the nursery is warranted. Splenectomy is the definitive treatment for hereditary spherocytosis, but it is best deferred until the child is at least 5 years of age because of the

increased risk of overwhelming sepsis with encapsulated organisms such as *Haemophilus influenzae* or *Streptococcus pneumoniae* (Diamond, 1969) that occurs following splenectomy in infants and young children. Partial splenectomy may reduce the rate of hemolysis without increasing the risk of overwhelming infection and is an attractive therapeutic option in young children with severe hemolysis (Bader-Meunier et al, 2001).

### Hereditary Elliptocytosis

Hereditary elliptocytosis is an autosomal dominant, clinically heterogeneous group of disorders that are caused by mutations of the RBC membrane cytoskeletal proteins (usually spectrin or protein 4.1) that weaken skeletal protein interactions and increase RBC mechanical fragility (Mentzer et al, 2004; Palek and Jarolim, 1993). Heterozygotes usually exhibit elliptocytes on the blood smear, but in most instances hemolysis is absent. Homozygotes or compound heterozygotes may have sufficient weakening of the cytoskeleton to cause significant hemolysis accompanied by striking abnormalities in RBC morphology (homozygous hereditary elliptocytosis or hereditary pyropoikilocytosis). Transient poikilocytosis and hemolysis may occur during the newborn period in infants destined ultimately to have asymptomatic elliptocytosis (Austin and Desforges, 1969). RBC membrane mechanical fragility is strikingly abnormal in these infants, probably as a consequence of the destabilizing influence of large amounts of free intraerythrocytic 2,3-DPG, a byproduct of the presence of fetal hemoglobin (Mentzer et al, 1987). As fetal hemoglobin levels decline postnatally in affected infants, membrane mechanical fragility lessens, hemolysis disappears, and RBC morphology undergoes a transition from poikilocytosis to elliptocytosis. Without knowledge of the membrane protein mutations present in the infant and the infant's family, it is difficult to predict at birth who will have transient poikilocytosis with ultimate recovery and who is destined to have lifelong pyropoikilocytosis with hemolysis.

### Red Blood Cell Enzyme Abnormalities

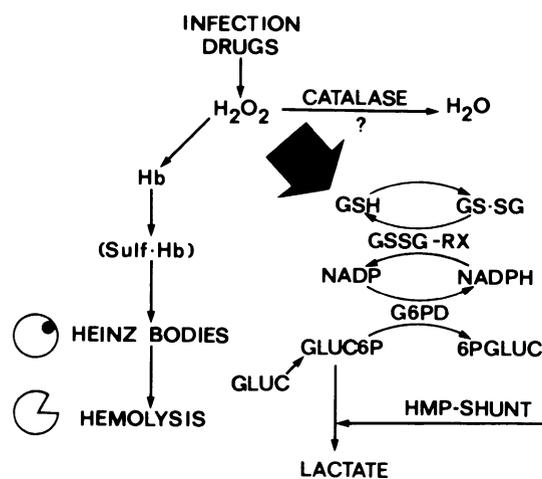

Hyperbilirubinemia, anemia, and even hydrops fetalis can be the result of inherited RBC enzymopathies. Except for G6PD deficiency (sex-linked) and adenosine deaminase excess (autosomal dominant), these disorders are inherited in autosomal recessive fashion, and heterozygotes are clinically normal. RBC morphology is usually normal, and diagnosis requires assay of the activity of the enzyme suspected to be abnormal. It usually is prudent to rule out common causes of hemolysis that are easily diagnosed before embarking on an expensive search for RBC enzymopathies, which, except for G6PD deficiency, are rare. Overviews of this group of disorders are available elsewhere (Luzzato, 1997; Mentzer, 2003), and the special features of RBC enzymopathies in the newborn period have also been summarized (Matthay and Mentzer, 1981).

### Glucose-6-Phosphate Dehydrogenase Deficiency

G6PD deficiency is a sex-linked disorder that affects millions of people throughout the world, particularly in Mediterranean countries, Africa, and China. Like sickle cell trait and thalassemia, G6PD deficiency is thought to have become common because it provides a measure of protection against malaria. In all but a few G6PD-deficient persons, hemolysis and anemia are present only after exposure to medications that are potent oxidants or during infections. Occasionally, hemolytic anemia is chronic rather than episodic and is present even in the absence of obvious exposure to oxidant stress. Rarely, anemia may be so severe as to require regular RBC transfusions. The clinical heterogeneity of G6PD deficiency is due to the very large number of different mutations, usually single amino acid substitutions, that lead to altered enzyme function (Beutler et al, 1996; Miwa and Fujii, 1996). Normal RBCs contain abundant amounts of reduced glutathione (GSH), a sulfhydryl-containing tripeptide that serves as an intracellular antioxidant, neutralizing peroxides that form during metabolism or are introduced directly from the extracellular environment. Because of their enzyme deficiency, G6PD-deficient RBCs have a limited capacity to regenerate GSH from oxidized glutathione (Fig. 77-9). In the absence of GSH, RBCs are vulnerable to oxidant injury. The effects of oxidants on the RBC are multifocal. Denatured globin precipitates termed *Heinz bodies* bind to the cell membrane, unfavorably altering its structure and function. Membrane lipid peroxidation may contribute to altered function. The activity of intracellular enzymes may decline. The ultimate result of these insults is hemolysis.

#### Severity of Clinical Disease

Race and gender are determinants of the severity of hemolysis and neonatal hyperbilirubinemia in G6PD deficiency.

**FIGURE 77-9.** Glucose-6-phosphate hemolysis pathophysiology. GSH, reduced glutathione; GS-SG, oxidized glutathione; GSSG-RX, glutathione reductase; GLUC6P, glucose-6-phosphate; 6PGLUC, 6-phosphogluconate; G6PD, glucose-6-phosphate dehydrogenase; HMP-SHUNT, hexose monophosphate shunt.

**Race.** The mutation G6PD A- that is responsible for nearly all of the G6PD deficiency seen in Africans (and is present in approximately 10% of American blacks) affects the stability of the enzyme, causing a gradual decline in activity during the life span of the RBC. Only in the oldest RBCs does enzyme activity reach low enough levels to create vulnerability to oxidant hemolysis. For this reason, hemolysis, if it occurs, is usually mild and self-limited. In contrast, in Asians and persons of Mediterranean descent, the common mutations causing G6PD deficiency alter enzyme activity in young and old RBCs alike. Hemolysis is usually more severe and can be fatal. In these ethnic groups, inheritance of an as-yet-unidentified factor renders some G6PD-deficient persons susceptible to severe and even fatal episodes of hemolysis following exposure to fava beans (favism). The hemolytic factor can be transmitted to neonates via breast milk (Kaplan et al, 1998). Favism is not seen in blacks.

**Gender.** The gene for G6PD is located on the X chromosome. All of the RBCs of hemizygous G6PD-deficient males are affected by the enzyme deficiency. In contrast, a variable proportion of the RBCs of heterozygous G6PD-deficient females are enzyme deficient, depending on whether the process of random inactivation of the X chromosome that occurs early in embryonic development involves the chromosome carrying the normal or the mutant G6PD gene (Lyon, 1961). When a large proportion of their RBCs are enzyme deficient, females exhibit hemolysis, after exposure to oxidants, in similar degree to that seen in their male counterparts. When a smaller proportion of cells are affected, hemolysis is milder or absent. For these reasons, hemolysis is more commonly seen in G6PD-deficient populations of male hemizygotes than those of female heterozygotes. It is worthy of note that both homozygotes and heterozygotes may exhibit hyperbilirubinemia even in the absence of evidence of hemolysis (Kaplan et al, 1999).

### Diagnosis

The diagnosis of G6PD deficiency is suggested by the appearance of a Coombs-negative anemia in association with infection or the administration of drugs. Cells that appear as if a "bite" had been taken from them (as a result of splenic removal of Heinz bodies) are occasionally seen on the peripheral blood smear. Supravital stains of the peripheral blood with crystal violet may reveal Heinz bodies during hemolytic episodes. Although screening tests are available, definitive diagnosis requires assay of RBC G6PD activity or identification of a specific G6PD mutation by DNA analysis (Beutler, 1996; Miwa and Fujii, 1996). Measurement of enzyme activity may not reveal the deficiency in American blacks immediately after a hemolytic episode, because the population of deficient cells has been eliminated, or in transfused patients because of the presence of normal, enzyme-replete RBCs. Repeating the assay after at least 3 months ensures that any transfused cells are gone and that the population of deficient cells has been regenerated so that a more accurate determination of the presence of G6PD deficiency can be made.

### Etiology

Hemolysis and/or hyperbilirubinemia resulting from G6PD deficiency are well documented in the newborn period (Valaes, 1994). In fact, the onset of jaundice may often occur in utero (Kaplan et al, 2001a). Early and continuing monitoring of serum bilirubin levels in infants known to be G6PD deficient is warranted (Kaplan et al, 2000, 2001b). Although the usual factors (drugs and infection) may be implicated, often there is no obvious cause for hemolysis. Premature (Eshaghpour et al, 1967) but not term (O'Flynn and Hsia, 1963) black G6PD-deficient newborns have more hyperbilirubinemia than is seen in normal infants. Severe hemolysis and hyperbilirubinemia can follow exposure to known hemolytic agents in black G6PD-deficient newborns (Brown, 1992) but can be seen even in the absence of exposure to such agents in Asian or white G6PD-deficient infants. These ethnic differences reflect the different G6PD mutations that are present in blacks, Asians, and whites. In one study from Greece (Doxiadis and Valaes, 1964), approximately 30% of all exchange transfusions done in the nursery were in G6PD-deficient infants who had no evidence of isoimmune hemolytic anemia. In Taiwan, the incidence of hyperbilirubinemia requiring phototherapy was higher in G6PD-deficient than in normal infant males, particularly if the nt 1376 mutation was present. Other mutations were associated with lesser degrees of hyperbilirubinemia and responded more favorably to phototherapy (Huang et al, 1996). The degree of hyperbilirubinemia reflects both the increased bilirubin load presented to the liver by hemolysis of G6PD-deficient RBCs and the presence or absence of the variant form of uridine-diphosphoglucuronylsyl-transferase responsible for Gilbert syndrome (Kaplan et al, 2001b). The relative importance of the latter is underscored by the observations that most jaundiced G6PD-deficient neonates are not anemic and that often, evidence for increased bilirubin production secondary to hemolysis is lacking (Kaplan et al, 1999).

### Treatment

Therapy for neonatal hemolysis and hyperbilirubinemia resulting from G6PD deficiency includes (1) phototherapy or exchange transfusion to prevent kernicterus, (2) RBC transfusion for symptomatic anemia, (3) removal of potential oxidants that may be contributing to hemolysis, and (4) treatment of infections using agents that do not themselves initiate hemolysis. In infants known to be G6PD deficient, prevention of severe hyperbilirubinemia by administration of a single intramuscular dose of tinmesoporphyrin, an inhibitor of heme oxygenase, is highly effective and safe (Valaes et al, 1994; Kappas et al, 2001). Neonatal screening for G6PD deficiency has been very effective in reducing the incidence of favism later in life in Sardinia (Meloni et al, 1992) and in other regions where this potentially fatal complication is common (Valaes, 1994). In the United States, where the most common G6PD mutation is the A- variant found in blacks (who are not susceptible to favism and in whom life-threatening hemolytic episodes are rare), neonatal screening has not been thought to be cost-effective.

**Comment**

As illustrated by this case, G6PD deficiency should be considered in the differential diagnosis not only for hyperbilirubinemia and hemolytic anemia but also for hydrops fetalis. The reason for the disastrous course in this infant is not known. Infection, ascorbic acid (an intracellular oxidant), or favism could have been responsible.

**CASE STUDY 1**

A male infant weighing 2722 g was born at 38 weeks of gestation to a 30-year-old Chinese, gravida 3, para 1, aborta 1 mother. Apgar score at birth was 1. Despite intensive resuscitative measures, the infant died after 2 hours, never having established spontaneous respirations. Autopsy disclosed hepatosplenomegaly, bile-filled canaliculi within the liver, bone marrow erythroid hyperplasia, and other evidence of severe intrauterine hemolysis. Hemoglobin was 9.8 g/100 mL, and the white blood cell count was 7200/ $\mu$ L. There was marked polychromatophilia (reticulocytosis), and numerous nucleated RBCs were seen in the peripheral smear. The infant's blood type was AB-positive, the mother's blood type was B-positive, and the Coombs test (direct and indirect) was negative. Hemoglobin electrophoresis revealed 52% hemoglobin F, 45% hemoglobin A, and no hemoglobin Barts or hemoglobin H. RBC G6PD activity was decreased in the infant and in his mother. Four weeks before delivery, the mother had an upper respiratory infection and took ascorbic acid (250-500 mg/day) for a period of 2 weeks as treatment. On at least one occasion during the last month of pregnancy, she also ate fava beans (Mentzer and Collier, 1975).

**Pyruvate Kinase Deficiency**

Pyruvate kinase (PK) deficiency is an autosomal recessive disorder that occurs in all ethnic groups (Mentzer, 2003). Although the most common of the Embden-Meyerhof glycolytic pathway defects, it is rare in comparison with G6PD deficiency. Over 400 cases, mostly in Northern Europeans, have been described (Zanella and Bianchi, 2000). PK is one of the two enzymes that generate adenosine triphosphate (ATP) in RBCs. Impairment of ATP production is the central pathophysiologic abnormality in PK deficiency. Because nonerythroid tissues have alternative means of generating ATP, clinical abnormalities in PK deficiency are limited to RBCs. More than 130 PK mutations have been defined at the nucleic acid level and many more in terms of abnormalities of the PK protein (Zanella and Bianchi, 2000). Reflecting this genetic diversity, the hemolytic anemia that characterizes PK deficiency varies considerably in severity from family to family. Approximately one third of PK-deficient babies experience hyperbilirubinemia during the newborn period. Jaundice tends to appear early (on the first day of life) and may necessitate exchange transfusion (Matthay and Mentzer, 1981). Death or kernicterus may occur. Severe intrauterine anemia and hydrops fetalis have been reported (Zanella and Bianchi, 2000).

The diagnosis of PK deficiency should be considered in a jaundiced newborn with evidence of nonimmune hemolysis in the absence of infection or exposure to hemolytic agents. Hemoglobinopathies and membrane disorders

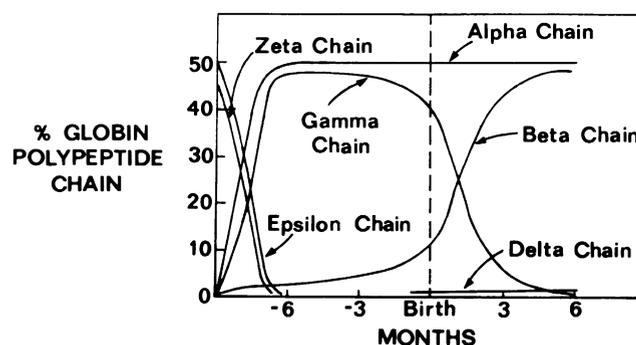

should be ruled out by examination of the blood smear and other appropriate diagnostic tests before proceeding to assay of RBC PK activity, which is the definitive test for the disorder. RBC morphology is basically normal in PK deficiency, although a few dense cells with irregular margins (echinocytes) are occasionally seen. PK heterozygotes are clinically and hematologically normal but usually have roughly half the normal amount of RBC PK activity.

Treatment of hyperbilirubinemia by phototherapy and exchange transfusion if necessary is usually the only therapy necessary in the newborn period. RBC transfusions for anemia may occasionally be required. Splenectomy may reduce the rate of hemolysis but should be avoided in infancy and early childhood owing to the high risk of infection after splenectomy.

**Hemolysis Due to Hemoglobin Disorders**

To understand the hemoglobinopathies that are seen in the newborn, it is first necessary to review the normal developmental changes that occur in globin synthesis during fetal and neonatal life. In adults, the predominant hemoglobin tetramer—hemoglobin A—is composed of two alpha globin chains and two beta globin chains. In very young embryos, alpha chains are replaced by zeta chains and beta chains by epsilon chains. The transition from zeta to alpha globin chains is complete by the end of the first trimester. Epsilon chains disappear more slowly and are replaced first by gamma chains and then later by the beta chains of adult hemoglobin. By the time of birth, the transition from gamma to beta globin synthesis is well under way (Fig. 77-10). The various possible combinations of these different globin chains form a number of different hemoglobin tetramers that are characteristically found in embryonic, fetal, or postnatal life (Fig. 77-11). In contrast with globin, the heme moiety is unchanged in structure in embryonic, fetal, and postnatal hemoglobin molecules.

Fetal hemoglobin ( $\alpha_2\gamma_2$ ) is the major hemoglobin found in fetuses after the first trimester. Its replacement by adult hemoglobin (hemoglobin A) begins before birth, so that only approximately 60% to 90% of the hemoglobin found in the normal term infant is fetal hemoglobin (hemoglobin F). After birth, gamma chain synthesis declines rapidly as beta chain synthesis increases (see Fig. 77-10) so that most newly formed hemoglobin is hemoglobin A. As RBCs made before birth are replaced

**FIGURE 77-10.** Fetal and neonatal hemoglobin production.

	HEMOGLOBIN	GLOBIN POLYPEPTIDES	% IN CORD BLOOD

	ADULT	Hgb A Hgb A <sub>2</sub>	Alpha-2, Beta-2 ( $\alpha_2\beta_2$ ) Alpha-2, Delta-2 ( $\alpha_2\delta_2$ )

FIGURE 77-11. Hemoglobin composition of cord blood.

by cells made postnatally, the percentage of hemoglobin F declines rapidly, reaching a level of approximately 5% by 6 months of age (Fig. 77-12). Only trace amounts of the minor adult hemoglobin, hemoglobin A<sub>2</sub> ( $\alpha_2\delta_2$ ), and of the homotetramer of gamma globin chains, hemoglobin Barts, are present in cord blood. With postnatal maturation, the hemoglobin A<sub>2</sub> level increases gradually to the adult level of 2% to 3%, while hemoglobin Barts quickly disappears.

Beta globin disorders such as sickle cell disease or beta-thalassemia major do not become apparent clinically until several months of age, when the switch from hemoglobin F to hemoglobin A synthesis reveals the defect. In contrast, gamma globin mutations are most evident in fetal and neonatal life and then disappear by approximately 3 months of age as gamma globin synthesis is replaced by beta globin synthesis. Structural mutations of gamma globin may be associated with transient cyanosis during the newborn period if they form methemoglobin (see later section, Methemoglobinemia) or are associated with low oxygen affinity (Kohli-Kumar et al, 1995). The alpha globin disorders are evident at all stages of development from fetal to adult.

### Thalassemia Syndromes

The fundamental lesion in the thalassemias is absent or deficient synthesis of one or another of the normal globin chains, leading to a relative excess of the complementary or partner chain. For example, in alpha-thalassemia there

is diminished synthesis of alpha globin chains, leading to an excess of beta chains (or, in the fetus, of gamma chains). The opposite is true of beta-thalassemia, in which it is excess alpha globin chains that accumulate. Aggregates of free alpha chains or homotetramers of beta chains (hemoglobin H) or of gamma chains (hemoglobin Barts) form in the absence of more suitable partner globin chains, leading to RBC membrane damage and rapid hemolysis. In addition, the decrease in overall production of hemoglobin produces small RBCs (microcytosis) that are often filled with less than the normal amount of hemoglobin (hypochromia). Although in most instances the globin chains produced by the thalassaemic locus are normal in structure, there are mutations, termed *thalassaemic hemoglobinopathies*, in which a structurally abnormal globin chain is found. In these cases, the instability of the hemoglobin tetramer formed from abnormal globin chains may also contribute to the hemolytic process.

### Alpha-Thalassemia

Alpha-thalassemia is of particular importance to neonatologists because its clinical manifestations are present in utero and at birth. The more severe forms of alpha-thalassemia are found in Southeast Asians (Glader and Look, 1996) and less commonly in infants of Mediterranean origin. The molecular basis for alpha-thalassemia is usually deletion of one or more of the four alpha globin genes. Nondeletional forms of alpha-thalassemia also are known but are less common. A thalassaemic hemoglobinopathy involving the abnormal hemoglobin Constant Spring also may behave functionally as a mild form of alpha-thalassemia. Clinical severity is dictated by how many alpha globin genes are absent or nonfunctional. An infant can inherit no, one, or two alpha-thalassemia genes from each parent, giving rise to the following four clinical syndromes:

1. *Silent carrier state*. Deletion or nonfunction of a single alpha globin gene is not accompanied by any clinical or hematologic abnormalities.

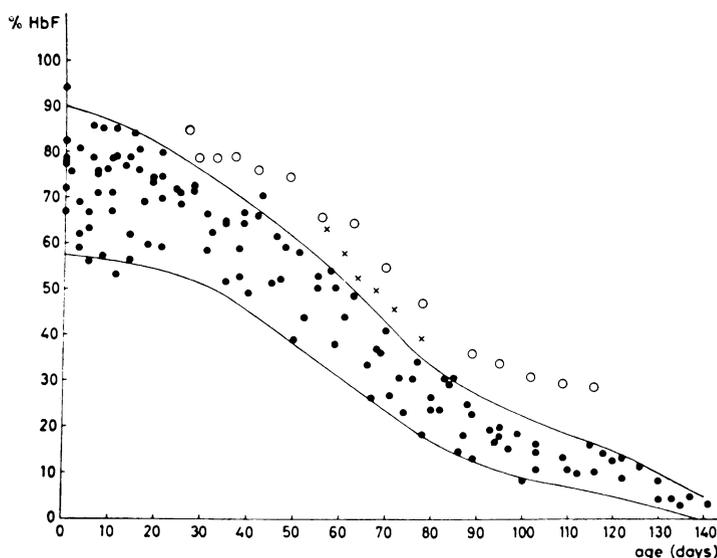

FIGURE 77-12. Decreasing concentration of fetal hemoglobin after birth. (From Garby L, Sjöhn S, Vuille JC: *Studies of erythro-kinetics in infancy. II. The relative rates of synthesis of haemoglobin F and haemoglobin A during the first months of life. Acta Paediatr* 51:245, 1962.)

2. *Alpha-thalassemia trait*. Deletion or nonfunction of two alpha globin genes, in *cis* or *trans*, is associated with mild microcytic anemia, without hemolysis or reticulocytosis.
3. *Hemoglobin H disease*. When three of four alpha globin genes are deleted or nonfunctional, a moderate hemolytic anemia is found. The RBCs are hypochromic and microcytic and contain inclusions of hemoglobin Barts or hemoglobin H when appropriate staining is performed. Surprisingly, the clinical severity of deletional hemoglobin H disease is less than that of nondeletional hemoglobin H disease (Chen et al, 2000).
4. *Homozygous alpha-thalassemia*. Lack of all four alpha globin genes is associated with a severe intrauterine hemolytic anemia and hydrops fetalis, with massive hepatosplenomegaly, and, in most instances, fetal demise. The RBCs are very hypochromic, fragmented, and bizarre in shape. Erythroblastosis is present (Chui and Waye, 1998).

The diagnosis of the alpha-thalassemia syndromes is easily made during the newborn period by correlation of the clinical and hematologic appearance of the child with the amount of hemoglobin Barts ( $\gamma_4$ ) present in the RBCs (Lorey et al, 2000) (Table 77-8). Screening of all newborns for hemoglobin H disease is justified in populations with a substantial number of at-risk pregnancies (Lorey et al, 2000). The large amount of hemoglobin Barts found in the RBCs of homozygotes for alpha-thalassemia contributes to the clinical severity of the syndrome, because the markedly increased oxygen affinity of this hemoglobin makes it incapable of delivering oxygen to the tissues. DNA-based diagnostic tests are available for prenatal diagnosis, which is often carried out when a pregnancy at risk for a fetus with homozygous alpha-thalassemia is identified (Chui and Waye, 1998). The increased risk of

eclampsia in mothers of such fetuses is an important justification for early identification and termination of the pregnancy.

No treatment is needed for the silent carrier state or for alpha-thalassemia trait, but studies to determine the thalassemia status of other family members, particularly those in their reproductive years, are recommended so that genetic counseling (and prenatal diagnosis if indicated) can be provided. Parents of infants who have hemoglobin H disease should be instructed to avoid oxidant agents that can cause hemolysis (the same list that is given to patients with G6PD deficiency). Although these infants are usually only mildly anemic, they may experience severe episodes of hemolysis during infections or with exposure to oxidant agents. Fetuses with homozygous alpha-thalassemia that are not aborted are usually stillborn, but several affected children have been born alive, resuscitated, and placed on chronic RBC transfusion programs (Beaudry et al, 1986; Bianchi et al, 1986; Singer et al, 2000). If a suitable donor is available, these infants can be considered for curative bone marrow transplantation (Chik et al, 1998). Experimental treatment of homozygous alpha-thalassemia in utero by means of hematopoietic stem cell transplantation is currently under evaluation.

### Beta-Thalassemia

Like alpha-thalassemia, beta-thalassemia is found in regions of the world where malaria was formerly endemic: Southeast Asia, India, Africa, and the Mediterranean basin. Although deletion of the beta globin locus is an occasional cause of beta-thalassemia, most cases are caused by point mutations that affect transcription, messenger RNA (mRNA) processing, or translation (Galanello, 1995; McDonagh and Nienhuis, 1993; Olivieri, 1999). Two general types of beta-thalassemia are recognized. In

TABLE 77-8

#### Alpha-Thalassemia Syndromes

		Anemia	Hemolysis	$\alpha:\beta$ Chain Synthesis	Abnormal Hemoglobins	
					Cord Blood	Adult Blood
Normal	$\alpha/\alpha$	None	None	0.95-1.10	0%-1% $\gamma_4$	—
Silent carrier	$\alpha/\alpha$ $\alpha/-$	None	None	0.85-0.95	1%-2% $\gamma_4$	—
Alpha-thalassemia trait	$\alpha/\alpha$ $\alpha/\alpha$	Mild Hypochromic Microcytic	None	0.72-0.82	5%-6% $\gamma_4$	—
Hemoglobin "H" disease	$-/-$ $\alpha/-$	Moderate Hypochromic Microcytic	Moderate	0.30-0.52	20%-40% $\gamma_4$ 0%-5% $\beta_4$	20%-40% $\beta_4$
Homozygous alpha-thalassemia ("hydrops")	$-/-$ $-/-$	Severe Hypochromic Microcytic	Severe	0	70%-80% $\gamma_4$ 15%-20% $\beta_4$ 0%-10% $\zeta_2\gamma_2$	

beta<sup>0</sup>-thalassemia, no beta globin at all is produced by the thalassemic locus, whereas in beta<sup>+</sup>-thalassemia, there is reduced but measurable output of beta globin. The severity of homozygous beta-thalassemia (or beta-thalassemia major) is greatest when two beta<sup>0</sup>-thalassemia genes are inherited; clinical disease usually is much milder when two beta<sup>+</sup>-thalassemia genes are inherited. Severe beta-thalassemia is associated with lifelong hemolytic anemia, dependence on regular RBC transfusions for survival, and the gradual development of transfusion-associated hemosiderosis (Olivieri, 1999). The clinical abnormalities of beta-thalassemia are not evident at birth but first manifest only after 3 months of age, when beta globin normally becomes the dominant form of non-alpha globin synthesized. Although affected newborns appear clinically normal, the diagnosis of beta<sup>0</sup>-thalassemia can be made at birth by detecting a complete absence of hemoglobin A, using hemoglobin electrophoresis or similar techniques. Definitive diagnosis of beta<sup>+</sup>-thalassemia by these techniques, however, is not possible in the newborn period, because the reduced amount of hemoglobin A produced overlaps the range for normal babies. Direct identification of beta-thalassemia mutations by DNA diagnostic techniques is increasingly available and allows the identification at birth of all infants with beta-thalassemia major. These techniques, however, are more commonly used for prenatal diagnosis of beta-thalassemia syndromes. DNA can be obtained during midtrimester from fetal amniocytes (15 to 17 weeks) or during the first trimester from chorionic villi (9 to 11 weeks) and the assay completed within a few days, allowing families to make informed decisions regarding termination of pregnancy (Kazazian and Boehm, 1988). The implementation of a strategy of carrier detection, genetic counseling, and prenatal diagnosis in countries where beta-thalassemia is common has led to a striking reduction in the number of births of infants with beta-thalassemia major (Cao et al, 1996).

### **Hemoglobin E/Beta-Thalassemia**

Hemoglobin E is a structurally abnormal hemoglobin that results from an amino acid substitution (lysine for glutamine) at the number 26 amino acid of beta globin, counting from the N terminus. Because this mutation also adversely affects mRNA processing, there is reduced output of beta globin mRNA. Hemoglobin E trait is therefore an example of a thalassemic hemoglobinopathy. The thalassemic component of the condition is mild (a beta<sup>+</sup>-thalassemia) so that hemoglobin E carriers are microcytic but not anemic. Even hemoglobin E homozygotes have little or no anemia. However, coinheritance of hemoglobin E trait and beta<sup>0</sup>-thalassemia trait can give rise to a transfusion-dependent form of beta-thalassemia major (Fucharoen et al, 2000). As with other types of beta-thalassemia major, clinical abnormalities are not seen until the infant is 3 to 6 months of age. However, the presence of hemoglobin E is easily detected at birth by hemoglobin electrophoresis or related techniques. Infants found to have hemoglobin E need careful follow-up evaluation to exclude the possibility of hemoglobin E beta-thalassemia. DNA-based detection of the hemoglobin E mutation is

feasible (Embury et al, 1990) and has been applied to both prenatal and neonatal diagnosis.

### **Gamma-Thalassemia**

Large deletions within the beta globin gene cluster may remove both gamma globin genes (<sup>A</sup>γ and <sup>G</sup>γ) as well as the delta and beta globin genes. The resulting gamma-delta-beta-thalassemia is lethal in the homozygous state but in the heterozygote produces a transient but moderately severe microcytic anemia in the newborn. Over the first few months of life, the anemia resolves to a variable extent without specific therapy, and eventually the hematologic picture is that of beta-thalassemia trait. At least eight different gamma-delta-beta deletions have been reported, all but one in families of European origin (McDonagh and Nienhuis, 1993).

### **Comment**

We frequently see newborns with severe hemolytic anemia that resolves or decreases in severity spontaneously over the first few months of life, suggesting that some unique property of the fetal RBC contributes to the severity of hemolysis. The presence of a hypochromic microcytic anemia not related to iron deficiency (which can occur with chronic fetal blood loss) suggests one of the thalassemia disorders. Either alpha- or gamma-thalassemia could produce this degree of anemia. The absence of hemoglobin Barts in the cord blood RBCs rules out alpha-thalassemia. Measurement of reticulocyte globin chain synthesis in vitro showed diminished production of both gamma and beta chains, consistent with a diagnosis of gamma-beta-thalassemia. The severe neonatal hemolytic anemia was due to accumulation of excess alpha globin chains, unable to form normal hemoglobin tetramers because of the lack of partner gamma or beta chains. As the infant matured and began to synthesize more beta chains, the globin chain imbalance lessened and hemolysis diminished. Eventually, the hematologic picture in the infant resembled that in her father, that is, classic beta-thalassemia trait.

### **CASE STUDY 2**

A full-term 2300-g girl became jaundiced at 24 hours of age (total bilirubin 13.7 mg/dL). The hemoglobin was 10.4 g/dL, hematocrit 32%, RBC count  $3.8 \times 10^6/\text{mL}$ , MCV 84 fl, and MCH 27 pg/cell. The reticulocyte count was 26%, and there were 400 nucleated RBCs/100 WBCs. Rh and ABO incompatibility were absent; the Coombs test was negative. Iron and iron-binding capacity were normal, and there was no detectable RBC enzyme deficiency. The hemoglobin F level was 52% (normal is 60% to 85%). Hemoglobin Barts was not detected. An RBC transfusion was given, and over the next few days, nucleated RBCs disappeared, the reticulocyte count decreased, and the hematocrit remained stable. The mother was hematologically normal, but the father had a mild hypochromic microcytic anemia that resembled beta-thalassemia trait. At several months of age, the infant had improved and had only a mild hypochromic microcytic anemia that clearly resulted from beta-thalassemia trait (Kan et al, 1972).

### Sickle Cell Disease

The sickling hemoglobinopathies are beta globin mutations that, as with beta-thalassemia, do not become clinically evident until the infant reaches several months of age. Sickle cell anemia, the most severe of the disorders, is the result of inheritance of two beta<sup>S</sup> mutations (substitution of valine for glutamic acid at the sixth amino acid on the beta globin chain), one from each parent. Sickle-beta<sup>0</sup>-thalassemia, phenotypically identical to sickle cell anemia, is caused by inheritance of one beta<sup>S</sup> and one beta-thalassemia mutation. The third common form of sickle cell disease, hemoglobin S-C disease, is somewhat milder than sickle cell anemia or sickle-beta<sup>0</sup>-thalassemia. It is the consequence of inheritance of one beta<sup>S</sup> mutation and one beta<sup>C</sup> mutation (the substitution of lysine for glutamic acid at the sixth amino acid on the beta globin chain). Although no clinical abnormalities are present at birth, early diagnosis is important, because two potentially fatal but largely preventable complications may occur during the first year of life (Lenfant, 2002). The first is the splenic sequestration crisis, an unpredictable pooling of large numbers of RBCs in the spleen, which leads to a rapid decrease in hematocrit and, in the most severe cases, cardiovascular collapse and death. The second is overwhelming septicemia, usually caused by *S. pneumoniae* or *H. influenzae*. The unusually high susceptibility to infection with encapsulated organisms such as *S. pneumoniae* is the consequence of functional asplenia, which commonly appears by 1 year of age in infants with sickle cell anemia or sickle-beta<sup>0</sup>-thalassemia (but not until later in persons with hemoglobin S-C disease). Prompt treatment of splenic sequestration with RBC transfusions is lifesaving so that parents are taught to recognize early manifestations such as splenic enlargement, lethargy, or pallor. Overwhelming sepsis can be prevented in most instances by early immunization with *H. influenzae* and conjugated pneumococcal vaccines, beginning at 2 months of age, and by institution of daily prophylactic penicillin at a dose of 125 mg twice daily (Gaston et al, 1986). It is the need to institute these prophylactic measures within the first 1 to 2 months of life that provides a compelling rationale for neonatal diagnosis of the sickling disorders. In many states, all newborns are screened for these disorders, whereas in others, only high-risk ethnic groups are targeted. Usually a dried sample of blood on filter paper, collected at the same time as for other screening tests for inherited metabolic disorders, is used, but cord blood also is satisfactory. Tests that quantitate the amount of hemoglobin S, such as high-performance liquid chromatography, thin-layer isoelectric focusing, or electrophoresis on both cellulose acetate (in an alkaline buffer) and citrate agar (in an acid buffer), are adequate, but sickle solubility tests or the sodium metabisulfate "sickle prep" are not, because sickle cell disease cannot be distinguished from sickle cell trait and the tests are not sensitive enough to detect reliably the small percentage of hemoglobin S present in the RBCs of the newborn.

Prior transfusion with normal adult RBCs may cause a false-negative newborn screening result and delay the diagnosis (Reed et al, 2000). An excellent overview of issues related to newborn screening for sickle cell disease

has been published by Wethers and colleagues (1989). Extensive experience with mandatory statewide screening for all infants has been accumulated in New York (Diaz-Barrios, 1989), California (Lorey et al, 1996), and elsewhere (Wethers et al, 1989).

Infants without a hemoglobinopathy born to mothers with sickle cell disease present more of a clinical problem during gestation and the neonatal period than is the case with infants who actually have sickle cell disease. Spontaneous abortion, intrauterine growth restriction (present in approximately 15% of cases), stillbirth (in 6%), preterm labor and delivery, and perinatal mortality (in approximately 15%) all are more frequent in the infants of mothers with sickle cell anemia (Koshy and Burd, 1995). These problems may be traced to abnormalities of the placenta such as small size, infarction, and an increased incidence of placenta previa and abruptio placentae, which appears to be the consequence of sickle vaso-occlusive events within the maternal side of the placental circulation. They are not caused by the presence of the sickle trait, beta-thalassemia trait, or hemoglobin C trait in the infant, because no hematologic disease is associated with the carrier state for these mutations, even in adult life when they are fully expressed, except under conditions of extreme hypoxia.

One caveat regarding sickle trait blood is that blood from an adult donor who has sickle trait should not be used for exchange transfusions in the newborn, particularly if hypoxemia is present, because use of sickle trait RBCs in this setting may contribute to a fatal outcome (Veiga and Vaithianathan, 1963).

### HYPOPLASTIC ANEMIA

The two major causes of pure RBC aplasia in children are Diamond-Blackfan anemia (DBA) and transient erythroblastopenia of childhood (TEC). Approximately 25% of infants with DBA are anemic at birth. In contrast, TEC is a disease that rarely manifests before 1 to 2 months of age (Alter and Young, 1998), and although it can manifest in the first year of life (Miller and Berman, 1994; Ware and Kinney, 1991), most children with this disorder are older infants or young children.

#### Diamond-Blackfan Anemia

Also known as *congenital hypoplastic anemia*, DBA is a red cell aplasia characterized by the absence of recognizable erythroid precursor cells in the bone marrow (Alter and Young, 1998). An as-yet-uncharacterized defect in erythroid progenitor cells appears to be responsible for the profound erythroid hypoplasia. Most cases are sporadic, although 10% to 20% clearly are inherited, most commonly following an autosomal dominant pathway. Recent studies have identified that a significant fraction of DBA cases are linked to genes on chromosome 19q (Gustavsson et al, 1997) and chromosome 8p (Gazda et al, 2001). The relationship of these findings to the pathophysiology of DBA currently is being defined. Anemia is lifelong, but the onset of the disease is variable. Approximately 10% of affected infants are severely anemic in the

newborn period, and pallor at birth or soon thereafter has been a feature of the disease in most cases (Alter and Young, 1998). Growth retardation, skeletal abnormalities, or other congenital anomalies are seen in almost one third of patients. The diagnosis of DBA is suggested by anemia and reticulocytopenia appearing in the first 6 months of life. Certain unusual features of the RBCs (macrocytosis, elevated fetal hemoglobin, increased adenosine deaminase activity) may assist in diagnosis. Many patients achieve durable remissions from anemia when treated with corticosteroids. Those who do not receive corticosteroids will require chronic RBC transfusions and are at risk of transfusion hemosiderosis. Transfusion-dependent DBA can be cured by allogeneic bone marrow transplantation from tissue-compatible siblings (Vlachos et al, 2001). At present, the use of unrelated donors for bone marrow transplants is not recommended, but this may change in the future. The incidence of leukemia may be increased in older patients with DBA, but the basis for this predisposition is unknown (Alter and Young, 1998; Glader, 1987). An increased incidence of osteosarcoma also is now recognized (Lipton et al, 2001).

### Transient Erythroblastopenia of Childhood

TEC is an acquired hypoplastic anemia that usually appears several weeks after an acute viral infection (Wranne, 1970). Evidence of a humoral or cellular immune response directed against erythroid precursor cells has been obtained in many affected children. As in DBA, the hallmarks of the disorder are anemia and reticulocytopenia, with an absence of erythroid precursors in the bone marrow. The platelet count sometimes is increased, and neutropenia may be present (Rogers et al, 1989). The abnormal RBC features seen in DBA are not seen in TEC. The natural history of TEC is one of spontaneous recovery over a period of several weeks, and because most children are recognized at the nadir of their anemia, evidence of recovery may already be present. RBC transfusion may be required to treat symptomatic anemia, but steroid therapy is unnecessary and not effective. There are no long-term hematologic sequelae of TEC, and recurrences are rare.

## PHYSIOLOGIC ANEMIA OF INFANCY AND PREMATUREITY

At birth, the mean hemoglobin of term infants (17 g/100 mL) is slightly greater than in premature infants (16 g/100 mL). The hemoglobin concentration in term infants subsequently decreases to a plateau at which it remains throughout the first year of life (Table 77-9). Termed *physiologic anemia of infancy*, this anemia characterized by low (relative to adult values) hemoglobin is a normal part of development and has no adverse clinical effects. A similar process (*anemia of prematurity*) occurs in premature infants, but the hemoglobin decreases more rapidly and reaches a lower nadir. After 1 year of age, there is little difference between the hemoglobin values of term and premature infants.

### Physiologic Anemia of Infancy

With the onset of respirations at birth, considerably more oxygen is available for binding to hemoglobin, and the hemoglobin-oxygen saturation increases from approximately 50% to 95% or more. Furthermore, the normal developmental switch from fetal to adult hemoglobin synthesis actively replaces high-oxygen-affinity fetal hemoglobin with lower-oxygen-affinity adult hemoglobin, which can deliver a greater fraction of hemoglobin-bound oxygen to the tissues. Therefore, immediately after birth the increase in blood oxygen content and tissue oxygen delivery down-regulates erythropoietin production; as a consequence, erythropoiesis is suppressed. In the absence of erythropoiesis, hemoglobin levels decrease because there is no replacement of aged RBCs as they are normally removed from the circulation. Iron from degraded RBCs is stored for future hemoglobin synthesis. The hemoglobin concentration continues to decrease until tissue oxygen needs are greater than oxygen delivery. Normally, this point is reached between 6 and 12 weeks of age, when the hemoglobin concentration is 9.5 to 11 g/dL. As hypoxia is detected by renal or hepatic oxygen sensors, erythropoietin production increases and erythropoiesis resumes. The iron previously stored in reticuloendothelial tissues can then be used for hemoglobin synthesis. The supply of stored iron is sufficient for hemoglobin synthesis, even in

**TABLE 77-9**

### Hemoglobin Changes During the First Year of Life

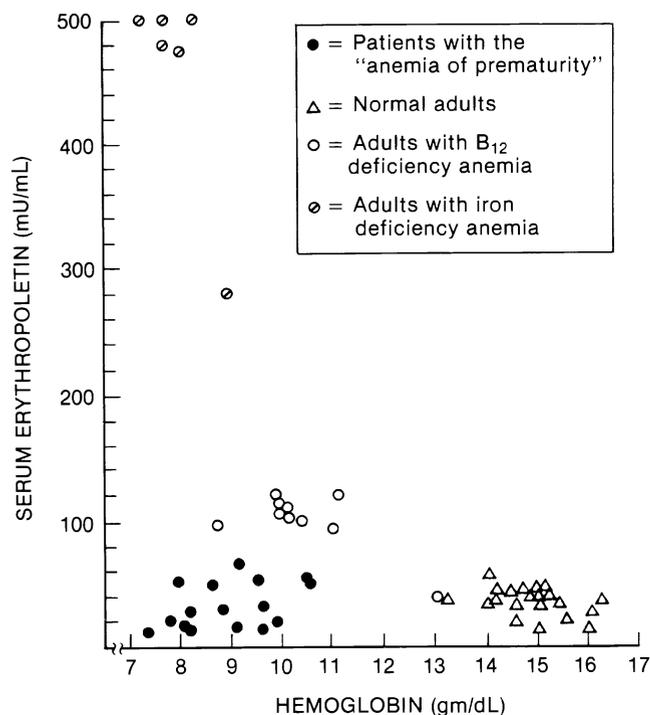

Week	Term	Premature (1.2-2.5 kg)	Premature (<1.2 kg)
0	17.0 (14.0-20.0)	16.4 (13.5-19.0)	16.0 (13.0-18.0)
1	18.8	16.0	14.8
3	15.9	13.5	13.4
6	12.7	10.7	9.7
10	11.4	9.8	8.5
20	12.0	10.4	9.0
50	12.0	11.5	11.0
Lowest hemoglobin: mean (range)	10.3 (9.5-11.0)	9.0 (8.0-10.0)	7.1 (6.5-9.0)
Time of nadir	6-12 wk	5-10 wk	4-8 wk

the absence of dietary iron intake, until approximately 20 weeks of age. It is unnecessary to administer iron during this period, because it does not prevent the physiologic decrease in hemoglobin. Any iron administered is added to stores for future use. This physiologic hemoglobin decrease does not represent anemia in the true sense of the term; rather, it is a normal adjustment reflecting the presence of excess capability for oxygen delivery relative to tissue oxygen requirements. There is no hematologic problem, and no therapy is required.

### Anemia of Prematurity

The physiologic anemia seen in preterm infants is more profound and occurs earlier (see Table 77-9). Because symptoms may occur, the anemia of prematurity is considered nonphysiologic. The cause of anemia is multifaceted. The lower hemoglobin may be in part a physiologic response to the lower oxygen consumption in premature infants compared with that in term infants, a consequence of their diminished metabolic oxygen needs (Mestyan et al, 1964). An important component in the first few weeks of life is blood loss due to sampling for the many laboratory tests necessary to stabilize the clinical status of these infants, particularly those with cardiorespiratory problems. The erythropoietic response to anemia also is suboptimal, a significant problem because demands on erythropoiesis are heightened by the short survival of the RBCs of premature infants (approximately 40 to 60 days instead of 120 days as in adults) and the rapid expansion of the RBC mass that accompanies growth. The basis for suboptimal erythropoiesis in prematurity appears to be inadequate synthesis of erythropoietin in response to hypoxia. Figure 77-13 illustrates the magnitude of the deficiency, which, as shown by Stockman and colleagues (1984), is greatest in the smallest, least mature infants. Because the liver is the predominant source of erythropoietin during fetal life, it has been proposed that relative insensitivity of the hepatic oxygen sensor to hypoxia explains the blunted erythropoietin response seen in premature infants (Dallman, 1993). The spontaneous resolution of the anemia that occurs by approximately 40 weeks of gestational age is in keeping with a developmental switch from the relatively insensitive hepatic oxygen sensor to the renal oxygen sensor, which is exquisitely sensitive to hypoxia, because by this time the predominant site of erythropoietin synthesis has shifted to the kidneys. The problem does not lie with altered sensitivity of erythroid progenitors to erythropoietin because this has been shown to be normal (Shannon et al, 1987).

The anemia of prematurity occurs even in nutritionally replete infants, but it may be heightened by deficiencies of folate, vitamin B<sub>12</sub>, or vitamin E (Worthington-White et al, 1994). Premature infants are endowed at birth with significantly less vitamin E than is present in term infants, and unless supplemental vitamin E is provided, this deficiency state persists for 2 to 3 months. Vitamin E is an antioxidant compound vital to the integrity of erythrocytes, and in its absence, these cells are susceptible to lipid peroxidation and membrane injury. One clinical consequence of vitamin E deficiency is that hemolytic anemia

**FIGURE 77-13.** Hemoglobin levels and corresponding serum erythropoietin levels are shown. Values are from infants with the anemia of prematurity, normal adults, adults with vitamin B<sub>12</sub> deficiency anemia, and adults with iron deficiency anemia. (From Ross MP, Christensen RD, Rothstein G, et al: A randomized trial to develop criteria for administering erythrocyte transfusions to anemic preterm infants from 1 to 3 months of age. *J Perinatol* 9:246, 1989. Reprinted by permission of Appleton & Lange, Inc.)

can occur in small premature infants (weighing less than 1500 g) at 6 to 10 weeks of age (Oski and Barness, 1967; Ritchie et al, 1968). This hemolytic anemia, which is characterized by reduced vitamin E levels and increased RBC peroxide hemolysis, rapidly disappears following vitamin E administration. A logical conclusion is that vitamin E deficiency might contribute to the anemia of prematurity in a more general sense. In fact, premature infants given daily vitamin E (15 IU/day) had higher hemoglobin levels and lower reticulocyte levels than a control group not given the vitamin, as shown in Table 77-10 (Oski and Barness, 1967). A more recent study found no hematologic benefit for the administration of 25 IU of vitamin E daily to premature infants (Zipursky et al, 1987). Although it has become standard practice to administer vitamin E to all premature infants, the hemoglobin nadir in these babies is still lower than that in term newborns, indicating that anemia is largely caused by other factors such as erythropoietin deficiency.

### Treatment of Anemia of Prematurity with Recombinant Human Erythropoietin

Because a relative deficiency of erythropoietin is present in the anemia of prematurity, a number of studies have evaluated the safety and efficacy of rHuEPO therapy in this setting. If adequate doses of rHuEPO are used,

TABLE 77-10

**Effect of Supplemental Vitamin E on Anemia of Prematurity\***

	Control	Vitamin E
Birth weight	1176 ± 182 g	1278 ± 180 g
Vitamin E (mg/100 mL)	0.22 ± 0.10	1.00 ± 0.25
H <sub>2</sub> O <sub>2</sub> hemolysis (%)	66 ± 21	9 ± 9
Lowest hemoglobin (g/100 mL)	7.7 ± 1.5	9.2 ± 1.3
Highest reticulocytes (%)	6.7 ± 2.5	3.1 ± 0.7

\*Premature infants were given prophylactic vitamin E (15 international units [IU]/day), and the vitamin E level, peroxide hemolysis, hemoglobin concentration, and reticulocyte count were measured after 6 to 8 weeks. These values were compared with those from a group of control infants not given vitamin E supplements.

Data from Oski FA, Barness LA: Vitamin E deficiency: A previously unrecognized cause of hemolytic anemia in the premature infant. *J Pediatr* 70:211, 1967.

reticulocytosis and a retardation in the development of anemia are regularly achieved (Gallagher and Ehrenkranz, 1993; Mentzer and Shannon, 1995). Several large multicenter trials have documented a modest but statistically significant reduction in the RBC transfusion requirements of treated infants compared with control subjects (Maier et al, 1994; Meyer et al, 1994; Shannon et al, 1995). Erythropoietin treatment may have a particularly important role to play in the management of infants whose parents refuse to allow blood transfusions on religious grounds (Davis et al, 1991). The optimal timing for initiation of rHuEPO therapy and the optimal dose have yet to be determined. To achieve the best results, supplemental oral iron at a dose of at least 6 mg/kg per day needs to be administered. It may be possible to use parenteral iron supplements, particularly in young very-low-birth-weight infants who are not able to take oral iron (Heese et al, 1990). Adequate vitamin E supplementation is of particular importance if intramuscular iron is used (Graeber et al, 1977). Although concern was raised over two rHuEPO-treated infants in one study who subsequently died of sudden infant death syndrome (SIDS) (Emmerson et al, 1993), SIDS has not been a feature of rHuEPO treatment in other studies. Early concerns about rHuEPO-induced neutropenia (Christensen et al, 1991) have, similarly, not been borne out (Shannon et al, 1995). Therefore, the current consensus is that use of this agent appears to be safe in premature infants. Very small premature infants (less than 1300 g birth weight) are those most likely to benefit from therapy (Strauss, 1994). There is disagreement regarding the cost-benefit relation of rHuEPO therapy (Maier et al, 1994; Shireman et al, 1994; Wandstrat and Kaplan, 1995; Zipursky, 2000).

A meta-analysis of 21 prospective controlled trials of rHuEPO treatment of the anemia of prematurity was recently published (Vamvakas and Strauss, 2001). Although there was considerable variation between studies, in general the efficacy of rHuEPO in reducing the need for red cell transfusions was modest. The authors concluded that it was premature to recommend rHuEPO for standard therapy for the anemia of prematurity.

**Red Blood Cell Transfusion Therapy in Premature Infants**

It has been estimated that of the approximately 38,000 infants born weighing less than 1500 g in the United States each year, 80% will receive multiple RBC transfusions (Strauss, 1991). Most transfusions given in the first several weeks of life are to replace losses from phlebotomy required for laboratory monitoring during ventilator support and other intensive care measures. The mean blood loss resulting from phlebotomy during the first week of life in one group of 20 successive very ill premature infants admitted to the intensive care nursery was 38.9 mL, an impressive figure considering that the total blood volume of such infants is approximately 80 mL/kg body weight (Shannon, 1990). After the first few weeks of life, most transfusions are given to treat the symptoms of anemia of prematurity. The risks associated with use of allogeneic RBC transfusion in premature infants include exposure to viral infections, graft-versus-host disease, electrolyte and acid-base imbalances, exposure to plasticizers, hemolysis when T antigen activation of RBCs has occurred, and immunosuppression (Strauss, 1991).

Many strategies to reduce the need for allogeneic RBC transfusion in premature infants have been developed. Reducing phlebotomy losses by use of noninvasive monitoring techniques has been of only limited usefulness (Strauss, 1991). Donor exposures can be reduced by assigning a specified bag of adult donor blood to a sick neonate for multiple transfusions (Cook et al, 1993), particularly because it has been shown that blood stored for up to 35 days in CPDA-1 (Liu et al, 1994) or AS-3 (Goldman et al, 2001; Strauss et al, 2000) is safe for use in this setting. Defining strict criteria for RBC transfusions also can reduce the number of donor exposures in routine nursery practice (Batton et al, 1992). Traditionally, RBC transfusions have been given to replace phlebotomy losses or in the presence of symptoms thought to reflect hypoxia (e.g., tachycardia, tachypnea, dyspnea, apneic spells, poor feeding) (Oski and Naiman, 1982; Wardrop et al, 1978). However, studies to validate such practices have yielded conflicting results. Stockman and Clark (1984) showed a beneficial effect of transfusion on weight gain, but no benefit was found by Blank and coworkers (1984). Similarly, apneic spells were reduced in frequency following RBC transfusion in the studies of Joshi and associates (1987) and Ross and coworkers (1989) but not in those of Blank and colleagues (1984), Keyes and coworkers (1989), or Bifano and colleagues (1992). Lachance and colleagues (1994) measured oxygen consumption, myocardial function, resting energy expenditure, and other physiologic variables before and after RBC transfusions. They concluded that in asymptomatic anemic premature infants, oxygenation was well maintained without RBC transfusions when the hemoglobin level was 6.5 g/dL or more. Nelle and coworkers (1994) studied a similar group of asymptomatic anemic premature infants and found that RBC transfusion improved systemic oxygen transport as well as transport in the cerebral and gastrointestinal arteries. When clinical features of hypoxia are absent or findings are equivocal, an elevated blood lactate level may predict a need for transfusion (Izraeli et al, 1993) but in the experience of Frey and Losa (2001) adds little value to

the decision-making process in the individual patient. At present, most NICUs have abandoned earlier practices of automatically replacing phlebotomy losses in favor of transfusing for clear-cut symptoms of hypoxia or for significant anemia unaccompanied by evidence of an adequate erythropoietic response (Alagappan et al, 1998; Engelfriet and Reesink, 2001).

## POLYCYTHEMIA

Neonatal polycythemia usually is caused by one of two conditions: increased intrauterine erythropoiesis or fetal hypertransfusion (Table 77-11). Other causes seen in older children, such as arterial hypoxemia (cyanotic heart disease, pulmonary disease), abnormal hemoglobins, or hypersecretion of erythropoietin by tumors, are rare, and primary polycythemia or polycythemia vera is virtually nonexistent. In normal term infants, delayed clamping of the cord leading to an increased transfer of placental blood to the infant is the most common cause of polycythemia. In the setting of acute intrapartum hypoxia, increased placental transfusion also may account for the observed increase in fetal RBC mass, according to animal studies by Oh and coworkers (1975). Placental insufficiency and chronic intrauterine hypoxia, as seen typically in small-for-gestational-age infants, most commonly underlie increased intrauterine erythropoiesis.

As the hematocrit increases, blood viscosity increases exponentially (Fig. 77-14). Blood flow is impaired by hyperviscosity at hematocrits of 60% or more. Oxygen transport,

which is determined by both hemoglobin levels (i.e., oxygen-binding capacity) and blood flow, is maximal in the normal hematocrit range. At low hematocrits, oxygen transport is limited by reduced oxygen-binding capacity, whereas at higher hematocrits, reduction in blood flow secondary to hyperviscosity may similarly limit oxygen transport. At any given hematocrit, expansion of the blood volume beyond the normal level (hypervolemia) distends the vasculature, decreases peripheral resistance, and increases blood flow and, ultimately, oxygen transport. These physiologic observations have implications for therapy of polycythemia.

Most polycythemic infants have no symptoms, particularly if the polycythemia becomes apparent only on routine neonatal screening. Symptoms, when present, usually are attributable to hyperviscosity and poor tissue perfusion or to associated metabolic abnormalities such as hypoglycemia and hypocalcemia. Common early signs and symptoms include plethora, cyanosis (resulting from peripheral stasis), lethargy, hypotonia, poor suck and feeding, and tremulousness. Serious complications include cardiorespiratory distress (with or without congestive heart failure), seizures, peripheral gangrene, NEC, renal failure (occasionally resulting from renal vein thrombosis), and priapism. Because the elevated RBC mass increases the catabolism of hemoglobin, hyperbilirubinemia is common and gallstones occasionally occur.

In the symptomatic infant, a venous hematocrit of 65% or more (or a hemoglobin greater than 22 g/dL) confirms the presence of polycythemia. In screening apparently healthy newborns for polycythemia, however, account must be taken of a number of physiologic variables that influence the hematocrit during the first 12 hours of life:

1. Time of cord clamping—immediate clamping (within 30 seconds) minimizes placental transfusion.
2. Age at sampling—values increase from birth to a peak at 2 hours, gradually decreasing to cord levels around 12 to 18 hours (Ramamurthy and Berlanga, 1987; Shohat et al, 1984).
3. Site of sampling—values from blood extracted by the heelstick method exceed those from venous blood (the difference can be minimized by prewarming the heel).
4. Method of hematocrit determination—spun values are higher than those obtained by electronic cell counter and show better correlation with blood viscosity (Villalta et al, 1989).

One way to standardize and simplify screening for polycythemia is as follows: At birth, clamp the cord at about 30 to 45 seconds; at 4 to 6 hours of age, obtain a blood sample from a warmed heelstick and perform a spun hematocrit determination. If the result is greater than 70%, repeat the test on a venous sample. A venous hematocrit of 65% or more indicates polycythemia. By this approach, 1% to 5% of newborns are polycythemic; the range largely reflects differences in altitude at which the study population resides. Because the hematocrit is lower with increasing prematurity, polycythemia is seen less frequently in preterm infants than in term babies.

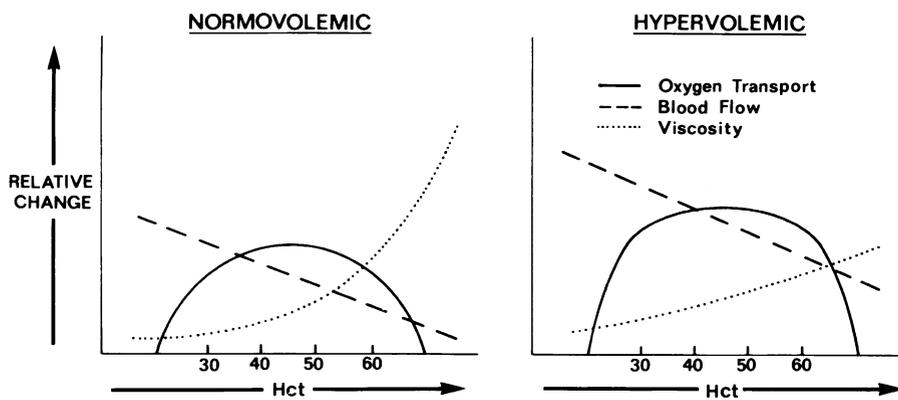

Following diagnosis, an attempt should be made to determine the cause of polycythemia (see Table 77-11). The condition is particularly common in infants of diabetic mothers or those with Down syndrome (Mentzer,

**TABLE 77-11**

### Etiology of Neonatal Polycythemia

Active (Increased Intrauterine Erythropoiesis)	Passive (Secondary to Erythrocyte Transfusions)
Intrauterine hypoxia	Delayed cord clamping
Placental insufficiency	Intentional
Small-for-gestational-age infant	Unassisted delivery
Postmaturity	Maternofetal transfusion
Toxemia of pregnancy	Twin-twin transfusion
Drugs (propranolol)	
Severe maternal heart disease	
Maternal smoking	
Maternal diabetes	
Neonatal hyperthyroidism or hypothyroidism	
Congenital adrenal hyperplasia	
Chromosome abnormalities	
Trisomy 13	
Trisomy 18	
Trisomy 21 (Down syndrome)	
Hyperplastic visceromegaly (Beckwith syndrome)	
Decreased fetal erythrocyte deformability	

Data from Oski FA, Naiman JL: Hematologic Problems in the Newborn, 3rd ed. Philadelphia, WB Saunders, 1982.

**FIGURE 77-14.** Effect of hematocrit on viscosity, blood flow, and oxygen transport.

1978) and may also occur in the setting of maternal hypertension (Kurlat and Sola, 1992) or, rarely, fumaric aciduria (Kerrigan et al, 2000). However, no apparent cause is found in most cases. Studies to determine the effects of polycythemia are dictated by the clinical findings but should usually include serum bilirubin, glucose, calcium, urea nitrogen, and creatinine levels.

Treatment by isovolumetric partial exchange transfusion is recommended to reduce the RBC mass without inducing hypovolemia. A beneficial effect of isovolumetric hemodilution on skin capillary perfusion (Norman et al, 1992) and on skin vasomotor activity (Norman et al, 1993) has been documented in polycythemic infants. At the University of California at San Francisco, all symptomatic newborns whose venous hematocrit is greater than 60% and asymptomatic newborns whose hematocrit is greater than 65% undergo partial exchange transfusion, using either normal saline or 5% albuminated saline (Levy et al, 1990). Unlike fresh frozen plasma, these products do not carry a risk of transmitting viral infections. Furthermore, partial exchange transfusion with fresh frozen plasma has been associated with the appearance of NEC (Black et al, 1985), whereas purified plasma protein derivatives such as albumin have not (Hein and Lathrop, 1987). Withdrawal of blood for a partial exchange transfusion is most easily done using an umbilical artery catheter. Any vessel may be used for blood withdrawal, and all but arterial lines can be used to infuse volume. An umbilical venous catheter inserted into the right atrium also provides acceptable access, but if correct placement cannot be achieved, the catheter should be inserted just far enough into the vessel to allow blood to be withdrawn. Calculation of the total volume of blood to be exchanged for diluent uses the following formula (Oski and Naiman, 1982):

$$\text{Exchange volume} = \frac{\text{observed Hct} - \text{desired Hct} \times \text{BV (mL/kg)} \times \text{weight (kg)}}{\text{observed Hct}}$$

where blood volume (BV) usually is 100 mL/kg but in infants of diabetic mothers may be lower (80 to 85 mL/kg).

**Example:** A 3-kg dyspneic infant with an 80% hematocrit requires a partial exchange transfusion.

$$\begin{aligned} \text{Blood volume} &= 3 \text{ kg} \times 100 \text{ mL/kg} = 300 \text{ mL} \\ \frac{\text{observed Hct} - \text{desired Hct}}{\text{observed Hct}} &= \frac{80 - 55}{80} = 0.31 \end{aligned}$$

Therefore, volume of exchange = 300 mL  $\times$  0.31 = 93 mL.

Some neonatal programs have more stringent hematocrit thresholds (e.g., >70%) (Carmi et al, 1992; Levy et al, 1990) for partial exchange transfusion of asymptomatic polycythemic infants than that cited previously (>65%). Although asymptomatic infants have an increased risk of late, mild neuropsychologic handicaps, prospective studies have failed to demonstrate major benefit from partial exchange transfusion (Delaney-Black et al, 1989). Because coexisting hypoglycemia is an important determinant of adverse neurologic outcome, careful monitoring and maintenance of adequate glucose levels and hydration are essential.

### Comment

The clinical findings in this infant were initially suggestive of organic heart disease. Rapid disappearance of the cardiac abnormalities following recognition and treatment of polycythemia indicated that these abnormalities were the result of polycythemia-induced hyperviscosity. In older children with cyanotic heart disease, polycythemia is a physiologic response that allows adequate oxygen transport to occur in the presence of arterial hypoxemia. Phlebotomy in these children may produce an acute hypoxic insult and should be undertaken with caution if at all. In striking contrast, in the newborn period, infants with cyanotic heart disease are not polycythemic (Gatti et al, 1966). Therefore, phlebotomy should improve, not worsen, oxygen transport, as it did in this case.

### CASE STUDY 3

A gravida 2, para 1 white woman delivered a 2950-g male infant after a normal pregnancy, labor, and delivery. At birth, the child had an Apgar score of 6. Physical examination revealed a cyanotic infant with a grade III/VI systolic heart murmur. The liver edge was palpable 2 cm below the right costal margin, and the spleen tip was palpable. Chest radiograph revealed a markedly enlarged heart with increased pulmonary vascular markings. The hemoglobin was 26 g/dL, and the hematocrit was 79%. There were no other hematologic abnormalities. The infant underwent partial exchange transfusion with 5% albumin, and the postexchange hematocrit was 62%. Subsequently, the infant's color improved, the heart murmur disappeared, and there were no remaining signs of congestive heart failure.

## METHEMOGLOBINEMIA

Methemoglobin is an oxidized derivative of hemoglobin in which heme iron is in the ferric ( $\text{Fe}^{3+}$ ) or oxidized state rather than the ferrous ( $\text{Fe}^{2+}$ ) or reduced state. Because methemoglobin is unable to bind (or release) oxygen, the presence of significant amounts of this respiratory pigment adversely affects blood oxygen-binding capacity and oxygen transport. Normally, small amounts of methemoglobin are formed daily *in vivo* by the action of endogenous agents, which may include oxygen itself (auto-oxidation). However, any methemoglobin formed is rapidly reduced through the action of RBC NADH-methemoglobin reductase (also known as cytochrome  $b_5$  reductase), so that in normal persons, levels of methemoglobin seldom exceed 1%. A second methemoglobin reductase, dependent on NADPH as cofactor, also is present in RBCs. Although this enzyme is not active under normal physiologic conditions, it is greatly activated by the presence of certain redox compounds such as methylene blue, forming the basis for treatment of methemoglobinemia by this agent.

*Acquired methemoglobinemia* occurs when normal persons are exposed to chemicals such as aniline dyes that readily oxidize hemoglobin iron. Newborns are particularly susceptible because fetal hemoglobin is more readily oxidized to the ferric state than is hemoglobin A (Martin and Huisman, 1963) and because RBC NADH-methemoglobin reductase activity is low during the first few months of life (Bartos and Desforges, 1966). Merely marking the diapers of newborns with aniline dyes has caused methemoglobinemia. Drugs such as prilocaine, administered before birth to provide local anesthesia, can produce methemoglobinemia in both mother and infant (Climie et al, 1967). Although in most infants, no increase in methemoglobin levels follows the use of lidocaine-prilocaine cream (Emla Cream) to provide analgesia during circumcision (Taddio et al, 1997), a few case reports of visible cyanosis due to methemoglobinemia in infants treated with this cream have appeared (Couper, 2000; Tse et al, 1995). Perhaps the best-known agent that may cause methemoglobinemia is nitrite, either present *de novo* in ingested material or generated by administering nitric oxide to term babies in high concentrations for treatment of persistent pulmonary hypertension (Davidson et al, 1998). Nitrates can be converted to nitrite by the action of intestinal bacteria. It is for this reason that well water (Comly, 1945) or foods with a high nitrate content (e.g., cabbage, spinach, beets, carrots) (Keating et al, 1973) can produce methemoglobinemia in infants. Accumulation of nitrate in the intestinal tract of infants with diarrhea and acidosis (Kay et al, 1990; Yano et al, 1982) or symptomatic dietary protein intolerance (Murray and Christie, 1993) is thought to underlie the transient methemoglobinemia that occurs in these conditions.

*Congenital methemoglobinemia* is due to inherited disorders of hemoglobin structure or to a severe deficiency of NADH methemoglobin reductase activity. The seven inherited abnormalities of hemoglobin structure that give rise to methemoglobinemia, known collectively as the hemoglobin M disorders, are rare autosomal dominant defects caused by point mutations that alter a single amino acid in the structure of normal globin. The altered conformation that ensues favors the persistence of the ferric rather than the ferrous

form of heme iron. The normal methemoglobin reductive capacity of the RBC cannot compensate for such instability of ferrous heme. Two of the mutations affect the alpha globin chain, three affect the beta globin chain, and two affect the gamma chain. Only the alpha and gamma globin chain mutations are associated with neonatal methemoglobinemia, because these are the globins that form hemoglobin F, the predominant hemoglobin found in neonatal RBCs. Neonatal methemoglobinemia is transient when produced by one of the two gamma chain mutations, hemoglobin FM- $\text{Osaka}$  (Hayashi et al, 1980) or hemoglobin FM-Fort Ripley (Priest et al, 1989), because the normal developmental switch from fetal to adult hemoglobin eliminates all but a trace of the mutant hemoglobin. Hemoglobin M heterozygotes inheriting alpha or beta globin mutations appear cyanotic all their lives because of the increased methemoglobin levels present in their RBCs, but they are otherwise asymptomatic. No therapy is needed (and none is possible). The homozygous state is incompatible with life. Diagnosis of the hemoglobin M disorders is by hemoglobin electrophoresis.

*NADH-methemoglobin reductase deficiency* is an uncommon autosomal recessive disorder. Heterozygotes are asymptomatic and do not have methemoglobinemia under normal circumstances. If challenged by drugs or chemicals that cause methemoglobinemia, however, patients become cyanotic and symptomatic at doses that have no effect in normal persons. Homozygotes have lifelong methemoglobin levels of 15% to 40% and are cyanotic but otherwise asymptomatic unless exposed to toxic agents. Diagnosis of NADH-methemoglobin reductase deficiency is by assay of the RBC enzyme activity, a procedure available only in specialized hematology laboratories.

The cardinal clinical manifestation of methemoglobinemia is cyanosis not resulting from cardiac or respiratory disease. Cyanosis present at birth suggests hereditary methemoglobinemia, whereas that appearing suddenly in an otherwise asymptomatic infant is more consistent with acquired methemoglobinemia (Table 77-12). The blood is dark and, unlike deoxygenated venous blood, does not turn red when exposed to air. Rapid screening for methemoglobinemia can be done by placing a drop of blood on filter paper and then waving the filter paper in air to allow the blood to dry. Deoxygenated normal hemoglobin turns red, whereas methemoglobin remains brown. Methemoglobin levels of 10% or more can be detected (Harley and Celermajer, 1970). More accurate determination of methemoglobin levels is accomplished in the blood gas laboratory by co-oximetry or in the clinical laboratory using a spectrophotometer. Cyanosis is first clinically evident when methemoglobin levels reach approximately 10% (1.5 g/dL), but symptoms attributable to hypoxemia and diminished oxygen transport do not appear until levels increase to 30% to 40% of total hemoglobin. Death occurs at levels of 70% or greater. Methemoglobinemia is not associated with anemia, hemolysis, or other hematologic abnormalities.

In newborns, treatment with intravenous methylene blue (1 mg/kg as a 1% solution in normal saline) is indicated when methemoglobin levels are greater than 15% to 20%. Doses greater than 1 mg/kg should be avoided, as they may be toxic (Porat et al, 1996). The response to methylene blue is both therapeutic and diagnostic. Methemoglobin levels decrease rapidly, within 1 to 2 hours, if

TABLE 77-12

**Approach to Infants with Cyanosis and Methemoglobinemia**

- Cyanosis with respiratory and cardiac abnormalities:**  
 Blood turns red when mixed with air  
 Decreased arterial PO<sub>2</sub>  
 Consider pulmonary, cardiac, or central nervous system disease
- Cyanosis with or without respiratory or cardiac abnormalities:**  
 Blood turns red when mixed with air  
 Normal arterial PO<sub>2</sub>  
 Consider polycythemia syndromes
- Cyanosis without respiratory or cardiac abnormalities:**  
 Blood remains dark after mixing with air  
 Normal arterial PO<sub>2</sub>  
 Consider methemoglobinemia syndromes
1. *With rapid clearing of methemoglobin following methylene blue:*
    - a. Consider toxic methemoglobinemia (look for environmental oxidants)
    - b. Consider NADH-methemoglobin reductase deficiency (perform enzyme assay)
  2. *With reappearance of methemoglobinemia after initial response to methylene blue:*
    - a. Consider NADH-methemoglobin reductase deficiency
  3. *With no change in methemoglobin following methylene blue:*
    - a. Consider hemoglobin M disorders (perform hemoglobin electrophoresis)
    - b. Consider associated glucose-6-phosphate dehydrogenase deficiency (perform enzyme assay)

methemoglobinemia is caused by a toxic agent or by a deficiency of NADH-methemoglobin reductase. In contrast, the hemoglobin M disorders do not respond to methylene blue. Reappearance of methemoglobinemia after an initial response to methylene blue suggests a deficiency of NADH-methemoglobin reductase or the persistence of an occult oxidant. A poor response to methylene blue also is seen in G6PD-deficient persons, not because G6PD deficiency is a cause of methemoglobin formation but because there is suboptimal generation of NADPH, a required cofactor in the reduction of methemoglobin by methylene blue in deficient persons. In general, most infants with hereditary methemoglobinemia are asymptomatic and require no therapy. Older children sometimes are given daily administration of oral ascorbic acid or methylene blue to decrease cyanosis for cosmetic reasons. Methylene blue produces blue urine, but this is harmless.

## Neonatal Leukocyte Physiology and Disorders

Elvira Parravicini, Carmella van de Ven, and Mitchell S. Cairo

This chapter presents an overview of neonatal leukocyte physiology and quantitative and qualitative disorders of leukocytes. Topics include the normal physiology and defects associated with neonatal hematopoiesis, neutrophils, lymphocytes, monocytes, and dendritic cells. Novel therapeutic approaches also are discussed.

### HEMATOPOIESIS

Hematopoiesis is a complex process that begins with an uncommitted pluripotent hematopoietic stem cell that progresses through a series of steps to development of a single-lineage progenitor cell. The final result of this physiologic process is a mature, lineage-restricted effector cell that circulates either in the bloodstream or within tissue. In 1961 Till and McCulloch demonstrated that when bone marrow cells were transfused into lethally irradiated mice, separate colonies of hematopoietic cells could be identified in the spleen of the recipient. Each colony, containing neutrophils, monocytes, erythrocytes, megakaryocytes, eosinophils, and basophils, was derived from an individual cell, and many of the colonies contained cells that were capable of such colony formation when transplanted into a second irradiated animal. Such cells, which are capable of unlimited self-renewal, have been referred to as *pluripotent stem cells*.

### Fetal and Neonatal Hematopoiesis

In human ontogeny, the process of maturation involves the orderly shift of hematopoiesis from extramedullary organs to the bone marrow (Nathan, 1989). Hematopoiesis is first observed by day 15 in blood islands formed by the yolk sac (Zon, 1995). The erythroid lineage is predominant during yolk sac hematopoiesis. Yolk sac erythrocytes are large nucleated cells, expressing the products of certain genes that are unique to this phase of development. Hematopoietic progenitor cells that migrate to the fetal liver and subsequently to the fetal bone marrow are thought to originate from either the yolk sac or dorsal mesenteric hematopoietic cells (Zon, 1995). The transition of embryonal hematopoiesis from the yolk sac to the

liver is associated with development of a differentiating program in proliferating stem cells as shown by their erythroid progeny and therefore parallels changes in multiple parameters (e.g., morphology and globin expression).

Granulocyte-macrophage colony-forming units (CFU-GMs) have been identified in fetal liver as early as 5 weeks of gestation. However, their number is low compared with that of cells of the erythroid lineage. Neutrophils have been identified in the bone marrow of fetuses as early as 14 weeks of gestation, but they are limited in number. Myeloid cells (neutrophil progenitor cells) constitute less than 5% of nucleated marrow cells in the fetus, compared with 31% to 69% in term neonates and 25% to 52% in adults.

### Hematopoietic Growth Factors

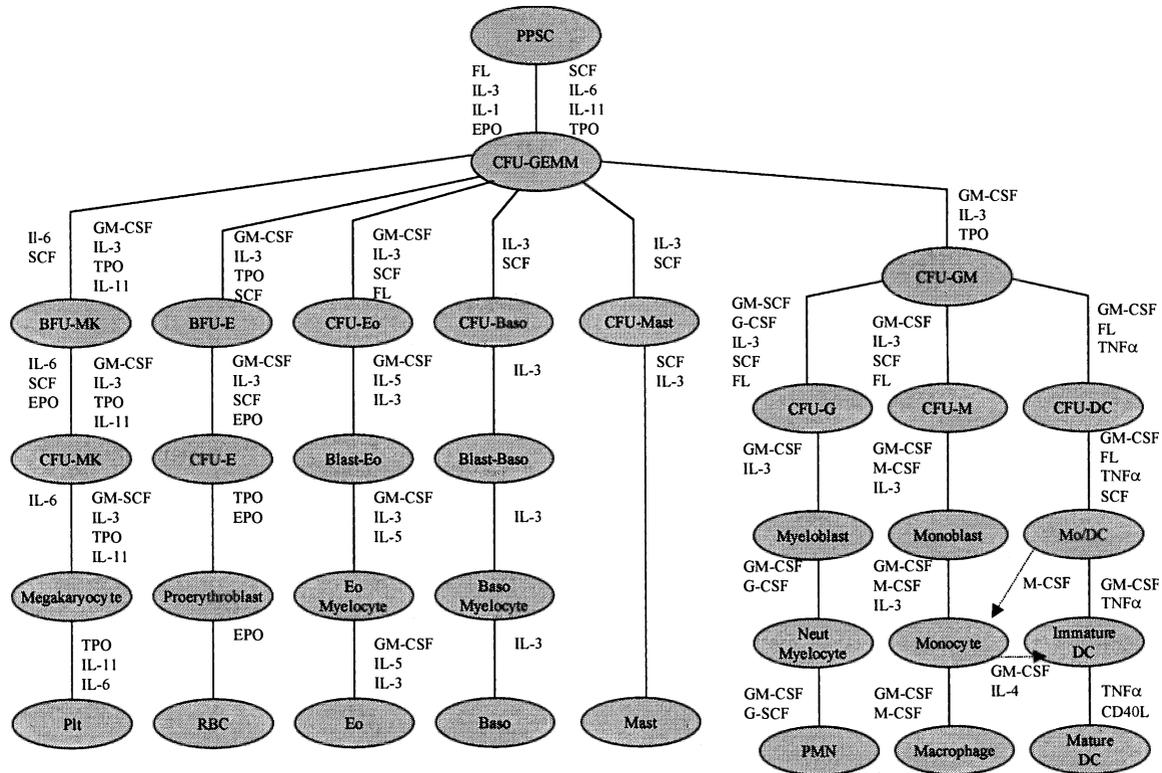

The regulation of hematopoiesis is a complex biologic process involving multifactorial mechanisms. As reported by our group (Abu-Ghosh et al, 2000), in vitro culture of hematopoietic progenitor cells has enabled the categorization, functional analysis, and definition of the growth factor requirements of the various committed progenitor cells (Fig. 78–1).

The hematopoietic pluripotent stem cell (PPSC) that expresses CD34 represents an early and primitive hematopoietic stem cell that can be identified by immunophenotyping. This cell can either undergo self-renewal or proliferate and differentiate into any of the hematopoietic blood lineages depending on its exposure to individual and combinations of hematopoietic growth factors (HGFs). Primitive progenitor cells maintain their multipotent potential, whereas more mature progenitor cells become committed as they differentiate into specific lineages. A relatively small and common set of pluripotent stem cells gives rise to large numbers of functionally diverse mature cells.

Cell proliferation and differentiation is regulated and controlled by highly specific protein factors, affecting single- and multiple-lineage hematopoiesis. These growth-promoting factors are named colony-stimulating factors (CSFs). CSFs are a group of glycoproteins with molecular masses of 18 to 90 kD, defined by their abilities to support proliferation and differentiation of hematopoietic cells of various lineages (see Fig. 78–1).

### Granulocyte Colony-Stimulating Factor

Human granulocyte colony-stimulating factor (G-CSF) was first purified to homogeneity from a medium conditioned by the bladder carcinoma cell line 5637. The molecular mass of this glycoprotein is between 18 and 20 kD and the gene has been localized to chromosome 17q11-21. It has been identified in the 15 to 17 chromosomal translocation commonly found in acute promyelocytic leukemia. G-CSF is produced primarily by mature macrophages, endothelial cells, fibroblasts, and mesothelial cells. Its production can be stimulated in these cells by tumor necrosis factor, lipopolysaccharide (LPS), and the interleukins IL-1, IL-3, and IL-6 and also stem cell factor

**FIGURE 78-1.** Hematopoiesis and hematopoietic growth factors. Baso, basophil; BFU, burst-forming unit; CFU, colony-forming unit; CSF, colony-stimulating factor; DC, dendritic cell; E, erythroid; Eo, eosinophil; EPO, erythropoietin; FL, Flt 3 ligand; G, granulocyte; GEMM, granulocyte, erythrocyte, macrophage, and megakaryocyte; GM, granulocyte-macrophage; IL, interleukin; M, macrophage; MK, megakaryocyte; Mo, monocyte; Neut, neutrophil; Plt, platelet; PMN, polymorphonuclear neutrophil leukocyte; PPSC, pluripotent stem cell; RBC, red blood cell; SCF, stem cell factor; TNF $\alpha$ , tumor necrosis factor- $\alpha$ ; TPO, thrombopoietin.

(SCF) (Lieschke and Burgess, 1992). G-CSF stimulates the proliferation of committed myeloid progenitor cells and has specific activity toward granulocyte colony formation with pure neutrophil colony proliferation. G-CSF affects mature neutrophil effector function in that it primes neutrophils to increase expression of chemotactic receptors and to enhance bactericidal and phagocytic activity, superoxide generation, and antibody-dependent cellular cytotoxicity.

Clinical studies have shown that G-CSF therapy results in a dose-dependent increase in the circulating neutrophil count in children and adults with congenital and acquired neutropenia syndromes as well as chemotherapy-induced neutropenia (Bonilla et al, 1989; Hammond et al, 1989). Significant differences in G-CSF production, G-CSF gene expression, and circulating G-CSF level exist between adults and newborns (Cairo et al, 1993). Gessler and coworkers (1995) reported G-CSF serum levels at birth with respect to neutrophil count, infection, and gestational age. Serum concentrations of G-CSF in term and preterm neonates without infection reached peak levels within the first 7 hours of life (mean values of 261 pg/mL and 126 pg/mL in term and preterm infants, respectively). Levels decreased to normal adult range (<50 pg/mL) between 4 and 7 days of age and were unchanged at 2 to 3 weeks of age.

From neonatal animal model studies it appears that the administration of recombinant human G-CSF (rhG-CSF) has significant effects on neonatal rat hematopoiesis, with a marked increase in the circulating neutrophil count, bone marrow myeloid progenitor pool, and neutrophil storage pool (NSP) (Cairo et al, 1990b). Combining G-CSF with earlier-acting cytokines such as SCF, IL-6, and IL-11 further enhances these effects on neonatal rat hematopoiesis (Cairo et al, 1991a, 1992a, 1993, 1994).

G-CSF acts in synergism with antibiotics in improving survival during neonatal sepsis, but only if given before or at the starting of the development of experimental sepsis (Cairo et al, 1990b, 1992b). Additionally, improved survival during experimental sepsis in neonatal rats has been demonstrated following prophylactic use of G-CSF in combination with antibiotics and either SCF or IL-11 (Cairo et al, 1992a, 1994; Chang et al, 1994).

G-CSF has been used in clinical trials for both prevention and therapy of neonatal sepsis. One study investigated the safety, pharmacokinetics, and biologic efficacy of administration of G-CSF to newborn infants with sepsis (Gillan et al, 1994). Forty-two newborn infants, both term and preterm, with presumed sepsis within the first 3 days of life were randomized to receive either placebo or varying doses of rhG-CSF. The growth factor was given for 3 days at doses of 1, 5, or 10  $\mu\text{g}/\text{kg}$  every day or 5 or 10  $\mu\text{g}/\text{kg}$

twice a day. The half-life of rhG-CSF was  $4.4 \pm 0.4$  hours. Intravenous rhG-CSF was well tolerated at all gestational ages and was not associated with any recognized acute toxicity. RhG-CSF induced a significant increase in the absolute neutrophil count (ANC) within 24 hours following doses of 5 and 10  $\mu\text{g}/\text{kg}$  given either every 24 hours or divided every 12 hours. The increased neutrophil count was maintained for 96 hours, 48 hours after the last rhG-CSF dose. Bone marrow aspirates demonstrated a dose-dependent increase in NSP following treatment with rhG-CSF. In addition, polymorphonuclear neutrophil (PMN) C3bi expression was significantly increased at 24 hours following administration of 10  $\mu\text{g}/\text{kg}$  of rhG-CSF every 24 hours. The enhancement of neonatal neutrophil C3bi expression indicates that rhG-CSF may induce functional maturation of neonatal neutrophils. A recent 2-year follow-up analysis in these patients has shown that rhG-CSF therapy for presumed neonatal sepsis was not associated with long-term hematologic, immunologic, or developmental adverse effects (Rosenthal et al, 1995).

A randomized, placebo-controlled trial of G-CSF administration to infants with neutropenia and clinical sign of early-onset sepsis was recently reported (Schibler et al, 1998). Twenty infants, term and preterm, were given G-CSF (10  $\mu\text{g}/\text{kg}/\text{day}$ ) or placebo for 3 days. ANC, ratio of immature to total neutrophils (I/T ratio), bone marrow NSP, bone marrow neutrophil proliferative pool (NPP), and plasma concentration of G-CSF were evaluated and found to be similar in treated and control infants. No significant differences were found in outcome measures such as severity of illness and mortality.

### **Granulocyte-Macrophage Colony-Stimulating Factor**

Granulocyte-macrophage colony-stimulating factor (GM-CSF) was purified from a medium conditioned by the human T-cell lymphotropic virus-II (HTLV-II)-infected T-lymphoblast cell line MO. Characterization of the purified material showed that GM-CSF is a glycoprotein of 22 kD, and the gene is located on chromosome 5q21-32. Potential physiologic sources for GM-CSF are T and B lymphocytes, macrophages, fibroblasts, mast cells, endothelial cells, mesothelial cells, and osteoblasts.

GM-CSF acts as a potent growth factor both *ex vivo* and *in vivo* by stimulating proliferation and maturation of myeloid progenitor cells, subsequently giving rise to neutrophils, eosinophils, and monocytes. GM-CSF has direct and indirect effects on human neutrophils. Direct effects include inhibition of neutrophil migration, enhanced degranulation, induction of adhesion, and changes in cytoskeleton and cell shape. Indirect actions enhance the ability of the neutrophil to respond to triggering stimuli. Among these effects are increased superoxide generation,  $\text{Ca}^{2+}$  fluxes, and production of inflammatory mediators such as leukotriene  $\text{B}_4$ .

Administration of GM-CSF in clinical trials results in an immediate and transient decrease in circulating neutrophils, eosinophils, and monocytes, followed by a recovery to baseline within 2 hours. A second phase follows in which the number of leukocytes increases, with a marked

“shift to the left” as a result of demargination from the bone marrow NSP and increased myeloid production in the marrow.

The effect of GM-CSF on the incidence of sepsis in human neonates also has been evaluated. A phase I/II trial determined the feasibility, safety, and biologic response of GM-CSF in very low-birth-weight (VLBW) ( $\leq 1500$  g) neonates. Twenty neonates (500 to 1500 g) were randomized in the first 3 days of life to receive GM-CSF at 5  $\mu\text{g}/\text{kg}/\text{day}$  or 5  $\mu\text{g}/\text{kg}$  twice a day or 10  $\mu\text{g}/\text{kg}/\text{day}$  or placebo. The study demonstrated that GM-CSF was well tolerated with no toxic acute effects. GM-CSF induced a significant increase in ANC, absolute monocyte count (AMC), bone marrow NSP, and neutrophil C3bi expression (Cairo et al, 1995).

A phase III multicentric, randomized, prospective, double-blind, placebo-controlled trial was performed to determine whether prophylactic administration of GM-CSF would reduce nosocomial infections in VLBW neonates. Two hundred sixty-four infants (500 to 1500 g) were randomized in the first 3 days of life to receive either GM-CSF (8  $\mu\text{g}/\text{kg}/\text{day}$ ) for 7 days and then every other day for 21 days or placebo. No toxicity was recorded. The ANC was significantly elevated in the GM-CSF group on days 7, 14, and 21, and the absolute eosinophil count (AEC) on days 7 and 28. However, there was no difference in the incidence of confirmed nosocomial infections between the two groups (Cairo et al, 1999).

## **NEONATAL NEUTROPENIA**

Manroe and colleagues (1979) established reference values for ANCs in term and preterm infants during the first 28 days of life for both healthy infants and those with perinatal complications. Mouzinho and associates (1994) studied serial white blood cells counts in healthy preterm VLBW infants to investigate whether this subgroup of patients had different neutrophil counts from those found in previous studies in cohorts consisting mostly of term infants. They found that there was a wider range of the absolute total neutrophil count, mostly resulting from a downward shift of the lower boundary, especially during the first 60 hours of life. However, there was no difference in absolute total immature neutrophil counts or in I/T ratio. Similar findings were noted by Gessler and colleagues (1995), who studied, retrospectively, neutropenia in low-birth-weight infants and its relationship to maternal disease, sepsis, and antibiotic therapy. They noted that neutropenia during the second week of life was most commonly related to antibiotic use.

Neutropenia may be caused by any one or a combination of defects in production or maturation of neutrophils or in release of neutrophils from the bone marrow to the peripheral blood. The pathophysiologic mechanism responsible for neonatal neutropenia may be either exhaustion of myeloid committed progenitor cells or inadequate response of progenitor cells to proliferative or maturational signals. In a series of studies, Christensen and Rothstein (1984) documented significant differences in myeloid progenitor pools and cell kinetics in fetal and

neonatal rats compared with adult rats. In the newborn rat, the myeloid progenitor pool, consisting of CFU-GMs in the bone marrow, is only 25% of that of adult animals and requires 4 weeks of maturation to reach adult levels. Additionally, despite a lower number, the CFU-GM of the newborn rat is in a state of near-maximal proliferative capacity, the maximal rate of proliferation being 75% to 80%, whereas that of the adult CFU-GM is only 25% (Christensen and Rothstein, 1984). Concomitantly with reduced numbers of myeloid progenitor cells (lower numbers of CFU-GMs) and lower expansion capacity (already near maximal proliferative rate), the neonatal rat also possesses reduced numbers (25% of adult) of NSP, defined as the percentage of metamyelocytes, bands, and mature neutrophils in the bone marrow. The NSP reach adult levels in the neonate rat at 4 weeks of age. Following experimental sepsis with group B streptococci (GBS), adult rats respond with a transient decrease in circulating neutrophil counts followed by significant neutrophilia associated with a two- to threefold increase in the progenitor pool (CFU-Meg) and an increase in the proliferative rate to 75% of the maximal capacity (Christensen et al, 1982, 1983). In contrast, neonatal rats under the same conditions had a decrease by 50% of their progenitor pool and failed to increase their myeloid proliferative rate, which, as discussed previously, was already at near-maximal levels. Most important, during experimental sepsis, neonatal rats had further depletion of their already reduced NSP reserves by almost 80%, compared with a decline of 33% in adult rats.

### **Kostmann Syndrome**

Kostmann syndrome is an autosomal recessive disorder that manifests within the first few months of life with severe, persistent neutropenia, with ANC of less than 500/mm<sup>3</sup> and often less than 200/mm<sup>3</sup>. Bone marrow examination typically demonstrates a maturational arrest at the promyelocyte stage (Kostmann, 1956). Affected children have recurrent infections, especially of the skin and oral mucosa.

Recently, Dale and colleagues (2000) described the occurrence of mutations of the gene encoding neutrophil elastase in 22 patients with severe congenital neutropenia. This is the well-known locus for autosomal dominant cyclic neutropenia. Neutrophil elastase is a protease that is synthesized and packaged in promyelocytes at early stages of neutrophil development. The pathogenic role of elastase mutation in causing neutropenia, in both congenital and cyclic neutropenia, may be linked to the poor survival of early myeloid precursor cells.

G-CSF has been used with success in increasing the ANC and decreasing the number of infections in patients with congenital neutropenia (Bonilla et al, 1989; Welte et al, 1990). Dale and associates (1993) have described the successful use of G-CSF in the treatment of infants, children, and adults with either congenital neutropenia or cyclic neutropenia, with significant laboratory and clinical responses. Bone marrow transplantation also has been used for those patients in whom medical therapy fails and who have a human leukocyte antigen (HLA)-identical unaffected sibling.

### **Alloimmune Neonatal Neutropenia**

Alloimmune neonatal neutropenia occurs as a result of maternal sensitization to neutrophil antigens present on the infant's neutrophils, paternally acquired, that are not present on the maternal neutrophils, with subsequent production of immunoglobulin G (IgG). Neutrophil-specific antibodies are found in the maternal and infant sera, but the mother has a normal neutrophil count. It is estimated to occur at a frequency of 3% of live births (Curnette, 1993). The most common antigens involved are NA1 and NA2. Peripheral blood counts show profound neutropenia and often demonstrate a monocytosis and eosinophilia. The condition is self-limiting and typically lasts for 6 to 7 weeks, during which time the neonate is susceptible to infections, mostly cutaneous in nature but occasionally life-threatening, necessitating intensive support. Therapeutic interventions that have been attempted include, in addition to antimicrobials, intravenous immune globulin (IVIG) infusions, with mixed success, as well as granulocyte transfusions that lack the disparate antigen.

### **Maternal Hypertension–Associated Neutropenia**

One of the most common and well-described causes of transient neonatal neutropenia is maternal hypertension. Infants of hypertensive mothers seem to have decreased production of neutrophils, but the cause is uncertain. Several studies showed a decrease in neutrophil progenitor cells, decreased cycling of these cells, a relatively normal NPP and NSP, and the absence of a "left shift" (Koenig et al, 1989). In fact, many investigators have documented an increased incidence of nosocomial infections if neutropenia is associated with maternal hypertension (Doron et al, 1994). In a prospective study, Mouzinho and colleagues (1994) analyzed the incidence of neonatal neutropenia in relation to birth weight, gestational age, and severity of maternal hypertension. They concluded that the neonatal neutropenia was inversely related to the birth weight and gestational age and directly related to the severity of the preeclampsia. The incidence was nearly 80% among neonates born at less than 30 weeks of gestation and was statistically different from that in similar infants born to normotensive mothers. In most cases, the neutropenia resolved within 72 hours, but in some cases the neutropenia persisted and G-CSF was used to increase the neutrophil count (La Gamma et al, 1995).

### **Congenital Disorders Associated with Neonatal Neutropenia**

#### ***Cartilage-Hair Hypoplasia***

Cartilage-hair hypoplasia (CHH), inherited as an autosomal recessive trait common among Amish populations, is characterized by short-limbed dwarfism, fine hair, and increased susceptibility to infections. Immunologic and hematologic investigations in patients with recurrent infections revealed the presence of chronic noncyclic neutropenia and lymphopenia. Neutropenia may be due to an arrest of myeloid maturation, with underproduction of

mature neutrophils and diminished bone marrow storage pools. Lymphopenia, decreased delayed hypersensitivity, and impaired in vitro responsiveness of lymphocytes to mitogens suggest functional dysfunction of small lymphocytes (Lux et al, 1970).

### Schwachman Syndrome

Schwachman syndrome is a rare multiorgan disease of unknown origin, characterized by metaphyseal chondrodysplasia, dwarfism, pancreatic exocrine insufficiency, and neutropenia. Clinical manifestations begin in neonatal age with diarrhea, weight loss, failure to thrive, eczema, otitis media, and pneumonia. By 2 years of age, dwarfism is evident; later, gait disturbances result from metaphyseal chondrodysplasia. Neutropenia is severe (ANC of 200 to 400/mm<sup>3</sup>) and causes recurrent infections. Aplastic anemia occurs in about 25% of the cases, and leukemic transformation has been described. In vivo administration of G-CSF has been reported to increase the neutrophil count to normal levels.

### Reticular Dysgenesis

Reticular dysgenesis is characterized by extremely severe neutropenia, leukopenia, agammaglobulinemia, and presence of rudimentary thymic, lymphoid, and splenic tissue. In the bone marrow, erythroid and megakaryocyte elements are normal, but myeloid cells are absent or sparse, possibly owing to a maturation defect in a progenitor cell (Roper et al, 1985). Use of GM-CSF or G-CSF has been ineffective. Allogeneic bone marrow transplantation remains the only available curative option.

## QUALITATIVE DEFECTS (DYSFUNCTION) OF NEONATAL PHAGOCYtic IMMUNITY

The immaturity of the neonatal phagocytic immune system in both humans and animals predisposes the neonate to greatly increased morbidity and mortality during bacterial sepsis. Neutrophils and macrophages play vital roles as effector cells in the phagocytic system. The efficient function of the phagocyte system depends on several factors, including the presence of adequate numbers of phagocytes in the peripheral blood, the ability to respond to signals from the sites of inflammation, the ability to migrate to these sites, and the capability to ingest and kill invading microorganisms. The immaturity of neonatal host defense is characterized by profound deficiencies in quantitative and qualitative phagocytic effector cell function.

Stressed and septic neonates exhibit significant dysfunction of the phagocytic process. Chemotaxis is the initial step in the inflammatory response. Chemotaxis is a process that involves numerous changes in cellular motility and mobility, followed by intracellular biochemical changes. It begins with stimuli from the invading microorganism and continues with the directed migration of neutrophils to the site of invasion, ingestion of the pathogen, and killing by oxygen-dependent and -independent mechanisms. Qualitative abnormalities of neonatal neutrophils include

decreased deformability and impaired functions including chemotaxis, phagocytosis, adherence, bacterial killing, aggregation, and oxidative metabolism (Cairo et al, 1990c).

GM-CSF increases adult neutrophil oxidative metabolism by augmenting *N*-formyl-L-methionyl-L-leucyl-phenylalanine (FMLP)-, C5a-, and leukotriene B<sub>4</sub>-induced superoxide anion production. Additionally, GM-CSF increases FMLP-stimulated chemotaxis, promotes phagocytosis of *Staphylococcus aureus*, and augments neutrophil aggregation by the increased expression of surface adhesion (Gasson et al, 1984; Weisbart et al, 1985) (Table 78-1). Our laboratory investigated the biologic effects of GM-CSF on cord blood (CB) neutrophil oxidative metabolism, bacterial killing, and chemotaxis (Cairo et al, 1989). We determined that GM-CSF is not a direct stimulant of in vitro neonatal neutrophil function; however, when CB was preincubated with GM-CSF and stimulated with FMLP or opsonized zymosan particles, a significant increase in superoxide production was observed. Priming with GM-CSF and subsequent stimulation with phorbolmyristate acetate (PMA) did not evoke a significant difference in superoxide release when CB neutrophils were compared with unprimed controls. Furthermore, when CB was compared with adult neutrophils, an earlier but less maximal superoxide generation was seen in CB.

The diminished inflammatory response of CB neutrophils results in a high incidence of microbial invasion. Significant defects in the up-regulation of surface-active glycoprotein receptors (C3bi) and reduced aggregation also predispose the neonate to impaired response to bacterial infection. C3bi expression has been compared in adult blood and CB neutrophils and found to be significantly less in CB when stimulated by FMLP- or zymosan-activated serum. (Cairo et al, 1990c). However, CB neutrophils incubated with GM-CSF demonstrated a significant induction of C3bi expression. Also, a significant increase of C3bi expression was seen when CB neutrophils were pretreated with GM-CSF and subsequently stimulated with calcium ionophore A23187. The up-regulation of C3bi receptor by GM-CSF also appears to correlate with enhancement of CB neutrophil aggregation. GM-CSF also primes CB neutrophils for increased neutrophil aggregation following agonist (FMLP) stimulation.

G-CSF and tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ) also have been reported to modulate the function of adult and CB neutrophils in a manner similar to that for GM-CSF.

TABLE 78-1

### Comparison of GM-CSF Effects on Adult and Cord Blood in Vitro Neutrophil Function

	Adult	Cord Blood
Superoxide production	↑ ↑ ↑ ↑	↑ ↑
Chemotaxis	↑	↑ ↑
Bacterial killing	↑ ↑	↑ ↑
C3bi receptor expression	↑ ↑	↑ ↑
Aggregation	↑	↑

GM-CSF, granulocyte-macrophage colony-stimulating factor.

Priming CB neutrophils with G-CSF or TNF- $\alpha$  and subsequent stimulation with FMLP induces the expression of C3bi receptors, enhances bacterial and phagocytic activity, and superoxide generation.

## LYMPHOCYTE PHYSIOLOGY AND DYSFUNCTION

### Granulocyte Colony-Stimulating Factor

Our laboratory has demonstrated a significant reduction in G-CSF messenger RNA (mRNA) transcript expression as well as decreased production of G-CSF protein in stimulated CB versus adult peripheral blood (APB) mononuclear cells (MNCs). (Cairo et al, 1992b). Furthermore, we have determined that circulating serum G-CSF levels, measured by enzyme-linked immunosorbent assay (ELISA), in CB from term infants are low but similar to healthy adult levels (50 pg/mL). However, we found that G-CSF levels are approximately threefold higher in CB from healthy preterm infants than in CB from term infants between days of life 1 and 3. G-CSF production in the first days of life is associated with peak values at 7 hours of life, followed by a peak neutrophil count approximately 6 hours later.

### Granulocyte-Macrophage Colony-Stimulating Factor

On stimulation of mononuclear cells with phytohemagglutinin and phorbol-12-myristate-6-acetate (PMA), we have observed a sevenfold decrease of GM-CSF protein production in CB versus APB. Additionally, a fourfold decrease in the expression of GM-CSF mRNA and a threefold lower GM-CSF half-life were measured in CB versus APB stimulated MNCs. Although no difference in rate of transcriptional activation from activated CB and APB MNCs was noted, actinomycin D transcriptional decay studies demonstrated reduced GM-CSF half-life in activated CB compared with APB mononuclear cells (Cairo et al, 1991a).

We thus established that the decrease in GM-CSF mRNA expression and protein in activated CB versus APB MNCs is due to a decrease in posttranscriptional mRNA stability and not to alterations in GM-CSF gene transcription. The cytoplasmic instability of GM-CSF mRNA is regulated in part by adenosine + uridine-rich elements in the 3'-untranslated region of the cytokine transcript. We have previously investigated the molecular basis for the differential stability of GM-CSF mRNA in CB and APB MNCs using electrophoretic mobility-shift assays. We demonstrated that the destabilization of GM-CSF mRNA in CB MNC is translation dependent and that increased levels of the specific RNA binding protein AUF-1 isoforms in the CB MNC may target transcripts for increased degradation and contribute to the dysregulation of phagocytic immunity (Buzby et al, 1996).

### Macrophage Colony-Stimulating Factor

Macrophage colony-stimulating factor (M-CSF) is a hematopoietic growth factor that regulates the proliferation,

differentiation and functional activation of monocytes. Normally detected in human serum, M-CSF plays an important role in enhancing the effector functions of mature monocytes and macrophages. M-CSF serum levels are increased in CB and further increased in the neonate. Our laboratory studied the regulation of the M-CSF gene expression under basal and activated conditions and the transcriptional and post-transcriptional regulation of M-CSF in CB versus APB. Both CB and adult blood MNCs constitutively express M-CSF mRNA on adhesion to tissue culture flasks. However, when GM-CSF was added as a costimulator, CB MNCs produced two- to threefold less M-CSF protein compared with APB MNCs, and a fourfold decrease in M-CSF mRNA expression was shown in both unstimulated and GM-CSF-induced CB versus APB MNCs. Furthermore, we determined that M-CSF mRNA expression peaked between 16 and 24 hours after stimulation and fell to normal levels by 48 hours in both CB and APB (Suen et al, 1994). This study also demonstrated that the transcriptional rates of the M-CSF gene were similar in CB and APB even after stimulation with rhGM-CSF. However, actinomycin D decay studies showed the half-life of M-CSF mRNA in CB MNCs was significantly lower, and the induction of M-CSF mRNA after cycloheximide administration in CB compared with APB MNCs was significantly increased, suggesting that one or more labile proteins may be involved in regulating M-CSF transcript stability (Suen et al, 1994).

## NEGATIVE REGULATORS OF HEMATOPOIESIS

Cytokines also play a predominant role as negative regulators of hematopoiesis. These negative growth factors regulate early hematopoiesis with suppressive effects on the proliferation of early myeloid and lymphoid progenitors. The most notable negative regulators of hematopoiesis are transforming growth factor- $\beta$ 1 (TGF- $\beta$ 1), macrophage inflammatory protein-1 $\alpha$  (MIP-1 $\alpha$ ), and IL-8. TGF- $\beta$ 1 induces a wide range of responses including the inhibition of lymphocyte, thymocyte, and epithelial cell proliferation as well as the suppression and proliferation of early progenitor cells. MIP-1 $\alpha$  and IL-8 also have suppressive effects on early progenitors, similar to TGF- $\beta$ 1. Our laboratory measured the protein levels of TGF- $\beta$ 1 and MIP-1 $\alpha$  in the conditioned media of phytohemagglutinin and PMA-stimulated CB and APB MNCs. Both TGF- $\beta$ 1 and MIP-1 $\alpha$  levels were significantly less in CB supernatants compared with APB supernatants. Furthermore, the mRNA expression of TGF- $\beta$ 1, MIP-1 $\alpha$ , and IL-8 in stimulated CB and APB MNCs was found to be significantly less in CB MNCs; yet no significant difference was seen in the transcription rate of either the TGF- $\beta$ 1 or MIP-1 $\alpha$  genes in CB compared with APB. These results suggested that the reduced mRNA of the negative regulators, TGF- $\beta$ 1 and MIP-1 $\alpha$ , may be secondary to alterations in posttranscriptional regulation, and that the altered expression of both positive and negative regulators may be involved in the immaturity of host defense in the neonate (Chang et al, 1994).

## MONOCYTES AND DENDRITIC CELLS

### Monocytes

#### Ontogeny

Embryonic macrophages are found among hematopoietic cells in the yolk sac at 3 to 6 weeks of gestation. After 6 weeks, the fetal liver becomes the primary site of hematopoiesis for the next 6 to 22 weeks of gestation, when the bone marrow becomes the lifelong center of blood cell production (Palis et al, 2001). Monocytes are present in high proportions in the early hematopoietic tissues, with approximately 70% of hematopoietic cells at 4.5 weeks of gestation morphologically identifiable as monocytes. This proportion decreases to 1% to 2% over the next 6 weeks as erythroid cells become predominant. The precursors of monocytes, monoblasts, and promonocytes continue to be present in the fetal liver; however, intravascular monocytes are not observed until the fifth month of gestation. Circulating monocytes do not appear with regularity until hematopoiesis is first established in the bone marrow after the tenth week of gestation.

At birth, the number of circulating granulocyte-monocyte progenitor cells (CFU-GMs), the committed progenitor precursor to monocytes, are increased in cord blood before 32 weeks, but levels fall shortly after birth. The estimated total bone marrow cellularity of the term neonate at birth is approximately  $1.36 \times 10^{11}$  cells/L, and the total cell numbers decline over the first 1 to 2 weeks to  $3.5 \times 10^{10}$ /L. These levels remain low through the neonatal period, in which circulating monocyte counts are highest in the first week of life, ranging from 1340 to 2200 cells/ $\mu$ L, and gradually fall in successive weeks to 700 cells/ $\text{mm}^3$  at 3 weeks and 450 cells/ $\text{mm}^3$  by 6 years of age.

#### Morphology

Immunophenotyping using fluorescent conjugated monoclonal antibodies also has been used to identify monocyte cell subpopulations and give insight to cell activation and function. During ontogeny, macrophages in the fetal liver express CD11b as early as 12 weeks of gestation. The classic monocyte marker, CD14, does not appear until about 15 to 21 weeks of gestation. CD14 expression on circulating MNCs is equivalent in CB and APB. CD11a, CD11b, and CD11c are expressed in lower densities on CB monocytes than on adult cells. There is also lower expression of class II major histocompatibility complex (MHC) antigens HLA-DR, HLA-DP, and HLA-DQ on neonatal monocytes compared with adult monocytes. HLA-DR expression also is significantly lower in CD14<sup>+</sup> populations in CB compared with APB CD14<sup>+</sup>. The density of these class II MHC antigens has been correlated with antigen-presenting capacity of monocytes in vitro; however, it has not been determined whether this deficiency affects neonatal host defense. Other important monocyte markers are the receptors for the Fc moiety of IgG (Fc $\gamma$ R). These receptors are important in the process of monocyte and macrophage phagocytosis of microbes and antibody-dependent cytotoxicity. Monocytes constitutively express the high-affinity receptor Fc $\gamma$ RI (CD64) and Fc $\gamma$ RII

(CD32). Fc $\gamma$ R-III<sup>+</sup> monocytes in adult blood are significantly higher compared with CB samples. Despite the difference in the Fc $\gamma$ R-III<sup>+</sup> populations, the intensity of Fc $\gamma$ R-III expression is higher in CB than in APB.

#### Function

Monocytes exhibit the characteristic properties of phagocytosis—namely, movement, adherence, endocytosis, and microbial activity. Monocytes are capable of directed movement (chemotaxis) in response to substances (chemokines) produced by bacteria or by accessory cells at the site of injury or invasion. Chemotactic capabilities of neonatal and adult peripheral blood monocytes have been compared, and chemotaxis was found to be less pronounced in neonates than in adults.

The cascade of reactions within the immune response to infection involves monocyte up-regulation and adherence via CD11b/CD18 receptors followed by cell activation and the release of cytokines (TNF, IL-1, and IL-6) and bactericidal products—superoxide radicals, nitric oxide, and granule contents released in the process of degranulation. Adherence requires the interaction of monocytes and the endothelium. Activated monocytes migrate from circulation into the tissues by firmly adhering to endothelial surfaces through the interaction of the integrins (CD11a-c and CD18) expressed on the monocyte cell membrane and the intercellular adhesion molecule-1 (ICAM-1) or ICAM-2 on the endothelial surface. Finally, the activated monocyte moves through the endothelium to the site of inflammation or infection. Preliminary studies demonstrate that levels of monocyte adhesion molecule expression are comparable in neonate and adult peripheral blood (Schibler, 2000). The  $\beta$ -2 integrin, CR3, plays a major role in the migration to sites of infection by mediating the binding to ICAM-1 and also is responsible for mediating the recognition of opsonized microbial pathogens. Neonatal monocytes express approximately 85% as much CR3 as that expressed by adult monocytes.

Antimicrobial activity of monocytes includes oxygen-dependent mechanisms such as the respiratory burst, which through a complex series of reactions forms highly reactive hydroxyl radicals that damage host and microbial membranes. The ability of monocytes of fetal and neonatal monocytes to kill pathogens (*Staphylococcus aureus*, *S. epidermidis*, *Escherichia coli*, and *Candida albicans*) is shown to be equivalent to that of APB monocytes. However, a recent study of isolated CB plastic adherent monocytes from preterm and full-term infants revealed a significant decrease in superoxide production and degranulation in preterm compared with full-term monocytes.

Activated monocytes and macrophages produce several cytokines and chemokines contributing to the inflammatory process. IL-1, interferon- $\alpha$  (IFN- $\alpha$ ), and TNF- $\alpha$  are synthesized at similar levels in adults and neonates. Kaufman and colleagues (1999) found a significant decrease in the secretion of TNF- $\alpha$  by LPS-stimulated adherent monocytes from preterm infants compared with full-term infants; however, no difference was seen in the production of IL-1 $\beta$  or IL-6. They showed a significant decrease in

the expression of CD11b and CD18 adhesion receptor subunits in monocytes collected from preterm infants compared with that in full-term infants.

### Dendritic Cells

Dendritic cells (DCs) are specialized mononuclear cells with highly developed antigen-presenting capabilities that play a pivotal role in humoral and cellular immunity by initiating primary and secondary T cell responses. DCs can be categorized into several types: follicular, lymphoid, and circulating blood DCs. Follicular DCs are located in the paracortical areas of the spleen and lymph nodes and express receptors for immunoglobulin and complement. Their role is to present antigen to B lymphocytes. Lymphoid DCs are highly motile, low density cells found in several locations. These DCs express high levels of costimulatory molecules and class II MHC and function to present antigen to T cells. Circulating blood DCs constitute from 0.1% to 1.0% of peripheral blood mononuclear cells and migrate to the lymph nodes. The function of circulating DCs is similar to that of the lymphoid DCs—stimulating T cells by the presentation of antigen. DCs are derived from pluripotent hematopoietic stem cells (CD34<sup>+</sup>) that differentiate along myeloid or lymphoid lineages. Recent studies have suggested that DCs derived from a novel population of progenitors (CD34<sup>+</sup>/CD7<sup>+</sup>/CD45RA<sup>+</sup>) in cord blood represent an original lymphoid DC population. These DCs produce two- to fourfold higher levels of IL-6, IL-12, and TNF- $\alpha$  on stimulation with CD40L and demonstrate a higher allogeneic T-lymphocyte reactivity. Two classes of dendritic cells have been characterized on the basis of expression of CD8a. CD8a<sup>+</sup> DCs are derived from lymphoid tissue, and CD8a<sup>-</sup> DCs are derived from myeloid tissue.

Caux and colleagues (1997) generated DCs *in vitro* from CB D34<sup>+</sup> hematopoietic stem cells stimulated with GM-CSF plus TNF- $\alpha$ . Two subsets of DCs were generated: one expressing CD1a and the other, CD14 surface antigens. These subsets further differentiated along two independent DC pathways, with cells expressing either the CD1a<sup>+</sup> or CD14<sup>+</sup> membrane antigen. CD1a<sup>+</sup> cells differentiated into Langerhans cells, characterized by Birbeck granules, the Lag antigen, and E-cadherin. CD14<sup>+</sup> progenitors matured into CD1a<sup>+</sup>DCs that expressed CD2, CD9, and CD 68 and could be induced to differentiate into circulating blood DCs. CD40 activates CB CD34<sup>+</sup> cells to proliferate and differentiate independently of GM-CSF into a cell population with prominent DC characteristics. DCs generated with CD40 are able to prime allogeneic T cells and express high levels of HLA-DR but lack the characteristic CD1a and CD40 surface molecules (Flores-Romo et al, 1997).

Mature DCs express high levels of CD80 and CD83 on the cell membrane. Several agents have been shown to increase CD80 and CD83 expression on DCs, including TNF- $\alpha$ , bacterial LPS, and monocyte-conditioned media. Interactions with other cells also can induce activation and maturation of DCs, as demonstrated by the cross-linking of CD40 that is mediated by T cells.

We have recently demonstrated the ability to generate CB DCs *ex vivo* in serum-free media with GM-CSF, IL-4,

Flt-3 ligand, TGF- $\beta$ , and TNF- $\alpha$ . We found that the *ex vivo*-generated CB DCs from plastic adherent MNCs exhibit morphology and immunophenotypic characteristics similar to those of APB DCs; however, CB adherent MNC-derived DCs have differential potency in stimulating allogeneic mixed leukocyte reaction when compared with adult adherent MNC-derived DCs (Bracho et al, 2001).

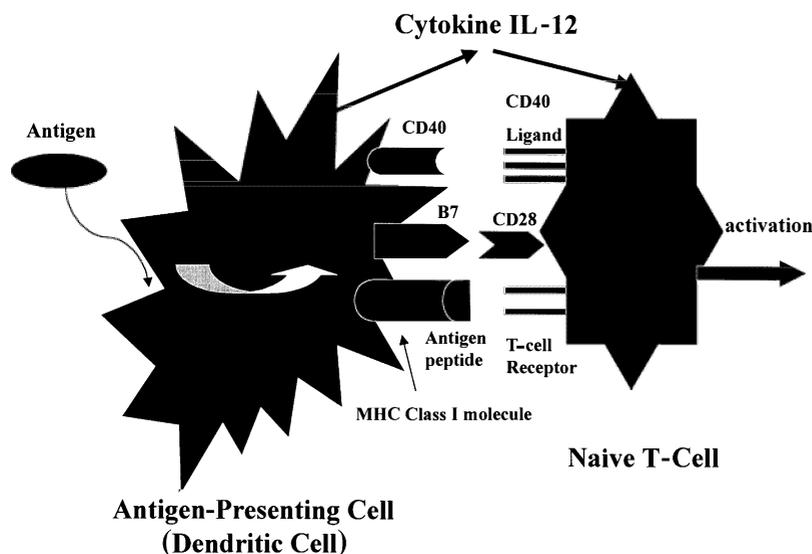

### Morphology

The cardinal properties of DCs include the ability to take in, process, and present antigen and the ability to migrate selectively through tissues and interact with, stimulate, and direct T-cell responses. DCs have a distinct morphology and are noted for their irregular shape with veil-like ruffled cell membranes (lamellipodia) that include many pseudopods and numerous membrane processes. Microscopic examination of DCs reveals prominent mitochondria and endosomes and lysosomes within the cytoplasm, which are necessary for the processing of antigen. The morphology of DCs in CB and APB is identical; however, the mean percentage of DCs is lower in CB (0.5%) than in adult blood (1%).

Immunophenotyping studies have shown that DCs express numerous surface molecules commonly found on mononuclear cells, MHC molecules, CD4, CD45 isoforms, adhesion molecules (ICAM-1, -2, -3 and leukocyte function-associated antigen-1 [LFA-1]), and Fc receptors (Fc $\gamma$ I [CD64], Fc $\gamma$ II [CD3]). Maturation of DCs is commonly associated with high expression of CD80 and CD83 (Fig. 78–2). On stimulation, DCs up-regulate costimulatory molecules CD40, CD80, and CD86. Flow cytometric studies, however, show levels of ICAM-1 (CD54), MHC class I (HLA-ABC) and II (HLA-DR), CD80, and CD40 antigens to be significantly lower on CB DCs (Goriely et al, 2001; Hunt et al, 1994). Liu and colleagues (2001) compared the phenotypic and functional characteristics of monocyte-derived DCs in CB versus APB. After 7 days of culture with GM-CSF plus IL-4, CB monocytes generated fewer CD1a<sup>+</sup> cells than those generated by APB monocytes, and the cultured CB DCs had a reduced intensity of CD1a expression and MHC class II molecules. These investigators further reported that both the endocytotic ability and ability to stimulate CD3<sup>+</sup> T cells was reduced in CB DCs compared with APB DCs.

### Function

Functional differences between neonatal and adult DCs have been examined by several investigators. CB DCs have been found to be poor stimulators of T cells in a mixed leukocyte reaction when either adult blood or CB mononuclear cells or T cells were used as responder cells (Bracho et al, 2001). In contrast, CB T cells and mononuclear cells responded normally to allogeneic adult DCs. Furthermore, CB DCs performed poorly as accessory cells for T-cell mitogenic responses (Hunt et al, 1994). Recent studies of the ontogeny of DCs have shown that DCs from 3- and 7-day-old mice were severely defective in presenting tetanus toxoid to antigen-specific T-cell clones. However, the ability of the neonatal DCs to present antigen improved with age, reaching adult levels by 4 weeks of age.

**FIGURE 78-2.** Dendritic cell (DC) (antigen-presenting cell [APC]) stimulation of naive T cell. The DC encounters and takes up an antigen; processes the antigen, subsequently releasing interleukin-12 (IL-12); and expresses CD40 and B7 proteins on its cell membranes. Once the antigen is processed by the DC, it is presented as a major histocompatibility complex (MHC) class I molecule at the cell surface. The naive T cell is stimulated by IL-12 and responds to the DC via CD40 ligand, T-cell receptor, and CD28 cell surface proteins.

Cytokine production by stimulated neonatal DCs can provide insight into the defect of their impaired immune response. IL-12 plays a critical role in the stimulation of T cells by mature DCs. Goriely and colleagues (2001) reported comparable levels of IL-6, IL-8, TNF- $\alpha$ , and IL-10 in newborn and adult DCs after stimulation with LPS or CD40 ligand. However, IL-12 (p40) levels secreted by neonatal DCs were significantly lower on stimulation with LPS but not with CD40 ligand. Also, after either LPS or CD40 ligand stimulation, neonatal DCs produced lower levels of IL-12 (p70) than adult DCs. CB DCs stimulated with LPS, CD40 ligand, or poly(I:C) showed a selective defect in the synthesis of IL-12. Furthermore, when stimulated with poly (I:C), neonatal DCs produced deficient levels of IL-12 (p70) but their production of IL-12 (p40) was similar to that of adult DCs. Neonatal DCs were also placed in mixed leukocyte culture with adult CD4<sup>+</sup> T cells, and neonatal DCs induced significantly lower levels of IFN- $\gamma$  but higher levels of IL-10 than did adult DCs. Analysis of IL-12 (p35) mRNA from LPS stimulated neonatal and adult DCs by real-time polymerase chain reaction (PCR) assay revealed significantly lower levels in neonatal versus adult DCs; however, the addition of rIFN- $\gamma$  to LPS-stimulated newborn DCs restored the expression of and synthesis of IL-12 to adult levels.

### SUMMARY

Immaturity of neonatal neutrophils, monocytes, lymphocytes, and dendritic cells predisposes the newborn to an increased incidence and/or severity of infectious complications. An increased understanding of the genetic mechanisms responsible for these defects will provide insight regarding future treatment strategies to prevent and/or treat serious or overwhelming infection in the newborn.

### Acknowledgment

The authors would like to thank Linda Rahl for her expert editorial assistance in the preparation of this chapter.

# Neonatal Hyperbilirubinemia

Ashima Madan, James R. MacMahon,  
and David K. Stevenson

## PHYSIOLOGIC JAUNDICE

The following terms are relevant to a discussion of jaundice and hyperbilirubinemia. This listing is of interest not only in an etymologic sense but also because it reflects a historical appreciation of these entities:

- Bile—from Latin *bilis* (“bile”), but the Latin probably had Celtic origins (*bistlis*).
- Bilirubin and biliverdin—simply “red bile” and “green bile,” latinized.
- Icterus—from Greek *ikteros*, meaning “yellow colored,” a word applied to a yellow bird as well.
- Jaundice—from Old French *jaundice*, a word rooted in the Latin *galbinus*, meaning “greenish yellow,” from *galbus* (“yellow”).

Jaundice is the visible manifestation in skin and sclera of elevated serum concentrations of bilirubin. Most adults are jaundiced when serum total bilirubin (STB) levels exceed 2.0 mg/dL (34  $\mu$ mol/L). Neonates, however, may not appear jaundiced until the STB concentration exceeds 5.0 to 7.0 mg/dL (86 to 119  $\mu$ mol/L). Some degree of jaundice develops in 60% to 70% of the approximately 4 million infants born each year in the United States. In those born prematurely, the incidence probably exceeds 80%.

Chemical hyperbilirubinemia, defined as an STB level of 2.0 mg/dL (34  $\mu$ mol/L) or more, is virtually universal in newborns during the first week of life. STB concentrations in premature infants are even higher, persist longer, and are more likely to be associated with neurologic injury than those in term neonates (Lockitch, 1994). Debate and controversy remain in efforts to define either normal or physiologic ranges of STB concentrations in newborns, because the data are influenced by such variables as length of gestation, birth weight, nutritional status, mode of feeding, race, and even geographic location. At issue is whether the normal range should be defined by the rate of increase in STB concentration, a level for a specific postpartum age, the duration of STB elevation, or the maximal level attained.

Traditionally, a distinction has been made between benign physiologic jaundice and hyperbilirubinemia, which is either pathologic in origin or severe enough to be considered deserving of further evaluation and intervention. This latter entity has been called “nonphysiologic,” although frequently no disease is identified as being causative or consequent.

STB concentrations have been defined as nonphysiologic if the concentration exceeds 5 mg/dL (86  $\mu$ mol/L) on the first day of life in a term neonate, 10 mg/dL (171  $\mu$ mol/L) on the second day, or 12 to 13 mg/dL (205 to 222  $\mu$ mol/L) thereafter, based on data from the National Collaborative Perinatal Project (Hardy et al, 1979). In recent years, the significance of these numbers has been questioned. Indeed, data from a mixed population of infants weighing 2500 g or more in San Francisco revealed that, using these parameters, 13.4% of the infants would be classified as having nonphysiologic jaundice (10% of whites, 4.4% of blacks, and 23% of Asians) (Newman et al, 1990). The data of Maisels and Gifford (1986) indicate that the 97th percentile of maximal STB concentration in healthy mature newborns is 12.4 mg/dL (212  $\mu$ mol/L) for formula-fed infants and 14.8 mg/dL (253  $\mu$ mol/L) for breast-fed infants. Any STB elevation exceeding 17 mg/dL (291  $\mu$ mol/L) should be presumed pathologic and warrants investigation for a cause and possible therapeutic intervention, such as phototherapy.

The elevation of STB concentrations in healthy-appearing infants results from the convergence of several developmental factors specific to the neonate. Gartner and coworkers (1977) divided the clinical course of physiologic jaundice into two phases. Phase I includes the first 5 days of life in term infants and is characterized by a rapid increase in STB levels for 3 or 4 days, after which the level begins to decline. Phase II is characterized by stable, but elevated STB levels lasting about 2 weeks. In contrast, in preterm infants, phase I lasts 6 to 7 days, and the STB levels reached are higher than those in term infants. After phase II, STB levels become comparable with adult levels. Data from multiple studies show that physiologic jaundice usually results in peak STB levels between days 3 and 5 of life. Maisels (1981) proposed criteria that can be used to exclude the diagnosis of physiologic jaundice. His original criteria have been amended to accommodate conditions related to breast-feeding, state of hydration, and so on. In addition, it must be remembered that absence of these criteria does not guarantee that the jaundice is physiologic (Table 79–1).

## PHYSIOLOGIC MECHANISMS

Distinctive aspects of normal newborn physiology that contribute to neonatal hyperbilirubinemia include: (1) increased bilirubin synthesis; (2) less effective binding and transportation; (3) less efficient hepatic conjugation and excretion; and (4) enhanced absorption of bilirubin via the enterohepatic circulation.

### Increased Bilirubin Synthesis

Bilirubin is a breakdown product of hemoglobin. The bilirubin load is greater in neonates because in this population, not only does hemoglobin break down at two to three times the adult rate (Maisels et al, 1971), but also there is an increased rate of red blood cell (RBC) degradation in the marrow even before release. In addition, bilirubin synthesis in healthy neonates results from a greater erythrocyte mass

TABLE 79-1

**Criteria that Rule Out the Diagnosis of Physiologic Jaundice**

1. Clinical jaundice in the first 24 hours of life
2. STB\* concentration increasing by more than 0.2 mg/dL (3.4  $\mu$ mol/L) per hour or 5 mg/dL (85  $\mu$ mol/L) per day
3. STB concentration exceeding the 95th percentile for age in hours<sup>†</sup>
4. Direct serum bilirubin concentration exceeding 1.5-2 mg/dL (26-34  $\mu$ mol/L)
5. Clinical jaundice persisting for more than 2 weeks in a full-term infant

\*STB, serum total bilirubin.

<sup>†</sup>Based on a nomogram for hour-specific serum total bilirubin values (see Fig. 79-1).

at birth and a shorter half-life of neonatal RBCs. Normal term newborns have a hemoglobin level of approximately 17 to 19 g/dL, and a hematocrit of approximately 50% to 60%. Polycythemia, defined as a hematocrit greater than 65%, occurs in 1.4% to 1.8% of infants born at sea level and in 4% of those born at higher altitudes.

The life span of erythrocytes is less than 70 days for premature infants. It is estimated to be approximately 70 to 90 days in healthy term infants, compared with 120 days in adults.

### Binding and Transport

Circulating bilirubin is bound to plasma albumin. It is believed that the neurotoxicity associated with hyperbilirubinemia is primarily the result of unbound or “free” bilirubin, so the amount of albumin available for binding is important. The full-term newborn infant has a significantly lower plasma albumin level than that for the adult and, correspondingly, fewer bilirubin binding sites. The albumin level is inversely correlated with gestational age, so this lack of binding sites is more pronounced in preterm infants. Plasma albumin level increases rapidly over the first few days after birth, resulting in a mean increase over the first 7 days of almost 30%. Adult levels are reached by about 5 months of age (Notarianni, 1990).

Albumin binding of compounds in neonates is similar to that in adults in that acidic drugs and bilirubin are bound to albumin, but the binding affinity may be altered. In particular, affinity may be altered in the first several days after birth. This may be due to the presence of endogenous displacing agents in newborns, as well as structural differences in the albumin that resolve with maturity, adult characteristics being attained by 10 to 12 months of age (Miyoshi et al, 1966).

### Conjugation and Excretion

During intrauterine life, fetal removal of bilirubin is accomplished by way of the placenta and maternal-fetal circulation, and the bilirubin in cord blood is virtually all unconjugated. At birth, blood supply to the right lobe of the liver changes from the high oxygen content of the

umbilical vein to the low oxygen content of the portal vein. Blood flow through the hepatic arteries develops only in the first week of extrauterine life. In addition, the ductus venosus may remain partially patent for several days, allowing blood to bypass the liver completely. All of these factors can contribute to a delay in the plasma clearance of bilirubin.

The conjugating capacity of normal infants varies greatly, with delayed conjugation and excretion, in some cases, related to the immaturity of the liver cell itself. The activity of the uridine diphosphate-glucuronosyltransferase (UGT) system in the newborn liver must be induced. Elevated conjugated bilirubin levels at birth, in cases of severe fetal hemolysis, suggest that elevated STB levels may be necessary to induce the conjugating enzymes. Production of UGT has been shown to be enhanced when certain drugs are administered. Phenobarbital is known to have this effect, and its clinical application is discussed later. Other pharmacologic substances, however, can inhibit UGT activity. Steroids structurally related to estrogen and progesterone have been shown to have this effect in vitro and in vivo, as have phenothiazines and the ester propionate preparation of erythromycin (Hsia et al, 1960).

### Enhanced Enterohepatic Circulation

Intestinal absorption of bilirubin successfully excreted into the intestine is enhanced by several features of newborn physiology, thereby adding to the tendency of newborns to become jaundiced. Conjugated bilirubin, as either the mono- or diglucuronide, is unstable and can be spontaneously or enzymatically hydrolyzed back to unconjugated bilirubin, which can be easily reabsorbed through the mucosa. In addition, absorption is enhanced by the sterility of the intestinal contents. Older children and adults have intestinal flora, which can metabolize conjugated bilirubin to the water-soluble and readily excretable breakdown products urobilin and stercobilin. Newborns have no such advantage; instead, the neonatal intestinal mucosa has a greater concentration of  $\beta$ -glucuronidase than is found in the adult. This enzyme can deconjugate bilirubin to form more unconjugated bilirubin, which can be absorbed via the enterohepatic circulation, adding further to the circulating unconjugated bilirubin load. Two other factors accelerating the deconjugation of bilirubin glucuronides in the newborn intestine are the mildly alkaline pH of the proximal intestine, which facilitates nonenzymatic hydrolysis, and the predominance of monoglucuronides as the main excretion form of bilirubin in the first few days of life.

### Clinical Relevance

All of the aforementioned factors have the combined effect of potentially increasing STB levels in the healthy newborn. The premature newborn is even more susceptible to almost all of these influences. Because individual variation in the maturation of any of these systems is great, STB levels in a normal neonatal population vary widely. Slight perturbations in any of these processes could result in increased STB levels. For example, through studies of carbon monoxide (CO) production, it has been determined

that infants of diabetic mothers have an increased propensity for jaundice because of enhanced formation and impaired elimination of bilirubin. Any pathologic process that increases the production or impairs the elimination of bilirubin can exacerbate the normally occurring physiologic jaundice in newborns. In the clinical setting, any such pathologic disorder should be identified and treated as appropriate. What remains controversial is the danger posed by increased STB levels encountered in the absence of pathologic disorders, as well as when to pursue investigations to identify or rule out disease.

## EPIDEMIOLOGY

Although all infants experience some degree of (hyper) bilirubinemia in the first few days of life and most have some physiologic jaundice, the extent and duration of the elevation vary among populations of different racial compositions or in different geographic distributions. The pattern of physiologic jaundice described previously in this chapter, with STB reaching maximal levels on the third or fourth day of life, is commonly seen in term infants of European or African ancestry. In the United States, black infants have slightly lower peak STB concentrations than those in other groups. In contrast, infants of Asian or Native American ancestry have a different pattern of neonatal jaundice, which is characterized by a more rapid increase of STB concentrations in the first few days, higher peak STB levels, and relatively prolonged courses, with the peak STB levels reaching their maximum several days later. The subsequent return to more normal levels occurs more slowly in these populations as well (Gartner, 1994).

Investigations involving infants in Japan, Asians born in the United States, Navajo, Sioux, Eskimos in Alaska, and Hispanics in Los Angeles (mostly from families in northern Mexico) have consistently shown higher STB levels in the first few days of life in all these groups. The reasons for such racial or ethnic differences are unclear. Studies assessing CO production suggest that an increased rate of heme catabolism leading to increased synthesis of bilirubin may be an important contributing cause. There is no strong evidence in favor of enhanced intestinal absorption or diminished conjugation or excretion in these populations (Johnson, 1992). However, in larger studies that have assessed the increase in bilirubin synthesis in Asians, it is clear that not all persons in a population are high producers of bilirubin (Fischer et al, 1988). Whether these populations are at higher risk for toxic effects of hyperbilirubinemia has not yet been determined. Italian studies looking for specific genetic markers within racial groups suggest that certain genetic traits involving red cell membrane stability as well as factors involved with bilirubin conjugation may contribute to neonatal jaundice, although environmental as well as genetic factors also may play a role (Lucarini et al, 1991). It has been shown that variations in the UGT 1A1 gene contribute to some of the observed racial differences. For example, polymorphisms due to differences in the number of thymine-adenine (TA) repeats in the promoter region of the gene vary among individuals of Asian, African, and Caucasian ancestry and correlate

with variations in UGT enzyme activity and affect bilirubin metabolism (Beutler et al, 1998). Another cause of racial variation is due to a common mutation in the UGT gene (Gly71Arg), which occurs in Asians and results in an increased incidence (approximately 20%) of severe hyperbilirubinemia (Akaba et al, 1998). The knowledge that racial groups differ in the peak STB levels could have important implications for management of these infants.

## BREAST-FEEDING AND JAUNDICE

For several years there has been considerable controversy regarding the influence of breast-feeding on STB levels. Most studies indicate that infants who are breast-fed are several times more likely to have STB levels greater than 12 mg/dL (205  $\mu$ mol/L) than infants who are formula-fed. In addition, breast-fed infants are believed to have higher STB levels throughout the first several weeks of life. Is physiologic jaundice in the newborn exaggerated in breast-fed babies? Many studies have attempted to answer this question, and the results are conflicting. A meta-analysis of a large series of studies showed that nearly 13% of breast-fed babies versus 4% of those formula-fed had STB levels of 12 mg/dL (205  $\mu$ mol/L) or higher on days 3 to 6 of life, and 2% of breast-fed infants versus 0.3% of formula-fed infants had STB levels exceeding 15 mg/dL (257  $\mu$ mol/L) (Schneider, 1986). The consensus of practitioners and investigators in the past decade is that breast-feeding is indeed associated with statistically significant elevations of STB concentrations.

Two separate patterns of jaundice in breast-feeding infants have been described. The first has been termed *breast-feeding-associated jaundice*, or simply *breast-feeding failure jaundice*, a condition that occurs in the first week of life; the second is less common and is called *breast milk jaundice* and manifests as prolonged hyperbilirubinemia lasting into the third week of life or beyond. As the epidemiology of these conditions is better understood, they may no longer be perceived as disease states; rather, they may be related to feeding practices or may simply represent an extension of physiologic jaundice.

### Breast-Feeding Failure Jaundice

Several reports suggest that the cause of breast-feeding failure jaundice may be nutritional and that it can be prevented by frequent (e.g., nine times daily) breast-feeding in the first 3 days of life, and avoidance of supplementation with water or glucose solutions (De Carvalho et al, 1982; Varimo et al, 1986; Yamauchi and Yamanouchi, 1990). Attention has focused on such factors as dehydration, caloric intake, frequency and volume of feedings, and supplementation. Of these, dehydration has been questioned as a major issue because of normal serum osmolalities, an absence of hematocrit changes consistent with the degree of hyperbilirubinemia, and the finding in some studies that water supplementation actually leads to further elevation of STB levels. Breast-fed infants pass fewer stools in the first few days of life, suggesting that increased amounts of bilirubin are absorbed into the enterohepatic circulation. To overcome this, early and frequent feedings may increase

evacuation and decrease intestinal transit time. Additional evidence indicates that caloric intake can influence STB levels independently of other factors. In studies with adults and a variety of animals, starvation or general deprivation of calories has been shown to increase STB levels in association with changes in liver function. The mechanisms for this “starvation jaundice” are not known but may involve shifts in bilirubin pools, less efficient hepatic conjugation, enhanced bilirubin absorption from the intestines, or a systemic effect modulating cell transport of bilirubin. Consistent with the concept that the increase in STB concentration is related to conjugation and absorption rather than bilirubin production or heme catabolism are findings from studies showing that there is no difference in CO production (a surrogate for bilirubin production) between breast-fed and formula-fed infants (Stevenson et al, 1994). With improved management of breast-feeding in conjunction with the use of lactation consultants, the incidence of breast-feeding failure jaundice in newborns might be reduced.

Changes in hospital breast-feeding policies and practitioner approaches to breast-feeding may not only prevent toxicity from hyperbilirubinemia but also lead to reductions in unnecessary laboratory testing, hospitalization, and medical intervention. Breast-feeding jaundice is an important issue for the practitioner, especially because the incidence of breast-feeding has increased from 33% of infants in the United States in 1975 (Gartner, 1994) to 50% to 60% in recent years (Martinez and Krieger, 1985; Ryan et al, 1991), and the length of routine newborn hospital length of stay has shortened to about 1 day. Breast-feeding jaundice is a diagnosis of exclusion, and most important, increased bilirubin production must be eliminated as a contributing cause.

### Breast Milk Jaundice

The second identified pattern of jaundice in some otherwise healthy breast-fed infants has been called “breast milk jaundice.” Considered by some researchers to be an extension of physiologic hyperbilirubinemia, this entity was first described in 1963 (Arias et al, 1963) and was considered to be a disease that occurred in less than 1% to 2% of the breast-feeding population. More recent epidemiologic studies suggest it is much more frequent, affecting as many as 10% to 30% of the breast-fed infants in the second to sixth weeks of life, with some experiencing hyperbilirubinemia well into the third month (Gartner, 1994; Linn et al, 1985).

One hypothesis addressing this prolonged jaundice associated with breast-feeding suggests that it results from enhanced enterohepatic absorption of unconjugated bilirubin related to the presence of an unidentified factor in human milk. This theory proposes that among breast-fed infants who do not have the prolonged jaundice, either the infants do not respond to this factor in their mother’s milk or their mother’s milk does not contain it. No specific factor has been identified, and these etiologic theories are still considered speculative.

The cause of breast milk jaundice has been pursued ever since it was first considered a disease state. Several

metabolites in breast milk have been considered as etiologic agents, and usually their proposed mechanism of action has been described as inhibiting conjugation or enhancing the intestinal absorption of bilirubin through the enterohepatic circulation. Early studies suggested that the prolonged unconjugated hyperbilirubinemia in otherwise healthy breast-fed infants was due to the inhibition of hepatic UGT. Initially, an unusual steroid metabolite of progesterone, pregnane-3 $\alpha$ ,20 $\beta$ -diol, was considered as a likely candidate because it was known to inhibit hepatic UGT *in vitro*. Later studies cast doubt on the relevance of this chemical to breast milk jaundice. Other inhibitors of UGT have been implicated, such as free fatty acids and several lipases (including lipoprotein lipase [serum-stimulated lipase] and bile salt-stimulated lipase). Other studies suggest that yet another factor such as  $\beta$ -glucuronidase might be present that could deconjugate bilirubin in the intestine, allowing for increased intestinal bilirubin reabsorption. However, no clear relationship between the levels of this enzyme in breast milk and the infant’s STB level has been demonstrated, and none of the aforementioned theories have been confirmed. Consideration that breast milk jaundice may be a normal event does nothing to explain its cause, so the search for a true link between breast milk composition and breast milk jaundice will continue.

Over the past 40 years, much investigation has been carried out to explain both breast-feeding failure jaundice and breast milk jaundice. No single and exclusive cause for either condition has been identified.

## UNCONJUGATED HYPERBILIRUBINEMIA: OVERVIEW

Overproduction of bilirubin combined with immature mechanisms for conjugation and enhanced intestinal enterohepatic circulation of bilirubin contributes to the development of neonatal jaundice. In most infants, this increase in STB is mild enough to be considered physiologic and nontoxic, and the excess bilirubin is composed almost entirely of the unconjugated form. When excessive production of bilirubin saturates the immature mechanism for bilirubin uptake and conjugation, however, or when the process of bilirubin uptake and conjugation is defective or deficient, the level of unconjugated bilirubin in the serum can accumulate to toxic concentrations. Accordingly, a variety of pathologic conditions may result in severe or prolonged unconjugated hyperbilirubinemia (Table 79–2). Even though the most prevalent of these involve the overproduction of bilirubin, impaired uptake and conjugation and excessive enterohepatic circulation of bilirubin can be responsible for severe clinical disorders. Because most cases of dangerous or extreme hyperbilirubinemia are related to hemolysis, identification of overproduction of bilirubin is useful in the early identification of the increased risk for bilirubin toxicity. Measurements of levels of end-tidal CO<sub>2</sub>, corrected for inhaled CO (ETCO<sub>c</sub>), or of carboxyhemoglobin, also corrected for inhaled CO (COHb<sub>c</sub>), can help identify these infants, as there is a one-to-one correlation of CO production with bilirubin production.

In a review of 88,000 liveborn infants in Melbourne, Australia, from 1971 to 1989, it was determined that 12.4%

TABLE 79-2

**Causes of Unconjugated Hyperbilirubinemia**

- A. Excessive production of bilirubin (hemolytic disease of newborn)
  1. Blood group heterospecificity (incompatibility)
    - a. Rh isoimmunization
    - b. ABO incompatibility
    - c. Minor blood group incompatibility
  2. Red blood cell enzyme abnormalities
    - a. Glucose-6-phosphate dehydrogenase deficiency
    - b. Pyruvate kinase deficiency
  3. Sepsis
  4. Red blood cell membrane defects
    - a. Hereditary spherocytosis
    - b. Elliptocytosis
    - c. Poikilocytosis
  5. Extravascular blood
  6. Polycythemia
- B. Impaired conjugation or excretion
  1. Hormonal deficiency
    - a. Hypothyroidism
    - b. Hypopituitarism
  2. Disorders of bilirubin metabolism
    - a. Crigler-Najjar syndrome type I
    - b. Crigler-Najjar syndrome type II (Arias disease)
    - c. Gilbert disease
    - d. Lucey-Driscoll syndrome
  3. Enhanced enterohepatic circulation
    - a. Intestinal obstruction, pyloric stenosis
    - b. Ileus, meconium plugging, cystic fibrosis

of all of the infants had hyperbilirubinemia, defined as STB levels greater than 9 mg/dL (154  $\mu$ mol/L) (Guaran et al, 1992). Correlates of jaundice were determined in 32% of the infants. Most often these were prematurity (20%) followed by isoimmunization (7%), with sepsis, bruising, and glucose-6-phosphate dehydrogenase (G6PD) deficiency accounting for less than 2% each. Of the infants defined as having hyperbilirubinemia, the maximum levels of STB exceeded 20 mg/dL (342  $\mu$ mol/L) in 2% (212 of 10,944), representing 0.25% of all the births. Nearly 60% of these infants had some determined cause of jaundice, with the hemolysis of isoimmunization (found in 54 of 212) being the most common identifiable cause of the severe hyperbilirubinemia. The largest single group with high STB levels, however, comprised infants with no known cause of jaundice (90 of 212).

### CAUSES OF UNCONJUGATED HYPERBILIRUBINEMIA

In the newborn period, unconjugated hyperbilirubinemia is the manifestation of a large and diverse group of clinical entities. To emphasize the pathophysiologic processes involved, the following discussion considers conditions associated with excess bilirubin production separately from those related to impaired conjugation, excretion, or elimination. This distinction is of clinical relevance in that excessive bilirubin production can be identified from the CO production resulting from heme degradation. In addition,

the risk of neurotoxicity in the newborn infant is greater in conditions associated with increased bilirubin production than in those associated primarily with impaired bilirubin excretion or elimination. The former conditions tend to manifest earlier in more unstable infants, and the latter manifest later in otherwise well infants.

The following sections describe the major pathologic conditions responsible for unconjugated hyperbilirubinemia (see Table 79-2).

## Excessive Production of Bilirubin: Hemolytic Disease of the Newborn

### Blood Group Incompatibility

#### Rh Isoimmunization

The most common identified pathologic cause leading to hyperbilirubinemia is hemolytic disease of the newborn. The destruction of RBCs in the fetus and newborn most commonly results from Rh or ABO blood group incompatibility with the maternal blood type.

The first understanding of hemolytic disease in the newborn resulted from studies of erythroblastosis fetalis due to Rh incompatibility. The Rh antibody is produced by an Rh negative mother in response to the presence of Rh antigen on the fetal RBC membrane. The initial maternal response to this antigenic stimulus is to produce immunoglobulin M (IgM) antibodies, which do not cross the placenta in significant amounts. Later, IgG antibodies are formed that cross into the fetus and attach to antigenic sites on the RBC membrane. Although small volumes of fetal RBCs may enter the maternal circulation throughout pregnancy, the major sensitizing event occurs during delivery, when a greater amount of fetal blood may enter the maternal circulation. For this reason, Rh incompatibility is less likely to cause hemolysis or hyperbilirubinemia with the first pregnancy, but repeated pregnancies can result in progressively more severe life-threatening complications. Mothers can be sensitized by the transplacental hemorrhage of as little as 0.5 mL of blood, an amount that can easily pass from fetus to mother during active labor or during obstetric complications or procedures such as amniocentesis or therapeutic abortions. The development of maternal sensitization can be identified by the indirect antiglobulin (Coombs) reaction in the mother, which identifies the presence of IgG antibody in her circulation, or from spectrophotometric examination of amniotic fluid. Because the placenta efficiently transports bilirubin to the mother, affected infants do not appear significantly jaundiced at birth, but the hemolysis can result in severe anemia, hydrops, or intrauterine death. After delivery of the infant, the hemolysis resulting from Rh sensitization may result in rapid development of hyperbilirubinemia, with attainment of bilirubin levels requiring intervention. Presence of the Rh antigen in an infant is identified by blood typing. Isoimmunization, which is the attachment of maternal antibody to fetal RBCs, can be identified with a positive direct antiglobulin (Coombs) reaction in the infant. RBCs coated with maternal antibodies are destroyed in the fetal or newborn liver and spleen, resulting in catabolism of excessive amounts of hemoglobin to bilirubin. The severity

of the Rh-induced hemolysis depends on several factors, including the antigenicity of the fetal erythrocytes (e.g., males in general are more antigenic than females), degree of sensitization, the specific Rh antigen involved, and the amount of maternal-fetal transfusion. Fifteen percent to 20% of Rh-positive infants born to Rh-negative sensitized mothers show no clinical signs of illness, whereas 25% have severe disease with fetal death, hydrops, or severe anemia at birth. The administration of blocking antibodies (RhoGAM) to pregnant Rh-negative women has greatly decreased the incidence of hydrops fetalis in the United States.

### **ABO Incompatibility**

Hemolytic disease caused by reaction of maternal anti-A or anti-B antibodies with fetal A or B antigens on the erythrocyte surface, a process similar to that in Rh incompatibility, is more common but generally milder than hemolytic disease caused by Rh incompatibility. This condition occurs almost exclusively in type O mothers, in that the relevant antibodies produced by type A mothers or type B mothers are mostly IgM antibodies that do not cross the placenta. The jaundice of ABO heterospecificity usually appears within the first 24 to 72 hours after birth, later than that of Rh incompatibility. In the circumstances of the ABO heterospecificity, only half of infants with a positive direct Coombs' test have significant hemolysis; and some infants without a positive direct Coombs' test may exhibit hemolysis. Thus, the measurement of an ETCO<sub>c</sub> level can identify hemolysis in these infants.

### **Minor Blood Group Incompatibility**

Traditionally, less than 2% of infants with hemolytic disease have isoimmunization caused by minor blood group antibodies, such as Kell, Duffy, and Kidd. However, because the cases resulting from Rh incompatibility have dramatically declined since the use of blocking antibodies (RhoGAM) was instituted, there is a higher percentage of contribution from minor blood group incompatibilities. Maternal antibody titers with some antigen such as Kell are not always predictive of the presence or degree of hemolysis. Only about 50% of infants with a positive direct Coombs test have hemolysis. The presence and severity of hemolysis can be followed using sequential hematocrits, reticulocyte counts, red blood cell smears in combination with STB, and if available, by estimating total CO production as an index of total bilirubin production using a surrogate measure, such as ETCO<sub>c</sub>. Diagnosis requires identification of the specific antibody in neonatal serum or an eluate from neonatal RBCs.

### **Red Blood Cell Enzyme Abnormalities**

A group of RBC enzymopathies have been identified which result in chronic spontaneous hemolysis of early onset that persists throughout life. In the newborn period, marked hyperbilirubinemia can occur as a result of the severe hemolysis (Matthay and Mentzer, 1981; Olsen, 1969;

Valaes, 1969). The two most studied defects, G6PD deficiency and pyruvate kinase (PK) deficiency, may be associated with hemolytic anemia and jaundice even in the absence of a recognized trigger agent or event in the neonatal period.

### **Glucose-6-Phosphate Dehydrogenase Deficiency**

G6PD deficiency is a heterogeneous sex-linked recessive trait whose occurrence has a geographic distribution, with increased prevalence in African, Mediterranean, and Asian regions. Some of the clinical manifestations of this condition, such as favism and hemolytic reactions to certain drugs, were well recognized long before identification of the enzyme deficiency. Although severe neonatal jaundice is the most common clinical manifestation of G6PD deficiency, the relationship between hyperbilirubinemia and the hemolytic anemia was established only when the enzyme deficiency was identified in the late 1950s (Newton and Frajola, 1958; Zinkham and Lenhard, 1959). Since then, it has become apparent that the situation in the neonatal period is special, because severe jaundice rather than the anemia may predominate in the clinical presentation. Moreover, severe neonatal jaundice can develop in the absence of significant hemolysis in some G6PD-deficient babies. In G6PD deficiency, RBCs cannot activate the pentose phosphate metabolic pathway and therefore are unable to defend adequately against oxidant stresses. Because of this phenomenon, severe hyperbilirubinemia can result from hemolysis associated with sepsis, exposure to chemicals such as naphtha in mothballs, or administration of pharmaceutical agents (Table 79-3). Even though some of these agents and stresses have received public attention, others represent generally unsuspected dangers, such as the intramuscular injection of vitamin K analogues or the inhalation of paradichlorobenzene, which is used in many countries in moth repellents, car and carpet fresheners, and bathroom deodorizers (Siegel and Wason, 1986; Valaes, 1994). Exposure of the newborn to a hemolytic agent can occur transplacentally, via breast milk, or directly by inhalation, ingestion, or injection. RBCs deficient in G6PD also are unable to reduce methylene blue to leukomethylene blue; therefore, exposure to even normally acceptable levels of methylene blue causes hemolytic anemia and hyperbilirubinemia when the dye accumulates and functions as a hemoglobin-oxidizing agent. Thus, severe hyperbilirubinemia and even kernicterus have resulted from the use of methylene blue in patients with unsuspected G6PD deficiency.

Understanding of the processes leading to the clinical manifestations of G6PD deficiency has come from studies examining the intracellular events following exposure of RBCs to naphthoquinones (Harley and Robin, 1962, 1963; Sass-Kortsak et al, 1962). In these studies, oxidation of hemoglobin to methemoglobin, Heinz body formation, and growth-stimulating hormone depletion were described even in normal erythrocytes. All of these phenomena are exaggerated in RBCs deficient in G6PD because the pentose phosphate pathway is essential to the defense against such oxidative stress. The data in these studies suggest that

<sup>o</sup>Associated with most severe and numerous hemolytic episodes.

Adapted from Oski FA, Nalman JL: Hematologic Problems in the Newborn, 2nd ed. Philadelphia, WB Saunders, 1972; and from Valaes F: Severe neonatal jaundice associated with glucose-6-phosphate dehydrogenase deficiency: Pathogenesis and global epidemiology. *Acta Paediatr Suppl* 394:58-76, 1994.

neonates with G6PD deficiency may be particularly susceptible to the hemolytic action of vitamin K analogues. Experts currently recommend that oral vitamin K<sub>1</sub> be given for prevention of hemorrhagic disease in newborns in populations with a high incidence of G6PD deficiency (Jørgensen et al, 1991; Valaes, 1994).

Different genetic forms of the enzyme deficiency have characteristic risks, with the form found in the Mediterranean region exhibiting a more severe type of deficiency (Gd<sup>Mediterranean</sup>) than the form found in West Africa (Gd<sup>A-</sup> type). The association between G6PD deficiency and neonatal hyperbilirubinemia and kernicterus initially was reported from Greece (Doxiadis et al, 1961), and in 1969 it was recognized as a serious public health problem there (Valaes et al, 1969). Reports from other Mediterranean countries followed. A similar relationship between G6PD deficiency and hyperbilirubinemia was reported in neonates in China and in ethnic groups of other East Asian countries (Lie-Injo et al, 1977; Phornphutkul et al, 1969), and

it appears that the Asian forms of this condition have a severe reduction in enzyme activity similar to that in the Mediterranean forms. Reports from Africa associating G6PD deficiency of the Gd<sup>A-</sup> type with neonatal hyperbilirubinemia and kernicterus in infants in Nigeria, Senegal, Ghana, and South Africa were significant because the earlier reports had suggested that only the Gd<sup>Mediterranean</sup> form of the enzyme deficiency was severe enough to cause kernicterus. Early reports suggesting that black infants with G6PD deficiency exhibit no increased incidence or severity of hemolysis and jaundice have been shown to be incorrect, although their enzyme deficiency, the Gd<sup>A-</sup> type form of the disease, is less severe than the others. The susceptibility to hemolysis is dependent not only on the level of enzyme deficiency but also on the amount of oxidant stress or degree of exposure to an offending agent.

Between 200 million and 400 million people are estimated to carry the G6PD deficiency gene. In Greece, for example, the prevalence is estimated at 2% to 4% (Valaes, 1994). Even though the distribution of this genetic trait has historically been centered in the tropics, where malaria has flourished, several centuries of migration have led to worldwide dissemination of the gene. Therefore, physicians in all countries need to be familiar with the clinical manifestations and risks of G6PD deficiency.

Severe jaundice develops in approximately 5% of white or Asian infants with this disorder, usually after 24 to 48 hours of life and sometimes only after some trigger event. Maximal STB level is reached between the third and fifth days of life. One report of such a case (Penn et al, 1994) is a reminder to practitioners that the cause may be subtle but the consequences devastating. A G6PD screen is recommended in infants of Mediterranean, Nigerian, or Asian descent who have STB levels greater than 17 mg/dL (291 μmol/L) and a Coombs'-negative hemolytic anemia. However, the G6PD screen can sometimes be falsely negative in infants experiencing a hemolytic crisis.

The incidence of hyperbilirubinemia is increased when infants have both the Gilbert polymorphism and G6PD deficiency. Kaplan and coworkers (1997) observed that infants with the normal variant in the Gilbert promoter region had a similar incidence of hyperbilirubinemia (greater than 15 mg/dL [257 μmol/L]) to that in infants with and without G6PD deficiency (9.7% versus 9.9%). However, among G6PD-deficient infants who were homozygous or heterozygous for the Gilbert variant, hyperbilirubinemia was more frequent (50% versus 32%).

### **Pyruvate Kinase Deficiency**

Pyruvate kinase (PK) deficiency is the second most common cause of enzymatic-related hemolytic anemia. It is an autosomal recessive disorder that occurs uncommonly in all ethnic groups. PK is a key enzyme in the production of adenosine triphosphate (ATP) in RBCs. Its deficiency leads to shortened RBC survival, with excess hemolysis. Unexplained jaundice in a newborn with no isoimmunization or no sepsis or drug administration, but with evidence of hemolysis (excessive CO production, anemia, reticulocytosis), raises the possibility of this disorder.

## Septicemia

Sepsis is one of the important treatable problems associated with bilirubin overproduction. From the earliest studies of septicemia in newborns, it was observed that 25% to 30% had clinical jaundice early in the illness, sometimes reaching extreme levels. The hyperbilirubinemia in septic neonates is thought to be a consequence of rapid hemolysis, although there are several theories regarding the mechanism of occurrence. Neonatal erythrocytes are susceptible to cell injury and Heinz body formation in response to oxidative stress. In addition, heme oxygenase (HO) is induced by oxidants, and its induction could lead to increased catabolism of heme to bilirubin. Unstable hemoglobins are known to precipitate to form Heinz bodies when exposed to certain chemicals (e.g., methylene blue), resulting in production of erythrocytes that tend to lyse. It is possible that some aspect of sepsis has similar effects.

Available evidence suggests that bilirubin is a protective antioxidant (Dennerly et al, 1995; Stocker et al, 1987) and that initially in infection, STB levels may be decreased as a result of its consumption (Benaron and Bowen, 1991). However, the hemolysis that can occur in association with sepsis probably overwhelms this effect, resulting in hyperbilirubinemia.

## Red Blood Cell Membrane Defects

### *Hereditary Spherocytosis*

Hereditary spherocytosis is characterized by spherocytic erythrocytes that are abnormally fragile under osmotic stress owing to abnormalities of the RBC cytoskeleton. This condition is inherited as a mendelian dominant trait, but in 10% to 25% of cases, neither parent is found to have spherocytes (Robinson, 1957). The incidence of this disorder in the United States is 1:5000 and may be higher in other parts of the world. Many families with hereditary spherocytosis have mutations in the gene encoding spectrin, an essential component of the RBC cytoskeleton. Cells from persons with spherocytosis also contain less lipid than normal.

Jaundice develops in approximately 50% of infants with spherocytes and may be misdiagnosed as physiologic jaundice. Because isoimmunization is not involved as an etiologic factor, the direct Coombs' test in the infant is negative. The diagnosis is made by examination of a peripheral smear of blood and recognition of the abnormal shape of erythrocytes. RBC osmotic fragility tests also are abnormal.

### *Hereditary Elliptocytosis*

Hereditary elliptocytosis is a heterogeneous group of autosomal dominant defects that, as with spherocytosis, result in an abnormal RBC cytoskeleton. The membrane defect is caused by abnormalities of either spectrin or glycophorin C. The incidence of hereditary elliptocytosis is approximately 1:4000; the disorder generally is defined by the presence of more than 25% elliptocytes on the RBC smear. This disorder usually is asymptomatic in the newborn

period; however, occasionally there is enough hemolysis resulting from increased osmotic fragility to cause hyperbilirubinemia. The peripheral smear in these cases demonstrates many budding erythrocytic forms similar to those seen in pyropoikilocytosis (Austin and Desforges, 1969).

## Extravascular Blood

Presence of blood that has been swallowed or remains entrapped after a hemorrhagic event, such as with severe bruising, cephalohematoma, or liver, splenic, or adrenal hemorrhages, commonly leads to hyperbilirubinemia because of the excess bilirubin production resulting from the breakdown of extravasated RBCs. The common sites for such substantial collections of blood in term infants are cephalohematomas and the space beneath the galeal aponeurosis; in preterm infants, intraventricular hemorrhages are more frequent.

## Polycthemia

Because neonatal erythrocytes have a shorter life span than that of erythrocytes of older infants and children, an excess in the number of erythrocytes at birth can be associated with increased heme degradation and bilirubin production. For this reason, any infant who is plethoric or polycythemic runs some risk for development of hyperbilirubinemia. Because polycythemia is regularly associated with specific clinical entities in newborns, such as late cord clamping, trisomy 21, or maternal diabetes, these conditions can be associated with increased risk of neonatal jaundice.

Infants of diabetic mothers may be at increased risk for development of hyperbilirubinemia secondary to certain contributory factors, in addition to polycythemia. For example, hypoglycemia can be associated with high levels of unconjugated bilirubin. In this instance, the cause is not only excess bilirubin production but also limitation of conjugation. Glucose is a substrate that participates in the synthesis of the bilirubin conjugate; its absence may reduce the capacity to conjugate bilirubin, accentuating jaundice in young infants.

## Impaired Conjugation or Impaired Excretion of Bilirubin: Nonhemolytic Unconjugated Hyperbilirubinemia

### Hypothyroidism

Congenital hypothyroidism can be accompanied by prolonged hyperbilirubinemia (unconjugated), presumably as a result of a delay in maturation of the bilirubin-conjugating enzymes (MacGillivray et al, 1967). First recognized in 1954, this association has been documented in approximately 10% of all newborns with hypothyroidism. Several mechanisms may be involved in this process, because only some of these hypothyroid patients with jaundice demonstrate rapid resolution of the problem after hormonal therapy. It is unclear whether the protracted jaundice in hypothyroidism is a consequence of delayed maturation of hepatic conjugating capacity, but a similar picture of protracted jaundice, often

in association with refractory hypoglycemia, is seen in infants with congenital hypopituitarism.

The exact impact of the thyroid hormones on conjugation, or other role, awaits further study. The prolonged jaundice associated with congenital hypothyroidism may stem from a delayed maturation of the ability of the liver to conjugate bilirubin because of the hormone-dependent variations in UGT activity. Reports also suggest that the thyroid hormones cause changes in protein expression, rather than enzyme latency, although some coordinated regulation of glucuronidation and levels of cytochrome P-450 also has been hypothesized (Goudonnet et al, 1990). Differential actions of thyroid hormones and chemically related compounds on UGT and cytochrome P-450 isozymes in animal studies suggest that the physicochemical characteristics of the hormones are important in determining the impact of these chemicals (Goudonnet et al, 1990). Clinically, a similar picture is seen in infants with congenital hypopituitarism, although this condition is much less common than hypothyroidism.

### Inherited Disorders of Bilirubin Metabolism

The entire group of inherited disorders of bilirubin metabolism (nonhemolytic unconjugated hyperbilirubinemia) can be simplistically divided into three major types according to the degree of bilirubin UGT activity and response to enzyme-inducing agents such as phenobarbital. The pattern of inheritance is different among these groups as well. The principal features of these three forms of the disorder are listed in Table 79-4.

### Crigler-Najjar Syndrome Type I

In the 1950s, just when the Rh isoimmunization problems were being clarified and understood as the major cause of kernicterus, a report of congenital familial nonhemolytic jaundice with kernicterus was published by Crigler and Najjar (1952). That report describes a severe, often lethal, unconjugated hyperbilirubinemia afflicting as many as 15 children in one family pedigree with no evidence of blood group incompatibility, hemolysis, or primary biliary obstruction. STB levels were 25 to 35 mg/dL (428 to 599  $\mu\text{mol/L}$ ), but other liver function tests were normal. Subsequent reports have documented STB levels as high as 45 mg/dL (770  $\mu\text{mol/L}$ ). Crigler-Najjar syndrome has come to be recognized as the most severe form of a group of inherited disorders of bilirubin metabolism that result from reduction or absence of UGT activity. In 1969, Arias and colleagues described a second type of severe non-hemolytic hyperbilirubinemia that is more common. The original condition described by Crigler and Najjar became known as Crigler-Najjar syndrome type I, and the new condition was called Crigler-Najjar syndrome type II, or Arias disease (Arias, 1971). The type I form of this inherited disorder is extremely rare (incidence estimated at 1 case per million). Family studies of type I patients have exposed partial deficiencies in glucuronidation of salicylates and menthol among siblings, parents, and grandparents of affected patients (Childs et al, 1959), supporting the view that this syndrome is inherited as an autosomal recessive characteristic that results in the virtual absence of UGT activity. The parents of these patients are anicteric heterozygotes. The patients with type I disease have pale

**TABLE 79-4**

#### Congenital Nonhemolytic Unconjugated Hyperbilirubinemia: Clinical Syndromes

Characteristic	Severity		
	Marked (Crigler-Najjar Syndrome type I)	Moderate (Arias disease, Crigler-Najjar Syndrome type II)	Mild (Gilbert Disease)
Steady-state serum total bilirubin	>20 mg/dL	<20 mg/dL	<5 mg/dL
Range of bilirubin values	14-50 mg/dL	5.3-37.6 mg/dL	0.8-10 mg/dL
Total bilirubin in bile	<10 mg/dL (increased with phototherapy)	50-100 mg/dL	Normal
Conjugated bilirubin in bile	Absent	Present (only monoglucuronide)	Present (50% monoglucuronide)
Bilirubin clearance	Extremely decreased	Markedly decreased	20-30% of normal
Hepatic bilirubin uptake	Normal	Normal	Reduced
Bilirubin UGT activity	None detected	None detected	Decreased
Genetics	Autosomal recessive	Heterogeneity of defect distinctly possible	Genetic polymorphisms including additional thymine-adenine (TA) repeats are present in the promoter region of the Ugt gene. Other polymorphisms, such as the Gly71Arg mutation identified in the Asian population, lead to a relative deficiency or decrease in conjugation and decreased elimination of bilirubin

\*UGT, uridine diphosphate glucuronosyltransferase.

Adapted and modified from Valaes T: Bilirubin metabolism: Review and discussion of inborn errors. Clin Perinatol 3:177, 1976.

bile containing no bilirubin. Whereas in the past, kernicterus resulted early in life, patients with this condition can currently be treated with long-term phototherapy and agents that reduce the enterohepatic circulation of bilirubin, allowing the possibility of leading a normal life.

If Crigler-Najjar syndrome type I is left untreated, bilirubin production from the breakdown of hemoglobin in erythrocytes and other heme proteins occurs normally, but the unconjugated bilirubin accumulates in plasma and tissues. A new steady state is eventually attained as bilirubin is degraded by other pathways.

The Gunn rat provides an animal model of Crigler-Najjar type I disease (Gunn, 1938). This animal produces no UGT and experiences severe jaundice. This animal model has served well in the understanding of the biologic processes involving bilirubin metabolism and the genetic defects associated with deficiency of conjugating enzymes.

### **Crigler-Najjar Syndrome Type II**

Crigler-Najjar syndrome type II, or Arias disease, is more common but more difficult to recognize in the first week of life. Children with type II disease excrete small amounts of bilirubin glucuronide into the bile, which is yellow. The hyperbilirubinemia experienced by these patients is less severe than in type I disease, with levels ranging from 8 to 25 mg/dL (137 to 428  $\mu\text{mol/L}$ ), with less risk of kernicterus. Type II disease usually is inherited in an autosomal recessive manner, although autosomal dominant transmission occurs in some cases. Initially the inheritance was thought to be autosomal dominant, because abnormalities of glucuronidation were found in only one parent of each patient. However, subsequent studies identified mild STB elevations and decreased UGT activity in some siblings and other parents (Labrune et al, 1989; Okolicsanyi et al, 1988). Some investigations have suggested that this condition could be a homozygous form of Gilbert disease. Patients with this form of UGT deficiency are clinically cured by the use of phenobarbital or other substances known to induce the enzyme activity.

This characteristic differentiates the two types of Crigler-Najjar syndrome, because type I patients experience no decrease in STB or enhanced conjugation in response to drug therapy (Sinaasappel and Jansen, 1991).

In the more than 50 years since the report by Crigler and Najjar, advances in molecular biology and genetics have led to an understanding of the molecular basis of these defects in glucuronidation. The organizational gene, termed UGT1A1, that expresses bilirubin uridine 5'-diphosphate glucuronosyltransferase (bilirubin UGT) in humans and rats has been identified and described. It consists of five exons, four of which encode the carboxyl-terminal domain of all UGT isoforms; the fifth exon encodes the amino-terminal half of each isoform. Because UGT is the only physiologically significant form of the enzyme, a mutation in any of the five exons can lead to either type I or type II disease, depending on the severity of the impact of the mutation on enzyme activity. Patients with as little as 4% of normal enzyme activity are clinically in the type II category; they have moderate elevations of bilirubin without ill health or neurotoxicity.

Because all of these patients are normal in every regard except for a single-gene defect that happens to code for this one enzyme, therapeutic intervention using gene therapy has been proposed. Several modes of gene therapy have been suggested, including transplantation of normal hepatocytes, retrovirus-mediated gene transfer, adenovirus-mediated gene transfer, and noninvasive receptor-mediated delivery of hepatocytes (Kren et al, 1999; Sauter et al, 2000; Tada et al, 1998). Until these techniques are successfully tested, liver transplantation will be the main mode of treatment for more severely afflicted persons.

### **Gilbert Disease**

A mild form of UGT deficiency was identified before Crigler and Najjar reported their severe family pedigree. Known as Gilbert disease, this condition initially was described in 1901 (Gilbert and Lereboullet, 1901) and later acquired a variety of names including *physiologic hyperbilirubinemia*, *icterus intermittens juvenilis*, *constitutional hepatic dysfunction*, and *familial nonhemolytic jaundice* (Crigler and Najjar, 1952). Although many patients with this condition have severe neonatal hyperbilirubinemia, the diagnosis most often is made in later adolescence. It is estimated that 5% to 10% of the general population may have this condition, which is characterized by a hereditary, mild chronic or recurrent nonhemolytic jaundice with otherwise normal results on liver function tests and no excess pigment in the urine (Odell and Gourley, 1989). Affected persons have a two-base-pair (TA) addition mutation in the TATAA element of the promoter region of the gene encoding UGT. The variant promoter contains seven TA repeats (Bosma et al, 1995) instead of the usual six. This results in a decreased (one-third normal) production of the UGT enzyme. Although Gilbert disease typically manifests in the older child or adolescent, homozygous newborns have an increased likelihood of developing jaundice during the first 2 days of life compared with heterozygotes. In addition, hyperbilirubinemia has been shown to be more frequent in G6PD-deficient infants who were homozygous (50%) for the Gilbert variant than in those who were heterozygotes (32%) (Beutler et al, 1998; Bosma et al, 1995; Kaplan et al, 1997; Koiwai et al, 1995). Older patients often complain of fatigue and asthenia associated with their jaundice. Because caloric deprivation results in hyperbilirubinemia in the child or adult with this disease, it is possible that many infants with unexplained hyperbilirubinemia are actually demonstrating the earliest manifestations of this disease. Like Crigler-Najjar syndrome type II, Gilbert disease can be treated with phenobarbital, which induces the necessary enzymes, although no specific treatment is usually necessary. This condition represents a heterogeneous group of disorders that result in at least a 50% decrease in UGT activity (Gourley, 1994).

### **Lucey-Driscoll Syndrome**

The Lucey-Driscoll syndrome originally was described in 24 infants born to eight mothers. Kernicterus developed in four of the infants in the original report as a result of their intense hyperbilirubinemia. The sera from the mothers of

these infants contained a substance that markedly inhibited the conjugation in vitro of aglycones such as *O*-aminophenol. This inhibitory material also was detected in the sera of the infants and was postulated to have been transplacentally acquired. The substance eventually disappears from the circulation of both the mother and the infant and is believed to be a gestational hormone. This syndrome should be considered in those circumstances in which siblings experience intense, transient hyperbilirubinemia of unexplained cause.

### Enhanced Enterohepatic Circulation of Bilirubin

In young infants, unconjugated hyperbilirubinemia has been documented with high intestinal obstruction, especially with hypertrophic pyloric stenosis. Jaundice rapidly disappears after operation. It was previously thought that this entity represented a condition in which enhanced enterohepatic circulation of bilirubin resulted in unconjugated hyperbilirubinemia. Studies have now shown that an essential etiologic feature of jaundice with pyloric stenosis is a markedly reduced activity of UGT at the time of corrective surgery. Normal enzyme activity is seen in nonjaundiced infants with pyloric stenosis. Therefore, concerns have been raised that jaundice with pyloric stenosis may represent an early manifestation of Gilbert syndrome exposed by factors related to undernutrition. Other researchers have suggested that this jaundice results from reduced portal and hepatic artery blood flow or simply a delay in maturation of the enzymes needed for conjugation. Until long-term enzyme presence and activity have been assessed after treatment of upper intestinal obstruction, the cause of this jaundice may be unclear.

Other intestinal conditions thought to cause hyperbilirubinemia via increased enterohepatic circulation include lower intestinal obstruction, hypoperistalsis, paralytic ileus regardless of cause (e.g., drug-induced), and meconium plugging. In all of these conditions, there is virtually no removal of bilirubin secreted into the intestines, and reabsorption is enhanced by the stasis and the sterility of the intestinal lumen.

### BILIRUBIN TOXICITY, ENCEPHALOPATHY, AND KERNICTERUS

Neonatal jaundice can be an entirely benign physiologic process, or it can also be the first sign of serious illness with associated toxicity manifested in the nervous system. The terms *bilirubin encephalopathy* and *kernicterus* represent clinical and pathologic abnormalities resulting from bilirubin toxicity in the central nervous system. Often the term *kernicterus* is used to include an entire spectrum of clinical and pathologic manifestations attributed to bilirubin. However, kernicterus, by strict definition, includes only the neuropathologic changes that are characterized by pigment deposition in specific regions of the brain, especially the basal ganglia, pons, and cerebellum. Of all infants in whom kernicterus develops, 50% die, and the survivors may have choreoathetoid cerebral palsy, high-frequency auditory nerve deafness, and mental retardation. The term *bilirubin encephalopathy* is correctly applied to

the clinical manifestations of the effects of bilirubin on the central nervous system; a broad spectrum of neurologic signs is attributed to bilirubin, ranging from subtle behavioral changes such as lethargy and irritability to seizures, hearing deficits, mental retardation, and death. Because it is not clear under what conditions neurotoxicity develops or at what STB concentration this damage occurs, little agreement exists about what constitutes a "safe" level of bilirubin. The effect of even moderate increases in STB levels on early development remains a source of controversy, especially because some clinical manifestations are reversible on reduction of the STB concentration.

Before exchange transfusions were used to control STB levels in isoimmune hemolytic disease, kernicterus was a common postmortem finding in infants dying with severe jaundice. Kernicterus has been documented in ill, low-birth-weight (mainly premature) infants whose STB levels remained much lower than the levels formerly associated with kernicterus. Whether this "low-bilirubin kernicterus" is associated with prematurity alone or is necessarily associated with stresses such as hypoxia, acidosis, respiratory distress, and neonatal septicemia is uncertain.

In the following paragraphs, the history of kernicterus is reviewed, clinical findings are described, and the current understanding of the processes leading to bilirubin neurotoxicity is discussed. Finally, new approaches to diagnosis, prediction of risk, and prevention are presented.

### Historical Overview

The relation between the clinical encephalopathy associated with elevated STB concentration and the gross pathologic changes seen as yellow staining of specific areas of the central nervous system was observed and described as early as 1875 (Orth, 1875). Schmorl, in 1904, coined the term *kernikterus* for such focal icteric pigmentation in degenerated zones of the brain (*kern*, "nucleus" or "ganglion," and *ikterus*, "yellow") (Schmorl, 1904). He observed that the staining of the neural tissue occurred in only a minority of infants having severe jaundice; he identified only six instances of kernicterus in 120 cases of jaundice of the newborn that came to autopsy.

Benke (1907) was the first to suggest that septicemia might play an important role in icterus gravis neonatorum, and he theorized that the pigmentation of brain tissue was caused by: (1) a peculiar attraction of bile pigments to ganglion cells, leading to their necrosis; (2) damage to ganglion cells by bile salts, which then became pigmented; or (3) chemic or traumatic insult that allowed the cells to become pigmented.

As early as 1915, the literature included descriptions of children who survived severe neonatal jaundice with resultant mental retardation and neuromuscular dysfunction, the jaundice being considered the causal agent (Guthrie, 1913; Spiller, 1915). In 1916, an advance in the understanding of this disease was made possible by the observation of Van den Bergh and Muller that serum from patients with hemolytic jaundice could be differentiated from serum of patients with obstructive jaundice on the basis of chemical reactions. They observed that the hemolytic serum did not react promptly with diazotized sulfanilic acid except in

the presence of alcohol; the other serum reacted in an aqueous solution. They termed these reactions “indirect” and “direct,” which have come to be recognized as unconjugated and conjugated bilirubin, respectively (Van den Bergh and Muller, 1916).

Diamond and colleagues in 1932 recognized that generalized edema of the fetus (hydrops fetalis), icterus gravis, and congenital anemia of the newborn (until that time considered three unrelated syndromes) were in fact all part of a single condition, which they termed *erythroblastosis fetalis* (Diamond et al, 1932). This was followed by the demonstration in 1939 of a serologic basis for maternal-fetal blood group incompatibility and the identification of the Rh system of antigens (Landsteiner and Weiner, 1940; Levine and Stetson, 1939).

By 1950, kernicterus was thought to occur almost entirely as a sequel to erythroblastosis fetalis, and the relationship between the damage and the severity of jaundice was recognized. Even then, only the Rh incompatibility was considered critical. There was debate about whether other blood groups played any role at all; prematurity, sepsis, pulmonary damage, and maternal diabetes were seen as cofactors in the development of clinical or pathologic disease.

With the publication describing congenital familial non-hemolytic jaundice with kernicterus in 1952, Crigler and Najjar not only exposed a new disease or family of diseases (currently understood to be hereditary deficiencies of UGT) but also advanced the understanding of kernicterus as a process related more to elevated unconjugated bilirubin levels than to specific blood group incompatibilities or even hemolysis (Crigler and Najjar, 1952).

In a series of publications between 1950 and 1952, Diamond, Allen, Hsia, and coworkers summarized the contemporary knowledge and state-of-the-art approaches regarding kernicterus, erythroblastosis, and interventions to prevent neurologic damage from high serum concentrations of unconjugated bilirubin (Allen et al, 1950). In concluding the series of articles, they wrote “kernicterus is likely to occur in babies with serum bilirubin above 30 mg per 100 cc and unlikely to occur when serum bilirubin remains below 20 mg per 100 cc” (Hsia et al, 1952). Often taken out of context, this sentence has had an enduring effect on decisions regarding clinical intervention, standards of care, hospitalization policies, and even legal concerns. Controversies about appropriate treatment of hyperbilirubinemia to prevent kernicterus continue.

In a review of the incidence of kernicterus, Johnson and Brown (1999) identified 41 cases occurring in the United States in the last 30 years. Of these, 31 occurred after 1990. This increase has been attributed partly to shorter hospital stays, decreased vigilance in diagnosing jaundice, lack of physician compliance with current guidelines, and an altered physician perception of the toxicity of bilirubin. Indeed, physicians trained after the 1970s have rarely seen classical kernicterus, owing to the successful implementation of the use of RhoGAM to prevent isoimmunization and the treatment of jaundice with phototherapy. Many of the recently reported cases are found in healthy, breast-feeding term male infants with no other obvious cause for jaundice.

The progress in preventing maternal-fetal blood group incompatibility and in reducing STB concentration

coincided with the development of neonatology as a specialty and the ability to rescue sick premature infants. Kernicterus was reappearing in the autopsies of sick low-birth-weight infants, particularly in those who had experienced severe respiratory distress, acidosis, or sepsis. It was evident in neonates whose STB level was never elevated to the extremes reported earlier, suggesting that bilirubin toxicity in low-birth-weight infants might be in some way different from that in full-term infants with erythroblastosis fetalis. Again the question arises: Is bilirubin the cause of the damage or is staining of tissue caused by antecedent injury? Are patients dying with kernicterus or of kernicterus? In some cases, bilirubin encephalopathy is observed before death, and the yellow neuronal staining in a classic distribution of kernicterus is the only prominent finding in the central nervous system at autopsy, providing evidence of a real toxicity attributed to bilirubin itself.

### Clinical Manifestations of Bilirubin Toxicity

Bilirubin toxicity usually does not become overt until high STB levels have been established for several hours. Acute bilirubin encephalopathy typically progresses through three stages. Stage 1 occurs during the first few days, with the infant having decreased activity, poor sucking, hypotonia, and a slightly high-pitched cry. If the STB level is rapidly decreased (e.g., by way of exchange transfusion), the abnormalities often can be reversed. Stage 2 develops after a week, with the infant demonstrating the features of stage 1 and also rigid extension of all four extremities, tight-fisted posturing of arms, crossed extension of the legs, and a high-pitched, irritable cry. Sometimes these changes are accompanied with seizure activity, backward arching of the neck (retrocollis) and trunk (opisthotonos), and fever. Stage 3 typically begins after the first week, with the infant demonstrating hypertonia with marked retrocollis and opisthotonos, stupor or coma, and a shrill cry. After several months in patients who survive, chronic bilirubin encephalopathy develops and has three major features: movement disorder (chorea, ballismus, tremor), gaze abnormalities (especially limitation of upward gaze), and auditory abnormalities. The most common findings later in childhood are choreoathetosis, ocular paralysis, and eighth nerve deafness; severe mental retardation and spastic cerebral palsy occur in a minority. In general, the motor findings are the most obvious abnormalities in long-term survivors. In addition to the neurologic abnormalities, some children with bilirubin encephalopathy have dental enamel hypoplasia.

A scoring system developed by Johnson and coworkers (1999) can be used to define the presence and severity of the neurologic sequelae associated with excessive hyperbilirubinemia. Mental state, muscle tone, and cry are characterized and then grouped into three levels of increasing abnormalities: stage IA, minimal signs; stage IB, progressive but reversible with treatment (4 to 6); and stage II, advanced and largely irreversible (7 to 9). Characteristics for each category are weighted as 1, 2, or 3 according to severity and then summed for an overall score; the higher the score, the greater the risk.

The first magnetic resonance imaging (MRI) study showing brain damage associated with hyperbilirubinemia

was reported in a full-term infant with G6PD deficiency. MRI at 8 days of life showed abnormally high signal intensity on T1-weighted images in the basal ganglia, thalamus, and internal capsule. Similar but less intense signal was seen on T2-weighted images. Subsequently, there have been several reports of abnormalities seen in the globus pallidus on MRI in infants with bilirubin encephalopathy. A high-intensity signal in the posteromedial aspect of the globus pallidus on MRI is diagnostic of bilirubin injury.

Classic features of kernicterus are not often seen in neonatal follow-up clinics for premature and low-birth-weight infants, because even mild hyperbilirubinemia is usually aggressively treated in this population. However, a spectrum of mild neurologic disabilities and subtle developmental delays has been associated with moderate elevation of serum indirect bilirubin concentration. Because developmental delays related to other factors of prematurity, neonatal illness, or environmental situations are commonly associated with neonatal intensive care, there is controversy regarding the reversibility or long-term implications of the subtle neurologic damage attributed to bilirubin in low-birth-weight babies. Debates about the need for aggressive or conservative treatment for mild to moderate hyperbilirubinemia in infants persist.

Results from the Collaborative Perinatal Project (Hardy et al, 1979) showed that neurodevelopment during the first year of life was correlated with maximal STB concentration soon after birth. Results from a multicenter study from Netherlands reported that, although there was a dose-response relationship between maximum STB concentration and the risk of impaired development at 2 years of age, the effect did not persist at 5 years of age (van de Bor et al, 1989). A 17-year follow-up study revealed an association between severe hyperbilirubinemia and low intelligence quotient (IQ) in boys but not in girls (Seidman et al, 1991). This finding also was noted in a large study of 31,759 untreated infants with an STB of less than 20 mg/dL (342  $\mu$ mol/L).

### Pathophysiology of Bilirubin Toxicity

To understand neonatal bilirubin toxicity more completely, several factors need further exploration, including how bilirubin enters the brain, what it does to the neurons, whether neurotoxicity can be predicted in time to be prevented, and what effects are reversible (Table 79–5).

#### Entry of Bilirubin into the Brain

The mechanism by which unconjugated bilirubin enters the brain and damages it is unclear. Several hypotheses regarding entrance of bilirubin into the brain have been advanced and are not yet disproved.

One hypothesis involving free bilirubin (i.e., bilirubin that is not bound to albumin) has been widely accepted although never conclusively proved. Recognizing the lipophilic nature of free bilirubin, this hypothesis presumes that free bilirubin, in equilibrium with bound bilirubin, has access to tissues. Thus, any increase in the amount of free bilirubin or reduction in the amount or binding capacity of albumin could increase the level of unbound bilirubin

**TABLE 79-5**

#### Factors that Increase Susceptibility to Neurotoxicity Associated with Hyperbilirubinemia

Asphyxia	Caloric deprivation
Hyperthermia	Prolonged hyperbilirubinemia
Septicemia	Young gestational age
Hypoalbuminemia	Low birth weight
Acidosis	Excessive hemolysis

within the brain tissue, saturating membranes and causing precipitation of bilirubin acid within the nerve cell membrane. This hypothesis arose to explain an outbreak of kernicterus in premature infants given sulfisoxazole (Odell, 1959). The drug was shown to compete with bilirubin for albumin binding sites, thereby increasing plasma free bilirubin levels. Benzoate, a metabolite of benzyl alcohol (a preservative found in intravenous flush solutions), also has been found to compete with these binding sites and, in sufficient quantities, can produce toxic levels of free bilirubin (Ahlfors, 2000b). Consistent with this hypothesis is the knowledge that even during physiologic hyperbilirubinemia, some unbound bilirubin crosses the blood-brain barrier freely.

The clinical significance of this passage of free bilirubin into the brain during physiologic jaundice is unclear. Could this be the cause of transient changes in attention, alertness, and motor performance documented during moderate STB elevations? This theory raises concern about the duration of jaundice as well as the peak STB level attained and suggests that any situation that decreases the affinity or binding capacity of albumin, or increases movement of bilirubin into tissue (e.g., acidosis, hypoalbuminemia, action of competitively bound drugs), would thus exacerbate the entry of bilirubin into brain tissue.

A second hypothesis not only involves the binding of bilirubin to albumin but also focuses on the state of the bilirubin available to cross cell membranes. This hypothesis is based on close examination of the chemical nature of bilirubin in solution and seeks to explain the increased risk to acidotic infants. At alkaline pH, bilirubin forms a water-soluble sodium salt, but the solubility of this substance at neutral or lower pH is extremely low. Bilirubin is therefore found in plasma as a dianion bound to albumin after dissociation of two hydrogen ions. The amount of bilirubin acid (i.e., bilirubin that has not dissociated the hydrogen ions) may be excessive, however, and bilirubin acid tends to precipitate readily from serum only when a lipid membrane is present, suggesting that it is the supersaturated bilirubin acid that precipitates in the tissues of icteric infants (Brodersen and Stern, 1990). In this model, the degree of supersaturation is determined by the concentration of free bilirubin, relative to the solubility at the pH of plasma. However, it is accepted that some bilirubin can pass from albumin to tissues by direct contact of the bilirubin-albumin molecule with a cellular surface. In this theory, the rate of tissue uptake of bilirubin would depend on both the concentration of albumin-bound bilirubin and the pH, with low pH enhancing precipitation and tissue

uptake. Any increase in free albumin could reverse the process. This theory provides an explanation for the role that acidosis may play in the development of kernicterus (Gartner et al, 1970; Stern and Denton, 1965). The low albumin levels of premature infants coupled with the acidosis of respiratory distress place these infants at risk for kernicterus in the face of only moderate hyperbilirubinemia. Whether brain bilirubin oxidase can degrade bilirubin rapidly enough to prevent the deposition of bilirubin acid at the cellular level is controversial, and variations of this hypothesis have been suggested (Wennberg, 1988). It is still unclear whether bilirubin acid or bilirubin acid salt (monobasic bilirubin) is the form of bilirubin involved in the crossing of cell membranes or in tissue binding.

A third theory suggests that bound bilirubin enters the brain mainly through a damaged blood-brain barrier. The importance of a mature and intact blood-brain barrier stems from demonstration that the barrier to albumin and bilirubin can be reversibly opened under conditions of vascular injury, abnormal circulation, or abnormal osmolality (Bratlid, 1991). Hyperthermia and septicemia may have similar effects (Levine, 1983). Such loss of integrity of the blood-brain barrier could make entry of bilirubin into the brain possible at any STB concentration. According to this hypothesis, the local toxicity of bilirubin to the central nervous system would still require dissociation of the bilirubin from albumin at the cell membrane or in the cell, because free bilirubin is known to be more toxic than bound bilirubin in *in vitro* preparations. Even with a damaged blood-brain barrier, however, more bilirubin than albumin enters the brain, suggesting that several mechanisms of bilirubin entry may be operant simultaneously (see Table 79–5).

Recent studies suggest that unconjugated bilirubin is a substrate for P-glycoprotein (P-gp) (Jetté et al, 1995; Watchko et al, 1998) and that the blood-brain barrier P-gp may play a role in limiting the passage of bilirubin into the CNS. P-gp is an ATP-dependent integral plasma membrane transport protein that translocates a wide range of substrates across biologic membranes.

### **Bilirubin Toxicity at the Cellular Level**

Similar to the controversy regarding the entry of bilirubin into brain tissue is that concerning how bilirubin actually exerts its toxic effect at the cellular level. Four possible mechanisms have been proposed: interruption of normal neurotransmission, mitochondrial dysfunction, cellular and intracellular membrane impairment, and interference with enzyme activity (Palmer and Smith, 1990).

*Neurotransmission* has been theorized as an early target of bilirubin toxicity because reversible changes in brainstem auditory evoked responses (BAERs) have been recorded at moderate levels of hyperbilirubinemia. Bilirubin has been shown *in vitro* to inhibit phosphorylation of enzymes (e.g., synapsin I) that are critical in neurotransmitter release (Hansen et al, 1988; Morphis et al, 1982). In addition, changes in membrane potential in cells involved in synapse transmission are known to occur in the presence of varying levels of bilirubin. Bilirubin also has been reported to inhibit uptake of tyrosine, a marker for synaptic

transmission, as well as the function of *N*-methyl-D-aspartate receptor ion channels.

*Mitochondrial dysfunction* has long been believed to be important in the pathogenesis of irreversible bilirubin encephalopathy. Some researchers have hypothesized that bilirubin acid precipitates in phospholipid membranes, resulting in mitochondrial dysfunction. Others, however, postulate *cellular/intracellular membrane impairment*, suggesting that bilirubin forms reversible complexes with various cellular membranes. This pathomechanism would explain the reversal of some clinical signs of bilirubin toxicity in response to exchange transfusions and rapid reduction of STB levels. Further research is necessary to elucidate the molecular mechanisms more fully. Perhaps the impact of bilirubin on either neurotransmission or on mitochondrial function relates to the effect of bilirubin acid on the ability of ions (e.g., hydrogen, sodium, potassium) to cross the membranes. Bilirubin inhibits ion exchange and water transport in renal cells, which may explain the neuronal swelling that occurs in bilirubin encephalopathy associated with kernicterus. Hydrogen ion gradients across cellular and mitochondrial membranes may be important in controlling mitochondrial function and neurotransmitter release at the synapses. Any changes in the ability of the membranes to maintain hydrogen ion gradients may be critical in bilirubin toxicity, especially because the binding of bilirubin to cells or mitochondria is proportional to the hydrogen concentration in the local environment (Nelson et al, 1974; Odell, 1965; Wennberg, 1988). In addition, increased levels of lactate, decreased levels of cellular glucose and impaired cerebral glucose metabolism have been shown to be associated with hyperbilirubinemia in the neonatal rat.

A fourth hypothesis to explain intracellular bilirubin toxicity is *interference with enzyme activity*. This theory holds that bilirubin acid is capable of binding receptor sites on specific enzymes, rendering the enzymes inoperative or at least severely diminishing their activities.

The pathogenesis of kernicterus, especially the “low-bilirubin” variety, and the exact mechanism of bilirubin toxicity to the central nervous system are still not fully understood. Bilirubin encephalopathy is a multifactorial process that requires a critical level of free bilirubin, access to the brain across the blood-brain barrier, and presence of susceptible nerve cells. The severity and duration of hyperbilirubinemia, the maturity of the structures involved, the binding capability of albumin, the physiologic environment, and the cell membrane composition and metabolic state probably all are critical to the development of neurodysfunction. Decisions based simply on the total or unconjugated serum bilirubin levels seem simplistic; these other factors must be taken into consideration as well.

### **Predicting Encephalopathy and Reversibility of Damage**

From the aforementioned information, it is understandable that controversy remains regarding the toxicity of low and moderate levels of bilirubin in the premature and the full-term infant. Despite progress made in clinical management, there is no agreement on what constitutes a “safe”

level of bilirubin. New assessment tools have been sought to identify factors that could be used to predict impending encephalopathy or to identify subtle findings that could be reversed. Various new techniques are being used in this regard (Vohr, 1990).

### **Brainstem Evoked Auditory Response**

Because the auditory pathway of the neonate is particularly vulnerable to insult from bilirubin, BAER testing has been suggested as a tool that could identify or predict early effects of hyperbilirubinemia on the central nervous system. Studies have regularly correlated increased bilirubin concentrations with changes in amplitude and latency of these responses. BAER testing is accurate and noninvasive and assesses the functional status of the auditory nerve in the brainstem auditory pathway. A sound stimulus is introduced to the infant, and the waveforms that are generated as the electrical impulse passes through the auditory pathway are measured. Recorded parameters include the threshold sensitivity, latency (the conduction time interval from sound stimulus to the appearance of waveforms), the interpeak latency, the amplitude of the waves, and the slope of latency changes with time and magnitude of the stimulus. Wave I reflects peripheral conduction time, wave III reflects the superior olive, and waves IV and V represent the inferior colliculus. Interpeak latencies I to III and I to V are useful in assessing damage from bilirubin. When electrodes are left in place, serial examinations can be made to assess response to therapy or impending brain injury. In a study of 50 full-term infants with moderate hyperbilirubinemia (STB levels of 10 to 20 mg/dL [171 to 342  $\mu\text{mol/L}$ ]), the latency of BAER waves IV and V was longer than in those infants with lower STB levels (Shapiro and Nakamura, 2001). These abnormalities in most infants resolve as STB values become normal by 6 months of age. Some of the changes in BAER can also be reversed with an exchange transfusion. Changes in BAER also have been noted with elevated free bilirubin levels. An abnormal BAER and normal otoacoustic emission (OAE) suggest an auditory neuropathy. Auditory neuropathy has been observed in one third to one half of infants reported to have significant hyperbilirubinemia. Recent findings indicate that it is more likely to be reversible than are other types of auditory neuropathy. BAER testing could be used to screen hyperbilirubinemic full-term and premature infants for sensorineural hearing loss and could be incorporated into the assessment of need for exchange transfusions (Nwaesei et al, 1984; Wennberg et al, 1982).

### **Infant Cry Analysis**

Analysis of characteristics of infant crying, or “cry analysis,” has progressed so that alterations in cry characteristics have been documented in several perinatal risk situations including hyperbilirubinemia. Early work in this field involved spectrographic methods, but recent advances in high-speed computer technology have improved the ability to measure cry characteristics efficiently and accurately (Lester, 1987). It has been shown that with moderately elevated STB levels, there is interference with neural con-

duction, as demonstrated by the BAER, and changes in neural function in adjoining pathways, with resultant effects on the vocal cords (increased tension or phonation).

### **Nuclear Magnetic Resonance Techniques**

Nuclear magnetic resonance (NMR) techniques, both imaging and spectroscopy, have been proposed as a rapid, noninvasive measure of impending or actual brain cell injury in the face of hyperbilirubinemia (Palmer and Smith, 1990). NMR spectroscopy is a form of spectroscopy using magnetism and radio-frequency energy. It is a noninvasive method that could be used to characterize anatomic structural changes in variable metabolic states. Compared with ultrasonography or computed tomography (CT), MRI provides superior anatomic detail without exposing the neonate to ionizing radiation. NMR spectroscopy, especially using phosphorus<sup>31</sup>, with its ability to measure phosphorus metabolites, is being used to improve understanding of the interaction of hyperbilirubinemia and asphyxia. Phosphorus<sup>31</sup> NMR spectroscopy captures the phosphorus metabolites as levels decline, elevate, and shift in relation to each other to maintain cellular homeostasis in the face of oxygen depletion.

Brain biochemical activity and “energy failure” are detectable by these techniques, allowing for identification and study of the progression from initial to irreversible tissue damage. Using phosphorus<sup>31</sup> NMR spectroscopy, studies involving animal models have demonstrated that the cumulative effect of bilirubin and hypoxia is far more significant than either alone in disrupting brain energy metabolism (Ives et al, 1988). Similarly, hyperosmolar blood-brain barrier opening and hyperbilirubinemia have been shown to disturb cortical energy metabolism only when they coexist (Ives et al, 1989). NMR spectroscopic changes have also been reported in a jaundiced newborn rhesus monkey after displacement of bilirubin with a sulfa drug (Ahlfors et al, 1986).

NMR technology may enable the diagnosis of reversible brain injury in sufficient time to intervene and to determine what changes are irreversible for timely prognostication. Diffusion-weighted NMR imaging (DWI) applies a special gradient on the water signal to measure its diffusivity, which can be used as an early physiologic marker of neuronal injury. In other models of brain injury, such as neonatal hypoxic-ischemic encephalopathy or stroke, DWI shows significant changes quite early while still reversible and before the more permanent injury occurs that is normally shown by conventional NMR imaging (Fisher et al, 1995; Rhine et al, 1994). This capability could have important implications in bilirubin encephalopathy if DWI is shown to demonstrate ongoing, severe neuronal dysfunction in the affected regions of the brain (e.g., basal ganglia), which might prompt intervention such as exchange transfusion. In brain studied after exposure to extreme hyperbilirubinemia, conventional NMR images have been anatomically specific and symmetrical, the observed abnormalities having the distribution characteristic of kernicterus (Martich-Kriss et al, 1995; Penn et al, 1994). Further spectroscopic and imaging studies are needed to better characterize kernicterus and to help

determine which changes suggestive of neurotoxicity might be found in more moderate hyperbilirubinemia.

### Practical Considerations

The question of what constitutes a critical threshold of bilirubin for the neonate in terms of long-term or permanent morbidity remains unanswered. A safe level of STB and a safe duration of exposure have not been determined, nor have all the factors (e.g., acidosis, hypoxia) that influence the risk of long-term neurodevelopmental handicaps been fully explained. Until these issues are adequately understood, a cautious approach to clinical management must be pursued.

## MANAGEMENT OF NEONATAL HYPERBILIRUBINEMIA

Hyperbilirubinemia remains a common, important, and sometimes pathologic condition of the newborn. Because the risk of jaundice-associated neurotoxicity continues to be a major concern of physicians caring for newborns, management of neonatal hyperbilirubinemia is a subject of considerable discussion and debate. Issues affecting management decisions and current recommendations are discussed in this section.

The occurrence of bilirubin encephalopathy in newborns has been greatly reduced since the introduction of blood exchange transfusion in the 1950s for the treatment of hyperbilirubinemia associated with hemolytic disease of the newborn, and since Rh-negative mothers have routinely received the anti-Rh globulin as a measure to prevent isoimmunization. A single reliable criterion for instituting treatment of hyperbilirubinemia has not been possible, however, because low STB levels can be associated with bilirubin encephalopathy in small premature infants, and hypoxia, acidosis, and sepsis also may be associated with higher risk. The neurotoxicity of bilirubin is not an all-or-none phenomenon but instead ranges from subtle reversible changes in neural function to permanent structural and functional impairment related to discrete cell death and regional yellow staining of brain tissue. Besides the classic signs of kernicterus, neurologic sequelae (e.g., disturbances of visual-motor function, impaired nonverbal intelligence) have been described in surviving premature infants who had hyperbilirubinemia in the neonatal period. However, whether such nonspecific findings may have been related to either the degree or the duration of hyperbilirubinemia or to some other factors is uncertain and will not be ascertained by further analysis of current data. Thus, predictors of bilirubin encephalopathy, besides STB concentration, have been sought, and guidelines for intervention have been fraught with lively controversy. Criteria based entirely on clinical experience and measurement of STB have weaknesses and may result in overtreatment of term infants. In contrast, more liberal criteria may lead to undertreatment of some infants, inadvertently contributing to permanent damage in susceptible infants. Understanding susceptibility is key to solving this clinical problem. Some researchers have argued for a case-based approach using not only the determination of total unconjugated serum bilirubin

concentrations to develop criteria for treatment plans but also measures of albumin binding capacity, determination of the integrity and maturity of the blood-brain barrier, and an assessment of the conjugating power of the liver. Because the basic mechanisms behind the development of bilirubin toxicity are not completely understood, however, such new treatment criteria have not been systematically or successfully implemented (Bratliid, 1995).

### The Term Infant

Because health term neonates are as a group at less risk for bilirubin encephalopathy than premature or sick infants, most authors discussing clinical management of neonatal hyperbilirubinemia frame their discussion in the context of only one of these groups. As medical practice faces increasing economic constraints, decisions regarding the management of hyperbilirubinemia include not only which tests to complete and which clues to follow but also the balance of risks of undertreatment with the cost and consequences of overtreatment.

With regard to management of the jaundiced term neonate who is deemed to be “healthy,” controversy has characterized the discussions for several decades. In 1959, Mores and associates evaluated 54 full-term infants without evidence of isoimmunization who had STB levels greater than 20 mg/dL (342  $\mu$ mol/L) and who received no exchange transfusion. Citing normal development in all 54 subjects after 2 years of follow-up, these investigators concluded that “it is useless to perform an exchange transfusion on full-term infants with intensive jaundice without isoimmunization because these infants are neither in danger, nor ill; they are only icteric” (Mores et al, 1959). Since that time, much has been learned about the processes of bilirubin metabolism but not much more about the mechanisms of neurotoxicity. Although many studies confirm the low risk to term infants who do not have excessive hemolysis or rigid elements in STB levels, any statement suggesting total absence of risk is viewed as overly simplistic and dangerous.

In response to these controversies, the American Academy of Pediatrics (AAP) published guidelines for the management of the jaundiced neonate (AAP, 1994). Intended to apply only to the healthy full-term neonate, these guidelines describe a range of acceptable practices, recognizing that more precise recommendations cannot be formulated from current scientific literature, and acknowledging that: (1) “factors influencing bilirubin toxicity to the brain cells of newborn infants are complex and incompletely understood”; (2) “It is not known at what bilirubin concentration or under what circumstances significant risk of brain damage occurs or when the risk of brain damage exceeds the risk of treatment”; and (3) “Concentrations considered harmful may vary in different ethnic groups, or geographic locations. . . . Reasons for apparent geographic differences in risk for kernicterus are not clear.” In addition, these recommendations were presented at a time when the management decisions were increasingly problematic because of mounting pressures for early discharge from the hospital and a greater prevalence of breast-feeding in the American population.

## Evaluation and Diagnostic Procedures

The AAP “practice parameter” lists factors to be considered in assessing a jaundiced infant (Table 79–6). Regarding the evaluation of the jaundiced newborn, the AAP recommendations reinforce the fact that because the determination of specific risk factors and the identification of illnesses early are crucial in the management of these patients, a careful history and physical examination remain the most important diagnostic procedures.

Of particular significance is a family history of severe unexplained jaundice requiring exchange transfusion, suggesting the possibility of G6PD deficiency or some other cause of hemolytic disease. When the family history, ethnic or geographic origin, or timing of jaundice suggests such a diagnosis, appropriate laboratory assessment in the infant should be performed (Table 79–7).

Maternal prenatal testing should routinely include ABO and Rh typing and a serum screen for unusual isoimmune antibodies. When the mother has not had prenatal determination of blood group or is Rh- negative, a direct Coombs’ test and Rh typing of the infant’s cord blood are recommended to anticipate and closely monitor an infant at risk of severe hemolysis and to determine the need for the mother to receive Rho(D) antibody (anti-Rh globulin).

STB determinations are indicated in all infants who appear jaundiced in the first 24 hours of life, because such an early appearance of jaundice is almost always associated with hemolytic disease or illness. In other infants,

STB levels are indicated if estimates from sequential observations show that the jaundice is moderate or worse (estimate of STB in excess of 12 mg/dL [200  $\mu$ mol/L]).

## Prediction of the Risk of Hyperbilirubinemia

Visual assessment of STB levels as suggested by Kramer (1969), which relies on the cephalocaudal progression of jaundice with a rising STB level (head and neck, 4 to 8 mg/dL [68 to 292  $\mu$ mol/L]; upper trunk, 5 to 12 mg/dL [86 to 205  $\mu$ mol/L]; lower trunk and thighs, 8 to 16 mg/dL [137 to 274  $\mu$ mol/L]; palms and soles, greater than 15 mg/dL [257  $\mu$ mol/L]), is now known to be fraught with error. There is also considerable interlaboratory variation among STB levels measured at different laboratories (Vreman et al, 1996b). Bhutani and colleagues (1999), in a study of 1997 infants, found the practice of reporting the STB level on the basis of age in days rather than hours to be misleading and ineffective at accurately predicting which infants are at high risk for severe hyperbilirubinemia. Because jaundice is a common occurrence in newborn infants and severe hyperbilirubinemia is a relatively rare event, there has been considerable interest in developing a selective approach to follow-up evaluation and surveillance of these infants. The approaches that are currently suggested include universal bilirubin screening of all infants prior to discharge by either STB level determination or a transcutaneous bilirubin measurement (TcB) and ETCOc to assess rate of bilirubin production and to diagnose hemolysis.

Bhutani and colleagues (1999) generated a percentile-based bilirubin nomogram using hour-specific pre-discharge STB levels from a racially diverse group of term healthy newborns with no Rh or ABO incompatibility (42% white, 42.4% African American, 8% Hispanic, 4.3% Asian, other 2.8%, and 4.7% undisclosed) who did not need phototherapy before 60 hours of age and of whom 60% were breast-fed (Fig. 79–1). Postdischarge STB levels were measured by a hospital-based bilirubin assay within 3 days after discharge. The risk for significant hyperbilirubinemia (STB greater than 17 mg/dL [291  $\mu$ mol/L]) for infants with a pre-discharge STB above the 95th percentile (high-risk zone) was 57%, for infants with STB between the 75th and 95th percentiles (high-intermediate risk) it was 13%, for infants with STB between the 40th and 75th percentiles (low-intermediate risk) it was 2.1%, and for infants with STB below the 40th percentile (low risk) it was 0. The applicability of the nomogram was not significantly altered by including near-term infants or those who had hemolysis secondary to blood group incompatibility except for jaundice at less than 24 hours of age. Measurement of a pre-discharge bilirubin at the time of newborn screening (beyond 24 hours) along with an assessment of individual risk factors for jaundice such as gestational age, race, method of feeding, presence of polycythemia, blood group incompatibility or bruising, can help in the timing of follow-up examination of a select group of infants. Limitations of this approach are the need for blood sampling (although this can be done with the newborn screen) and the cost of STB measurement.

TcB is based on the measurement of light reflected from the skin. Older devices reported a jaundice index that, despite correlation with serum bilirubin levels, was

**TABLE 79–6**

### Factors to Be Considered in Assessment of the Jaundiced Infant

Factors that suggest the possibility of hemolytic disease
Family history of significant hemolytic disease
Onset of jaundice before age 24 hours
An increase in STB levels of more than 0.5 mg/dL/hour
Pallor, hepatosplenomegaly
Rapid increase in the STB level after 24 to 48 hours (consider G6PD deficiency)
Ethnicity suggestive of inherited disease (e.g., G6P deficiency)
Failure of phototherapy to lower the STB level
Clinical signs suggesting other diseases (e.g., sepsis, galactosemia) in which jaundice may be one manifestation
Vomiting
Lethargy
Poor feeding
Hepatosplenomegaly
Excessive weight loss
Apnea
Temperature instability
Tachypnea
Signs of cholestatic jaundice suggesting the need to rule out biliary atresia or other causes of cholestasis
Dark urine or urine positive for bilirubin
Light-colored stools
Persistent jaundice for more than 3 weeks

\*G6PD, glucose-6-phosphate dehydrogenase; STB, serum total bilirubin.

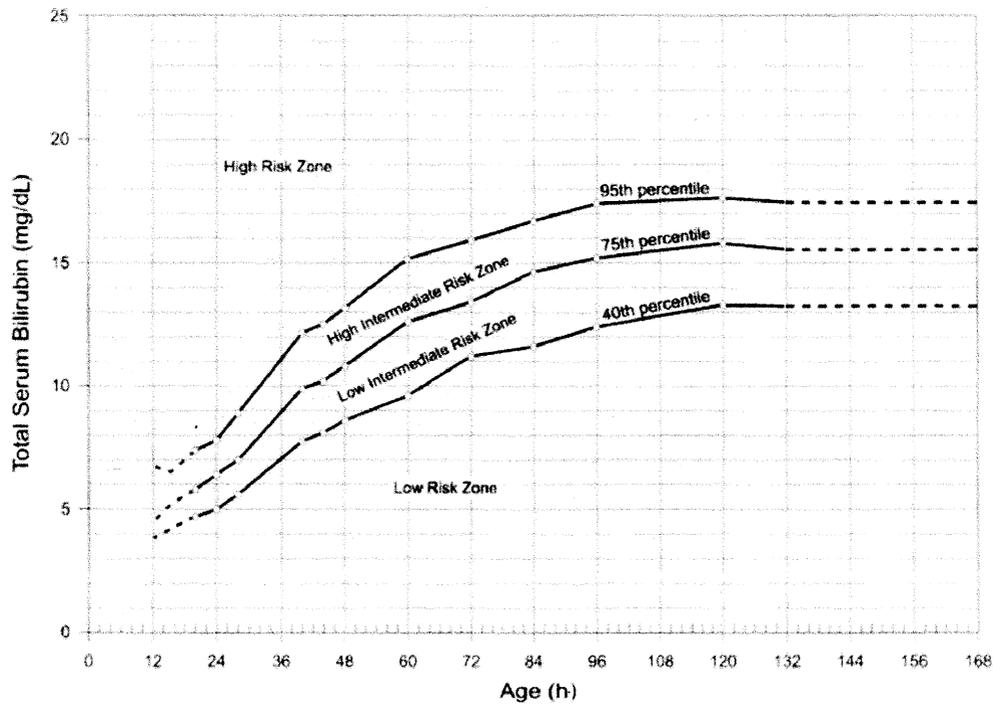

Data from the American Academy of Pediatrics: Practice parameter: Management of hyperbilirubinemia in the healthy term newborn. Pediatrics 94:559, 1994.

TABLE 79-7

## Data Collection in the Diagnosis of Neonatal Jaundice

Information	Significance
<b>Family History</b>	
Parent or sibling with history of jaundice or anemia	Suggests hereditary hemolytic anemia such as hereditary spherocytosis
Previous sibling with neonatal jaundice	Suggests hemolytic disease due to ABO or Rh isoimmunization
History of liver disease in siblings or disorders such as cystic fibrosis, galactosemia, tyrosinemia, hypermethioninemia, Crigler-Najjar syndrome, or $\alpha_1$ -antitrypsin deficiency	All associated with neonatal hyperbilirubinemia
<b>Maternal History</b>	
Unexplained illness during pregnancy	Consider congenital infections such as rubella, cytomegalovirus, toxoplasmosis, herpes, syphilis, hepatitis A or B, Epstein-Barr virus
Diabetes mellitus	Increased incidence of jaundice among infants of diabetic mothers
Drug ingestion during pregnancy	Ingestion of sulfonamides, nitrofurantoin, antimalarials may initiate hemolysis in G6PD-deficient infant
<b>History of Labor and Delivery</b>	
Vacuum extraction	Increased incidence of cephalhematoma and jaundice
Oxytocin-induced labor	Increased incidence of hyperbilirubinemia
Delayed cord clamping	Increased incidence of hyperbilirubinemia among polycythemic infants
Apgar score	Increased incidence of jaundice in asphyxiated infants
<b>Infant History</b>	
Delayed passage of meconium or infrequent stools	Increased enterohepatic circulation of bilirubin; consider intestinal atresia, annular pancreas, Hirschsprung disease, meconium plug, drug-induced ileus (hexamethonium)
Caloric intake	Inadequate caloric intake results in delay in bilirubin conjugation
Vomiting	Suspect sepsis, galactosemia, or pyloric stenosis; all associated with hyperbilirubinemia
<b>Infant Physical Examination</b>	
Small for gestational age	Infants frequently polycythemic and jaundiced
Head size	Microcephaly seen with intrauterine infections associated with jaundice
Cephalhematoma	Entrapped hemorrhage associated with hyperbilirubinemia
Plethora	Polycythemia
Pallor	Suspect hemolytic anemia
Petechiae	Suspect congenital infection, overwhelming sepsis, or severe hemolytic disease as cause of jaundice
Appearance of umbilical stump	Omphalitis and sepsis may produce jaundice
Hepatosplenomegaly	Suspect hemolytic anemia or congenital infection
Optic fundus abnormalities	Chorioretinitis suggests congenital infection as cause of jaundice
Umbilical hernia	Consider hypothyroidism
Congenital anomalies	Jaundice occurs with increased frequency among infants with trisomic conditions
<b>Laboratory Data</b>	
<i>Maternal</i>	
Blood group and indirect Coombs' test	Necessary for evaluation of possible ABO or Rh incompatibility
Serologic studies	Rule out congenital syphilis
<i>Infant</i>	
Hemoglobin determination	Anemia suggests hemolytic disease or large entrapped hemorrhage; hemoglobin above 22 g/dL associated with increased incidence of jaundice
Reticulocyte count	Elevation suggests hemolytic disease
Red blood cell morphology	Spherocytes suggest ABO incompatibility or hereditary spherocytosis; red blood cell fragmentation seen in disseminated intravascular coagulation
Platelet count	Thrombocytopenia suggests infection
White blood cell count	Total white blood cell count less than 5000/mm <sup>3</sup> or band-to-neutrophil ratio >0.2 suggests infection
Sedimentation rate determination	Values in excess of 5 during the first 48 hours indicate infection or ABO incompatibility
Direct bilirubin assay	Elevation suggests infection or severe Rh incompatibility
Immunoglobulin M assay	Elevation indicates infection
Blood group studies and direct and indirect Coombs' test	Required to rule out hemolytic disease as a result of isoimmunization
Carboxyhemoglobin level determination	Elevated in infants with hemolytic disease or entrapped hemorrhage
Urinalysis	Presence of reducing substance suggests diagnosis of galactosemia

G6PD, glucose-6-phosphate dehydrogenase.

**FIGURE 79-1.** Nomogram displaying risk designation of term and near-term well infants based on hour-specific serum total bilirubin values. The high-risk zone is designated by the 95th percentile track. The intermediate risk zone is subdivided into upper and lower risk zones by the 75th percentile track. The low risk zone is below the 40th percentile. (From Bhutani VK, Johnson L, Sivieri EM: Predictive ability of a pre-discharge hour-specific serum bilirubin for subsequent significant hyperbilirubinemia in healthy and near-term newborns. *Pediatrics* 103:6-14, 1999. Reproduced by permission of Pediatrics, Copyright 1999.)

affected by skin thickness and skin color. One device also required a baseline skin color measurement, thus limiting its usefulness for widespread use. A newer point-of-care device (BiliCheck, SpectRx Inc., Norcross, Georgia) that measures the entire spectrum of visible light reflected from the skin (380 to 760 nm) has been shown to provide an accurate assessment of STB in term and near-term newborn infants of diverse races and ethnicities. It is important to note that transcutaneous devices measure not serum bilirubin but the amount of bilirubin that has moved into the tissue. The efficacy of this device in preterm infants, infants undergoing phototherapy, and those with STB levels less than 15 mg/dL (257  $\mu$ mol/L) needs to be tested. Use of TcB for screening may decrease the need for phlebotomy and possibly reduce costs. An alternative approach is measurement of STB in all jaundiced infants and follow-up evaluation within 2 days of all infants discharged prior to 48 hours.

### Measurement of ETCO<sub>c</sub>

Because the breakdown of heme by the rate-limiting enzyme HO leads to the formation of equimolar amounts of CO and biliverdin, with biliverdin immediately reduced to bilirubin, the measurement of CO in the exhaled breath of the newborn can be used as an index of heme degradation and bilirubin production in vivo. The ETCO<sub>c</sub> is an index of the rate of bilirubin production and can aid the practitioner

in diagnosing hemolysis. A large multicenter trial conducted at nine centers with the objective of determining whether a measurement of ETCO<sub>c</sub> at  $30 \pm 6$  hours of age, alone or in combination with an STB measurement obtained at the same time, could predict the development of severe hyperbilirubinemia showed that addition of the ETCO<sub>c</sub> measurement did not improve the predictive ability of the hours of age-specific STB (Stevenson et al, 2001). However, use of the ETCO<sub>c</sub> along with the STB level has several benefits. It can help distinguish between cases of increased bilirubin production versus decreased elimination or impaired bilirubin conjugation. In a retrospective study of results of 2443 direct Coombs' tests, 8% were found positive, suggesting Gilbert syndrome or a condition affecting conjugation. Only 17% of infants with a positive Coombs' test subsequently developed hyperbilirubinemia that needed treatment with phototherapy (unpublished observation). Therefore, routine measurement of the Coombs' test is not necessary in infants delivered to O-positive mothers. The Coombs' test is not a good predictor of the risk of hemolysis. In addition, use of the peripheral blood smear and reticulocyte counts has not been useful in diagnosing hemolysis.

Assessment of risk factors for jaundice helps in identification of infants who are most at risk for development of hyperbilirubinemia. It is recommended that depending on the incidence of hyperbilirubinemia and the demographics of the population, each institution develop its own criteria for decision making and timing for follow-up evaluation of infants.

With increasing pressure to discharge babies from the hospital at 24 hours of age or younger, most jaundiced infants will not be diagnosed by nursery personnel. Therefore, 2 to 3 days after discharge (corresponding with the time of the normal transitional peak of hyperbilirubinemia), follow-up evaluation should be provided by a health care professional in an office or clinic or at home for all newborns discharged at less than 48 hours after birth. Because bacterial sepsis is a significant risk factor for bilirubin encephalopathy and may be associated with elevated bilirubin levels caused by hemolysis or inadequate nutrition or hydration, further evaluation of newborns in whom abnormal signs such as feeding difficulty, lethargy, apnea, or temperature instability develop must be initiated to rule out underlying illness or sepsis (see Table 79–6).

Because approximately one third of healthy breast-fed infants have jaundice that persists beyond 2 weeks of age (Linn et al, 1985), breast-feeding need not be routinely interrupted solely for the purpose of establishing a diagnosis of breast milk or breast-feeding jaundice (Gartner, 1994).

Any report of dark urine, light stools, or persistence of jaundice beyond 2 weeks should prompt a measurement of direct (conjugated) serum bilirubin levels. Otherwise, determination of direct bilirubin levels is most often not useful in the healthy neonate. Other data that are useful in evaluating an infant with neonatal jaundice are listed in Table 79–7.

### Susceptibility to Bilirubin Neurotoxicity

An appreciation of the factors that may be associated with increased risk for brain injury associated with increased hyperbilirubinemia is central to determining which patients should be treated and which intervention should be undertaken. Some patients demonstrate a steady and excessive increase in STB levels over the first several days of extrauterine life, enabling clinicians to predict STB levels by extrapolation. Other infants exhibit a more sudden change in STB concentration, making prediction of the course of hyperbilirubinemia impossible (e.g., in G6PD-deficient or septic infants).

Specific clinical situations such as sepsis, isoimmunization, and other causes of hemolysis are known to be associated with elevated risks for neurotoxicity, even at STB levels otherwise considered moderate or mild. The reason for this increased risk is not known with certainty, but increased bilirubin production is a finding common to these situations.

Some experts think that bilirubin production rates may be the critical piece of information distinguishing jaundiced infants at excessive risk of encephalopathy from those who, although equally jaundiced in appearance and having similarly elevated STB concentrations, are at less risk. The saturation of the albumin binding sites and elevated levels of unbound bilirubin may be critical to the neurotoxic effects of bilirubin. In addition to the capacity of albumin to bind bilirubin in the circulation, the total tissue load of bilirubin may be important to consider.

When STB concentrations are lower than the level that saturates the bilirubin-binding sites of albumin, the measured “STB” represents all the unconjugated bilirubin in circulation, whether bound to albumin or not. However,

this STB concentration does not reflect the tissue load or total body load of bilirubin. This is a critical difference, because a high bilirubin production rate is thought to result in a more rapid transfer of bilirubin to tissue, causing patients with high rates of production to have substantially higher tissue loads than in patients with low production rates. If the capacity to keep bilirubin in circulation is exceeded more rapidly, a surrogate for this circumstance is the rate of increase of bilirubin in circulation or the postnatal age at which a particular level is reached; for example, a STB concentration of 20 mg/dL (342  $\mu\text{mol/L}$ ) at 48 hours of age represents a different risk from that of 20 mg/dL (342  $\mu\text{mol/L}$ ) at 7 days of age. When the STB concentration increases enough to “saturate” the albumin binding sites and the body load is particularly heavy, the tissue load is already high, and any further increase in serum bilirubin represents bilirubin with great potential to enter the brain, which may have been spared until that time. If the tissue load is small, however, further deposition of bilirubin in the body may be possible, relieving the brain of immediate risk. It has been hypothesized that this high tissue load in patients with increased bilirubin production may explain why these patients are vulnerable to brain damage at the same STB levels that do not seem to endanger babies with low rates of bilirubin production. This concept of a total body load or tissue load also may explain why infants with increased bilirubin production (e.g., hemolysis) have a more profound rebound in STB levels after treatment with either exchange transfusion or phototherapy. If this hypothesis is sustained, identifying patients with increased bilirubin production will be extremely useful in determining the level of risk for neurotoxicity and scheduling interventions.

### Treatment Guidelines

The AAP guidelines for treatment of and intervention for hyperbilirubinemia in the healthy term newborn are summarized in Table 79–8 and in Figure 79–2. The guidelines are recommended for infants initially seen with elevated STB levels as well as for infants requiring follow-up evaluation for clinical jaundice. Because direct bilirubin measurements vary substantially as a function of differences of individual laboratories and their instrumentation, the direct bilirubin measurement should not be subtracted from the STB level in determining management strategy (Vreman et al, 1996b). Infants less than 24 hours of age who are jaundiced are generally considered to have a “pathologic” process and require further evaluation. Uncertainty remains about what specific STB levels warrant exchange transfusion, and intensive phototherapy is recommended while preparations are being made for exchange transfusion. Implementation of phototherapy is especially relevant for infants who have an STB concentration in the exchange transfusion range when initially seen (see Table 79–8). Intensive phototherapy is expected to cause a decline in STB level of 1 to 2 mg/dL (17 to 34  $\mu\text{mol/L}$ ) within 4 to 6 hours (AAP, 1994); if no decline occurs, the presence of hemolytic disease or some other pathologic process is suggested and warrants further investigation, and most experts recommend exchange

TABLE 79-8

Age (h)	Serum Total Bilirubin Level (mg/dL [ $\mu\text{mol/L}$ ])			
	Consider Phototherapy <sup>a</sup>	Phototherapy	Exchange Transfusion if Intensive Phototherapy Fails <sup>b</sup>	Exchange Transfusion and Intensive Phototherapy
25-48 <sup>§</sup>	$\geq 12$ [170]	$\geq 15$ [260]	$\geq 20$ [340]	$\geq 25$ [430]
49-72	$\geq 15$ [260]	$\geq 18$ [310]	$\geq 25$ [430]	$\geq 30$ [510]
>72	$\geq 17$ [290]	$\geq 20$ [340]	$\geq 25$ [430]	$\geq 30$ [510]

<sup>a</sup>Phototherapy at these serum total bilirubin (STB) levels is a clinical option, meaning that the intervention is available and may be used on the basis of individual clinical judgment.

<sup>b</sup>Intensive phototherapy should produce a decline in STB of 1-2 mg/dL within 4-6 hours, and the STB level should continue to decline and remain below the threshold level for exchange transfusion. If this does not occur, phototherapy has failed. Intensive phototherapy includes the use of more than one bank of lamps containing "special blue" bulbs, maximizing the surface area illuminated by using a phototherapy blanket or other means, and providing phototherapy on a continuous, uninterrupted schedule.

<sup>§</sup>Term infants who are clinically jaundiced at <24 hours old are not considered healthy and require further evaluation.

transfusion. Practices vary between ordering sequential individualized laboratory tests and "batching" them in a "hyperbilirubinemia workup." For example, once an STB level is obtained and is seen to be elevated, some clinicians obtain a direct Coombs' test and blood group type and await the results before proceeding to further tests. Others, to minimize patient inconvenience and to gather more complete information initially, study hemoglobin, reticulocyte count, blood group, direct Coombs' test, and blood cell count and differential and inspect a blood film all at once. Consideration of practical and economic issues plays a role in such decisions, and practice variations are expected.

The controversies remaining in the AAP recommendation center on two areas. First, the guidelines are said to apply to infants without signs of illness or apparent hemolytic disease. The bilirubin levels cited by the committee's policy for initiating phototherapy are high enough that increased bilirubin production could well be a contributing cause, and it becomes the responsibility of the physician to determine whether such a contributing cause is likely. Assuming the absence of hemolysis when the Coombs test' result is negative does not suffice, because this test identifies isoimmunization primarily. Obtaining a

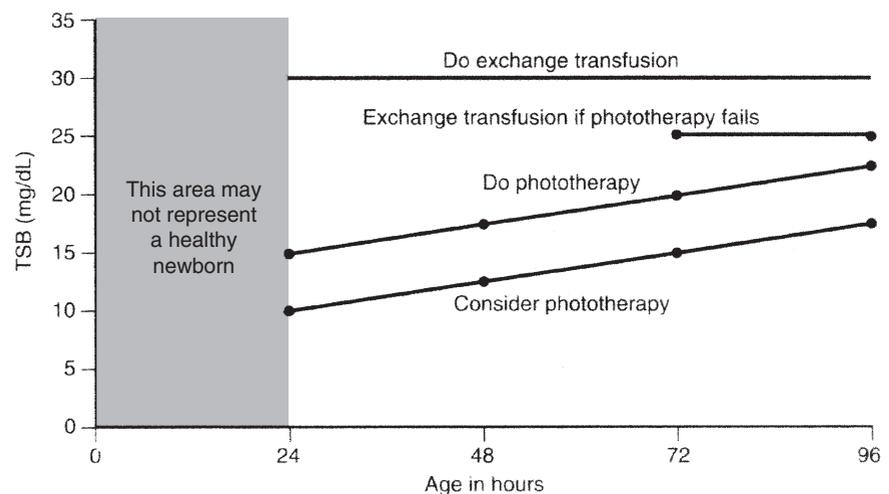

direct estimate of bilirubin production by measuring the COHb<sub>c</sub> level or ETCO<sub>c</sub> can be a very useful way to exclude hemolysis. Although the feasibility of both of these techniques has been demonstrated, they have not been available to most physicians until recently.

The second area of controversy involves the levels of STB cited for initiating phototherapy or considering exchange transfusion. Some experts think that the AAP recommendation is overly simplistic because the guidelines do not consider the duration of moderate to severe hyperbilirubinemia and because they belittle the risk of hyperbilirubinemia when the STB level ranges from 25 to 30 mg/dL (425 to 510  $\mu\text{mol/L}$ ), especially without knowing the albumin binding capacity or its affinity for bilirubin.

### Management of the Preterm Infant

The increased intensity and duration of hyperbilirubinemia in the preterm infant as well as the assumed immaturity of the blood-brain barrier have led to concern about greater risks of bilirubin encephalopathy in this patient population. Is the "healthy" preterm infant at greater risk

**FIGURE 79-2.** Guidelines for treatment and intervention of hyperbilirubinemia in the healthy term newborn. (From Gartner LM: Neonatal jaundice. *Pediatr Rev* 15:429, 1994. Reproduced by permission of Pediatrics in Review, Copyright 1994.)

of bilirubin encephalopathy at STB concentrations less than 20 mg/dL (340  $\mu$ mol/L)? Or is the premature infant at greater risk because of the greater frequency of pathologic conditions such as sepsis, acidosis, hypoxia, shock, and intracranial hemorrhage in such patients? Many clinicians use gestational age, birth weight, and health status adjustments to determine the need for phototherapy and exchange transfusion, although controlled trials supporting these policies have not been carried out. The guidelines in Table 79–9 suggest one approach to the implementation of exchange transfusion in premature babies.

Because neurotoxicity has been related to the STB level, this measure has traditionally been the parameter most often used in assessing the severity of hyperbilirubinemia and in decisions regarding management. During the years in which practice guidelines suggested instituting phototherapy to keep the STB level less than 20 mg/dL (340  $\mu$ mol/L) in term infants, severe bilirubin encephalopathy rarely occurred. In infants weighing less than 1500 g, efforts were usually made to keep the STB concentration less than 12 mg/dL (200  $\mu$ mol/L) and less than 14 mg/dL (240  $\mu$ mol/L) in infants weighing 1500 to 2500 g, with similar good results. There is concern, however, that more subtle neurodevelopmental abnormalities may occur at these levels and that prolonged elevations at lower levels also may be damaging, suggesting that the current guidelines for premature or low-birth-weight infants may still not be adequate to eliminate risk.

### Other Management Considerations: Identifying Treatment Criteria

The importance of excess bilirubin production as a risk factor for encephalopathy must be stressed. Excess bilirubin production includes hemolysis resulting from isoimmune reactions, hemolysis from other causes (e.g., G6PD deficiency, erythrocyte membrane disorders), and non-hemolytic processes leading to excess bilirubin production.

A Coombs' test is not sufficient to identify all causes of excess bilirubin production and is not a good measure of the degree or intensity of hemolysis.

Researchers continue to work toward identifying parameters to help clinicians evaluate hyperbilirubinemia so that intervention can be instituted appropriately, and in a timely manner. In addition to the factors listed in Table 79–6, the STB concentration has been the critical parameter in developing management guidelines. Other measures are listed in Table 79–10, and some of these hold promise for becoming useful tools in the decision-making process. However, they have not yet been included in standard practice parameters (see Table 79–7).

### Free Plasma Bilirubin

Free plasma bilirubin is the fraction of bilirubin not bound to albumin. This has been considered the critical portion of unconjugated bilirubin because of its ability to cross the blood-brain barrier easily. Although there is a constant dynamic state between bound and unbound bilirubin at the albumin binding sites, free bilirubin levels are known to increase when plasma albumin levels are diminished or when bilirubin is displaced from the albumin by drugs and chemicals that competitively attach to the albumin binding sites. Encephalopathy is virtually nonexistent if the unbound bilirubin levels are maintained at less than 0.8  $\mu$ g/dL in infants weighing less than 1500 g and at less than 0.1  $\mu$ g/dL (1.7  $\mu$ mol/L) in infants weighing 1500 to 2500 g (Bratlid, 1995; Nakamura et al, 1992). Studies using BAER have demonstrated significantly more abnormalities in newborns with unbound bilirubin concentrations of 1.0  $\mu$ g/dL (17  $\mu$ mol/L) or greater, suggesting that measuring unbound bilirubin concentrations may be helpful for evaluating bilirubin effects and may predict the risk of bilirubin encephalopathy in full-term newborns with hyperbilirubinemia. Until recently, there has been no simple accurate method of determining free

bilirubin levels, but unbound bilirubin concentrations can now be measured by the peroxidase method using a commercially available device (Nakamura et al, 1992). A recent modification of this method overcomes the limitations, such as inaccuracy due to the presence of bilirubin-binding competitors (e.g., benzoate), rate-limiting dissociation of bilirubin from albumin, or high levels of antioxidants, conjugated bilirubin, or free radical-producing drugs (Ahlfors, 2000a, 2000b).

**Reserve Albumin Binding Capacity**

Some authors have suggested the use of the reserve albumin binding capacity to determine how much of a range of safety is available before albumin binding sites become saturated. The conceptual basis for this proposal is the knowledge that unbound bilirubin accumulates in the brain only after the albumin binding sites have been saturated, and the theory that the oversaturation by bilirubin allows unbound bilirubin to gain access to the brain. However, the dynamic process involved in attachment of bilirubin to albumin suggests that this parameter might be an unreliable measure of the amount of unbound bilirubin. Even when the binding sites are not fully occupied with bilirubin, there is some unbound bilirubin that can diffuse across the blood-brain barrier. Using the availability of binding sites, as a proxy for unbound bilirubin levels could therefore be unreliable, underestimating risks of neurotoxicity. Among the tests currently suggested for estimating albumin binding capacity are bilirubin titration tests, dye binding tests, and selective binding of tracer ligands. Some of these tests are semiquantitative, and most are impractical in the neonatal clinical setting (Bratlid, 1995).

**Bilirubin Production Rates**

Unconjugated bilirubin production has traditionally been estimated from the rate of increase in STB concentration during the first 24 to 48 hours after birth. However, the rate of increase in STB reflects not only bilirubin production but also distribution and elimination.

Techniques have recently been developed that result in clinically useful measurements of ETCO<sub>c</sub> or percutaneous measurement of COHb<sub>c</sub>. These measures correlate well with bilirubin production rates. Monitoring bilirubin production rates as well as STB concentration has been suggested as a guide to initiation of treatment and management for severe neonatal jaundice. Continuous monitoring of these parameters would be ideal, especially in situations of rapid increase in STB concentration, and instruments capable of such measures are becoming available for clinical application using portable electrochemical sensors (Stevenson et al, 1994; Vreman et al, 1994, 1996a).

**Modes of Intervention to Reduce Serum Bilirubin Concentration**

Once the clinician has determined that a neonate's STB concentration is elevated enough to present a risk of encephalopathy or is increasing in a way that predicts significant risk, intervention to reduce the STB concentration becomes imperative. Therapeutic intervention decisions must be tempered by clinical judgment based on the history, course, and physical findings. The currently accepted modes of intervention and others that are still in various stages of investigation are listed in Table 79-11.

**Hydration**

There is no evidence that excess fluid administration affects the STB concentration. Some infants however, especially those being breast-fed, may be mildly dehydrated and may need supplemental fluid intake to correct their dehydration. Reduction in STB concentration, which appears to be a response to rehydration, especially with increased oral nutrition, may be related to the correction of dehydration, to more effective intestinal motility (with the increased oral intake leading to elimination of conjugated bilirubin via stool), or to enhanced removal of photoproducts in both urine and stool. Because milk-based formula is less likely to enhance reabsorption of bilirubin by the enterohepatic circulation, it often is recommended for use for oral correction of mild dehydration in hyperbilirubinemic children.

**Phototherapy**

Although Native Americans had long been aware of the beneficial effects of the sun in reducing the yellow color

Inhibition of bilirubin production

of babies exposed to its light, phototherapy for neonatal hyperbilirubinemia was first proposed in 1958 by Cremer and colleagues in England (Cremer et al, 1958). Subsequently, this therapy has been used for the reduction of elevated STB levels and for the “prophylactic” prevention of hyperbilirubinemia in premature infants. With the development of Rh-immune globulins to prevent maternal isoimmunization and the introduction of phototherapy, the need for exchange transfusions in healthy term infants was reduced significantly. Phototherapy has remained the mainstay of treatment for hyperbilirubinemia.

Phototherapy has become the most common treatment used for neonatal hyperbilirubinemia (Costarino et al, 1985). Still, there is no standardized method for delivering phototherapy. The phototherapy units vary widely, the types of lamps used differ, the amount of skin exposed to phototherapy often depends on other clinical issues, and the intensity of the light varies according to the lamp power and the distance from the skin. Usually the dose of phototherapy is based on what is convenient to administer, rather than what is most effective.

The efficacy of phototherapy is influenced by the following factors: (1) the spectrum of light delivered, the blue-green region of the visible spectrum being the most effective; (2) the energy output or irradiance of the phototherapy light, measured in  $\mu\text{W}/\text{cm}^2/\text{nm}$ ; and (3) the surface area of the infant exposed to phototherapy (Landry et al, 1985).

The amount of light to which an infant is exposed during phototherapy is minute compared with exposure later in life, even during the first year of life. With the light sources currently used, it is impossible to overdose the patient with phototherapy. Conventional phototherapy involves exposing a maximal area of skin to an irradiance of 6 to 12  $\mu\text{W}/\text{cm}^2/\text{nm}$  (Dennery et al, 2001; Garg et al, 1995).

High-intensity phototherapy involves increasing the irradiance to more than 25  $\mu\text{W}/\text{cm}^2/\text{nm}$  and was first described in 1977 (Tan, 1977). The rationale for high-intensity phototherapy is the demonstration of a dose-response relationship to bilirubin degradation until a saturation dose is reached at about 40  $\mu\text{W}/\text{cm}^2/\text{nm}$  of appropriate light. The use of high-intensity phototherapy has been advocated by investigators who have documented more effective reduction of STB levels with no long-term complications.

Commonly used phototherapy units contain a number of “daylight,” “cool white,” or “special blue” fluorescent tubes. Others use tungsten-halogen lamps. These lamps may be part of a radiant warming device, included as a bank of lights shining on the baby, or included in fiberoptic vests or blankets, which are used to increase the surface area exposed or to aid in continuing phototherapy while a baby is held or fed. The special blue fluorescent tubes make the baby appear blue, occasionally causing discomfort to nursery personnel. Recently, high-intensity gallium nitride light-emitting diodes (LEDs) have been proposed as a potential light source for delivering phototherapy (Vreman et al, 1998). LEDs deliver high-intensity narrow-band light with minimal heat generation, are lightweight and portable, and can be used in a variety of applications. In a preliminary clinical trial, blue LED phototherapy was as efficacious as conventional fluorescent phototherapy (Seidman et al, 2000). The potential benefits and versatility of this type of phototherapy are promising.

Recommendations to optimize phototherapy include using the most effective spectrum, using the maximum irradiance available, and exposing as much skin as possible to the therapy. Intermittent skin exposure using one continuous light source and rotating the baby to expose different areas of the skin has not been shown to improve the effect of phototherapy. There is no convincing rationale for using intermittent phototherapy, but interrupting phototherapy for feeding or brief parental visits may be tolerated in less severely affected infants. Therefore, the systems that provide a fiberoptic light source in the mattress under the baby and standard lighting above have been recommended. The administration of high-intensity phototherapy using a transparent waterbed has been shown to be significantly more effective at reducing bilirubin levels than conventional phototherapy (Garg et al, 1995).

Despite its apparent safety and enthusiastic application, the photochemical reactions responsible for the decline in STB levels are incompletely understood. Bilirubin is known to undergo photodegradation *in vivo* and *in vitro*, resulting in photoproducts that are more polarized and therefore more water soluble and potentially excretable than native bilirubin. Bilirubin is a yellow pigment with a peak absorption at a wavelength of 450 nm. The initial and most rapid reactions occurring as a result of phototherapy produce configurational isomers, characterized by changes in the shape of the bilirubin molecule but not its structure (McDonagh and Lightner, 1988). These isomers are the most abundant serum photoisomers and may account for up to 20% of STB in infants undergoing phototherapy. The most prominent of these configurational isomers is called 4Z,15E bilirubin (native bilirubin being 4Z,15Z bilirubin). The second most rapid photochemical reaction leads to the formation of structural isomers, the most prominent known as lumirubin. Formation of this compound appears to be irreversible. Although certain phototherapy reactions reach their peak at relatively low levels of irradiance (6 to 9  $\mu\text{W}/\text{cm}^2/\text{nm}$ ), the production of lumirubin is directly proportional to the energy output on the skin (Garg et al, 1995). High-intensity phototherapy results in greater amounts of lumirubin among the photoisomers.

In summary, it appears that the decrease in STB levels resulting from phototherapy is mainly a result of excretion of photoproducts in the bile and subsequent removal in stool. Configurational isomers are maximally produced at conventional levels of irradiance, but structural isomers are more efficiently produced by high-intensity phototherapy and may account for the increased efficacy of high-intensity phototherapy. Because these photoproducts are not conjugated for excretion but merely rendered more polar, their reabsorption by way of the enterohepatic circulation can diminish the effectiveness of phototherapy.

Phototherapy is relatively a safe and simple method of treatment. The possible side effects of phototherapy have been subject to extensive and controversial debate. Associated side effects that may occur, especially in premature infants, include rashes (erythema), oxidative injury, dehydration (transdermal water loss), and ultraviolet (UV) light irradiation (Aouthmany, 1999; Ente and Klein, 1970; Porat et al, 1996). Although irradiation of cells with light intensities similar to those used in phototherapy can produce DNA damage (Speck and Rosenkranz, 1976), no changes in growth, development, or infant behavior have been reported

in long-term follow-up studies of infants who have received phototherapy (Granati et al, 1984; Teberg et al, 1977).

### **Rebounding Bilirubin Levels**

In the absence of hemolytic disease in healthy term infants, the cessation of phototherapy results in a mild rebound in the level of STB concentration. In one small study involving term and preterm infants, the average rebound after cessation of phototherapy was less than 1 mg/dL (17  $\mu$ mol/L) (Lazar et al, 1993; Maisels and Kring, 2002).

Hospital discharge does not need to be delayed for observation for rebound in such cases. However, in the presence of hemolytic disease or in sick or low-birth-weight infants, such reassurance may not be warranted. Because hemolysis or other processes responsible for increased bilirubin production may continue, the rebound in these cases depends not only on the effectiveness of phototherapy but also on the severity of the bilirubin production.

### **Exchange Transfusion**

Although the first successful exchange transfusion performed on an infant with familial icterus gravis was reported in 1925 (Hart, 1925), this mode of intervention was not accepted until hemolytic disease of the newborn was conceptually understood in the 1940s. Exchange transfusion decreases the risk of bilirubin encephalopathy by reducing the total bilirubin load, increasing the binding sites of plasma albumin, and shifting bilirubin out of tissue into the plasma as well as providing erythrocytes less apt to hemolyze. Early attempts at exchange transfusion involved removing blood from the sagittal sinus or radial artery and infusing blood into the saphenous vein. With the development of polyethylene tubing, Diamond and coworkers in 1946 introduced the technique of alternate removal and administration of blood for each transfusion via umbilical vein catheterization (Diamond et al, 1951).

Before exchange transfusion came into common usage in the 1950s, kernicterus affected 15% of liveborn infants with erythroblastosis. Seventy percent of patients with kernicterus died within 1 week of birth, and many of the remainder died during the first year of life (Hsia et al, 1952). Survivors had permanent neurologic sequelae, and this entity was thought to account for 10% of all cases of cerebral palsy. Considering the severe morbidity of this condition, the major contribution provided by exchange transfusion can be appreciated, even though the procedure was recognized as having inherent risks of its own. With the initiation of exchange transfusion as an intervention for the hyperbilirubinemia of erythroblastosis fetalis, the history of kernicterus in newborns was forever changed. Despite many advances in the understanding of hemolytic and neonatal physiology, exchange transfusion remains the ultimate treatment to prevent neurotoxic damage from hyperbilirubinemia.

Exchange transfusion should be considered in cases of hemolysis in which intensive phototherapy has failed to decrease the STB levels by 1 to 2 mg/dL (17 to 34  $\mu$ mol/L) in 4 to 6 hours or when the rate of rise of STB indicates that the level will reach 25 mg/dL (428  $\mu$ mol/L) within 48 hours.

It also should be performed in infants with high STB concentrations and early signs of kernicterus and in cases of hemolysis with anemia and hydrops. Exchange transfusion removes much of the circulating bilirubin and “sensitized” red cells (erythrocytes with maternal antibodies attached), replacing them with red cells compatible with the mother’s antibody-rich serum and providing fresh albumin with binding sites for bilirubin. The process is tedious in that 5- to 10-mL aliquots are removed and replaced sequentially until about twice the volume (blood volume is 85 to 90 mL/kg) of the neonate’s circulating blood volume has been exchanged. The anticoagulant of choice in the blood being infused is citrate-phosphate-dextrose. Because the citrate chelates calcium ions, there may be a need for calcium gluconate infusion during the course of the exchange. High concentration of glucose in the infusate may stimulate insulin production, increasing the risk of severe hypoglycemia (Rubaltelli and Griffith, 1992).

Blood stored for more than 4 days has excessive potassium levels, and such blood requires erythrocyte washing and resuspension in compatible plasma. All of these issues, as well as the temperature of the infusate and the environment, lead to possible stress and instability in the infant, especially in one who is ill and of low birth weight. The amount of bilirubin removed by each transfusion is a function of the initial STB level and the amount of blood exchanged. After an exchange transfusion, low levels of STB concentration may increase rapidly for several hours as bilirubin in tissues “migrates” back into the circulation. Typically, STB levels fall to one half of the pre-exchange value. In some cases (particularly in infants with hemolytic disease), the procedure may need to be repeated to lower the STB concentration sufficiently. Administration of 1 g/kg of albumin 1 to 2 hours before the procedure helps to shift more extravascular bilirubin into the circulation. Intravenous immune globulin (500 mg/kg) given over 2 hours may reduce the chance for a repeat exchange transfusion. Correction of metabolic acidosis by administration of sodium bicarbonate is recommended.

Exchange transfusions are not free of risk. Some reports estimate a risk of morbidity resulting from the procedure at 5%, with apnea, bradycardia, cyanosis, vasospasm, and hypothermia being the most common problems. Other risks include coagulation disturbances, electrolyte imbalances, thrombocytopenia, necrotizing enterocolitis, portal vein thrombosis, blood-borne infections, cardiac arrhythmias, and sudden death. Monitoring of electrolytes, platelet count, coagulation parameters, and arterial blood gases is recommended during the procedure. The procedure should therefore be instituted only when intensive phototherapy does not control the rapid rate of rise of STB levels and the risk of bilirubin encephalopathy outweighs the risk from the procedure itself. Mortality rate estimates run as high as 0.5%.

### **Inducing Enzymes to Increase Conjugation**

Increasing the ability of the body to excrete bilirubin by stimulating the ability of the liver to conjugate it has been attempted since Trolle (1961) observed less hyperbilirubinemia in infants of mothers receiving phenobarbital as anticonvulsant therapy.

Several pharmacologic agents have been identified as liver enzyme inducers, and those inducing UGT have been shown to increase the conjugation and excretion of bilirubin. Phenobarbital and nicotinamide were the first agents used for prevention and treatment of hyperbilirubinemia in newborns, and phenobarbital continues to be used in Gilbert disease and Crigler-Najjar syndrome type II (Arias disease). Type I disease does not respond well to this therapy (Rubaltelli and Griffith, 1992).

The effect of phenobarbital (at a dosage of 2.5 mg/kg/day) on STB levels begins within a few days of its administration. This characteristic has made it less than optimal for use in the usual neonatal hyperbilirubinemia, because the STB is already high or rapidly increasing in the first few days. Phototherapy has been shown to be more effective in this situation, and adding phenobarbital to phototherapy has not been shown to have any advantage. However, postnatal phenobarbital administration may provide a useful approach to later elevation of STB levels, such as that seen in the hyperbilirubinemia in Asians, Native Americans, and other ethnic and genetic subgroups. It has been used with some success in congenital disorders of bilirubin metabolism, in which it lowers STB levels for 15 to 20 days, after which a new steady state is reached that is lower than pretreatment levels.

Prenatal administration of phenobarbital in anticipation of hyperbilirubinemia has been suggested in an effort to “prime the pump” of the conjugation process. One untoward side effect of this approach, however, is a decrease in prothrombin levels in the newborn, but this effect can be remedied by vitamin K administration. In a study involving prenatal administration of phenobarbital during the last week of the pregnancy to mothers whose infants were at risk for jaundice, treated infants had a reduced incidence of STB levels greater than 16 mg/dL (274  $\mu$ mol/L) (Yaffe and Dorn, 1990).

Several chemicals used in traditional Chinese medicine have an enzyme-inducing effect similar to that of phenobarbital (Yin et al, 1991a). In studies involving rats and rabbits, *yin zhi huang* in a dose of 30 to 60 mg/kg/day has been shown to accelerate the plasma clearance and conjugation of bilirubin to an even greater degree than occurs with phenobarbital at 60 mg/kg/day. Both drugs increase glucuronyltransferase activity, but because they have dissimilar effects on other liver enzymes, it appears that their mechanisms of action may be different. *Yin zhi huang*, which is widely used in Asia to treat neonatal hyperbilirubinemia, is a decoction of four plants: *Artemisia*, *Gardenia*, *Rheum*, and *Scutellaria baicalensis*. The gardenia portion and phenobarbital have similar inducing effects also on glutathione-S-transferase, an enzyme involved in intracellular bilirubin transport in the liver (Yin et al, 1991b).

### Blocking Bilirubin Reabsorption

Neonatal hyperbilirubinemia is exacerbated by, if not caused by, enhanced reabsorption in the enterohepatic circulation. The absence of intestinal flora in neonates prevents the degradation of bilirubin in meconium and stool to products such as urobilinogen, which could be excreted. Bilirubin glucuronide arriving in the intestines is

readily deconjugated to bilirubin and reabsorbed. Some of the products of phototherapy, especially the configurational isomers of bilirubin, also return to the native bilirubin form and may be reabsorbed. To counteract this process, various strategies have been used to bind the bilirubin in the intestinal lumen to substances that resist absorption. Seen as an effective low-risk, low-cost therapy, products such as activated charcoal and dried agar (an extract of seaweed) have been used with inconsistent results. A review of the early studies involving agar identified methodologic problems, allowing neither recommendation nor rejection of this approach (Kemper et al, 1988).

More recent studies using doses of 500 mg/kg of agar every 6 hours suggest that agar therapy can be used to augment the efficacy of phototherapy, and perhaps it could be used as therapy by itself (Caglayan et al, 1993). Besides resulting in a more rapid decline in STB levels, the use of agar increased stool frequency, suggesting enhanced clearance of intraluminal bilirubin regardless of binding. Cholestyramine was similarly considered but was found to cause hyperchloremic acidosis (Nicolopoulos et al, 1978).

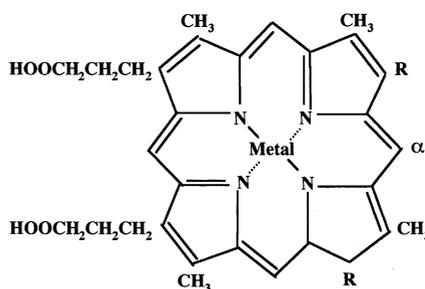

Bilirubin oxidase derived from the fungus *Myrothecium verrucaria* has been suggested as another oral agent, but its effectiveness in interrupting reabsorption is based on its ability to degrade bilirubin to biliverdin and other nontoxic substances enzymatically, rather than by binding the pigment in the lumen (Murao and Tanaka, 1981). Studies involving the Gunn rat support this approach, but adequate data in humans are not yet available (Johnson et al, 1988).

### Inhibiting Bilirubin Production

Whereas other modes of intervention are directed at disposing of excess bilirubin already produced, attempts to decrease the production of bilirubin have met with moderate success. Studies in vitro and in both animals and humans have shown that certain metalloporphyrins can reduce the production of bilirubin, substantially reducing STB levels. These studies suggest that, in cases of hyperbilirubinemia caused by excess bilirubin production (i.e., catabolism of heme), these metalloporphyrins could be used to prevent the accumulation of dangerous STB levels, thus obviating more expensive, time-consuming, or hazardous interventions such as phototherapy and exchange transfusion. The mechanism of action of these compounds is competitive inhibition of the activity of HO, the rate-limiting enzyme in heme catabolism. Tin or zinc protoporphyrin, tin or zinc mesoporphyrin, and other synthetic analogues of the natural metalloporphyrin (ferroporphyrin-heme) are potent competitors of HO, the critical enzyme in the catabolism of heme. Their action is based on the fact that the catalytic site of HO recognizes metalloporphyrins with central metal ions other than iron (Fig. 79-3). HO actually favors some of these metalloporphyrins over heme as a substrate, sometimes by a large factor (Cornelius and Rodgers, 1984; Valaes et al, 1994; Vreman et al, 1990, 1991).

The potency of metalloporphyrins and their side effects are influenced by the central metal cation and the nature of the side chains. Tin porphyrins are more potent than zinc or cobalt porphyrins. With side chains composed

**FIGURE 79-3.** Metalloporphyrin complexes and their chemical structures. Substrates and inhibitors of heme oxygenase belong to a large family of metalloporphyrins with varying metal moieties and porphyrin ring substituents. Heme or FePP is indicated in bold. Magnesium (Mg <sup>2+</sup> )	MgDP	MgMP	MgPP	MgBG

of ethyl groups, mesoporphyrins are far more potent and stable than the other forms. When these agents were administered intramuscularly in doses from 1 to 6  $\mu\text{mol}/\text{kg}$ , a 76% reduction in phototherapy requirements with a lowering of peak STB levels of 41% was observed, with minimal side effects (Valaes et al, 1994). In another randomized trial, the need for phototherapy was completely eliminated in full-term infants treated with 6  $\mu\text{mol}$  of tin mesoporphyrin (SnMP)/kg (Martinez et al, 1999). These infants also had significantly shorter hospital stays and peak STB levels less than 19.6 mg/dL (335  $\mu\text{mol}/\text{L}$ ). Even with these promising results, metalloporphyrins are not currently approved for use in newborn infants. In another study, term infants with G6PD deficiency given SnMP at approximately 27 hours of age had lower and earlier peak STB values than those seen in control infants with and without G6PD deficiency. No treated infant required phototherapy, compared with 31% and 15% in the controls with and without G6PD deficiency, respectively.

Because these synthetic metalloporphyrins do not bind molecular oxygen, they are not metabolically degraded by ring rupture and do not add to the body pool of bilirubin. The metalloporphyrins also do not affect the metabolic disposition of preformed bilirubin, but they may have some inhibitory effect on the biliary excretion of bilirubin (Beri and Chandra, 1993).

The potential benefits of this chemopreventive approach to the management of hyperbilirubinemia could be substantial, especially in premature infants, in whom threshold levels for the manifestation of bilirubin toxicity are controversial and uncertain. Proponents of metalloporphyrins have demonstrated the effectiveness and apparent innocuousness of these compounds, but research continues in identifying which of the compounds is most effective at reducing bilirubin production without toxic side effects. For example, if phototherapy were to be used in conjunction with metalloporphyrin therapy, the effect of photodegradation on the metalloporphyrin and any ensuing risks

would become substantial issues. For example, adults and children with cholestasis have high levels of copper porphyrins that are vulnerable to photo-induced chemical alterations resulting in the formation of brown pigments, made famous by the term *bronze baby syndrome* (Rubaltelli et al, 1983).

Each metalloporphyrin currently being evaluated has its own characteristics related to efficacy and side effects. These compounds are administered intramuscularly in a dose based on body weight, and their effectiveness appears to be dose related (and compound specific) in all gestational age groups tested. Administration of these compounds also produces a dose-dependent decrease in the proportion of newborns requiring phototherapy. When phototherapy is used as an adjunct to metalloporphyrin administration, a decrease in the duration of phototherapy is seen, especially on days 3 to 7 of life, which is related to metalloporphyrin dose. It is not clear which of these metalloporphyrins will eventually prove to be most efficacious and safe, and research in their use continues (Vreman et al, 2001). Although metalloporphyrins hold promise for the future, especially in countries where phototherapy or exchange transfusions are not easily available, they have currently not been approved by the Food and Drug Administration for use in newborns.

### Interruption of Breast-Feeding

Breast-fed babies generally have STB concentrations slightly above those of formula-fed babies. Some babies may experience prolonged jaundice, termed *breast milk jaundice*. Interrupting or continuing breast-feeding is a management decision that clinician and mother must decide on together. Options include continuing breast-feeding with optimal support, supplementing breast-feeding with bottle-feeding to guarantee optimal hydration, and discontinuing breast-feeding and relying on formula or parenteral feeding.

The choice among these options may depend on the strength and condition of the infant, the availability of the parents, the infant's environment, and the intensity of the treatments prescribed. There is no one certain way, but every attempt to accommodate long-term breast-feeding should be encouraged. The 1994 AAP practice parameter "Managing Hyperbilirubinemia in the Healthy Term Newborn" included a statement discouraging the interruption of breast-feeding in healthy term newborns and encouraging continued and frequent breast-feeding (at least 8 to 10 times every 24 hours).

## SUMMARY

The management of hyperbilirubinemia presents a complicated scenario to the clinician. The purpose of treatment is to prevent neurotoxic effects of bilirubin and to identify and treat illnesses that can be associated with excess bilirubin production, impaired conjugation, or inadequate elimination of the pigment. Modes of treatment include interfering with bilirubin production; enhancing the transport, binding, or conjugation of bilirubin; and removing bilirubin in urine, feces, and blood. Controversies remain regarding which treatment or combination of therapies is safest and most effective and which criteria should serve as indicators for instituting therapy.

## Acknowledgments

We acknowledge the contribution of Dr. Frank A. Oski, whose work on the original chapter served as an invaluable template for subsequent revisions. We also thank Ronald J. Wong for his contributions and critical review of this chapter.

# RENAL AND GENITOURINARY SYSTEMS

Editors: ROBERTA A. BALLARD and ISTVAN SERI

PART XVI

## CHAPTER 80

### Renal Morphogenesis and Development of Renal Function

Jean-Pierre Guignard

#### RENAL MORPHOGENESIS

The fetal kidney develops from three successive mesodermic structures: the pronephros, the mesonephros, and the metanephros. The pronephric tubule extends into the intermediate mesoderm of the mesonephros to form the wolffian duct. The metanephros develops from an out-branch of the wolffian duct called the *ureteric bud* that extends into a mass of undifferentiated metanephric mesenchyme. Reciprocal inductive interactions between the ureteric bud epithelium and the metanephric mesenchyme result in the formation of both the collecting duct system and the nephrons of the permanent kidney. Cells of the metanephric mesenchyme adjacent to the tip of the ureteric bud are induced to aggregate and signal the ureteric bud to grow and branch repeatedly (branching morphogenesis), eventually leading to the formation of the renal collecting system. The ureteric bud also induces the mesenchyme to undergo a mesenchymal-epithelial transformation resulting in the formation of the glomeruli and renal tubules. Ureteric bud outgrowth requires inductive signals derived from the metanephric mesenchyme under the control of transcription factors and signaling molecules including Wilms tumor gene 1 (WT1) and glial cell line-derived neurotrophic factor (GDNF). Normal ureteric bud response to these inductive signals is under the control of several transcription factors such as Pax2 and Lim1 and the *Formin* gene.

Differentiation of the metanephros starts around 5 weeks of gestation, and the first nephrons are formed by week 8. Nephrogenesis continues up to weeks 34 to 35, with the deep nephrons being formed first. From the completion of nephrogenesis around week 35 until birth, the nephrons only grow in size. At birth, juxtamedullary nephrons are more mature than superficial nephrons. The total number of nephrons varies widely from 600,000 to 1.2 million per

kidney. Fetal growth retardation reduces the number of nephrons, so that a positive correlation exists between birth weight and the final number of nephrons (Merlet-Bénichou et al, 1999). Exposure to drugs and vitamin A deficiency can also impair nephrogenesis, leading to a permanent nephron deficit (Gilbert and Merlet-Bénichou, 2000).

Mutations in any one of the genes controlling renal morphogenesis result in severe renal developmental defects. The angiotensinogen and angiotensin receptor genes, best known for controlling renal hemodynamics, also play a role in the development of calyces and pelvis. Mutational inactivation of the angiotensin receptor 2 (*Agtr2*), encoded on the X chromosome, results in a range of anomalies including vesicoureteral reflux, duplex kidney, renal ectopia, ureteropelvic junction stenosis, ureterovesical junction stenosis, renal dysplasia, renal hypoplasia, multicystic dysplastic kidney, and renal agenesis (the *CAKUT* sequence—congenital anomalies of the kidney and urinary tract) (Nishimura et al, 1999).

Major renal malformations resulting from mutations in transcription factors, signaling molecules and gene products have been discussed in recent reviews (Burrow, 2000; Piscione and Rosenblum, 1999).

The glomerular diameter approximates 110  $\mu\text{m}$  at birth (200  $\mu\text{m}$  in the adult), and the average proximal tubular length reaches 2 mm (20 mm in the adult). Postnatal growth is characterized by accelerated growth of the proximal tubular volume compared with the glomerular filtering area. The glomerular basement membrane, which behaves as a filtration barrier, is thinner in neonates (100 nm) than in adults (300 nm). The size of the apertures in this “barrier” limits the passage of compounds through the capillary wall. In addition, an electrostatic barrier, resulting from the presence of negatively charged glycosialoproteins in the glomerular capillary wall, further restricts the filtration of negatively charged molecules. In the adult, the molecular weight cutoff for the filter is about 70,000. Molecules with a radius less than 1.8 nm are filtered freely. Molecules larger than 3.6 nm are not filtered. The permeability of the glomerular basement membrane is greater in newborn animals than in more mature animals (Savin et al, 1985).

During the second half of gestation, kidney weight increases proportionally to gestational age, body weight, and the body surface area. The kidney and bladder can be visualized by ultrasonography from week 15 of gestation; the precise renal architecture is only clearly defined by week 20. Kidney size as measured by ultrasonography increases proportionally to gestational age:  $Y$  (kidney size in mm) =  $16.19 + 0.61$  gestational weeks (Jeanty et al, 1982). The ratio between the renal and the abdominal circumferences at the level of the umbilical vein remains

constant during gestation, with values ranging from 0.27 to 0.30 (Grannum et al, 1980). At birth, renal volume approximates 10 mL, and it reaches 23 mL by the third week of life. Each kidney weighs about 12.5 g (~150 g in the adult) and has a length of about 4.5 cm (11.5 cm in the adult) at birth. The surface of the kidney is lobulated and remains so for months after birth. Fetal bladder volume can also be assessed by ultrasonography. With a maximal capacity of 10 mL at 32 weeks, the bladder can contain up to 40 mL near term.

### RENAL FUNCTION IN UTERO

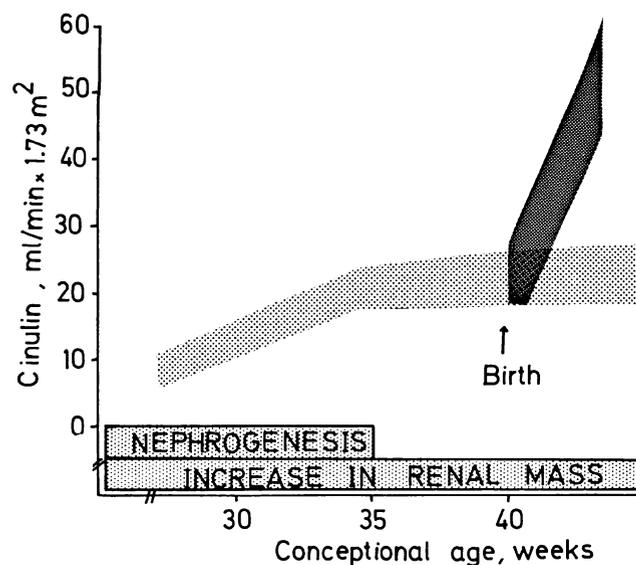

The placenta is the major regulatory organ of the fetus, so that renal growth does not appear to be governed by functional requirements. Urine formation starts around 10 to 12 weeks of gestation. Fetal urine is a major constituent of amniotic fluid, and its production increases with age. Mean hourly urine flow rate is high and approximates 5 mL at 20 weeks, 10 mL at 30 weeks, and 30 mL at 40 weeks of postconceptional age (Rabinovitz et al, 1989). Fetal oliguria with a consequent decrease in amniotic fluid results in the oligohydramnios sequence, which includes facial compression (loose skin folds, flattened or beaked nose, large flat ears), positional deformities (asymmetrical club feet, major contractures, broad flat hands), and pulmonary hypoplasia.

The fetal urine is hypotonic throughout gestation, with sodium as the major osmotic component. The kidney actively reabsorbs electrolytes and solutes from the glomerular ultrafiltrate. Elevated concentrations of sodium (>100 mmol/L), chloride (>90 mmol/L), and osmolality (>210 mOsm/L) in the urine of a dilated kidney have been considered as indicating poor renal postnatal prognosis (see Chapter 81). However, the sensitivity (40% to 80%) and the specificity (<80%) of these parameters are not ideal.

Fetal renal blood flow (RBF), as measured by Doppler ultrasonography, reaches 20 mL/minute at 25 weeks of gestation and 60 mL/minute near term (Veille et al, 1993). The low rate of RBF in the fetus is associated with an elevated renal vascular resistance (RVR). Of interest, the fetus appears to be able to autoregulate RBF within modest limits.

Fetal glomerular filtration rate (GFR) increases rapidly as the number and size of nephrons increase. When the full complement of nephrons is attained, GFR increases in parallel with renal mass, and hence with body weight and body surface area. From 28 to 35 weeks of gestation, GFR (measured by inulin clearance in 1- to 2-day-old neonates) increases proportionally to gestational age ( $GFR = -28.1 + 1.37 \times \text{weeks of gestation}$ ) and then levels off up to the time of birth (Fig. 80-1).

Several vasoactive agents and hormones play a major role in modulating the fetal RBF and GFR, including the renin-angiotensin system, the catecholamines, the prostaglandins, the kallikrein-kinin system, endothelin, nitric oxide, and atrial natriuretic peptide (Table 80-1). Interference with these systems can lead to severe renal dysfunction in the fetus. A clinical example is fetal renal failure after administration to the mother of inhibitors of angiotensin-converting enzyme (ACE) or of prostaglandin synthesis (see Chapter 87).

**FIGURE 80-1.** Maturation of GFR ( $C_{\text{inulin}}$ ) in relation to conceptional age. (From Guignard J-P: *The Neonatal Stressed Kidney*. In Gruskin AB, Norman ME [eds]: *Pediatric Nephrology*. The Hague, Martinus Nijhoff, 1981.)

With that due to ACE inhibition, the decrease in the GFR probably results from the attenuated vasoconstriction of the efferent artery by angiotensin II inhibition, whereas reduced prostaglandin-dependent afferent vasodilation and the unopposed vasoconstrictive effects of angiotensin II and catecholamines may explain the drop in GFR observed in fetuses of mothers given nonselective or cyclooxygenase type 2 (COX-2)-selective nonsteroidal anti-inflammatory drugs (NSAIDs) (Guignard, 2002).

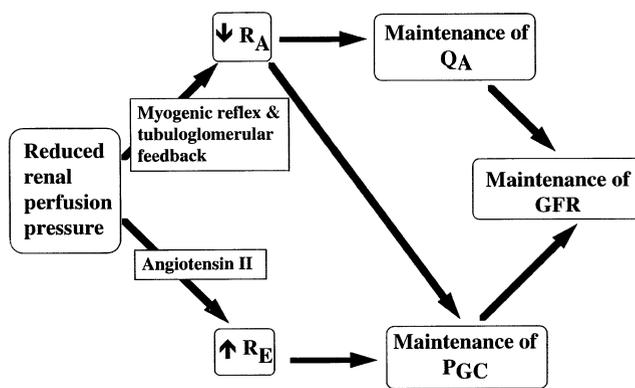

### POSTNATAL MATURATION OF RENAL BLOOD FLOW

Renal blood flow is determined primarily by the mean arterial pressure and the resistance at the level of the renal arterioles. In the adult, physiologic intrinsic autoregulation maintains a constant RBF at perfusion pressures varying from 80 to 200 mm Hg. This means that as perfusion pressure increases, the resistance to flow also increases. Both afferent and efferent arterioles participate in the vasoconstriction. In children and adults, RBF approximates 20% to

**TABLE 80-1**

#### Vasoactive Factors Modulating Renal Blood Flow and Glomerular Filtration Rate in the Immature Kidney

Adenosine	Nitric oxide
Angiotensin II	Norepinephrine
Atrial natriuretic peptide	Prostaglandin E <sub>1</sub>
Bradykinin	Prostaglandin E <sub>2</sub>
Dopamine	Thromboxane A <sub>2</sub>
Endothelin	Vasopressin
Epinephrine	

**FIGURE 80-2.** Mechanisms contributing to the autoregulation of renal blood flow and glomerular filtration rate (GFR).  $P_{GC}$ , glomerular capillary hydraulic pressure;  $Q_A$ , glomerular plasma flow rate;  $R_A$ , afferent arteriolar resistance;  $R_E$ , efferent arteriolar resistance. (From Badr KF, Ichikawa I: *Prerenal failure: A deleterious shift from renal compensation to decompensation. N Engl J Med* 319:623, 1988.)

25% of cardiac output, and it is around 1200 mL/minute  $\times$  1.73 m<sup>2</sup> of body surface area. The major part of the blood flow supplies the cortex, with medullary blood flow representing only 10% of the total RBF.

During fetal life, RBF is low, representing only 2% to 4% of the total cardiac output. This proportion increases after birth, from a value of 5% in the first 12 hours of life to 10% at the end of the first week. During the first 5 months, RBF increases rapidly from a value of 250 mL/minute  $\times$  1.73 m<sup>2</sup> at 8 days of age to approximately 770 mL/minute  $\times$  1.73 m<sup>2</sup> by 5 months of age. The postnatal maturation of RBF is associated with a striking decrease in RVR and a marked increase in systemic blood pressure. The decrease in RVR occurs along with a decrease in the resistance of both the afferent and the efferent arterioles. Animal studies suggest that autoregulation of RBF is present in the immature kidney but is set at a lower range of blood pressure (Chevalier et al, 1987).

Several autocrine, paracrine, and endocrine factors regulate RBF, intrarenal hemodynamics, and GFR (Bailie, 1992; Guignard et al, 1991; Seri, 1995) (Fig. 80-2; see also Table 80-1). Overactivation of the vasoconstrictive forces that regulate renal hemodynamics in the neonatal period may impair the maturation of RBF and induce renal hypoperfusion. Such activation is seen during respiratory distress, hypoxemia, asphyxia, metabolic acidosis, hypercapnia, hyper- and hypothermia, and positive pressure ventilation as well as in response to the administration of various medications. (Guignard and John, 1986; Toth-Heyn et al, 2000)

## POSTNATAL MATURATION OF GLOMERULAR FILTRATION RATE

### Determinants of Glomerular Filtration Rate

The rate of filtration is governed by the rate at which plasma flows through the glomerular capillaries, the balance of Starling forces across the glomerular capillary walls, the permeability of the basement membrane of the

glomerular capillary wall to water and small solutes, and the total surface area of the capillaries. The ultrafiltration coefficient ( $K_f$ ) represents the product of the permeability of the glomerular membrane and the glomerular filtering area. GFR is proportional to the Starling forces across the glomerular capillaries times the  $K_f$ :

$$GFR = K_f \times [P_{GC} - (P_{IT} + \pi_{GC})]$$

where  $P_{GC}$  is the hydrostatic pressure in the glomerular capillary,  $P_{IT}$  is the proximal intratubular hydrostatic pressure, and  $\pi_{GC}$  is the oncotic pressure in the glomerular capillary. In adults, the average value of  $P_{GC}$  probably approximates 60 mm Hg, the pressure in Bowman's capsule 15 mm Hg, and the oncotic glomerular capillary pressure 25 mm Hg. Thus, the average net filtration pressure is probably close to 20 mm Hg at the afferent end of the glomerular capillaries. It decreases to 10 mm Hg at the end of the efferent glomerular capillaries. Because of the very low mean arterial pressure present in neonates, the net transglomerular filtration pressure is probably not greater than 3 to 5 mm Hg. The relative state of vasoconstriction of the afferent and efferent arterioles plays a major role in regulating the intracapillary hydrostatic pressure. The factors modulating the state of vascular contraction are listed in Table 80-1.

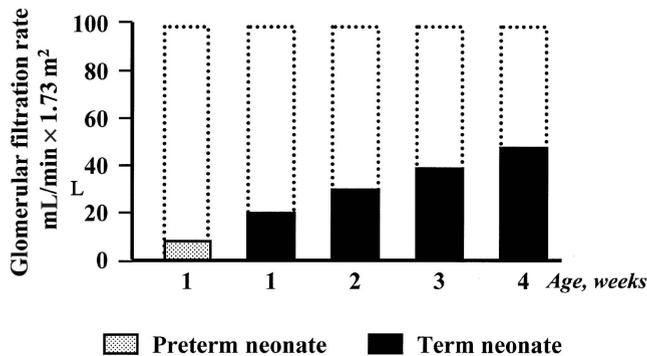

During the early neonatal period, the factors regulating GFR mature rapidly. Systemic blood pressure and mean transcapillary hydraulic pressure increase, followed by a parallel increase in GFR (Guignard and John, 1986). The plasma oncotic pressure also increases but at a lower rate than for the transcapillary hydraulic pressure, so that the net ultrafiltration pressure increases. The low glomerular plasma flow rate present at birth is due to elevated afferent and efferent arteriolar resistances. A systemic increase in the ultrafiltration coefficient also occurs during maturation and may be attributed to an increase in both the hydraulic permeability and the glomerular capillary area.

In the fetus and neonate, the low systemic blood pressure and hence the low glomerular capillary hydrostatic pressure are the main factors limiting the rate of filtration. Vasoactive factors modulating the intraglomerular filtration pressure thus play a key role in maintaining filtration (Bailie, 1992; Guignard et al, 1991). Vasodilatory prostaglandins, the concentration of which is elevated during fetal and early postnatal life, improve filtration by dilating the afferent arteriole. Angiotensin II also increases filtration by preferentially constricting the efferent arteriole. Minute-to-minute regulation of the contractile tone also depends on endothelium-released vasoactive factors such as nitric oxide and endothelin. Although endogenous endothelin behaves as a potent constrictor in the adult, it may actually vasodilate the afferent artery in the immature kidney (Semama et al, 1993). Atrial natriuretic peptide, the concentration of which also is elevated in the fetus, vasodilates the afferent arteriole (Robillard et al, 1992). Adenosine, a regulator of the tubuloglomerular feedback mechanism, is an efferent vasodilator. When acting in conjunction with elevated levels of angiotensin II, it also vasoconstricts the afferent arteriole (Gouyon and Guignard, 1989). Although the overactivation of adenosine plays a critical role in the pathogenesis of the hypoxemia-induced vasomotor insufficiency, the exact physiologic role of intrarenal adenosine in the fetus and neonate is still ill defined.

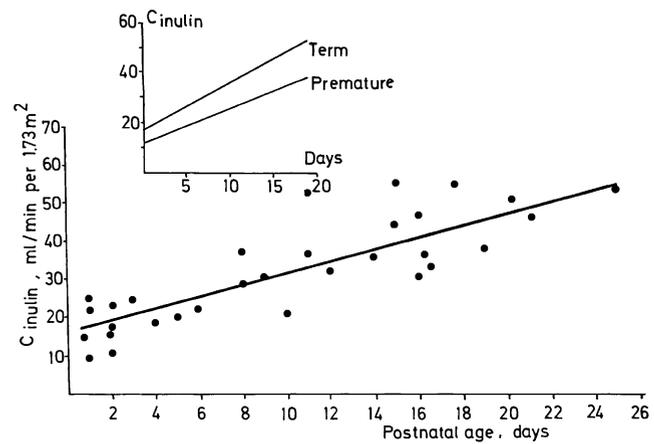

### Assessment of Glomerular Filtration Rate

Determination of inulin clearance is the “gold standard” for assessing GFR in both the immature and the mature kidney. Inulin is freely filtered even in the preterm neonate with a gestational age as low as 27 weeks. The postnatal development of GFR has been assessed in premature neonates at different gestational ages and in term neonates. From a value of 20 mL/minute  $\times$  1.73 m<sup>2</sup> at birth, GFR doubles in the first 2 weeks of life in term neonates (Guignard et al, 1975) (Figs. 80-3 and 80-4). GFR is lower in premature infants and, owing to incomplete nephrogenesis, also develops at a lower velocity.

Creatinine, the most commonly used glomerular marker in mature persons, also is frequently used to assess GFR in neonates. However, the use of creatinine presents several drawbacks. The concentration of creatinine is elevated at birth, reflecting maternal levels. A complete equilibration between the maternal and fetal plasma creatinine levels is achieved throughout pregnancy (Guignard and Drukker, 1999). During the first postnatal week, the highest levels are observed in the most premature neonates (Bueva and Guignard, 1994) (Fig. 80-5). In term neonates, serum creatinine decreases rapidly to reach stable neonatal levels close to 0.40 mg/dL (35  $\mu$ mol/L) by 1 to 2 weeks postnatally. In very premature infants, there is a transient increase in serum creatinine, peaking on postnatal day 4 (Gallini et al, 2000) (Fig. 80-6), followed by a progressive decline toward normal neonatal levels by 3 to 4 weeks of life. The transient increase in plasma creatinine is caused in part by passive reabsorption (back-diffusion) of creatinine across leaky tubules (Matos et al, 1998). The reabsorption of creatinine by the premature infant accounts for the negative correlation between gestational age and the plasma creatinine during the first postnatal weeks (see Fig. 80-4) as well as for the finding that, in very premature neonates, creatinine clearance underestimates inulin clearance (Coulthard and Ruddock, 1983). In spite of these drawbacks, creatinine clearance correlates with inulin clearance (Stonestreet et al, 1979; Van den Anker et al, 1995), and creatinine clearance studies in neonates have confirmed the rapid development of GFR during the first postnatal weeks and that GFR develops

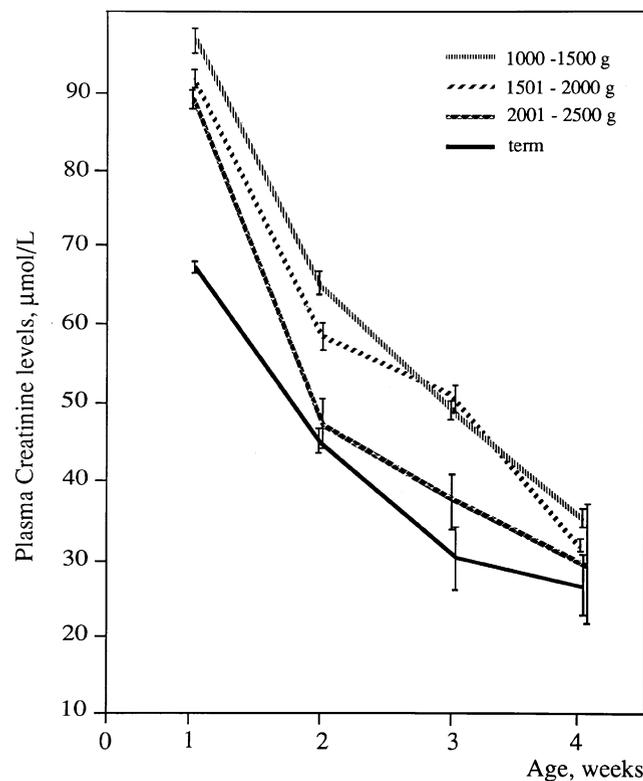

**FIGURE 80-3.** Glomerular filtration rate during the first month of life of preterm and term neonates, compared with adult values (open columns). (Adapted from Guignard JP, Torrado A, Da Cunha O, et al: Glomerular filtration rate in the first three weeks of life. *J Pediatr* 87:268, 1975.)

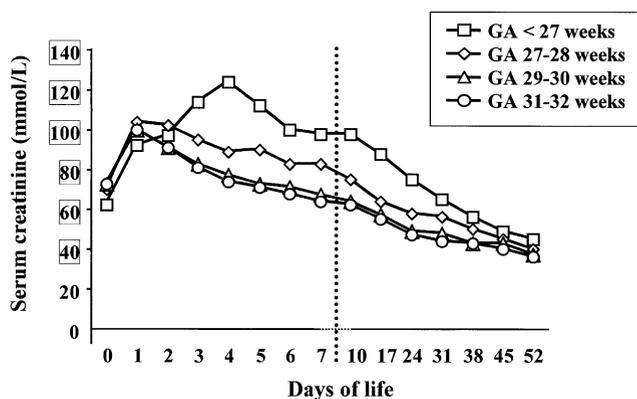

**FIGURE 80-4.** Maturation of GFR (C<sub>inulin</sub>) in relation to postnatal age in term and preterm infants. (From Guignard J-P: *The Neonatal Stressed Kidney*. In Gruskin AB, Norman ME [eds]: *Pediatric Nephrology*. The Hague, Martinus Nijhoff, 1981.)

at a lower velocity in premature infants (Bueva and Guignard, 1994; Vanpee et al, 1992). The differences in the GFR among infants with different gestational and postnatal ages explain why the specific dosage recommendations are tailored to the given gestational and postnatal ages for medications eliminated primarily via glomerular filtration (e.g., aminoglycosides, vancomycin, digoxin).

(Adapted from Gallini F, Maggio L, Romagnoli C, et al: Progression of renal function in premature neonates with gestational age  $\leq 32$  weeks. *Pediatr Nephrol* 15:119, 2000.)

## REGULATION OF BODY FLUID TONICITY AND VOLUME

The kidney is responsible for maintaining the extracellular fluid (ECF) volume and osmolality despite large variations in salt and water intake. By modulating the renal conservation of water, the antidiuretic hormone (ADH) system plays a central role in the regulation of body fluid tonicity. Sodium chloride, the major osmotically active solute in ECF, determines its volume. The balance between the intake and the renal excretion of sodium thus regulates ECF volume (see Chapter 30).

### Sodium, Chloride, and Water Reabsorption

Active sodium reabsorption occurs throughout the nephron, driven by the  $\text{Na}^+, \text{K}^+$ -ATPase localized at the basolateral membrane. Two thirds of the filtered  $\text{Na}^+$  load is reabsorbed in the proximal tubule via the  $\text{Na}^+$ -glucose,  $\text{Na}^+$ -amino acid,  $\text{Na}^+$ - $\text{P}_i$ , and  $\text{Na}^+$ -lactate symporters, and by the  $\text{Na}^+$ - $\text{H}^+$  antiporter. Because water passively follows  $\text{Na}^+$  across the highly water-permeable proximal tubule, the osmolality of the proximal tubule fluid remains isotonic. Twenty percent of the filtered sodium load is reabsorbed in the ascending limb of the loop of Henle, which is relatively impermeable to water. Accumulation of  $\text{NaCl}$  and recycling of urea into the medullary interstitium lead to the formation of a hyperosmotic medulla. The thick ascending limb also reabsorbs calcium, magnesium, and potassium. The distal tubule and collecting duct reabsorb 10% of the filtered  $\text{Na}^+$  and  $\text{Cl}^-$  load. In the distal tubule, the continuing  $\text{NaCl}$  reabsorption in the absence of water reabsorption further decreases the osmolality of the tubular fluid, allowing the formation of hypotonic urine. Excretion of solute-free water thus is dependent on  $\text{Na}^+$  delivery to and reabsorption at the distal diluting site. The permeability of the collecting duct to water depends on the presence of ADH or arginine vasopressin (AVP). The release of AVP by the posterior pituitary is regulated by osmoreceptors located in the supraoptic nucleus of the hypothalamus. By binding to its cell mem-

brane receptors and activating adenylate cyclase, AVP increases the intracellular levels of cAMP. This increase ultimately leads to phosphorylation of the aquaporin water channels, which in turn results in insertion of these channels into the luminal membrane of the collecting duct cells, rendering the collecting duct permeable to water. In the absence of AVP, a large volume of hypotonic urine is excreted. In contrast, when elevated levels of AVP are present, water passively diffuses out of the collecting duct into the hyperosmotic interstitium, and a small volume of concentrated urine is excreted.

Water transport depends on the intact function of the aquaporin water channels. Ten aquaporins (AQPs), designated 0-9, have been described in mammals, six of which—AQP1-4, AQP6, AQP7—are expressed in the kidney (Nielsen et al, 2000). AQP2 is the vasopressin-responsive AQP in collecting duct cells. Mutations in the AVP V2 receptor gene located on Xq28 are responsible for *X-linked recessive diabetes insipidus*. When inherited as an autosomal recessive or dominant trait, diabetes insipidus usually is caused by various mutations in the AQP2 gene located on chromosome 12q13.

### Sodium

During development, proximal  $\text{Na}^+$  reabsorption increases three- to fourfold (Celsi et al, 1986). The increase in active  $\text{Na}^+$  reabsorption is associated with a threefold increase in  $\text{Na}^+, \text{K}^+$ -ATPase activity in the corresponding segment (Celsi et al, 1986) and with an increase in the number of cotransporters for glucose and bicarbonate reabsorption (Schwartz and Evan, 1983). The immature proximal tubule has a lower reflection coefficient for mannitol, indicating increased permeability of the proximal tubule to various solutes. The low capacity of the immature thick ascending limb of the loop of Henle to reabsorb  $\text{Na}^+$  is associated with a low activity of the tubular  $\text{Na}^+, \text{K}^+$ -ATPase. As a consequence of the reduced  $\text{Na}^+$  reabsorption in the loop of Henle, immature nephrons deliver a greater fraction of filtered  $\text{Na}^+$  to the distal nephrons. The activity of the  $\text{Na}^+, \text{K}^+$ -ATPase also increases in this segment during development. As a result of the maturational process, the fractional excretion of  $\text{Na}^+$  (FENa) decreases during development, from a value of 13% in the fetus to 3% in premature neonates less than 30 weeks of gestation, and to 1% in term neonates (Bueva and Guignard, 1994). Very low-birth-weight (VLBW) infants may be at risk for negative sodium balance around postnatal weeks 2 to 3, when  $\text{Na}^+$  retention is required for growth.

The study of the developmental changes in the various tubular epithelial transport mechanisms and the delineation of the molecular basis of such mechanisms and associated genetic defects have shed new light on a number of rare pediatric renal tubular disorders (Zelikovic, 2001) related to abnormalities of sodium and water homeostasis. Constitutive activation of the amiloride-sensitive epithelial  $\text{Na}^+$  channel (ENaC) is seen in Liddle syndrome, characterized by salt retention, early-onset hypertension, metabolic alkalosis, and hypokalemia. Autosomal recessive pseudohypoadosteronism, characterized by renal salt wasting and end-organ unresponsiveness to mineralocorticoids, is due to

decreased activity of ENaC. The activity of ENaC is under the tight control of aldosterone and vasopressin (Rossier et al, 2002). ENaC is composed of three subunits:  $\alpha$ ,  $\beta$ , and  $\gamma$ . The  $\alpha$  subunit of ENaC is the most important and it is also expressed in other organs such as the lungs. Thus, the  $\alpha$  subunit of ENaC is required not only for channel function in the collecting duct of the kidney but also for active lung fluid clearance.

### Chloride

A major fraction of chloride reabsorption in the proximal tubular occurs by paracellular diffusion. Active chloride countertransport with organic anions (fumarate, oxalate) also takes place in the proximal tubule. In the ascending limb of Henle, the  $\text{Na}^+, \text{K}^+$ -ATPase is the driving force for active NaCl reabsorption and accumulation in the medullary interstitium. Here,  $\text{Na}^+ - \text{K}^+ - 2\text{Cl}^-$  cotransporters and  $\text{Cl}^-$  channels are involved in the transport of chloride. Renal salt wasting with hypokalemic metabolic alkalosis, hyperreninemic hyperaldosteronism, and normal blood pressure are the features of *Bartter syndrome*. Antenatal Bartter syndrome, called “hyperprostaglandin E syndrome,” is the most severe form of the disease. Congenital defects in the genes encoding various chloride transporters, cotransporters, and channels in the thick ascending limb and distal tubule are responsible for the various forms of Bartter syndrome and Gitelman syndrome (Rodriguez-Soriano, 1998; Scheinmann et al, 1989).

### Body Fluid Tonicity

Although the volume of body fluids varies during growth, the tonicity of ECF is maintained constant by the kidneys, which excrete or retain appropriate amounts of water.

### Excretion of Free Water

When plasma osmolality decreases, the release of ADH also diminishes, leading to the excretion of dilute urine. The newborn infant, preterm or term, is able to decrease urine osmolality to values as low as 40 mOsm/kg  $\text{H}_2\text{O}$  (Guignard et al, 1976). Because GFR is low in the newborn infant, ability to excrete large amounts of free water and consequently to cope with a hypotonic fluid load is limited. Excessive hypotonic fluid loading leads to hyponatremia.

Hyponatremia also may occur in the syndrome of inappropriate secretion of antidiuretic hormone (SIADH), when the excretion of free water is impaired. This syndrome can occur in term as well as in preterm infants presenting with various cerebral injuries or pulmonary disorders, in infants undergoing mechanical ventilation, and in response to some drugs. Because the renal response to AVP is maturation dependent, the more immature the neonate, the less severe the clinical presentation of the SIADH.

### Concentration of Urine

By comparison with adults, who can concentrate urine up to 1400 mOsm/kg  $\text{H}_2\text{O}$ , the concentrating ability is limited in the neonate. The maximal urine osmolality achieved

following dehydration or exogenous vasopressin (DDAVP) administration (10  $\mu\text{g}$ ) remains below 430 mOsm/kg  $\text{H}_2\text{O}$  and 630 mOsm/kg  $\text{H}_2\text{O}$  in 1- to 3-week-old and 4- to 6-week-old term infants, respectively. Osmolalities achieved by preterm neonates are slightly lower (Svenningsen and Aronson, 1974). The relative ineffectiveness of the concentrating ability of the neonate is related to several factors including the low corticomedullary solute gradient associated with a limited accumulation of sodium chloride and urea in the medullary interstitium, the decreased formation of cAMP in response to ADH, the shortness of the loops of Henle, and the interference of prostaglandins with the vasopressin-stimulated cyclic adenosine monophosphate (cAMP) synthesis.

### Extracellular Fluid Volume

The ECF volume is a function of the ECF sodium content. Under normal conditions, plasma volume is closely related to ECF volume. Volume receptors distributed both on the venous (low-pressure receptors) and the arterial (high-pressure receptors) sides of the circulation sense the changes in plasma volume. Arterial sensors perceive the “effective arterial volume.” Atrial filling volume is monitored by stretch receptors, which mediate the release of the natriuretic peptide (Semmekrot and Guignard, 1991) promoting diuresis and natriuresis. Effective renal arterial volume also is sensed by baroreceptors located in the juxtamedullary apparatus of the kidney. A decrease in renal perfusion pressure activates the renin-angiotensin-aldosterone system (see Fig. 80–2). Angiotensin II, a potent renal and peripheral vasoconstrictor, promotes sodium reabsorption, stimulates thirst, and favors the renal production of prostaglandins and bradykinin, hormones that play a role in sodium homeostasis. Aldosterone increases sodium reabsorption in the distal tubule, leading to further conservation of ECF volume.

The neonatal period is characterized by the rapid physiologic constriction of the expanded ECF volume, as well as by elevated levels of several hormonal systems participating in the regulation of sodium balance. Although angiotensin II induces sodium retention by a direct action on the proximal tubule and by stimulating aldosterone secretion, the role of atrial natriuretic peptide in defending the plasma volume is still unclear. The elevated levels of plasma renin activity, which are inversely correlated with gestational age, may be of importance in the maintenance and distribution of blood flow to various organs. The integrity of the renin-angiotensin system also appears to be crucial for the maintenance of renal blood flow and GFR at low perfusion pressure in the neonate (Guignard et al, 1991). Other factors that may be involved in regulating sodium excretion include atrial natriuretic peptide, bradykinin, dopamine, nitric oxide, endothelin, and adrenomedullin. Dopamine, synthesized by the proximal tubule cells in the kidneys, reduces sodium reabsorption by inhibiting the  $\text{Na}^+, \text{K}^+$ -ATPase and by decreasing  $\text{Na}^+ - \text{H}^+$  antiporter and sodium–inorganic phosphate ( $\text{Na}^+ - \text{P}_i$ ) cotransporter activity (Seri, 1995). Agents such as nitric oxide, endothelin, and adrenomedullin all can increase sodium excretion and may participate in the homeostasis of sodium.

## REGULATION OF ACID-BASE BALANCE

The kidneys maintain the acid-base balance by preventing the loss of bicarbonate in the urine and by excreting the daily production of fixed acids. Bicarbonate reabsorption occurs mainly in the proximal tubule (80%) and to a lesser extent in the thick ascending limb of Henle (15%) and the cortical collecting duct (5%). It is mediated by active secretion of hydrogen ions and is closely linked to the tubular reabsorption of sodium. Hydrogen ion secretion occurs through the  $\text{Na}^+\text{-H}^+$  antiporter (NHE-3) but also is mediated in part by  $\text{H}^+\text{-ATPase}$ . In the tubular lumen, secreted  $\text{H}^+$  reacts with filtered  $\text{HCO}_3^-$  to form  $\text{H}_2\text{CO}_3$ , which quickly dissociates under the influence of the brush border carbonic anhydrase enzyme (CA IV). Luminal  $\text{CO}_2$  diffuses freely back into the tubular cells.  $\text{H}_2\text{CO}_3$  is then formed within the cell by the hydration of  $\text{CO}_2$ , a reaction catalyzed by carbonic anhydrase type 2 (CA II). After crossing the luminal membrane as  $\text{CO}_2$ , most  $\text{HCO}_3^-$  exits the tubular cells via an  $\text{Na}^+\text{-HCO}_3^-$  cotransporter (NBC I, II, and III) which couples the transport of 1  $\text{Na}^+$  with 3  $\text{HCO}_3^-$ , or in exchange for  $\text{Cl}^-$  via a  $\text{Cl}^-\text{-HCO}_3^-$  antiporter.

The excretion of fixed acids occurs mainly in the distal tubule, where secreted  $\text{H}^+$  is buffered by  $\text{NH}_3$  and  $\text{HPO}_4^{2-}$  and is excreted as  $\text{NH}_4^+$  and  $\text{H}_2\text{PO}_4^-$  (titratable acid). Free  $\text{H}^+$  concentration determines the urine pH. The ability of the collecting duct to lower the urine pH is critically important for the excretion of urinary buffers and ammonium.  $\text{NH}_4^+$  is produced by the kidneys; its synthesis and subsequent excretion can be regulated in response to acid-base requirements of the body. To produce  $\text{NH}_4^+$ , the kidneys metabolize glutamine, excrete  $\text{NH}_4^+$  with the acid salts, and return the generated  $\text{HCO}_3^-$  to the blood.  $\text{NH}_3$  synthesis is up-regulated by metabolic acidosis and by hypokalemia.

During fetal life, the placenta is responsible for the excretion of  $\text{H}^+$ . In experimental studies, the fetus responds to acid loading by increasing the excretion of  $\text{NH}_4^+$  and titratable acid, and by decreasing the urine pH. In early postnatal life, several transporters and enzymes involved in bicarbonate reabsorption are weakly expressed, so that the functioning of the  $\text{Na}^+\text{-H}^+$  antiporter is clearly impaired (Rodriguez-Soriano, 2000). The proximal reabsorption of bicarbonate is reduced, resulting in low bicarbonate threshold. This low threshold is responsible for the low "physiologic" plasma bicarbonate concentration in neonates: 16 to 20 mmol/L in extremely immature infants and 19 to 21 mmol/L in term infants (Schwartz et al, 1979). In addition to immature carbonic anhydrase activity, the relative expansion of ECF volume at birth may account for the reduced bicarbonate threshold. Immature carbonic anhydrase (CA II and CA IV) enzyme activities also may play an important role in the low bicarbonate proximal reabsorption rate. Maturation of  $\text{HCO}_3^-$  reabsorption increases proportionally to the increase in proximal tubular basolateral area and  $\text{Na}^+\text{,K}^+\text{-ATPase}$  activity (Rodriguez-Soriano, 2000). Administration of glucocorticoids stimulates the maturation of both the  $\text{Na}^+\text{-H}^+$  antiporter activity and the expression of the  $\text{Na}^+\text{-H}^+$  antiporter messenger RNA (mRNA) (Shah et al, 1999).

Distal tubular acidification is more mature than proximal tubular bicarbonate reabsorption. The ability of the neonate to excrete an acid load is well developed. Deficient

ammoniogenesis results, however, in low glutamine uptake, decreased  $\text{NH}_3$  production and excretion, and, ultimately, impaired ability to excrete an acid load.

Mutation in the various genes encoding the  $\text{Na}^+\text{-HCO}_3^-$  cotransporter (NBC-1), the  $\text{Cl}^-\text{-HCO}_3^-$  exchanger (AE1), the  $\text{H}^+\text{-ATPase}$ , and CA II are responsible for the various forms of renal tubular acidosis (Rodriguez-Soriano, 2000, 2002).

Under normal conditions, very little bicarbonate is lost in the urine. The reabsorption of bicarbonate is increased by extracellular volume contraction, hypercapnia, hypokalemia, chloride deficiency, glucocorticoids, angiotensin, aldosterone and alpha-adrenergic stimulation; it is depressed by volume expansion and parathormone (PTH) (Rodriguez-Soriano, 2000, 2002). The postnatal renal compensation for hypercapnia involves increased bicarbonate reabsorption and excretion of fixed acids, in order to blunt a decrease in plasma pH. Animal studies and clinical observations indicate that this compensating mechanism is functional in the neonate (van der Heijden and Guignard, 1989).

## REGULATION OF POTASSIUM HOMEOSTASIS

Ninety-eight percent of the potassium in the body is intracellular, resulting in a high intracellular concentration of potassium. High intracellular concentration of potassium also is required for cell growth and division. Potassium homeostasis depends on an internal balance that maintains a constant potassium concentration in the intracellular and extracellular fluid space, and also on an external balance that requires that the potassium absorbed by the gastrointestinal tract in excess of the amount needed for growth be eventually excreted by the kidneys.

In the proximal tubule, some 70% of filtered potassium is reabsorbed, predominantly passively, although active reabsorption against a concentration gradient also occurs. About 20% of filtered potassium is reabsorbed in the ascending limb of the loop of Henle. The overall rate of potassium excretion is determined by the function of the distal tubule and collecting duct. Plasma potassium concentration and aldosterone are the major physiologic regulators of potassium secretion. Hyperkalemia stimulates the  $\text{Na}^+\text{,K}^+\text{-ATPase}$  activity, increases the permeability of the luminal membrane to potassium, and stimulates the secretion of aldosterone by the adrenal cortex. Aldosterone in turn stimulates sodium reabsorption and enhances potassium secretion by stimulating the basolateral  $\text{Na}^+\text{,K}^+\text{-ATPase}$ , leading to an elevation of the intracellular concentration of potassium, and also by increasing the permeability of the luminal membrane to potassium. Aldosterone probably plays a more important role in determining potassium balance than in regulating sodium excretion. The aldosterone-sensitive transport mechanisms for sodium and potassium are largely independent of each other. Other factors favoring potassium secretion by the distal tubule and collecting duct include a rise in tubular flow rate, alkalosis, and an increase in the tubular fluid sodium concentration.

Potassium excretion remains low throughout gestation, and the fetal potassium concentration is maintained at levels exceeding 5 mmol/l. Postnatal growth is associated with an increase in total body potassium from approximately

8 mmol/cm body height at birth to more than 14 mmol/cm body height by 18 years of age (Butte et al, 2000).

In neonatal tissues,  $K^+$  content is significantly higher than in adult tissues. The plasma  $K^+$  concentration is also more elevated during the first 3 to 4 postnatal months. The intracellular versus extracellular potassium distribution in infancy may be influenced not only by the expression of the  $Na^+, K^+$ -ATPase and potassium transporters and channels but also by the expression of hormone receptors and intracellular messengers.

In healthy preterm infants with a positive potassium balance, potassium excretion remains stable during the first postnatal month, with mean values ranging from 1.29 to 1.48 mmol/kg/day (Guignard and John, 1986). Some 85% to 90% of ingested potassium is eliminated in the intestine, and the remaining in the urine (Aizman et al, 1998). The high urine sodium-to-potassium ratio present at birth decreases significantly with gestational age and postnatal age (Sulyok et al, 1979), and it is thought to indicate the relative unresponsiveness of the distal tubule and collecting duct to aldosterone. The limited potassium excretory capacity of the collecting duct and the increased distal tubular reabsorptive activity of the neonate contribute to the positive potassium balance necessary in early postnatal life. Transient hyperkalemia sometimes occurs in the early neonatal period in VLBW infants. Lower renal  $K^+$  excretory and tissue  $K^+$ -binding capacities and a low tissue  $K^+$  uptake due to low  $Na^+, K^+$ -ATPase activity are thought to be responsible for this non-oliguric hyperkalemia (Lorenz et al, 1997). In contrast with healthy premature infants, critically ill and stressed premature neonates may develop a negative potassium balance. In sick neonates, potassium losses can be exaggerated by the use of diuretics, and volume expansion.

### REGULATION OF CALCIUM, PHOSPHATE, AND MAGNESIUM HOMEOSTASIS

The kidney, in conjunction with the gastrointestinal tract and bone, plays a major role in maintaining calcium, phosphate, and magnesium homeostasis.

#### Regulation of Calcium Homeostasis

The blood ionic calcium concentration in plasma is maintained within narrow limits at approximately 1.10 to 1.30 mmol/L. The distribution of calcium between the intracellular (bone) and extracellular compartment is regulated mainly by PTH. The parathyroid gland has the ability to determine the level of blood-ionized calcium by a calcium sensor (CaSR) located on the extracellular membrane. The CaSR appears to act via a G protein-coupled signaling system and its gene has been cloned (Brown, 1999). Loss-of-function and gain-of-function mutations in the *CaSR* gene are responsible for the *autosomal dominant familial hypercalcemia with hypocalciuria* and *autosomal dominant hypoparathyroidism with hypocalcemia* (Langman, 2000).

PTH increases plasma calcium concentration by stimulating bone resorption, by activating the synthesis of 1,25-dihydroxyvitamin  $D_3$  ( $1,25(OH)_2D_3$  or calcitriol), and by increasing calcium reabsorption by the kidney. Normally,

99% of the filtered calcium is reabsorbed by the nephron, mainly by the proximal tubule and the loop of Henle. In the proximal tubule and the thick ascending limb, calcium reabsorption is passive and closely linked to sodium reabsorption. By contrast, in the distal tubule and collecting duct, calcium reabsorption is active and independent of sodium transport, so that net calcium and sodium excretions do not always change in parallel. PTH is the main regulator of the renal excretion of calcium, and it strongly stimulates calcium reabsorption in the distal tubule and collecting duct, resulting in a reduced calcium excretion. Volume expansion depresses both sodium and passive calcium reabsorption in the proximal tubule and thus increases calcium excretion. Calcium excretion is increased by acidosis and decreased by alkalosis. Finally,  $1,25(OH)_2D_3$  stimulates distal calcium reabsorption and thus decreases its excretion. Whereas the single most important action of PTH is on bone, that of vitamin  $D_3$  is on the intestine.

During weeks 26 to 36 of gestation, the mean intrauterine accumulation of calcium is about 130 mg/kg/day (Forbes, 1976; Wharton et al, 1987). The calcium levels in fetal plasma are higher than the maternal levels (Delivoria et al, 1967), averaging 1.40 to 1.60 mmol/L. Of interest, the fetal kidney also is able to effectively produce  $1,25(OH)_2D_3$  (Moore et al, 1985). The 25-hydroxyvitamin  $D_3$ - $1\alpha$  hydroxylase is produced by the renal proximal tubule mitochondria. The  $1,25(OH)_2D_3$  binds to an intracellular receptor to stimulate intestinal calcium reabsorption. During the neonatal period, the urinary calcium-to-creatinine ratio is higher in neonates than later in infancy (2.5 versus 0.7) (Matos et al, 1997). Loop diuretics are potent calciuric agents that may lead to neonatal nephrocalcinosis.

#### Regulation of Phosphate Homeostasis

Plasma phosphate concentration is regulated by the kidney. In the urine, phosphate binds  $H^+$  ions and is eliminated as acid phosphate (a component of titratable acid). Phosphate release from the intracellular stores (mainly bone) is increased by PTH and  $1,25(OH)_2D_3$ . The proximal tubule reabsorbs approximately 80% of the filtered phosphate load; 10% is reabsorbed by the distal tubule; and 10% is excreted in the urine. Factors that increase the excretion of phosphate include PTH, glucocorticoids, volume expansion, dopamine administration, and acidosis. PTH is the main physiologic hormone regulating renal phosphate excretion, and it exerts this effect mainly by the inhibition of the  $Na^+-P_i$  cotransporter in the proximal tubule. There are three  $Na^+-P_i$  cotransporters: type I and type IIa and IIb. The type IIa cotransporter plays a key role in determining brush border  $Na^+-P_i$  cotransport, and thus the overall  $P_i$  homeostasis (Mürer et al, 2000). Several genetic defects resulting in isolated renal phosphate wasting are X-linked hypophosphatemic rickets, autosomal dominant hypophosphatemic rickets without hypercalciuria, and hereditary hypophosphatemic rickets with hypercalciuria. The X-linked syndrome is caused by mutation in the *PheX* gene that indirectly affects the  $Na^+-P_i$  cotransporter. Calcitonin and glucagon increase the excretion of phosphate. Phosphate renal transport also is modulated by changes in dietary intake.

During weeks 26 to 36 of gestation, the mean intrauterine accumulation of inorganic phosphate is close to 75 mg/kg/day (Wharton et al, 1987). At birth, approximately 80% of the phosphorus is in the bones (Royer, 1981). During early postnatal life, owing to the efficient intestinal absorption and renal retention of phosphate, the neonate is in a positive phosphate balance and presents with elevated plasma concentrations of this anion (Brodehl et al, 1982; Key and Carpenter, 1990). Although fetuses and neonates appear to synthesize PTH in response to hypocalcemia (Garel, 1987), the phosphaturic response to PTH is attenuated. This phenomenon may be due to a decreased sensitivity of the proximal tubule to the hormone and probably reflects homeostatic regulation at a time when phosphate retention is essential for growth. Growth hormone stimulates renal phosphate retention and increases the plasma concentration of phosphate.

### Regulation of Magnesium Homeostasis

Magnesium is the second most abundant intracellular cation. It plays a major role in the regulation of protein synthesis and bone formation and also plays a role in the regulation of potassium and calcium channels in cell membranes. The kidney maintains magnesium balance by excreting in the urine the amount of magnesium that is absorbed by the gastrointestinal tract in excess of the amount retained for growth. In normal conditions, approximately 3% of the filtered magnesium load is excreted in the urine. Magnesium is passively reabsorbed by the proximal tubule and the thick ascending limb. Regulation of magnesium excretion takes place in the thick ascending limb, where approximately 65% of the filtered load is reabsorbed. Factors that increase magnesium excretion include ECF volume expansion, acidosis, hypercalcemia, and hypermagnesemia. PTH decreases the excretion of magnesium. Most diuretics increase magnesium excretion.

During weeks 26 to 36 of gestation, the mean intrauterine accumulation of magnesium approximates 3.5 mg/kg/day (Wharton et al, 1987). At birth, the urinary excretion of magnesium is low (Chan et al, 1984). Magnesium excretion increases 10-fold during the first month of life, reaching values close to 2 mg/kg/day (De Santo et al, 1988). Plasma magnesium levels follow a circadian rhythm, being higher at night (De Santo et al, 1988). Neonatal hypomagnesemia is associated with intrauterine growth restriction, whereas neonatal hypermagnesemia frequently occurs following maternal magnesium administration in the immediate prenatal period. Mutations in the gene encoding the Na<sup>+</sup>,K<sup>+</sup>-ATPase  $\gamma$  subunit, localized on the basolateral membrane of the distal convoluted tubule, lead to magnesium wasting in the so-called *isolated renal magnesium wasting syndrome*, a rare autosomal dominant disorder.

### SUMMARY

Normal renal maturation and adaptive responses at birth play an essential role in the neonate and contribute to the establishment of an intracellular and extracellular milieu necessary for survival and appropriate growth. Renal development and function are regulated by numerous hormones,

paracrine factors, and signaling molecules. Recent advances in the understanding of the molecular basis of renal development and function have provided invaluable insights in the pathophysiology of inherited and acquired renal conditions during development. An understanding of the basic principles of renal developmental physiology is essential for the successful clinical management of sick preterm and term neonates.

## Clinical Evaluation of Renal and Urinary Tract Disease

Philippe S. Friedlich, Jacquelyn R. Evans,  
and Istvan Seri

### PRENATAL EVALUATION OF RENAL AND URINARY TRACT DISEASE

#### Prenatal Diagnosis

Ultrasound has become the most widely used and effective diagnostic tool in the prenatal evaluation of the fetal kidneys and urinary tract. Since the first report of the in utero ultrasound diagnosis of congenital renal disease in 1970 (Garett et al, 1970), the prenatal diagnosis of most forms of congenital renal and urinary tract malformations has been described. The detection rate of fetal congenital urologic abnormalities by ultrasonography is approximately 0.2% (Arger et al, 1986; Shackelford et al, 1992). Because the incidence of renal and urinary tract malformations in the general population is close to 1%, approximately 1 in 5 cases is diagnosed prenatally by ultrasound.

The most common indication for an ultrasound survey of the fetal genitourinary tract is the presence of oligohydramnios (Bruno et al, 1985). Another important indication is a positive family history of renal disease, because fetal urinary tract abnormalities have been reported in 8% of pregnancies in women with a family history of renal anomalies (Reuss et al, 1987).

The fetal kidneys can be identified by early in the second trimester (Patten et al, 1990). However, a more detailed view of the kidneys is usually appreciated only from weeks 28 to 30 of gestation. The normal ureter cannot be visualized by prenatal ultrasound examination. The normal fetal bladder can be routinely identified by 16 weeks of gestation, although it sometimes can be seen as early as 13 weeks (Patten et al, 1990).

Hydronephrosis is readily identifiable by prenatal ultrasonography and is most frequently due to ureteropelvic obstruction. Other causes of fetal hydronephrosis include bladder outlet or ureteral obstruction, polycystic kidney disease, multicystic dysplastic kidney disease, renal agenesis, congenital megaureter, duplication anomalies, reflux, and prune-belly syndrome. A mildly dilated (1 to 2 mm) renal pelvis has been reported in 41% of routine prenatal ultrasound examinations (Cohen and Haller, 1987). This is often a normal prenatal finding reflecting the functional dilatation of the urinary tract secondary to high fetal urine flow rates.

Although prenatal ultrasonography has become standard for fetal evaluation, there are many potential pitfalls

with use of this technique even in experienced hands. Because diagnostic error may occur up to 30% of the cases (Colodny, 1987), appropriate postnatal studies should always confirm the prenatal diagnosis. More recently, ultrafast magnetic resonance imaging (MRI) has been found to be a potentially useful adjunct to ultrasound examination in the evaluation of fetal renal diseases (Hubbard et al, 1999).

Fetal karyotype analysis and, in cases of certain types of obstructive uropathy, serial measurements of urine osmolality and electrolyte and protein excretion assist in the intrauterine diagnostic evaluation of fetuses with suspected renal and urinary tract anomalies (Johnson et al, 1994; Sullivan and Adzick, 1994). Detection of elevated amniotic fluid  $\alpha$ -fetoprotein in conjunction with normal acetylcholinesterase activity suggests the intrauterine diagnosis of congenital nephrotic syndrome (Ghidini et al, 1994). Recently, prenatal diagnosis of the autosomal dominant form of polycystic kidney disease using DNA probes also has become available.

#### Prenatal Management

In fetuses with severe obstructive uropathy, if the condition is bilateral or if there is a solitary kidney, the decrease in fetal urine output results in severe oligohydramnios or anhydramnios, leading to pulmonary hypoplasia, the Potter sequence, and extremely high neonatal mortality rates. Early obstruction affects normal glomerular and tubular differentiation and, if untreated, leads to the development of irreversible renal dysplasia. Percutaneous vesicoamniotic shunt, bladder stenting, and open bladder marsupialization constitute the choices for fetal intervention (Sullivan and Adzick, 1994). The goal of prenatal management is to relieve the obstruction during the most active period of nephrogenesis—that is, between 20 and 32 weeks of gestation (Crombleholme et al, 1988).

The integrated evaluation of the findings on prenatal ultrasonography, fetal karyotyping, and fetal urine electrolyte, osmolality and protein studies has been used to identify those fetuses with bilateral obstructive uropathies whose have not yet progressed to a stage of irreversible renal damage. Because only the third or fourth urine sample is predictive of long-term prognosis (Evans et al, 1991; Johnson et al, 1994), performance of serial vesicocenteses at 48- to 72-hour intervals is recommended. On the third or fourth urine examination, a sodium level of less than 100 mg/dL, osmolality of less than 200 mOsm/L, total protein of less than 20 mg/dL, and  $\beta_2$ -microglobulin of less than 4 mg/L are considered to be indications for fetal surgery.

In addition to the predicted long-term renal outcome, other important factors influencing prenatal management of fetuses with obstructive uropathy include gestational age, lung maturity, and presence of associated anomalies. If associated life-threatening anomalies or chromosome abnormalities are detected, the options are expectant management and termination of pregnancy. For the fetus with isolated obstructive uropathy and predicted irreversible renal dysplasia, in utero decompression is not recommended. In fetuses with isolated obstructive uropathy but predicted good long-term renal outcome, treatment depends

on gestational age and lung maturity. At less than 32 weeks of gestation, intrauterine decompression is advocated. Indeed, preliminary long-term outcome studies in this group of patients suggest that antenatal vesicoamniotic shunt placement may benefit the fetus suffering from severe obstructive uropathy (Freedman et al, 1999). At 32 weeks of gestation or beyond, maternal steroid treatment and, once lung maturity is achieved, delivery of the infant is recommended. Fetuses with immature lungs and isolated obstructive uropathy with normal or only mildly diminished amniotic fluid volume do not require active intervention in utero (Johnson et al, 1994).

## POSTNATAL EVALUATION OF RENAL AND URINARY TRACT DISEASE

### History

Renal disease in the newborn is more likely when there is a family history of renal disease including urinary tract anomalies, renal agenesis, hereditary nephritis, polycystic kidney disease, medullary cystic disease, vesicoureteral reflux, and renal tubule disorders such as Fanconi syndrome, cystinuria, and nephrogenic diabetes insipidus. Appropriate screening of neonates for renal disease who have a positive family history of inherited diseases associated with renal anomalies also is indicated.

### Prenatal and Perinatal History

A history of oligohydramnios or anhydramnios suggests the presence of bilateral renal agenesis, severe renal dysplasia, or obstructive uropathy. Polyhydramnios, on the other hand, may occur with fetal nephrogenic diabetes insipidus. A difficult delivery secondary to increased abdominal girth may signal the presence of renal masses. A disproportionately large placenta should prompt appropriate studies to rule out congenital nephrotic syndrome in the neonate (Mahan et al, 1984). A history of perinatal asphyxia, acute hemorrhage, sepsis, hyaline membrane disease, antenatal or postnatal indomethacin therapy, and hypernatremic dehydration of the very low-birth-weight (VLBW) neonate are conditions that should alert the clinician to the possibility of the development of postnatal acute renal failure.

### Evaluation of Presenting Signs and Symptoms: Laboratory Tests and Methods of Evaluation of Renal Function

**Urine Collection.** Urine collection in the newborn is most commonly performed by the use of special collection bags. With the exemption of urine culture studies, this method provides an adequate sample for most of the routine tests. To document urinary tract infection, suprapubic bladder aspiration is recommended as the most reliable method of obtaining a urine specimen. Bladder catheterization is used mainly in infants who fail to pass urine after the first day of life, and in severely ill neonates who are paralyzed or heavily sedated.

**Urinalysis.** Analysis of the urine in the normal term newborn during the first few days of life shows a specific gravity

of 1.001 to 1.021, with a corresponding osmolality of 50 to 800 mOsm/L. Maximum urine osmolality in preterm infants is less than in term neonates. The impaired concentrating capacity of the newborn kidney is the consequence of renal anatomic and functional immaturity, including the decreased hypertonicity of the renal medulla and the relative insensitivity of the immature collecting tubule to vasopressin (Roy et al, 1992).

**Proteinuria.** During the first few days of life, proteinuria can be detected in 76% of healthy newborns. Conditions affecting renal blood flow and tubular function, such as dehydration or perinatal asphyxia, frequently result in a usually transient but significant proteinuria. However, proteinuria with levels greater than 30 mg/dL in a concentrated urine persisting beyond the first week of life suggests glomerular and/or tubular injury and requires further evaluation (Aviles et al, 1992). Persistent and massive proteinuria may indicate congenital nephrotic syndrome and necessitate renal biopsy.

**Hematuria, Hemoglobinuria, and Myoglobinuria.** Normal newborns do not have hematuria, hemoglobinuria or myoglobinuria. Hematuria may occur in patients with perinatal asphyxia, acute renal failure, renal vein or artery thrombosis, congenital urinary malformations including autosomal recessive polycystic kidney disease and obstructive uropathies, coagulopathies, urinary tract infections, and trauma. Hematuria in a neonate with an umbilical artery catheter in place should alert the clinician to the possibility of aortic or renal artery thrombosis. Finally, transient hematuria is a common finding in critically ill neonates. Hemoglobinuria and myoglobinuria may manifest in patients with intravascular hemolysis and rhabdomyolysis, respectively.

**Uric Acid, Electrolyte, Glucose, and Amino Acid Excretion.** Owing to increased uric acid production and fractional excretion, urinary excretion of uric acid is high during the first week in normal preterm and term infants, causing colored diaper stains and false-positive tests for proteinuria. However, because the newborn's urine is dilute and not significantly acidic, uric acid precipitation and acute urate nephropathy are rare in the neonatal period. As a result of the immaturity of their renal tubular transport processes, premature neonates also excrete more sodium, bicarbonate, phosphorus, glucose, and amino acids in the urine than is normal for term neonates (Jones and Chesney, 1992).

**Sediment.** The urinary sediment of the normal newborn contains fewer than 5 squamous epithelial cells, 0 to 2 red blood cells, and fewer than 5 white blood cells per high-power field. The most common cause of leukocyturia is urinary tract infection. The presence of casts in the sediment usually suggests an involvement of the upper urinary tract in the disease process. Red blood cell casts indicate glomerular injury; white blood cell casts are present with infection or interstitial and/or tubular damage. Epithelial cell casts and granular casts may be seen in newborns with severe dehydration or also may represent

interstitial and/or tubular injury. Hyaline casts are detected in cases of severe proteinuria or dehydration.

**Serum Chemistry and Clearance Studies.** Serum chemistry and clearance studies reflect the status of fluid and electrolyte balance and renal function. Owing mainly to their excessive insensible water losses during the first few days of life (Sedin, 1995), very immature preterm infants cared for under radiant warmers require frequent serum electrolyte studies as well as close monitoring of the changes in their body weight and urine output to guide daily fluid administration (see Chapter 30, Acid-Base, Fluid, and Electrolyte Management).

An ideal endogenous substance that can be utilized to characterize glomerular function must have a constant turnover rate and be freely filtered and must not be reabsorbed, secreted, protein bound, or subject to synthesis, metabolism, or storage by the kidney. Although the turnover rate of creatinine is unknown in sick neonates and creatinine is not only filtered but also secreted and reabsorbed by the immature kidney (Aviles et al, 1992; Bueva and Guignard, 1994), it is the endogenous substance that comes closest to fulfilling these requirements. In clinical practice, sequential determination rather than a single value of serum creatinine gives the most valuable information on glomerular filtration rate (GFR).

In term infants, serum creatinine is approximately 0.8 mg/dL at birth and remains between 0.7 and 0.9 mg/dL during the first 2 days of life (Bueva and Guignard, 1994; Feldman and Guignard, 1982). Thereafter, serum creatinine gradually decreases to approximately 0.5 mg/dL by 1 week of age and to approximately 0.4 mg/dL by the end of the first month (Bueva and Guignard, 1994; Feldman and Guignard, 1982). During the first few days of life, serum creatinine levels are significantly higher in preterm than in term infants (0.8 to 1.8 mg/dL versus 0.7 to 0.9 mg/dL), with the highest levels observed in the most immature neonates (Bueva and Guignard, 1994; Stonestreet and Oh, 1978). This finding supports the notion that GFR is very low in the preterm infant, who immediately after birth is unable to eliminate the excess creatinine transferred in utero from the mother (Aviles et al, 1992; Bueva and Guignard, 1994). However, by the second week of life, serum creatinine begins to fall, and drops below 0.6 mg/dL, even in the 1-month-old VLBW infant (Bueva and Guignard, 1994).

In addition to serum creatinine, blood urea nitrogen (BUN) has been used widely in clinical practice to assess renal function. However, as BUN is also influenced by the state of hydration, protein intake, and urinary flow rate, it is a much less reliable marker of renal function than serum creatinine.

Applying the concept of clearance measurements, the rate of sodium and water reabsorption also may be estimated in the different nephron segments (Aviles et al, 1992). Despite its limitations, this method is the only way to assess sodium and water reabsorption along the nephron in the intact human kidney. The information obtained may then be used to detect changes in proximal and distal tubule sodium and water handling during development and/or disease. For a concise review on this subject, the

reader is referred to the article by Avilles and coauthors (1992).

### Evaluation of Presenting Signs and Symptoms: Physical Examination

**Disorders of Micturition.** Although many healthy newborn infants do not void until 12 to 24 hours of life, 92% to 100% of them will pass urine by the end of the first day (Clark, 1977). The delay in voiding in the healthy newborn is mostly due to labor- and delivery-triggered cardiovascular and hormonal changes and their effects on renal function. Among others, a significant increase in vasopressin (Ramin et al, 1991) and catecholamine release (Lagercrantz and Bistoletti, 1973; Mehandru et al, 1993) occurs during labor and delivery. These hormonal changes contribute to the decrease in the effective circulating plasma volume (Brace, 1992) and also directly cause renal vasoconstriction and an augmentation of sodium and water reabsorption. If a newborn has not passed urine during the first 24 hours of life, the presence of hypovolemia or other causes of compensated shock or severe bilateral renal and/or urinary tract anomalies should be considered.

**Abdominal Masses.** Deep abdominal palpation can be most easily performed during the first 24 hours of life, when abdominal tone is still somewhat decreased and air does not completely fill the gastrointestinal tract. Thereafter, deep abdominal palpation is best done with the sucking reflex evoked, as this reflex also induces abdominal muscle relaxation. Palpable abdominal masses are present in 0.2% to 0.6% of newborns (Museles et al, 1971; Perlman et al, 1976). Two thirds of these masses are of renal origin; most of the remainder arise from the adrenal gland, the gastrointestinal tract, the female genitalia, or the liver. Hydronephrosis and dysplastic and polycystic kidney disease lead most frequently to palpable renal masses during the neonatal period. In the case of a midline abdominal mass, the presence of posterior urethral valves or a neurogenic bladder should always be considered. The discovered abdominal mass should then be further studied by ultrasonography, computed tomography (CT) scan, and/or MRI and, if appropriate, by renal cystourethrography, radionuclide scan, or intravenous pyelography.

**Edema.** Accumulation of fluid in the interstitial space is a frequent finding in preterm and term neonates and occurs as a result of an imbalance in Starling forces and/or decreased lymphatic drainage. In the newborn with acute renal failure, *generalized edema* is most frequently due to a relative fluid overload in face of the markedly decreased GFR. In neonatal nephrotic syndrome, edema develops because increased urinary protein losses result in a marked drop in colloid osmotic pressure. In the edematous neonate with renal disease, additional hormonal factors may also contribute to the pathophysiology of edema formation. Such factors include the elevated activity of the renin-angiotensin-aldosterone system, increased bradykinin and prostaglandin production, high neonatal plasma prolactin levels, and the attenuation of the renal effects of atrial natriuretic peptide.

However, generalized edema in the neonatal period occurs most frequently with conditions other than primary renal disease. Otherwise healthy premature neonates and term infants born to diabetic mothers may present with generalized edema due to complex, hormone-regulated alterations in the dynamics of their physiologic fluid shift during early neonatal adaptation. Frequent iatrogenic causes of edema formation include volume overload, aggressive sodium supplementation during the period of early neonatal adaptation, and, in cases of late edema formation in the preterm neonate, maintenance of a high sodium intake after the infant converts from the sodium losing to the sodium-retaining state (see also Chapter 30, Acid-Base, Fluid and Electrolyte Management). Generalized edema also is a prominent clinical feature of congestive heart failure and of neonatal conditions characterized by generalized capillary leak including hypoxia, sepsis, and shock. Other, less common causes of generalized edema include severe anemia, liver failure, protein-losing enteropathy, congenital infections, syndrome of inappropriate secretion of antidiuretic hormone, congenital analbuminemia, vitamin E deficiency, hyperaldosteronism, and hereditary angioneurotic edema.

Characteristic congenital *localized edema* is present in neonates with gonadal dysgenesis and primary lymphedema (Milroy disease) (Greenlee et al, 1993). Localized edema in the sick neonate also occurs with impairment of venous return and/or lymphatic drainage, as seen in the frequently catheter-related thromboses of major veins including the superior and inferior venae cavae and the femoral and axillary veins. Of iatrogenic origin and mostly of a benign nature is the localized limb edema associated with use of restrictive boards to protect intravenous sites.

**Ascites.** Renal causes of intraperitoneal accumulation of fluid in the neonate include congenital urinary tract obstruction and nephrotic syndrome. The ascites in congenital urinary tract obstruction represents urine that has entered the peritoneal cavity following the rupture of the renal pelvis or one of the calyces. The ascitic fluid usually undergoes peritoneal dialysis and may lose most of the chemical characteristics of urine. If the abdominal ultrasound examination also demonstrates the presence of a thickened bladder wall, bladder outlet obstruction is the most likely diagnosis. The ascetic fluid in nephrotic syndrome has the character of an exudate. Nonrenal causes of ascites include bacterial or chemical peritonitis, congenital anomalies of the abdominal lymphatic system or biliary tree, malrotation, incomplete volvulus, ruptured ovarian cyst, and, extremely rarely, pancreatitis secondary to congenital pancreatic duct anomaly.

**External Genitalia.** In general, an association between anomalies of the external genitalia and the upper urinary tract is infrequent. In the male, however, abnormalities of mesonephric development may lead to unilateral or bilateral renal agenesis and lack of testicular development. In the female, such abnormalities may result in unilateral or bilateral renal agenesis and uterine abnormalities. Furthermore, neonates with bilateral cryptorchidism, with unilateral cryptorchidism and hypospadias, or with penoscrotal or perineoscrotal hypospadias, who require thorough clinical

and genetic evaluation for appropriate gender assignment, may also benefit from a renal ultrasound study to rule out possible renal and/or upper urinary tract anomalies (Laurance et al, 1976).

**Hypertension** As discussed in Chapters 82, 83, and 87, renal parenchymal and vascular diseases as well as urinary tract anomalies may lead to the development of systemic hypertension. Therefore, a diagnostic work-up of neonatal hypertension should always include, but not be limited to, the evaluation of renal anatomy, function, and vascular integrity.

### Evaluation of Renal and Urinary Tract Morphology

**Ultrasonography.** Ultrasonography has become the primary imaging technique in the postnatal evaluation of renal and urinary tract disorders in the newborn. Prenatal findings suggestive of urogenital anomalies require follow-up evaluation with a postnatal sonogram. The most common reasons for postnatal ultrasonographic assessment of the urinary tract are a prenatal finding of fetal hydronephrosis, urinary tract infection, and the detection of an abdominal mass in the newborn. However, oligohydramnios in the absence of signs of placental dysfunction, unexplained tension pneumothorax in a nonventilated infant, failure to void, a poor urinary stream, the presence of a single umbilical artery, abnormal and/or low-set ears, perineal and/or anal anomalies, vertebral anomalies, with or without the VATER (vertebral defects, imperforate anus, tracheoesophageal fistula, radial and renal dysplasia) or VACTERL (i.e., VATER plus cardiac abnormalities and limb defects) association, decreased abdominal wall musculature, unexplained elevation of serum creatinine, significant hematuria, proteinuria, renal tubular acidosis, and/or a urinary tract infection also are indications for ultrasonographic evaluation of the urinary tract in the neonatal period. Finally, because prolonged administration of furosemide is associated with an increased incidence of nephrocalcinosis, screening ultrasound examinations are warranted in neonates on chronic diuretic treatment with furosemide in the presence of hematuria.

Doppler ultrasonography, a noninvasive method of detecting renal blood flow, is helpful in the evaluation of suspected renal arterial and venous thrombosis.

**Voiding Cystourethrography.** Voiding cystourethrography (VCUG), an important complement to ultrasonography, can identify anatomic and/or functional abnormalities in lower urinary tract disorders. It is particularly important in the evaluation of urinary tract infection for the detection and assessment of vesicoureteral reflux.

Radionuclide cystography is associated with significantly decreased radiation exposure to the patient compared to VCUG and has gained acceptance for use in the pediatric population, especially for follow-up evaluation of vesicoureteral reflux in children. However, it has considerable technical limitations in the newborn, and it has not been widely used in this patient population.

**Radionuclide Renal Imaging.** Renal scintigraphy provides information about renal blood flow and function and is utilized primarily in follow-up evaluation of infants with

obstructive uropathy. It has all but replaced intravenous urography in the neonate, especially during the first 2 weeks of life, when renal concentrating ability, essential to visualization of the iodinated agents used in the scan, is limited. Although renal scintigraphy provides less anatomic detail than is shown with intravenous urography, it offers useful physiologic information with reasonable anatomic definition and less radiation exposure. It also is a reliable quantitative method of monitoring renal function before and after surgery for obstructive uropathy.

**Angiography.** Because of advances in Doppler ultrasonography and radionuclide scintigraphy techniques, renal angiography has been used less frequently in the neonate. It provides accurate anatomic information of the renal arterial and venous circulation but is invasive and poses a significant radiation exposure to the newborn.

**Renal Computed Tomography and Magnetic Resonance Imaging.** Both renal CT and MRI techniques provide high-resolution cross-sectional imaging. However, with most indications for neonatal renal imaging, CT and MRI do not offer a significant advantage over sonography or renal scintigraphy. CT and MRI also usually require sedation and immobilization. They may play a role in neonatal uroimaging, however, when findings of other techniques are inconclusive.

**Renal Biopsy.** Ultrasound-guided renal biopsy is performed in neonatal renal diseases if a tissue sample is required for the final diagnosis. Such conditions include, but are not limited to, Finnish-type nephrotic syndrome, nail-patella syndrome, autosomal recessive and autosomal dominant polycystic kidney disease, glomerulocystic kidney disease, and complex tubular functional abnormalities.

## Developmental Abnormalities of the Kidneys

Bernard S. Kaplan

The increasing use of prenatal ultrasonography, continuing improvements in ventilator and nutritional support, and progress in dialysis techniques for newborns and renal transplantation for young children have changed the natural history of cystic and dysplastic kidney diseases. Information gathered from many sources must be evaluated carefully for optimal management of a newborn with a genetic or developmental disorder of the kidneys. Clearly, a team approach is needed. Errors occur with insufficient data, inadequate communication, and poor understanding of the natural history of these disorders (Guay-Woodford et al, 1998; Kaplan et al, 1992).

Many newborns who might have died in the past now can be dialyzed from birth and then undergo kidney transplantation when they attain a weight of about 10 kg. A precise diagnosis must be made before starting dialysis because some of these problems impose enormous emotional and financial burdens on families of affected children. The diagnosis depends on the evaluation of the findings on prenatal history, fetal ultrasonography, family history, clinical examination, imaging studies of the infants and parents when indicated, and laboratory studies (including DNA tests if available) and interpretation of pathologic examination findings. Several guiding principles are worth keeping in mind. Few genetic renal disorders are confined to the kidneys, and many syndromes have associated renal involvement. Therefore, ultrasonography of the kidneys and urinary tract should be done in all newborns with multiple defects. Also, ultrasonographic features can change over time. Variable expression of congenital renal defects may occur within and among kindreds; this is particularly true in autosomal recessive polycystic kidney disease. Many classifications of cystic and dysplastic kidneys have been devised, but the one shown in Table 82-1 lists the conditions that can be seen in newborns.

### ECTOPIC KIDNEY, HORSESHOE KIDNEY, AND CROSSED FUSED ECTOPIA

Ectopic kidney, horseshoe kidney, and crossed fused ectopia are abnormalities in the position of the kidney(s) that do not have important long-term effects unless these conditions are associated with lower urinary tract anomalies, such as reflux or obstruction. In essence, affected kidneys are at risk for the same problems as those in nor-

mal positions. Horseshoe kidney, however, does occur with increased frequency in Turner syndrome and other syndromes. Avoiding cystourethrogram should be done to exclude the possibility of reflux, and a technetium 99m-labeled diethylenetriaminepenta-acetic acid (DTPA) scan also should be performed if there is evidence on ultrasonography of an obstruction.

### MULTICYSTIC KIDNEY

Multicystic kidney is the second most common cause of a flank mass in the newborn, with a prevalence rate of 1/4300. Multicystic kidney is almost always a sporadic, nonsyndromal, congenital anomaly. The diagnosis is made by in utero ultrasonography or by detection of an abdominal mass. Multicystic kidney is rarely the cause of symptoms in the newborn. Pathologic findings are ureteropelvic dysplasia or atresia, enlarged kidney, and cysts of varying size that do not communicate, with no demonstrable pelvis or calyces (Bernstein, 1991) (Fig. 82-1). Multicystic kidney must be differentiated from obstructive cystic renal dysplasia associated with hydronephrosis and other causes of obstructive uropathy by doing a DTPA scan. The multicystic kidney does not function. The contralateral kidney usually is normal, but in up to 50% of the cases it may be hydronephrotic, ectopic, refluxing, or occasionally dysplastic, or it may be absent (Atiyeh et al, 1992). Some investigators have postulated a spectrum, within and among kindreds, of caliceal diverticulum, pyelogenous cyst, ureteropelvic junction stenosis, infundibular stenosis, pelvic stenosis, and multicystic kidney (Kelalis and Malek, 1981). In most patients, follow-up evaluation by ultrasonography is done, and spontaneous involution often occurs without complications of infection, bleeding, or malignancy (Wacksman and Phipps, 1993).

### RENAL ADYSPLASIA AND DYSPLASIA

The term *adysplasia* encompasses a spectrum of renal anomalies that include renal agenesis, hypoplasia, and dysplasia, any of which may occur in an individual patient (such as unilateral agenesis with contralateral dysplasia) or within a kindred (Buchta et al, 1973). Dysplastic kidneys can be unilateral or bilateral, often contain cysts, are disorganized, and may also contain ectopic cartilage and muscle. They may or may not function. The clinical picture depends on the severity of the renal anomaly, whether it is unilateral or bilateral, and the presence of associated anomalies. The newborn may look normal or may have features of the oligohydramnios sequence, prune-belly syndrome, or a malformation syndrome.

Adysplasia and dysplasia can be the result of a single autosomal recessive (Cole et al, 1976) or dominant gene disorder (McPherson et al, 1987). Absent or dysplastic kidneys also can occur by multifactorial inheritance (Holmes, 1989), in chromosomal disorders (Egli and Stalder, 1973), or as a consequence of in utero infections or exposure to toxins. Prenatal diagnosis by ultrasonography is possible, especially if there is oligohydramnios or associated anomalies such as limb defects.

TABLE 82-1

**Cystic and Dysplastic Kidneys in Newborns**

Ectopic kidney, horseshoe kidney, crossed fused ectopia
Multicystic kidney
Unilateral renal agenesis
Bilateral renal agenesis
Renal adysplasia/dysplasia
Isolated adysplasia/dysplasia
Dysplasia/adysplasia in regional defects
Prune-belly syndrome (PBS) [McKusick #100100]
Posterior urethral valves (PUV) [McKusick #100100]
Adysplasia/dysplasia with multiple-congenital-abnormalities syndromes
Branchio-otorenal dysplasia (BOR syndrome) [McKusick #113650]
Mayer-Rokitansky-Küster-Hauser syndrome
Kallmann syndrome (KAL1) [McKusick #308700]
Acrorenal syndromes
Ectodermal dysplasia, ectrodactyly, cleft lip/palate syndrome
Fanconi pancytopenia syndrome
Thrombocytopenia-absent radius syndrome
Townes-Brocks syndrome (TBS) [McKusick #107480]
Fraser syndrome [McKusick #219000]
Fryns syndrome
Pallister-Hall syndrome [McKusick #146510]
Polycystic kidneys
Autosomal recessive polycystic kidney disease [McKusick #263200]
Autosomal dominant polycystic kidney disease [McKusick #179300]
Tuberous sclerosis (TS) [McKusick #191100]
Cystic kidneys with autosomal recessive inheritance
Meckel syndrome (MKS 1, MKS 2) [McKusick #249000]
Jeune asphyxiating thoracic dystrophy syndrome [McKusick #208500]
Renal-hepatic-pancreatic dysplasia (Ivemark syndrome)
Hypoplastic kidneys
Glomerulocystic kidneys
Dysgenetic kidneys
Congenital hypernephronic nephromegaly with tubular dysgenesis [McKusick #267430]
Overgrowth syndromes
Beckwith-Wiedemann syndrome [McKusick #130650]
Perlman syndrome [McKusick #267000]
Simpson-Golabi-Behmel syndrome type 1 (SGBS1) [McKusick #312870]
In utero exposure to teratogens
Anticonvulsants; cocaine; indomethacin; lead; phenacetin; salicylate; warfarin; gentamicin
Inborn errors of metabolism
Glutaric aciduria type II (multiple acyl-CoA dehydrogenase deficiencies)
Zellweger cerebrohepatorenal syndrome [McKusick #214100]
Carbohydrate-deficient glycoprotein syndrome

CoA, coenzyme A.

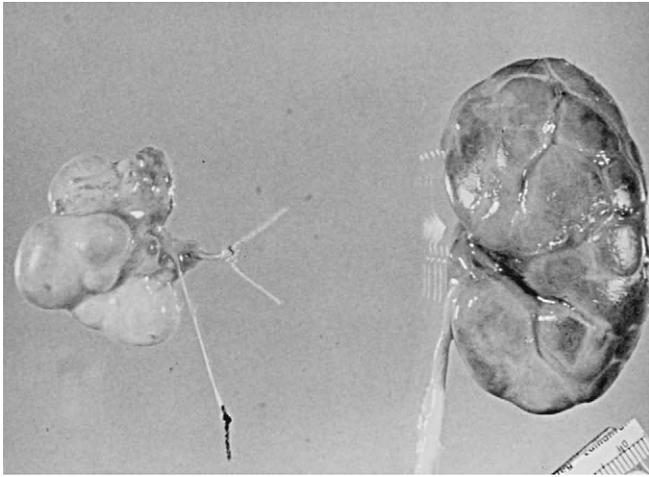

**Unilateral Renal Agenesis**

Unilateral renal agenesis usually is an isolated (nonsyndromic), sporadic abnormality that is detected during prenatal ultrasonography. Unilateral renal agenesis is an important finding if the solitary kidney is abnormal, is part of a syndrome, or is an expression of hereditary renal dysplasia (Moerman et al, 1994). The incidence is between 1/500 and 1/800 live births. If the solitary kidney is normal, there is little risk of chronic renal failure in adulthood. The newborn must be examined carefully for additional anomalies: cleft palate, preauricular pits, cardiac and vertebral defects, and müllerian duct aplasia (Tarry et al, 1986). A voiding cystourethrogram should be done to exclude reflux. No further evaluations are needed beyond 1 year of age if at that time

renal ultrasonography shows that the kidney is growing normally, with appropriate compensatory hypertrophy.

**Bilateral Renal Agenesis**

Bilateral renal agenesis can occur as an isolated (nonsyndromal), sporadic abnormality detected during prenatal ultrasonography. It also can be a component of a syndrome such as the branchio-otorenal dysplasia (BOR) syndrome or can be an expression of hereditary renal adysplasia. Variable expression within a family is possible, with both autosomal recessive and dominant modes of inheritance. The incidence is about 1 in 3000 births. Bilateral renal agenesis is an important cause of the oligohydramnios

**FIGURE 82-1.** Multicystic kidney with atretic ureter (*right*). Large cysts with no normal renal tissue.

sequence (Potter syndrome), in which decreased amniotic fluid causes uterine compression of the fetus. This produces the characteristic Potter facies with wide-set eyes, a prominent skin fold that extends from medial canthus to cheek, a parrot-beak nose, pliable low-set ears, and receding chin. Other features are lower limb deformations and, most important, a narrow, small chest with pulmonary hypoplasia. The infant is anuric and dies from pulmonary insufficiency. Bilateral renal agenesis is the most important cause of oligohydramnios, and the diagnosis can be confirmed by prenatal ultrasonography.

### Isolated Dysplasia and Adysplasia

The incidence of isolated (nonsyndromic) bilateral renal dysplasia is about 15 per 100,000 newborns (Holmes, 1989). Modes of transmission are autosomal dominant

inheritance with reduced penetrance and multifactorial inheritance. A parent and siblings may be unaffected or have unilateral dysplasia or unilateral agenesis. Sporadic adysplasia may be caused by a new mutation or inheritance of the gene(s) from a nonmanifesting parent. First-degree relatives should be screened by ultrasonography to provide genetic counseling. The empirical risk of bilateral renal adysplasia for future siblings is 3.5% (Carter, 1970). The recurrence risk increases if two siblings are affected.

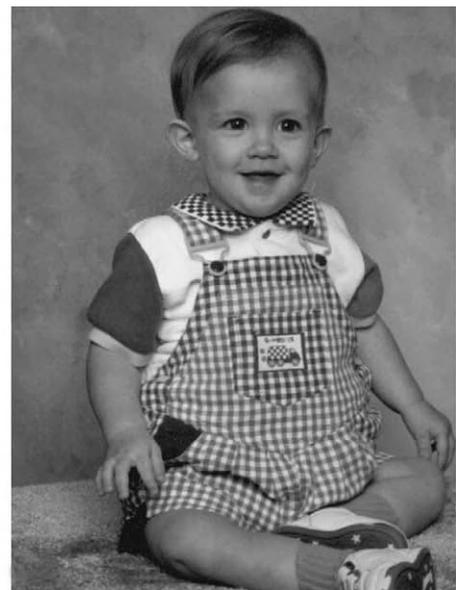

### Dysplasia and Adysplasia in Regional Defects: Prune-Belly Syndrome and Posterior Urethral Valve

Renal adysplasia occurs in prune-belly syndrome (PBS) [McKusick #100100] and posterior urethral valve (PUV) [McKusick #100100], possibly as a result of obstructive uropathy (Bernstein, 1991). Findings on renal pathologic examination range from minor anomalies to severe dysplasia with and without cysts. The features of PBS are deficient abdominal wall muscles (Fig. 82-2), unilateral or bilateral undescended testes, and urinary tract abnormalities. Females are rarely affected but may have uterine or vaginal anomalies. PBS also is associated with lower intestinal tract malrotation and atresias, lower limb deformations, and cardiovascular defects.

PUV is characterized by presence of a urethral valve (either a flap valve or a diaphragm in the prostatic urethra) and features of obstructive uropathy. A dilated prostatic urethra, megacystis, and megaureters can occur in both PBS and PUV. In both conditions, the most frequent clinical presentation in the newborn is that of the oligohydramnios sequence. The survival of newborns with PBS or PUV depends on the severity of pulmonary hypoplasia and the severity of renal dysplasia. Both

A

B

**FIGURE 82-2.** **A**, Newborn with prune-belly syndrome. The abdomen is protuberant, and the outlines of the intestines can be seen. The right ureter ruptured into the amniotic sac, thereby preventing development of the features of oligohydramnios sequence. **B**, The same patient at age 19 months.

conditions are usually isolated occurrences, although PUV may occur in families and in malformation syndromes. Prenatal diagnosis and treatment are discussed in detail in Chapter 81.

## Dysplasia and Adysplasia with Multiple Congenital Anomalies

### Branchio-otorenal Dysplasia (Branchio-otorenal Syndrome)

The spectrum of renal anomalies in BOR syndrome [McKusick #113650] ranges from unilateral dysplasia to bilateral agenesis. The kidneys may be even normal. Renal function ranges from normal to severe reduction in glomerular filtration rate. Extrarenal manifestations are preauricular pits, branchial clefts, sensorineural deafness, and lacrimal duct atresia. The incidence is about 1/40,000. Inheritance is autosomal dominant with high penetrance and variable expression. One mutant gene, *EYAI*, is on chromosome 8q13.3 (Abdelhak et al, 1997; Kumar et al, 1997). The prognosis depends on the severity of the renal disorder.

### Mayer-Rokitansky-Küster-Hauser Syndrome

Females with Mayer-Rokitansky-Küster-Hauser syndrome have renal adysplasia and müllerian anomalies of vaginal atresia and bicornuate or septate uterus (Tarry et al, 1986). The fallopian tubes, ovaries, and broad and round ligaments are normal. There is a normal female karyotype and normal secondary sexual development.

### Kallmann Syndrome (Hypogonadotropic Hypogonadism and Anosmia)

Males with Kallmann syndrome (KAL1) [McKusick #308700] have hypogonadotropic hypogonadism that manifests with delayed puberty and infertility, anosmia caused by agenesis of the olfactory lobes, and renal abnormalities (Colquhoun-Kerr et al, 1999; Deeb et al, 2001; Dissaneevate et al, 1998; Hardelin et al, 1992). Urogenital abnormalities include unilateral renal agenesis, bilateral renal agenesis, multicystic dysplastic kidney, cryptorchidism, testicular atrophy, and micropenis. Males may die at birth as a result of bilateral renal agenesis. Additional features include coloboma of the iris, deafness, midline anomalies, oculomotor apraxia, and congenital facial diplegia (Möbius anomaly). The X-linked form is the result of a mutation in the *KALI* gene on Xp22.3. Treatment with testosterone or estrogen for induction of puberty induces appropriate pubertal development.

### Acrorenal Syndromes

Radial and renal anomalies occur in many syndromes. In the *ectodermal dysplasia-ectrodactyly-cleft lip and/or palate (EEC 1) syndrome* [McKusick #128930], there are combinations of urogenital defects, ectrodactyly, ectodermal dysplasia, clefting, lacrimal duct anomalies, and conductive hearing loss. Inheritance is autosomal dominant,

with variable penetrance and expression. In the *VACTERL/VATER association* [McKusick #192350], there is variable occurrence of vertebral anomalies, anal atresia, congenital cardiac disease, tracheoesophageal fistula, renal abnormalities, and radial-limb dysplasia. Occurrence of VACTERL usually is sporadic. Neonates with features of VACTERL must be tested for Fanconi anemia. Congenital malformations occur in 60% of cases of *Fanconi anemia (pancytopenia) syndrome*. Affected patients may have renal malformations, short stature, café-au-lait spots, radial-ray abnormalities, gastrointestinal, microcephaly, skeletal abnormalities, and, in males, genital anomalies, hypogonadism and infertility (Giampietro et al, 1993). Other features are chromosomal instability and mutagen hypersensitivity in cells. Inheritance is autosomal recessive, with variable expression and mutations in one of at least seven different genes (Joenje and Patel, 2001). Renal anomalies also may occur in *thrombocytopenia-absent radius syndrome (TAR)* [McKusick #274000].

The clinical features of *Townes-Brocks radial-ear-anal-renal syndrome (TBS)* [McKusick #107480] include broad, bifid, or triphalangeal thumb; flat thenar eminences; small, “lop,” or “satyr” external ear and preauricular pits or tags; sensorineural hearing loss; and imperforate or stenotic or anteriorly placed anus. Renal and urologic anomalies encompass renal hypoplasia, renal dysplasia, unilateral renal agenesis, horseshoe kidney, posterior urethral valves, uretero-vesical reflux, and meatal stenosis (Salerno et al, 2000). Inheritance is dominant, with a defect in the gene encoding *SALL1* on chromosome 16q12.1. Renal anomalies can occur in association with numerous other abnormalities in *Fraser syndrome* [McKusick #219000] (Schauer et al, 1990), *Fryns syndrome* [McKusick #229850] (Moerman et al, 1988), and *Pallister-Hall congenital hypothalamic hamartoblastoma syndrome (PHS)* [McKusick #146510] (Killoran et al, 2000).

## POLYCYSTIC KIDNEYS

The term *polycystic kidneys* should be applied only to autosomal recessive polycystic kidneys and autosomal dominant polycystic kidneys. In these conditions, there are many cysts in both kidneys, there is no evidence of renal dysplasia, and there is continuity of the lumen of the nephron from the uriniferous space to the urinary bladder. Patients with tuberous sclerosis can have cystic kidneys that appear identical by ultrasonography to autosomal dominant polycystic kidneys.

### Autosomal Recessive Polycystic Kidney Disease

The incidence of autosomal recessive polycystic kidney disease (ARPKD) [McKusick #263200] is about 1 in 16,000 newborns. Inheritance is autosomal recessive; there may be variable expression within a sibship (Kaplan et al, 1988), and the parents are unaffected. The gene locus is chromosome 6p21.1-p12 (Guay-Woodford et al, 1995; Zerres et al, 1998). In the newborn, the kidneys are much more severely affected than the liver, whereas liver disease is more prominent when the disorder is

diagnosed in older children. Features of the oligohydramnios sequence are present if there is severe oliguria or anuria in utero. The abdomen is protuberant, and the kidneys are large and easily palpable. Hypertension often is severe, may be caused by volume expansion, and can be difficult to control. Peripheral renin activity and aldosterone excretion are reduced (Kaplan et al, 1989). Hyponatremia often is induced iatrogenically as a result of inappropriate administration of free water and is not associated with increased urinary losses of sodium (Kaplan et al, 1989). Furosemide or metolazone may correct hyponatremia, but additional sodium chloride also may be needed. The hypertension often responds to treatment with an angiotensin-converting enzyme (ACE) inhibitor and a loop diuretic.

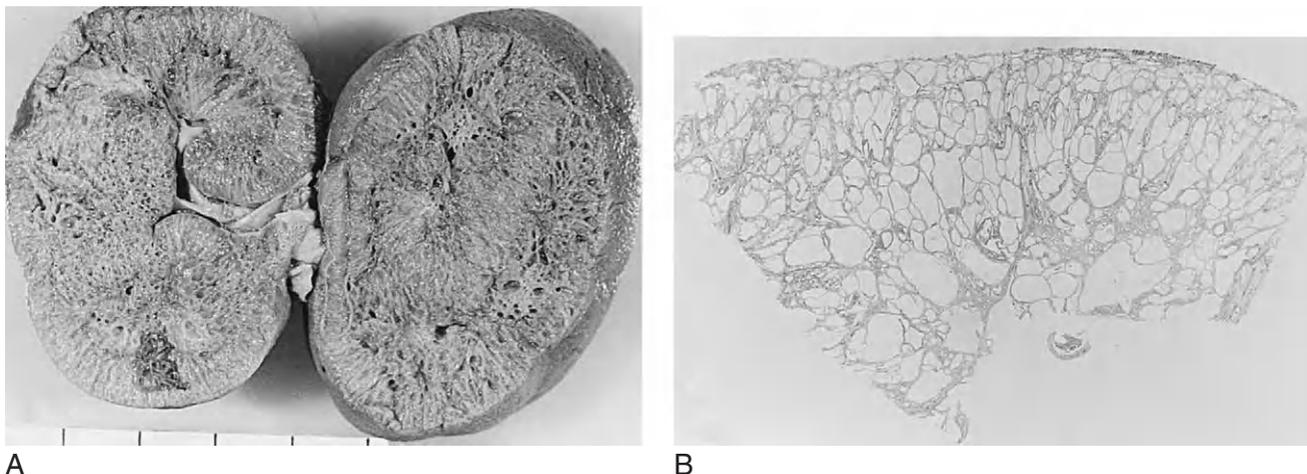

Renal sonography has superseded excretory urography and even histologic studies as the preeminent diagnostic procedure. The sonographic findings in the newborn are large kidneys, increased echogenicity of the parenchyma, loss of corticomedullary differentiation, and loss of central echo complex (Metreweli and Garel, 1980). The cortex is preserved, and the papillae are echogenic. There may be macrocysts that are less than 2 cm in diameter. The liver is echodense, and biliary ducts are dilated. It is important to remember that renal ultrasonography does not always distinguish between autosomal recessive polycystic kidneys and autosomal dominant polycystic kidneys, between autosomal recessive polycystic kidneys and transient nephromegaly (Stapleton et al, 1981), or between autosomal recessive polycystic kidneys and glomerulocystic kidneys (Fitch and Stapleton, 1986). Kidney and liver biopsies are indicated in ambiguous cases.

At postmortem examination, the kidneys are enlarged, are spongy, and maintain their renal contours (Fig. 82-3A). The dilated collecting ducts are neatly arranged perpendicular to the surface of the kidney (see Fig. 82-3B). There are no dysplastic elements. The liver is always involved; portal areas are expanded by increased numbers of dilated bile ductules surrounded by fibrous tissue. The dilated ductules may become cystic. The liver cells are normal.

Autosomal recessive polycystic kidneys can be diagnosed after 24 weeks of gestation by ultrasonographic demonstration of large hyperechogenic kidneys, oligohydramnios, and an empty bladder (Romero et al, 1984). Most infants who are symptomatic at birth die from respiratory or renal causes. Respiratory and renal function can improve in some cases, and a small number of patients who survive the neonatal period may maintain adequate renal function into adolescence. Massively enlarged kidneys may cause respiratory distress by restricting diaphragmatic excursion; therefore, bilateral nephrectomies may improve ventilation. Peritoneal dialysis may then be performed until the infant can have a kidney transplant (Sumfest et al, 1993). Seventy-five percent of infants with ARPKD who survive to 1 year of age can live for more than 15 years (Kaplan et al, 1989).

### Autosomal Dominant Polycystic Kidney Disease

The incidence of autosomal dominant polycystic kidney disease (ADPKD) [McKusick #179300] in liveborn infants is 1/100,000 to 3/100,000. Although the second most common autosomal dominant mutation in humans, with an estimated prevalence in the population of between 1/200 and 1/1000, ADPKD rarely manifests with clinical findings at birth (Fick et al, 1993). The inheritance is autosomal dominant, with variable expression. Negative findings on an ultrasound examination performed after the age of 10 years, and especially past the age of 30, provide reassurance for persons at 50% risk (Bear et al, 1992). Occasionally an infant may have symptoms before the parent does. Prediction by DNA analysis complements ultrasonography for detection, is not age dependent, and may not be informative in every family. Mutations in at least three genes cause ADPKD. Polycystic kidney disease 1 (PKD1), in 85% of families is caused by a mutation on chromosome 16p13.3-p13.12 (Breuning et al, 1987). Patients with PKD2, occurring in about 5% of affected families, have the same phenotype as in PKD1,

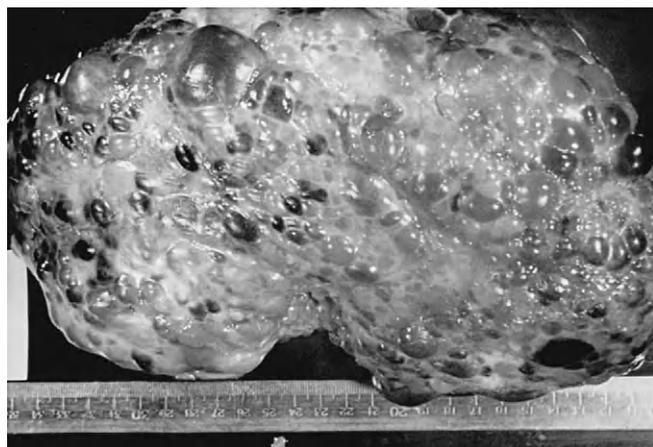

**FIGURE 82-3.** A, Large spongy kidneys (autosomal recessive kidneys). B, Photomicrograph of autosomal recessive kidneys with dilated tubules and paucity of glomeruli.

and the mutation is on chromosome 4q13-q23 (Kimberling et al, 1993; Peters et al, 1993). The location of the third gene, *PKD3*, is unknown. Polycystin-1, the gene product, is a matrix receptor that links the extracellular matrix to the actin cytoskeleton via focal adhesion proteins (Wilson, 2001). The mean age at onset of end-stage renal disease in persons with PKD1 is  $56.7 \pm 1.9$  years, as compared with  $69.4 \pm 1.7$  years in those with PKD2. Hypertension and renal impairment are less frequent and occur later in the families with PKD2. The kidneys are enlarged and lobular, and the calices are stretched and distorted by cysts, which produce smooth or irregular indentations. Numerous cysts of various sizes are seen in the parenchyma in severely affected cases. At post-mortem examination, the kidneys are large, with numerous round protuberances on their surfaces (Fig. 82-4). Cysts are irregularly dispersed through the parenchyma and arise from many nephron segments. Ultrasonography and computed tomography (CT) scanning are more sensitive methods for detecting the cysts than intravenous urography (IVU). Cysts may be seen in liver, pancreas, and spleen.

ADPKD may be detected prenatally by ultrasonography (Sedman et al, 1987). Some patients have the oligohydramnios sequence, enlarged kidneys, and hematuria. Associated abnormalities reported in infants with ADPKD are endocardial fibroelastosis, an intracerebral vascular anomaly, pyloric stenosis, and hepatic fibrosis (Cobben et al, 1990). The finding of hepatic fibrosis in some patients can make differentiation between ARPKD and ADPKD difficult. In the past, in about half the reported cases of ADPKD manifesting in utero or in the first few months of life, the patient died before 1 year of age, but recent studies of larger numbers of patients show a much more optimistic prognosis (Fick et al, 1993).

### Tuberous Sclerosis

Tuberous sclerosis (TS) [McKusick #191100] is characterized by hamartomata in numerous organs. Rarely, polycystic or unilateral cystic disease is found in a newborn in

**FIGURE 82-4.** Autosomal dominant polycystic kidney. The kidney is large, and there are numerous cysts on the surface.

whom a diagnosis of TS is made later (Brook-Carter et al, 1994; Sampson et al, 1997). Renal cysts or polycystic disease in TS are identical to simple cysts or ADPKD in their ultrasonographic, IVU, and CT scan appearances. Non-symptomatic renal lesions (cysts and/or angiomyolipomas) occur in about 60% of persons with TS (Cook, 1996).

Other features include skin lesions (in 96% of patients), epilepsy, learning difficulties, and behavioral problems. "Ash leaf" hypopigmented nevi may be the only skin manifestation of TS in infancy, and babies with polycystic kidneys must be examined for the nevi under ultraviolet light. Shagreen patches and adenoma sebaceum develop before the age of 14 years; nail fibromas appear after 5 years and increase in number and size with age. Ventricular rhabdomyomas and seizures may occur in infancy.

Patients usually survive to adolescence and adulthood, but those with early-onset polycystic kidneys may develop end-stage renal failure. Inheritance is autosomal dominant, with very variable expression within a family, nonpenetrance of the gene, or germinal mosaicism. A parent with the gene may appear unaffected, so the parents also must be examined clinically and radiologically for stigmata of TS. TS is linked in half of the cases to a gene *TSC1* ("hamartin") on chromosome 9q34. In other patients, TS is linked to a marker gene, *TSC2* ("tuberin"), near the locus for PKD1 on chromosome 16p13.3 (Kandt et al, 1992; van Slegtenhorst et al, 1998).

## CYSTIC KIDNEYS WITH AUTOSOMAL RECESSIVE INHERITANCE

### Meckel Syndrome

In Meckel syndrome (MKS 1, MKS 2) [McKusick #249000], polycystic kidneys are an invariable finding. A consistent feature is hepatic fibrosis with variable reactive ductule proliferation and dilation and plate fibrosis. Other features include a sloping forehead, posterior encephalocele, microphthalmia, postaxial polydactyly, and ambiguous genitalia. Fifty percent of the patients have oligohydramnios and die in the perinatal period. In Goldston syndrome, there are cystic kidneys, hepatic fibrosis, and Dandy-Walker malformation. This and other syndromes may be either part of the spectrum of MKS or discrete entities (Gloeb et al, 1989). The incidence of MKS is 1/9000. Inheritance is autosomal recessive, with variable expression within and among families (Fraser and Lytwyn, 1981). Gene loci are on chromosomes 17q22-q23 (MKS 1) and 11q13 (MKS 2) (Roume et al, 1998). Prenatal diagnosis is possible by ultrasonography and by detection of increased alpha-fetoprotein levels in amniotic fluid.

### Jeune Asphyxiating Thoracic Dystrophy Syndrome

Jeune asphyxiating thoracic dystrophy syndrome [McKusick #208500] is inherited as an autosomal recessive trait, with variable expression. Respiratory distress, dysostoses, renal cystic disease, and congenital hepatic fibrosis characterize the disorder. Dysostoses include short ribs, small and long thoracic cage, small pelvis, trident acetabular margins, short and thick second and third phalanges, cone-shaped

epiphyses, handle-bar clavicle, and mesomelic shortening of the limbs (Donaldson et al, 1985). Three different morphologic lesions of the kidneys have been described: (1) dilated proximal and distal tubules and Bowman capsule with interstitial fibrosis, (2) cystic dysplasia and disorganized renal architecture, and (3) chronic tubulointerstitial disease resembling juvenile nephronophthisis. The differential diagnosis includes Ellis-van Creveld syndrome, Saldino-Noonan short rib-polydactyly syndrome (type II), Majewski short rib-polydactyly syndrome, and Naumoff syndrome (type III). Survivors develop metaphyseal dysplasia with short-limb dwarfism. Treatment of renal failure may require dialysis and transplantation. Prenatal diagnosis by ultrasonography is possible by 18 weeks (Elejade et al, 1985).

### Renal-Hepatic-Pancreatic Dysplasia (Ivemark Syndrome)

Inheritance of renal-hepatic-pancreatic dysplasia (Ivemark syndrome) is autosomal recessive. Patients may have the oligohydramnios sequence. The kidneys may be dysplastic, with peripheral cortical cysts, primitive collecting ducts, glomerular cysts, and metaplastic cartilage (Bernstein et al, 1987). There is fibrosis of the liver and pancreas. Most patients die from respiratory insufficiency in the newborn period. Inheritance is autosomal recessive.

### HYPOPLASTIC KIDNEYS

Hypoplastic kidneys are small, have fewer calices, and may be dysplastic. Simple hypoplasia, oligomeganephronia, and renal dysplasia are the types of kidney hypoplasia that are seen in newborns. In older children, small kidneys also may be the result of chronic pyelonephritis, chronic glomerulonephritis, renovascular accident, or nephronophthisis.

In simple hypoplasia, the renal architecture is normal, but there are a decreased number of reniculi and small nephrons. Oligomeganephronic kidneys are small and have a decreased number of enlarged glomeruli. Oligomeganephronia probably is not a specific clinicopathologic entity. Some patients with oligomeganephronic kidneys have chromosome 4 abnormalities (Anderson et al, 1997), and others have heterozygous *PAX2* mutations (Salomon et al, 2001).

### GLOMERULOCYSTIC KIDNEYS

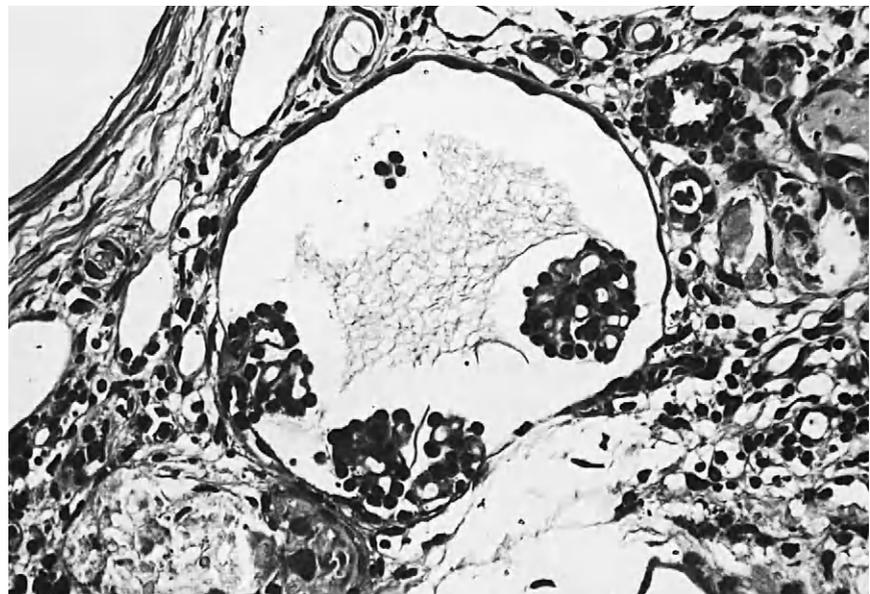

The purest form of glomerulocystic kidney is characterized by dilated Bowman spaces, with few or no cysts in the tubule (Bernstein, 1993). The rest of the renal architecture is normal. The kidneys may be large or small. The liver is normal. Glomerular cysts also are seen in obstructive uropathy, in autosomal dominant polycystic kidneys, in association with malformations of other organs, in dysplastic kidneys, and in the kidneys of infants whose mothers received phenacetin or indomethacin during pregnancy. Glomerular cysts are often subcapsular and may contain more than one glomeruloid structure (Fig. 82-5). Glomerulocystic kidneys may occur sporadically. Autosomal dominant inheritance is found in some kindreds in association with mutations in the gene encoding hepatocyte nuclear factor (HNF)-1 $\beta$  and early-onset diabetes (Bingham et al, 2001).

### DYSGENETIC KIDNEYS

#### Renal Tubular Dysgenesis: Congenital Hypernephronic Nephromegaly with Tubular Dysgenesis

Clinical features of congenital hypernephronic nephromegaly with tubular dysgenesis [McKusick #267430], an autosomal recessive condition, include late-onset

**FIGURE 82-5.** Glomerulocystic kidneys. Photomicrograph of glomerulus with three glomeruloid structures in a dilated Bowman capsule.

oligohydramnios after 24 weeks of gestation and large nonfunctioning kidneys (Allanson et al, 1992). The calvaria may be underdeveloped with wide sutures. Similar calvarial anomalies occur in patients with the Finnish-type congenital nephrotic syndrome and in infants exposed in utero to ACE inhibitors. The kidneys are seen to be enlarged symmetrically on ultrasonography, and the corticomedullary junction is poorly defined. Other features are an apparent increase in the number of glomeruli and immature tubules without proximal convolutions. Prenatal diagnosis is not possible before 20 weeks. All of the patients have died in the neonatal period.

## OVERGROWTH SYNDROMES

Beckwith-Wiedemann syndrome, Simpson-Golabi-Behmel syndrome, and Perlman syndrome are overgrowth syndromes with overlapping features and kidneys that may be abnormal at birth (Coppin et al, 1997).

### Beckwith-Wiedemann Syndrome

Patients with Beckwith-Wiedemann syndrome [McKusick #130650] may have nephromegaly, Wilms tumor, medullary renal cysts, caliceal diverticula, hydronephrosis, and nephrolithiasis (Choyke et al, 1998). The syndrome is caused by a mutation of a gene encoding a human cyclin-dependent kinase inhibitor, p57 (*KIP2*), on chromosome 11p15.5 (Matsuoka et al, 1996). Patients should be screened by renal ultrasound examination for Wilms tumor every 3 months for the first 7 years.

### Perlman Syndrome

In Perlman syndrome [McKusick #267000], characterized by renal hamartomas, nephroblastomatosis, and fetal gigantism, associated features include polyhydramnios, macrosomia, and bilateral nephromegaly with nephroblastomatosis, visceromegaly, cryptorchidism, diaphragmatic hernia, interrupted aortic arch, hypospadias, and polysplenia and renal findings of dysplasia, microcysts, and nephrogenic rests (Greenberg et al, 1988; Schilke et al, 2000). Inheritance is autosomal recessive.

### Simpson-Golabi-Behmel Syndrome

In patients with Simpson-Golabi-Behmel syndrome type 1 (SGBS1) [McKusick #312870], features include pre- and postnatal overgrowth, "coarse" face, hypertelorism, broad nasal root, cleft palate, full lips with a midline groove of the lower lip, grooved tongue with "tongue-tie," prominent mandible, congenital heart defects, arrhythmias, supernumerary nipples, splenomegaly, large dysplastic kidneys, cryptorchidism, hypospadias, skeletal abnormalities, and postaxial hexadactyly. Inheritance is X-linked. Some cases are caused by a mutation in the gene for glypican-3, which maps to Xq26 (Pilia et al, 1996). The gene responsible for a second SGB syndrome (SGBS2) is located on Xp22 (Brzustowicz et al, 1999).

## IN UTERO EXPOSURE TO TERATOGENS

No convincing proof of a cause-and-effect relationship has been provided for associations of in utero exposure to teratogens. Urogenital anomalies are found occasionally in infants exposed in utero to valproic acid and other anticonvulsant agents (Ardinger et al, 1988). Maternal cocaine (and polydrug) use may produce genitourinary abnormalities (Chasnoff et al, 1988). Indomethacin may cause renal dysgenesis in fetal monkeys and possibly in humans exposed early in utero to prolonged high doses (Kaplan et al, 1994). Prenatal lead exposure is incriminated as a possible cause of the VACTERL association (Levine and Muenke, 1991). Glomerulocystic disease was reported in an infant exposed to phenacetin and salicylate in utero (Krous et al, 1977). Unilateral renal agenesis and abnormalities of position were noted in three infants exposed prenatally to warfarin (Hall, 1989).

## INBORN ERRORS OF METABOLISM

In several inborn errors of energy metabolism that manifest in the newborn period, features include morphologic and functional abnormalities of the kidneys. These are all rare conditions.

### Glutaric Aciduria Type II

The clinical features of glutaric aciduria type IIa, the neonatal-onset form of multiple acyl-coenzyme A (CoA) dehydrogenase deficiencies, include prematurity, hypotonia, hepatomegaly, nephromegaly, craniofacial anomalies, rocker-bottom feet, anterior abdominal wall defects, and external genital anomalies. An odor of sweaty feet may be present. Within 24 hours there is severe hypoglycemia but no ketosis, a metabolic acidosis with an increased undetermined anion gap, lactic acidosis, and mild hyperammonemia. Elevated levels of organic acids are found in body fluids. Renal cystic dysplasia occurs in many cases (Wilson et al, 1989). The deficiencies in electron transfer flavoprotein or electron transfer ubiquinone oxidoreductase are inherited as autosomal recessive traits. Prenatal diagnosis may be possible by assaying enzyme in amniocytes and/or elevated glutaric acid in amniotic fluid. Ultrasonography in utero may show enlarged cystic kidneys. Death occurs within days to months. There is no successful treatment.

### Zellweger Cerebrohepatorenal Syndrome

Clinical features of Zellweger cerebrohepatorenal syndrome [McKusick #214100] are similar to those of glutaric aciduria type II, plus profound hypotonia, nystagmus, cataracts ("oil droplets"), pigmentary retinopathy, optic disc pallor, and stippled epiphyses of patella and acetabulum. Odor is not abnormal. All peroxisomal functions are abnormal: elevated plasma very-long-chain fatty acids, bile acids, pipecolic acid, and phytanic acid and urine dicarboxylic acids, and low cholesterol and triglycerides (Steinberg et al, 1999). Pathologic features are cortical renal cysts, micronodular cirrhosis, brain heterotopias, abnormal brain gyri, and absent corpus

callosum. Inheritance is autosomal recessive. Prenatal diagnosis is possible by enzyme assays in amniocytes or chorionic villus cells. Most affected infants die within 6 months but those with a milder form can survive into adolescence with retardation, deafness, and seizures.

### Carbohydrate-Deficient Glycoprotein Syndrome

Multiple renal microcysts are found in the carbohydrate-deficient glycoprotein syndrome (Strom et al, 1993). There is multisystem involvement with olivopontocerebellar atrophy, retinitis pigmentosa, testicular atrophy, hypothyroidism, and immune deficiency. Several glycoproteins are deficient in their carbohydrate moieties. Inheritance is autosomal recessive, and the prognosis is variable.

## Developmental Abnormalities of the Genitourinary System

Stephen A. Zderic

This chapter reviews the major presentations that prompt a urologic consultation in the neonatal period. Anomalies of the urinary tract are discussed first, followed by the disorders of the external genitalia. Prenatal ultrasonography allows most urinary tract anomalies and disorders of the external genitalia to be detected prenatally and thus managed early and effectively in the neonatal period. In the past, many neonates with these conditions presented in critical condition with urosepsis weeks or months after birth.

### PRENATAL DIAGNOSIS

Because of the widespread use of ultrasonography in screening for fetal problems, neonatal urology has undergone profound changes in the past two decades or so. Under optimal circumstances, a relationship already has been established between the urologist and members of the family who sought prenatal consultation. These families have a chance to learn about the possible diagnosis, to plan for evaluation and management in the postnatal period. Two decades ago, most children with congenital anomalies of the urinary tract presented with urosepsis. Prenatal ultrasonography identifies the patients at risk; if indicated, in utero decompression of an obstructed urinary tract (i.e., from posterior urethral valves or ureterocele) may be performed or antibiotic prophylaxis may be initiated in the immediate postnatal period. Prenatal diagnosis has also led to a decrease in the incidence of several major uncorrectable congenital urologic anomalies as parents have opted for termination (Cromie, 2001; Ransley, 1996).

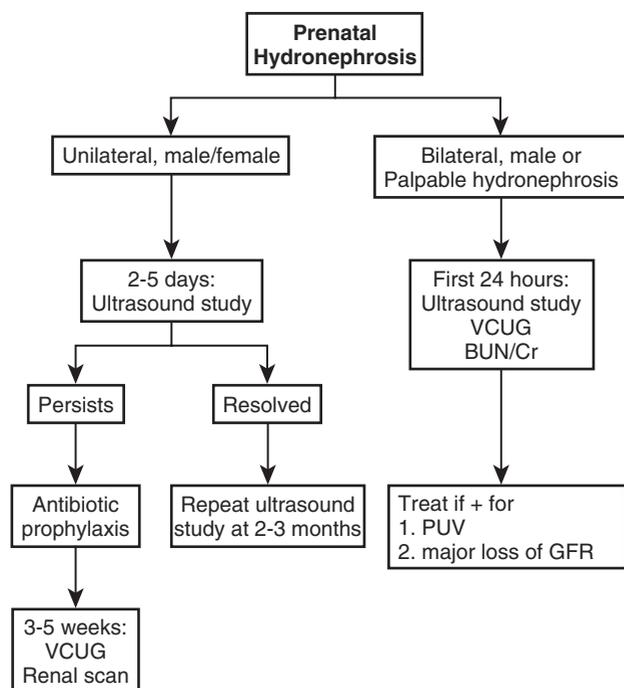

Due primarily to the high fetal urine output, most prenatally discovered cases of hydronephrosis will be benign and self-limiting in nature. Therefore, it is important to give realistic advice and also reassurance in cases of functional hydronephrosis. With congenital anatomic obstructions, fetal intervention may be considered in the most severe cases (Crombleholme, 1984). Recent studies suggest that such interventions offer little benefit to renal function (Coplen et al, 1996), however, but may improve pulmonary development. As mentioned earlier, in addition to the obstructive uropathies, intersex states and other disorders of the external genitalia are being detected with prenatal sonography (Rintoul and Crombleholme, 2002).

### HYDRONEPHROSIS

As mentioned earlier, most patients with prenatally diagnosed hydronephrosis have transient dilatations of the urinary tract (Homsy et al, 1986) that may reflect a more distensible fetal urinary tract and large volumes of dilute fetal urine. With the cardiovascular and hormonal changes in the immediate postnatal period, urine output per kilogram of body weight decreases, resulting in the resolution of the prenatally detected “functional” renal and ureteral dilatation. In addition, the ureter may contain small kinks or folds, which normalize over time. The list of explanations for the spontaneous improvement in these systems is seemingly endless. Despite the fact that most dilatations of the fetal urinary tract prove to be of no long-term significance, a subset of these patients will prove to have anatomic obstructions requiring surgical correction (Cendron et al, 1994).

The neonatal evaluation of antenatal hydronephrosis is dictated by the child's gender, whether the hydronephrosis is unilateral or bilateral, and whether a hydroureter is present. Several schools of thought exist regarding how extensive an initial work-up is required (Blyth et al, 1993; Cendron et al, 1994; Woodward and Frank, 2002; Yerkes et al, 1999) (Fig. 83–1). Bilateral hydroureteronephrosis in a boy should lead to a consideration of the presence of a posterior urethral valve (PUV). This condition can be ruled out by performing an ultrasound examination and voiding cystourethrogram (VCUG) within 24 hours of birth. Unilateral hydronephrosis in a male or female can be managed by performing an ultrasound study of the kidneys and bladder at 2 to 5 days of age. Performing an ultrasound study in the first postnatal hours may show minimal to no hydronephrosis, owing to the significant and physiologic decrease in the urine output during the period of transition to extrauterine life. In these cases, a follow-up study should be performed to ensure that, with the ensuing increase in the urine output over the first few days, the collecting system remains unobstructed (Djeter and Gibbons, 1989). For patients with persisting unilateral hydronephrosis, a VCUG and renal diethylene-triaminepenta-acetic acid (DTPA) scan should be performed at about 1 month of age. In the interim, it is absolutely essential that the infant be discharged to home on antimicrobial prophylaxis, usually one dose of amoxicillin (12.5 mg/kg) at bedtime. The algorithm presented in Figure 83–1 is a reasonable approach to the management of neonatal hydronephrosis.

However, ample controversy exists concerning some of the fine points of this management algorithm. Because 20% of children with prenatal hydronephrosis have reflux, should all children get a VCUG irrespective of their first ultrasound findings? Yerkes and colleagues (1999) have suggested that for patients with mild pelviectasis and no caliectasis or hydroureter, the diagnostic yield of the VCUG is low, and the study may be deferred. Other authors argue in favor of a VCUG for all patients with a prenatal diagnosis of hydronephrosis (Herndon et al, 1999). If results on their initial ultrasound examination are negative, should these children then be placed on antimicrobial prophylaxis until their next ultrasound study is done and judged to be normal?

**FIGURE 83-1.** An algorithm for the approach to the work-up of a patient with antenatally diagnosed hydronephrosis. With further experience and clinical outcomes studies, it may be possible to better select which patients require a voiding cystourethrogram (VCUG) and renal MAG3 on DTPA scan. BUN, blood urea nitrogen; Cr, serum creatinine; GFR, glomerular filtration rate; PUV, posterior urethral valve.

With increasing experience and the findings from prospective studies, the algorithm for the postnatal assessment of minimal prenatal hydronephrosis should become more streamlined. It is important to remember that while the urologic issues are being sorted out, antibiotic prophylaxis is cost effective and protects against urosepsis. Therefore, when the diagnosis is in doubt, the clinician should provide antibiotic prophylaxis.

## OBSTRUCTIVE UROPATHY

### Ureteropelvic Junction Obstruction

The most common obstructive uropathy is seen at the level of the ureteropelvic junction (UPJ). Ultrasonography will reveal a dilated renal pelvis with or without caliectasis, and with no dilatation of the ureter (Fig. 83-2). On the other hand, the presence of a dilated distal ureter is seen with ureterovesical junction obstruction (megaureter). The sonographic appearance of a UPJ obstruction does not always predict its functional significance. Many infants with fairly impressive dilatations of the renal pelvis in the neonatal period show partial or even complete resolution of their hydronephrosis with preservation of renal function (see Fig. 83-2). Functional imaging is obtained before any surgical repair. Although any kidney with an anteroposterior diameter of greater than 2 cm had a greater chance of showing functional compromise in one extensive series (Ransley et al, 1990), many of the patients

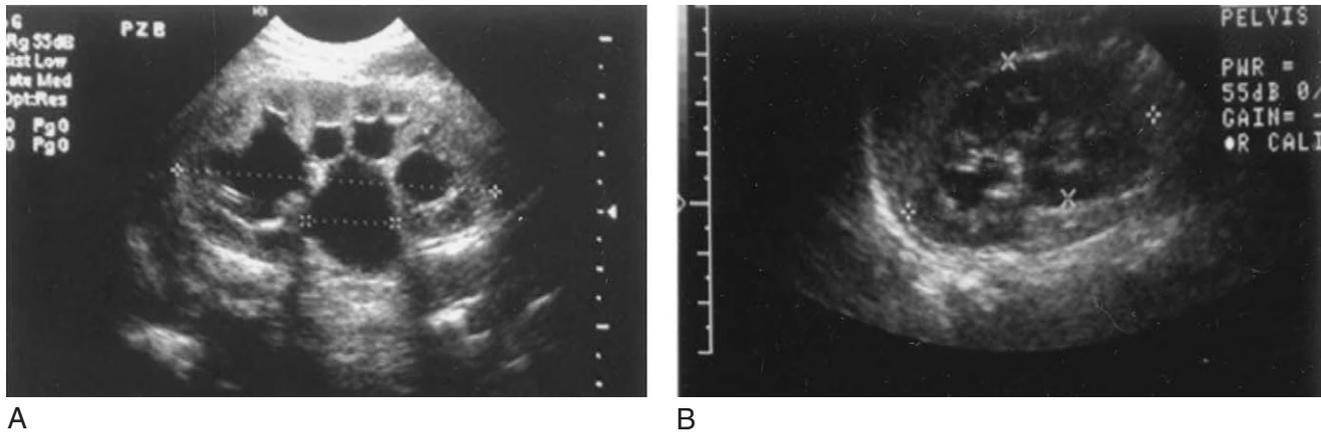

when evaluated over time may show stable renal function (Koff, 1994). DTPA renal scans allow for careful selection of those patients with a loss of function as defined by a decrease in the glomerular filtration rate. Disagreement remains on how much functional impairment necessitates intervention (Allen, 1992; Koff et al, 1994). Some authorities advocate intervention only if the differential function in the affected kidney falls below 35% (Cartwright et al, 1992), whereas others place the limit at 40%. Still others rely heavily on a “well-tempered” diuretic renogram and the furosemide washout curves to identify those patients whose urinary tract is truly obstructed (Conway and Maizels, 1993).

Many patients will be found to have good function and rapid washout curves despite a significant degree of hydronephrosis (Fig. 83-3). For those patients in whom a UPJ obstruction is diagnosed by sonography, and in whom the renal scan shows diminished function, pyeloplasty is indicated. Placing an infant with a poorly functioning kidney on antimicrobial prophylaxis is not effective because a kidney functioning this poorly will not deliver enough antibiotic into the collecting system, leaving the child at risk for urosepsis. It is important to note that with most severe UPJ obstructions, the kidney does not recover full function following surgical correction. In addition, infection in the presence of a UPJ obstruction makes recovery of function less likely. No preoperative test will predict recovery of renal function following relief of obstructive uropathy; clinicians are left with the option of placing a temporary percutaneous nephrostomy or carrying out a primary repair.

Finally, few prenatally diagnosed cases of UPJ obstruction require immediate repair. These cases rarely result in palpable hydronephrosis, and most affected infants will have good renal function, allowing elective evaluation and repair at 3 to 6 weeks of life. This group of patients may be divided into three subgroups, according to Homzy and colleagues (1990). One third will be obstructed and require immediate intervention, and one third will have a normal postnatal evaluation. The remaining one third may be observed with serial sonograms and renal scans. Of this observed group, up to one third of the patients may ultimately need surgical correction. The postnatal evaluation of prenatally diagnosed hydronephrosis must contain two key elements: (1) antimicrobial prophylaxis until such time as the urinary tract is judged normal, or the patient is less susceptible to infection, and (2) thorough follow-up evaluation. Although expectant management may eliminate surgical procedures that may offer little benefit, this advantage comes at the price of the need for careful follow-up evaluation. This aspect of management must be made clear to the family in no uncertain terms.

### Multicystic Dysplastic Kidney

The diagnosis of multicystic dysplastic kidney (MCDK) is applied to a kidney that on ultrasound examination is seen to consist of multiple cysts of roughly equal size, which gives rise to a fairly classic “bunch of grapes” pattern (Fig. 83-4). The contralateral kidney will show signs of hypertrophy, as manifested by increases in length and width, and the affected kidney will have no function on the DTPA scan. If

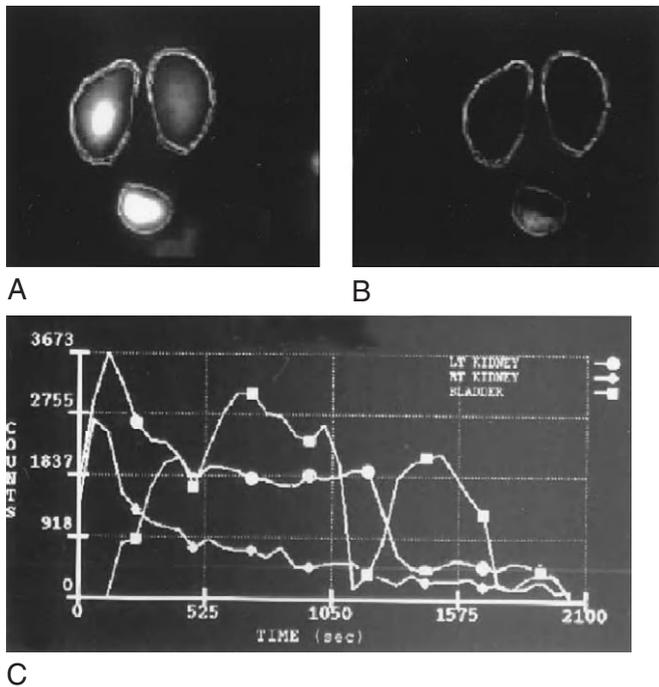

**FIGURE 83-2.** An example of antenatal hydronephrosis consistent with a partial ureteropelvic junction obstruction (A) that spontaneously resolved over a 6-month interval (B).

the MCDK has one large, centrally located cyst, it may not be possible to rule out a severe UPJ obstruction. In these rare instances it may prove necessary to explore the kidney to see if there is any salvageable renal function that might be amenable to relief of the obstruction. In most cases of MCDK, the cysts will involute completely. Should these children have yearly ultrasound examinations to check for involution? It might be argued that no follow-up evaluation is needed. It is reassuring, however, to check on the solitary remaining kidney, as metachronous contralateral obstruction has been reported (Weiser et al, 2002). Concerns have been raised about the occasional case reports of malignancy in MCDK. It has been estimated that 80,000 nephrectomies would have to be performed to save one patient with

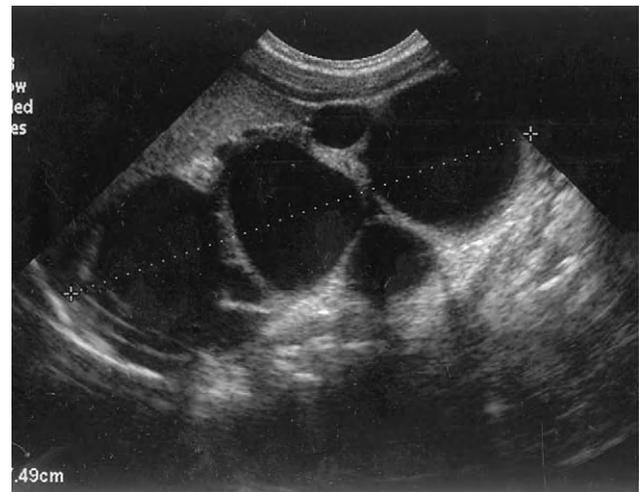

MCDK from developing a malignancy. In practice, some families opt for nephrectomy if, on yearly sonography, involution fails to occur.

#### Ureterovesical Junction Obstruction: Megaureter

Primary megaureters account for 15% of prenatally diagnosed cases of hydronephrosis and are characterized by pelviectasis, caliectasis, and ureteral dilatation. Ureteral dilatation is best seen behind a distended bladder, and a VCUG is indicated to rule out reflux. Reflux into a partially obstructed system can occur, creating the paradoxical refluxing obstructed megaureter. In such cases, the contrast that refluxes into the ureter is quite dilute when compared with that within the bladder. Furthermore, on the post-void views, the contrast will be “held up” within the ureter. Some investigators believe that refluxing primary megaureter should be repaired, because an infection

**FIGURE 83-3.** A, This renal MAG3 scan demonstrates equal function in the right and the left kidneys but marked stasis in the left kidney. B and C, Following administration of furosemide, the stasis in the left renal pelvis clear quickly.

**FIGURE 83-4.** Sonographic view of a multicystic dysplastic kidney in which multiple cysts that do not communicate with another are grouped together, giving the typical “bunch of grapes” appearance. No function was noted on the patient’s renal scan, confirming this diagnosis.

developing in a partially obstructed system can be especially severe. The renal DTPA scan is essential to the work-up (Fig. 83-5). If it shows good renal function, these patients may be safely managed on antimicrobial prophylaxis. In a longitudinal study, Baskin and colleagues (1994) showed that renal function is well preserved, and in many instances, the morphologic appearance of the system is substantially improved. Thus, unlike the UPJ obstructions, which are associated with a 20% to 30% risk of renal decompensation with need for subsequent surgery, primary megaureters seem to do better with very few changes in the course of management. The encouraging results achieved by restricting management to thorough follow-up evaluation, with no surgical intervention, in the study by Baskin and colleagues (1994) were obtained in a select group of patients with good renal function at the outset. Good renal function was defined as contribution by the involved kidney of greater than 35% to the overall GFR as determined by scan. On the other hand, for kidneys whose split function fell below 35%, the authors performed surgery to relieve the obstructive uropathy.

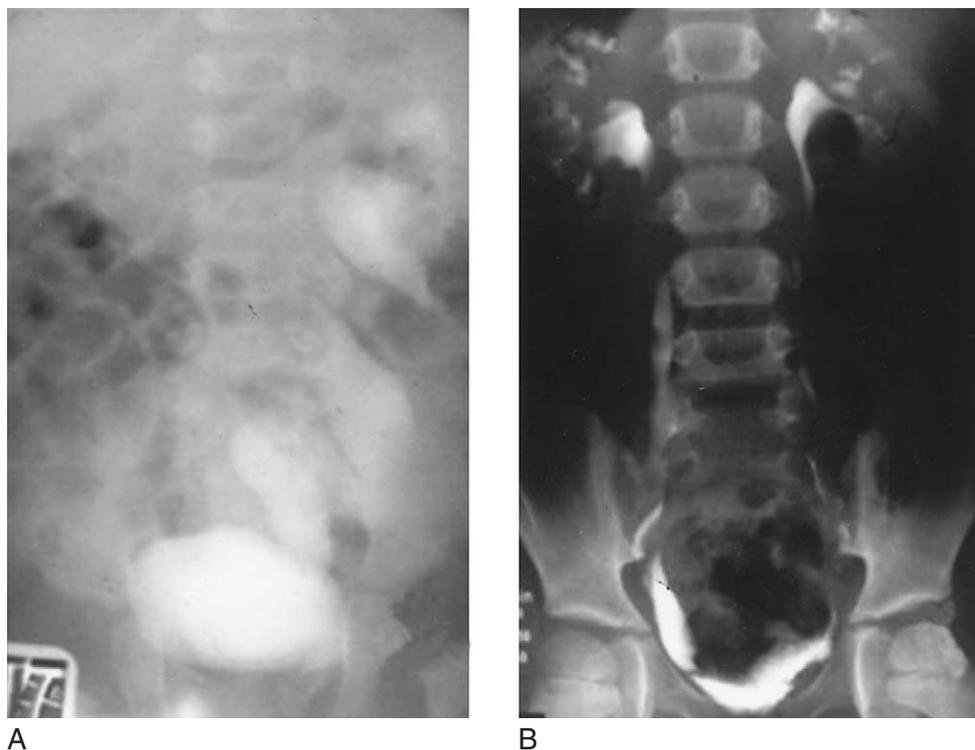

### Posterior Urethral Valves

Most cases of posterior urethral valves (PUVs) today will be detected on prenatal sonography; the clinical manifestations vary across a wide spectrum. An extreme example would be the case of a child who was born with chronic renal insufficiency and whose creatinine level is rising, in which prenatal sonography revealed severe oligohydramnios. If the oligohydramnios is severe enough, such infants also may suffer from severe respiratory insufficiency secondary to pulmonary hypoplasia. In highly selected cases, extracorporeal membrane oxygenation (ECMO) has been used to get past

the initial period of respiratory failure, and long-term survivors have been reported. Most of these survivors, however, will require renal transplantation at some point (Gibbons et al, 1993). At the other end of the spectrum would be the presence of PUVs of minimal functional significance. If the abnormality is not detected in utero, similar to neonates with other obstructive uropathies, patients with PUVs may present with urosepsis. The prenatal diagnosis by ultrasound examination offers the pediatric urologist an opportunity to intervene before the obstructive uropathy is further compromised by the additional burden of infection.

The postnatal evaluation of a child with suspected PUVs should begin with a renal and bladder ultrasound study. The examination should be performed first without a catheter in the bladder so as to reveal the anatomy of the urinary tract in its distended form. There will usually be severe bilateral hydronephrosis. In severe cases, the renal parenchyma will be of extremely poor quality, comprising a thin rim with a highly echogenic nature. When these findings are associated with a thick-walled bladder in a male infant, the diagnosis is unlikely to be anything other than PUVs. Ultrasound examination of the bladder also may reveal a dilated posterior urethra (Fig. 83-6). A catheter should be passed into the child's bladder and the sonographic examination with the same views repeated to get a sense of whether bladder decompression improves the morphology of the upper urinary tract at all. In some instances, the posterior urethra is so severely distorted that the catheter may curl up within it.

The diagnosis of PUVs is made from a fluoroscopic VCUG. This study will demonstrate a dilated posterior urethra, valve cusps at the distal aspect of the prostatic fossa (see Fig. 83-6), a heavily trabeculated bladder, and an associated high-grade vesicoureteral reflux in many cases. Once the diagnosis is established, endoscopic valve

**FIGURE 83-5.** **A**, This radiograph shows significant hydronephrosis that was diagnosed by antenatal sonography and was shown to be consistent with bilateral primary megaureters. Renal function was normal despite the abnormal morphologic appearance. **B**, With time, the radiographic findings showed marked improvement.

**FIGURE 83-6.** This voiding cystourethrogram shows a classic posterior urethral valve, with narrowing of the urethra at the most distal end of the prostate. This area corresponds to a flap of tissue that serves as an obstructing valve leaflet.

ablation is indicated (Zderic, 1996). In rare instances, the pediatric urologist may opt for a temporizing vesicostomy. A circumcision should be performed at the time of the valve resection, to minimize the chances for development of urinary tract infection (Wiswell and Geschke, 1989) in this patient population at high risk for this complication.

In severe cases of PUV, decompression may result in a postobstructive diuresis. For this reason, neonates with PUVs who undergo decompression with placement of a catheter should remain in the neonatal intensive care unit (NICU) for fluid and electrolyte monitoring. The diuresis can be quite dramatic, necessitating hourly tallies of urine output with appropriate replacement of fluid and electrolyte losses. Failure to keep up with losses can easily produce hypotension, further aggravating the renal insufficiency. Once the child has been catheterized, antibiotics should be started and the child's medical condition should be optimized before any thought is given to operative intervention.

Up to 30% of these patients may require renal replacement therapy during their lifetimes (Smith et al, 1996). In the neonatal period, every effort must be made to optimize renal function and to maintain a sterile urine with the use of antibiotic prophylaxis. In a subset of patients with valves who present with only unilateral reflux and dysplasia, the valve may act as a pop-off valve to lower bladder pressure, sparing the contralateral kidney. A number of these pop-off mechanisms have been described, and all are associated with better long-term renal (Rittenberg et al, 1988) and bladder (Kaefer et al, 1995) function. Families must be cautioned that these infants have poor urinary concentrating ability; their additional fluid

requirements make them especially susceptible to dehydration with even mild diarrhea or emesis. The initial follow-up evaluation within 1 month consists of a physical examination, renal-bladder ultrasound study, and serum creatinine measurement. Antibiotic prophylaxis should be maintained for a long period in these patients.

### Ureterocele

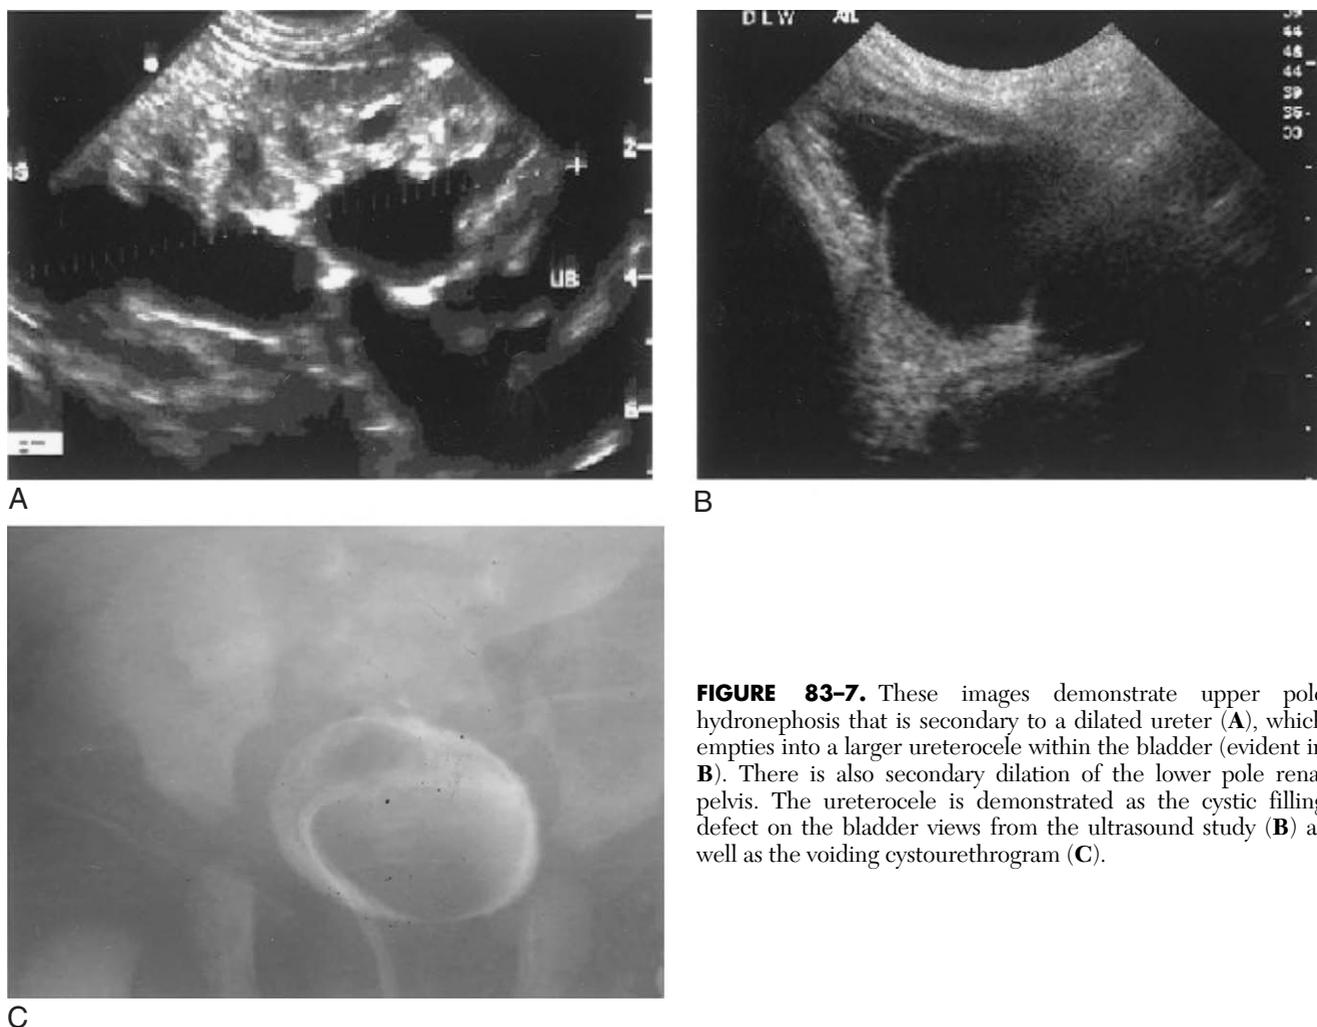

The ureterocele is a cystic dilatation of the distal ureter that protrudes into the urinary bladder and may extend past the bladder neck into the urethra. Ureteroceles are found primarily in duplex systems, where they are always associated with the upper pole renal parenchyma. The renal parenchyma seen in the upper pole of the duplex systems usually is of poor quality and may even contain dysplastic elements. The ureterocele is by definition an obstructed system; accordingly, measures must be instituted to prevent the neonate from developing urosepsis. Renal-bladder ultrasound examination of a ureterocele will show three characteristic findings (Fig. 83-7). First, hydronephrosis will always be associated with the upper pole of a duplex system (although single systems also may contain ureteroceles). Second, a significant ureteral dilatation down to the level of the bladder will be seen, and finally a cystic lesion within the lumen of the bladder close to the bladder base will be demonstrated. A VCUG will complete the work-up and aid the urologist in assessing whether any reflux is found into the ipsilateral or contralateral ureter(s). Ureteroceles may prolapse into the urethra; these lesions constitute the most common form of bladder outlet obstruction in female neonates, in whom they manifest as a cystic bulge within the labia.

Several surgical options exist for the management of the newborn with a ureterocele: endoscopic puncture, upper pole partial nephrectomy, and excision of the ureterocele with a combined reimplantation. Finally, an additional surgical approach is to perform a cutaneous ureterostomy and then wait to carry out a definitive lower tract reconstruction in the older child.

### Ectopic Ureters

Most ectopic ureters today will be detected with prenatal sonography that results in a neonatal evaluation. Findings on physical examination in these patients will often be unremarkable. A male will never be incontinent secondary to an ectopic ureter, because the ureter will always enter above the level of the external sphincter. However, in females, the ureter may be ectopic to the urethra or vaginal vault, where it may produce urine on a continuous basis and detected on physical examination. Making this diagnosis early in life prevents urosepsis from developing in an obstructed or partially obstructed system and simplifies the process of toilet training for a young female.

Most ectopic ureters will be found in duplex systems, where they always represent the upper pole moiety. The ultrasound findings in ectopic ureter include the presence of hydronephrosis, usually of an upper pole of a duplex system (although single systems also may be involved), a dilated distal ureter that lies behind the bladder, and an

**FIGURE 83-7.** These images demonstrate upper pole hydronephosis that is secondary to a dilated ureter (**A**), which empties into a larger ureterocele within the bladder (evident in **B**). There is also secondary dilation of the lower pole renal pelvis. The ureterocele is demonstrated as the cystic filling defect on the bladder views from the ultrasound study (**B**) as well as the voiding cystourethrogram (**C**).

extension of this dilated distal ureter past the bladder neck, with no cystic lesion within the bladder itself, as is seen with a ureterocele. The VCUG is important in the evaluation of these patients, because in 70% of the cases it may demonstrate reflux into the ectopic ureter. However, the reflux may not be apparent on the first void, and it may be necessary to “cycle” the bladder several times before such reflux may be demonstrated.

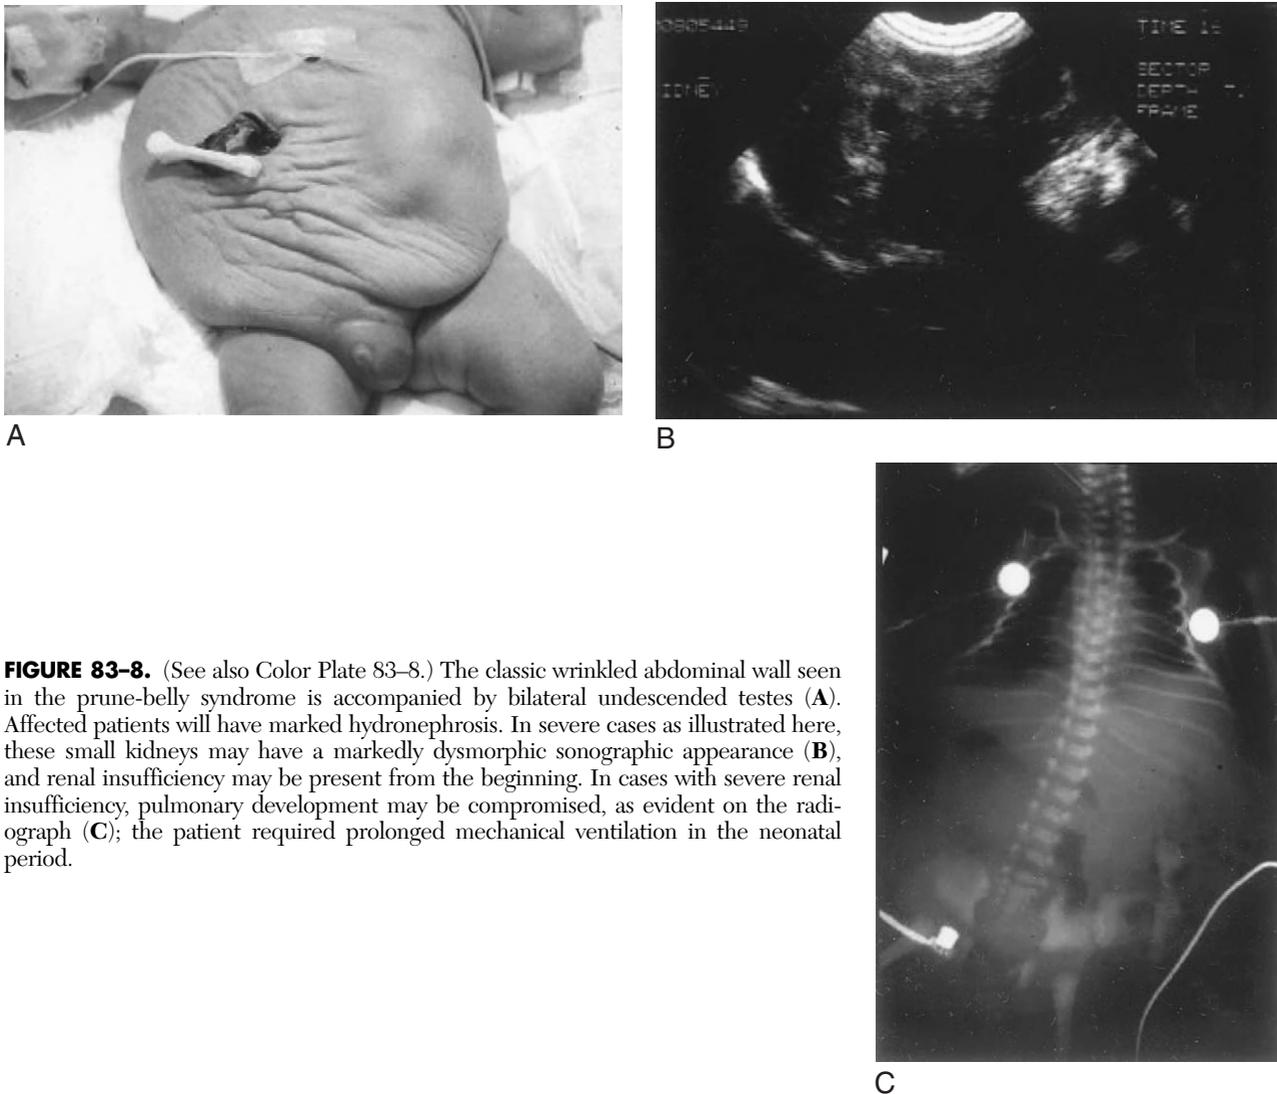

An endoscopic option does not exist for repairing an ectopic ureter. The open surgical options (Snyder, 1996) include a partial nephrectomy of the upper pole with or without an excision of the distal stump, a complete nephrectomy in a nonfunctioning kidney, a temporizing cutaneous ureterostomy with delayed reimplantation and excision of the distal stump, and an immediate complete reconstruction with reimplantation and excision of the ectopic stump. The urologist’s choice among these options will be dictated by the amount of function present within the upper pole segment, which is often 15% or less of total GFR.

### Prune-Belly Syndrome

Patients with prune-belly syndrome present with a lax and floppy abdominal wall that is extremely thin, bilateral undescended testes, a flattened diaphragm with flaring of

the ribs, and a massively dilated upper urinary tract and bladder (Fig. 83-8). In severe cases, respiratory insufficiency may mandate temporary mechanical ventilation until the infant is strong enough to be weaned off support. In older series, pulmonary complications were a common source of neonatal demise. Today, with the advent of prenatal sonography, such severe cases are being diagnosed earlier. These neonates are often born with significant renal dysplasia and go on to develop end-stage renal disease. Indeed, if the serum creatinine fails to fall below 1.0 mg/dL by 1 year of age, the infant with prune-belly syndrome is more likely to develop end-stage renal disease (Noh et al, 1999). However, this disease manifests across a wide spectrum; some patients may not develop renal insufficiency until much later in life, if at all, despite their massively dilated urinary tracts.

Prune-belly syndrome is a clinical diagnosis that should lead to the institution of prophylactic antibiotics. An ultrasound study to assess the renal parenchyma also is warranted, but a VCUG is not. Instrumenting a neonate with prune-belly syndrome who is voiding satisfactorily is to be avoided, as such procedures will increase the risk of urosepsis owing to the presence of the huge, floppy, and poorly draining bladder. Furthermore, discovering whether such a child is refluxing or not will add little to neonatal management; these infants will stay on antibiotic

**FIGURE 83-8.** (See also Color Plate 83-8.) The classic wrinkled abdominal wall seen in the prune-belly syndrome is accompanied by bilateral undescended testes (A). Affected patients will have marked hydronephrosis. In severe cases as illustrated here, these small kidneys may have a markedly dysmorphic sonographic appearance (B), and renal insufficiency may be present from the beginning. In cases with severe renal insufficiency, pulmonary development may be compromised, as evident on the radiograph (C); the patient required prolonged mechanical ventilation in the neonatal period.

prophylaxis regardless of the VCUG results. The key is to maintain a sterile urine and to institute careful follow-up evaluation (Noh et al, 1999). If, in the neonatal period, the voiding dynamics are significantly altered, a vesicostomy may prove to be an ideal means of decompressing the urinary tract. It can be surprising that despite the tremendous distortions seen within the urinary tract, the bladder may empty quite adequately, and improvement may be seen over time in the quality of the upper tracts. Reconstructive procedures for these children consist of bilateral orchiopexies and an abdominal wall plication

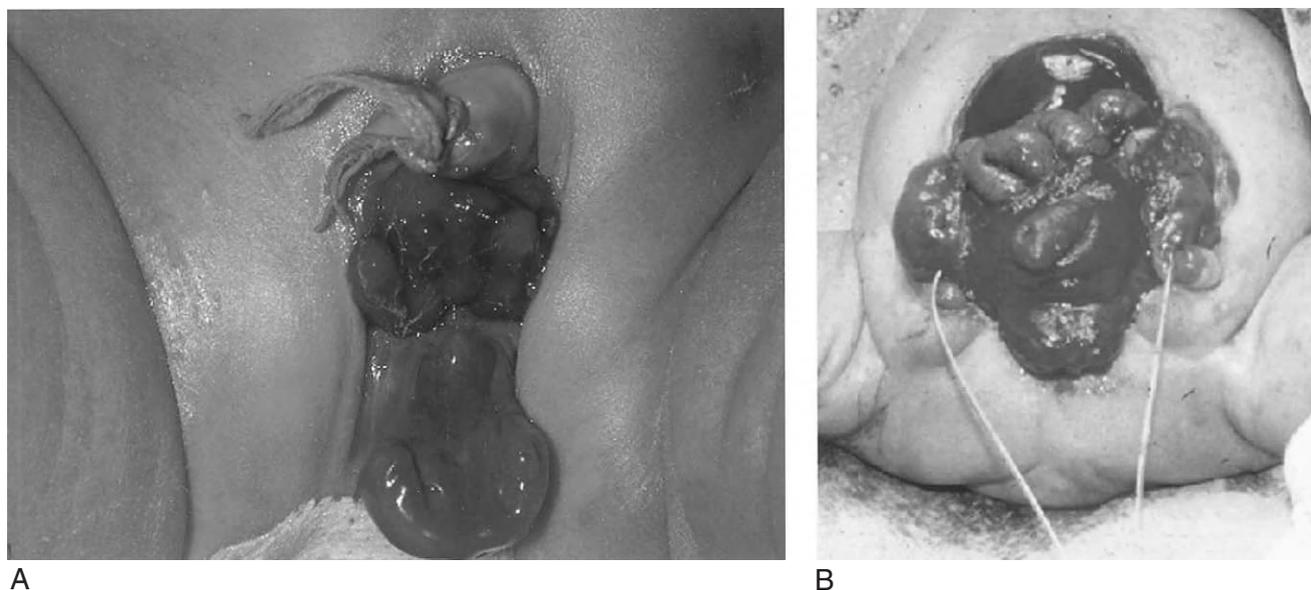

### The Exstrophies

#### Bladder Exstrophy

The patient with classic bladder exstrophy presents with a bladder plate that is protruding in the suprapubic area and that extends up to just below the umbilicus (Fig. 83-9). In males, there is an associated complete epispadias because the urethra never develops. In both

males and females, there is lack of formation of the bladder neck; thus, there is no mechanism for urinary continence. This diagnosis is being increasingly established in utero; failure to image the bladder on several prenatal sonograms should raise suspicion of this diagnosis. Classic exstrophy is not associated with any other associated anomalies, and many families opt to continue with the pregnancy. These children have an excellent prognosis and with proper management can lead nearly normal lives.

The traditional approach to the patient with classic exstrophy used to be a staged reconstruction beginning with a tubularization of the bladder plate within the first 24 hours of life (Canning et al, 1996). These children were left incontinent until the age of 5 to 7 years, when they underwent a second urologic reconstruction to create a competent bladder neck. This took place at a time when the child was capable of self-catheterization, to empty the bladder and to maintain safe storage pressures. In some series, up to 90% of these children required long-term clean intermittent catheterization (CIC) to achieve continence and maintain stable renal function.

**FIGURE 83-9.** (See also Color Plate 83-9.) The appearance of classic bladder exstrophy (**A**), in contrast with the dramatic appearance of cloacal exstrophy (**B**). In cloacal exstrophy, the bladder halves are separated by the presence of a large cecal plate, and a protruding ileal stump. **B**, In this intraoperative photograph, the omphalocele has been removed to expose the small bowel and liver.

These problems with staged exstrophy reconstruction outcomes led Mitchell and Bagli (1996) to propose a one-stage reconstruction within the first month of life. In males, this procedure includes a splitting of the penis with separation of the corporal bodies and urethral realignment. With this method, the bladder neck is reapproximated in an attempt to provide an anatomic closure offering a resistance that stimulates bladder growth; this approach probably will increase the percentage of patients who are able to void spontaneously while maintaining continence.

### **Cloacal Exstrophy**

The infant with cloacal exstrophy presents with several obvious clinical features (see Fig. 83-9) that include the presence of two bladder halves fully exposed on the abdomen; an abdominal midline that consists of the entire cecal plate that is wide open, allowing for egress of stool; often, a protruding prolapsed distal ileum; and an omphalocele of variable size (Canning et al, 1996; Zderic et al, 2002). In addition to these obvious malformations, 50% of these children will have associated spinal dysraphism of various degrees. From a medical standpoint, the risks of fluid loss, hypothermia, and infection from the exposed viscera mandate covering the exposed viscera with plastic wrap and immediately transferring the patient to the NICU.

The first stage of reconstruction should be undertaken as soon as the child's condition has stabilized. A central line is placed; all of these children will have some element of short bowel syndrome and will require hyperalimentation for varying periods postoperatively. The goals of the initial surgery are to tubularize the cecal plate and create a colostomy, followed by a reapproximation of the two

bladder halves. In some instances, only the omphalocele is closed first, and the bladder halves are left in place for a second-stage repair. For most of these children, continence will still come at the expense of intermittent catheterization, because 50% or more have a neural tube deficit.

Male infants with cloacal exstrophy will present with testes and rudimentary corporal bodies. The traditional recommendation for these patients was that they be assigned female gender of rearing, in light of the earlier dismal long-term phalloplasty results. However, today much more is known about the sexual differentiation of the fetal brain. This basic scientific information has been corroborated by several reassigned patients reverting to a male role (Reiner, 2002). Indeed, in view of this information and the newer surgical techniques available (Mitchell and Bagli, 1996), the pendulum is swinging away from reassignment and toward preserving male gender.

### **Spina Bifida**

The urologist's primary goal in management of the neonatal patient with spina bifida is the preservation of renal function. In these patients, the main threat to renal function may be traced to the abnormal bladder function. The traditional approach to management of patients with spina bifida called for closure of the defect in the neonatal period. However, as spina bifida is frequently diagnosed with prenatal sonography, a randomized clinical trial is being performed at present comparing outcomes of fetal versus neonatal spina bifida repair. Thus, in the next 5 years or so, more will be known about the long-term outcomes for these patients after in utero repair.

At present with postnatal repair, a renal bladder ultrasound study should be obtained within 1 week of closure

to look for any evidence of hydronephrosis. If this sonogram is normal, the child is discharged to home and a video-urodynamic assessment is performed at 4 weeks of age. The video-urodynamic studies are then repeated at 6 months of age and thereafter on a yearly basis until age 5. Yearly ultrasound examinations also must be performed to ensure the upper tracts are protected. If the initial ultrasound findings are abnormal, showing dilated upper tracts, the video-urodynamic studies are performed sooner.

The purpose of the urodynamic studies is to identify in advance the “hostile bladder.” A “hostile bladder” has poor function, with the potential to compromise renal function. Grading scales have been designed to identify in advance those infants at risk of upper urinary tract damage (Bauer et al, 1984; Bauer, 1992; McGuire et al, 1981; Perez et al, 1992). If there is evidence for the presence of a “hostile bladder,” many groups favor the immediate institution of CIC in conjunction with antimicrobial prophylaxis and anticholinergic medications (Kasabian et al, 1992; Sutherland et al, 1995). In addition to the benefits of CIC on preservation of renal function, recent studies suggest that early institution of CIC and anticholinergic therapy may improve bladder compliance in the long run and thus lessen the likelihood of future bladder augmentation surgery (Kaefer et al, 1999).

An additional option is the surgical creation of a vesicostomy. Although CIC offers many benefits, compliance may be difficult with the regimen required to maintain a safe storage pressure. Vesicostomy is a valid option because it is associated with preservation of the upper urinary tract (Snyder et al, 1983) and can dramatically diminish admission rates for urosepsis (Zhylyan et al, 1993). This last point is especially a factor in the child with spina bifida who experiences vesicoureteral reflux, because it is impossible to maintain sterile urine with use of CIC. Indeed, a child with spina bifida and vesicoureteral reflux who is maintained on CIC is at greater risk of developing pyelonephritis.

The child without evidence for having a “hostile bladder” may be followed with ultrasound examinations every 6 to 12 months, with the realization that the risk for upper urinary tract decompensation is less than 10%. Such children must, however, be evaluated with at least one examination annually, because the bladder may undergo changes over time, especially within the first 3 years of life. At 3 to 4 years of age, the issues of fecal and urinary continence must be dealt with. These children will require fecal training, and in most cases a daily enema followed by planned timed evacuation. Urinary continence also is rare in this subset of patients. For this reason, these children must master the process of CIC. Once this has been accomplished, further surgical reconstruction of the lower urinary tract may be required in order to achieve urinary continence.

### **Imperforate Anus**

The diagnosis of imperforate anus will prompt an immediate general surgical consultation and may result in a diverting colostomy. It is worth remembering that affected infants often have associated urologic findings (Rich et al,

1988). Urologic abnormalities are more likely for patients in whom the rectum ends in the supralelevator position (30%) as opposed to the infralevator position (15%). Up to 40% of these patients may have an associated lumbosacral lesion such as spina bifida occulta or a tethered cord. This is an important subset of patients to identify, for their bladders are already at risk for voiding dysfunction even before any rectal pull-through is performed. These patients will have a neurogenic bladder and often require intermittent catheterization to achieve continence.

The urologic radiographic work-up for these patients should consist of a renal-bladder ultrasound study and a VCUG. The renal sonogram will identify those patients with renal agenesis, anomalies of renal fusion, or occasional obstructive uropathy. The VCUG will identify those patients with reflux so that antibiotic prophylaxis can be initiated. In addition, the VCUG may identify any signs of a coloprostatic or colovaginal fistula and aid in the subsequent anorectal reconstruction. Finally, a magnetic resonance imaging (MRI) study of the lumbosacral spine will identify that subset of patients with a tethered cord or spinal dysraphism.

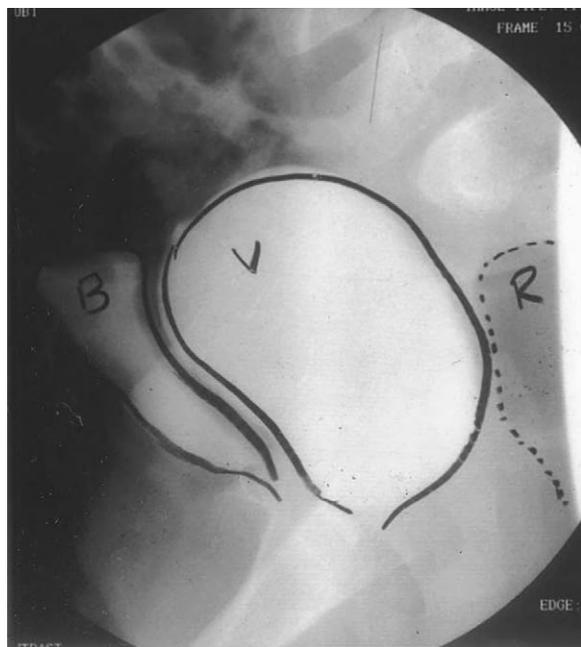

### **Cloacal Anomalies**

Cloacal anomalies of caudal differentiation manifest as a wide spectrum of abnormalities. One common variant in the female neonate is the combination of a completely “normal” although anteriorly placed rectum and a urogenital sinus into which the vagina and urethra merge (Fig. 83–10). Such neonates may present with a pelvic mass that is cystic and posterior to the bladder on pelvic sonography. Close inspection of their genitalia reveals one common sinus, which is narrow and offers high resistance to urinary flow. As a consequence, the bladder empties into a vaginal vault that progressively expands. In severe cases, it may even produce ureteral obstruction and hydronephrosis. The definitive diagnosis is made by a genitogram. Some cases demonstrate complete fusion, so that the urethra, vagina, and rectum empty into the perineum via one common channel. The embryology, anatomy, and complex management of these rare cases have been described in great detail by Hendren (1986) and Pena (1995). These anomalies constitute neonatal surgical emergencies, in which management decisions are highly individualized.

## **DISORDERS OF THE GENITALIA**

### **Undescended Testes**

Up to 3% of all term males may have evidence for an undescended testicle, although by 1 year of age, this drops to about 0.8%. Most of these testes that are going to descend do so by 6 to 9 months of life. Up to 30% of patients may present with bilateral undescended testes. The presence of bilateral impalpable undescended testes in a newborn male must be considered to represent an intersex state until proved otherwise. Failure to appreciate the significance of bilateral and impalpable undescended

**FIGURE 83-10.** This genitogram, performed by retrograde injection of contrast into a single sinus anterior to the patient's rectum, demonstrates the anteriorly placed bladder (B) and posteriorly placed vagina (V). The vagina and urethra merged into a common sinus, which then traveled a distance of 2 cm prior to emerging on the perineal body. The rectum (R) was normally placed. The vagina distended as a result of urinary entrapment, and the patient presented with a lower abdominal mass.

testes in the NICU means that a diagnosis of congenital adrenal hyperplasia may be missed (Fig. 83-11). Although in most cases of bilateral impalpable testes the infant proves to be a normal male, neonates with congenital adrenal hyperplasia often have inadequate cortisol and mineralocorticoid function, leaving the child susceptible to shock and delaying assignment of gender of rearing. Similar concerns arise if undescended testes are found in the presence of a hypospadias (see later section on ambiguous genitalia).

The neonate with a unilateral undescended testis and a normal phallus may be referred for a urologic follow-up evaluation at 6 months of age. At that time a careful examination will reveal whether the testis is impalpable, in which case surgical intervention should be undertaken. The impalpable testis may be a true intra-abdominal gonad or a testis that is intermittently passing in and out of a large patent processus vaginalis, or the testis may be completely absent secondary to an antenatal torsion. If testicular agenesis is present, the contralateral testis usually has undergone some degree of compensatory hypertrophy, with an increased volume noted on examination or by sonographic measurements (Huff et al, 1992). The measurement of volume alone, however, does not preclude the need for exploration. Parents need to be reminded that in 80% of cases in which exploration is undertaken for an impalpable testis, the testis is found and a successful orchiopexy is performed. The child who presents at 6 months of age with an undescended testis

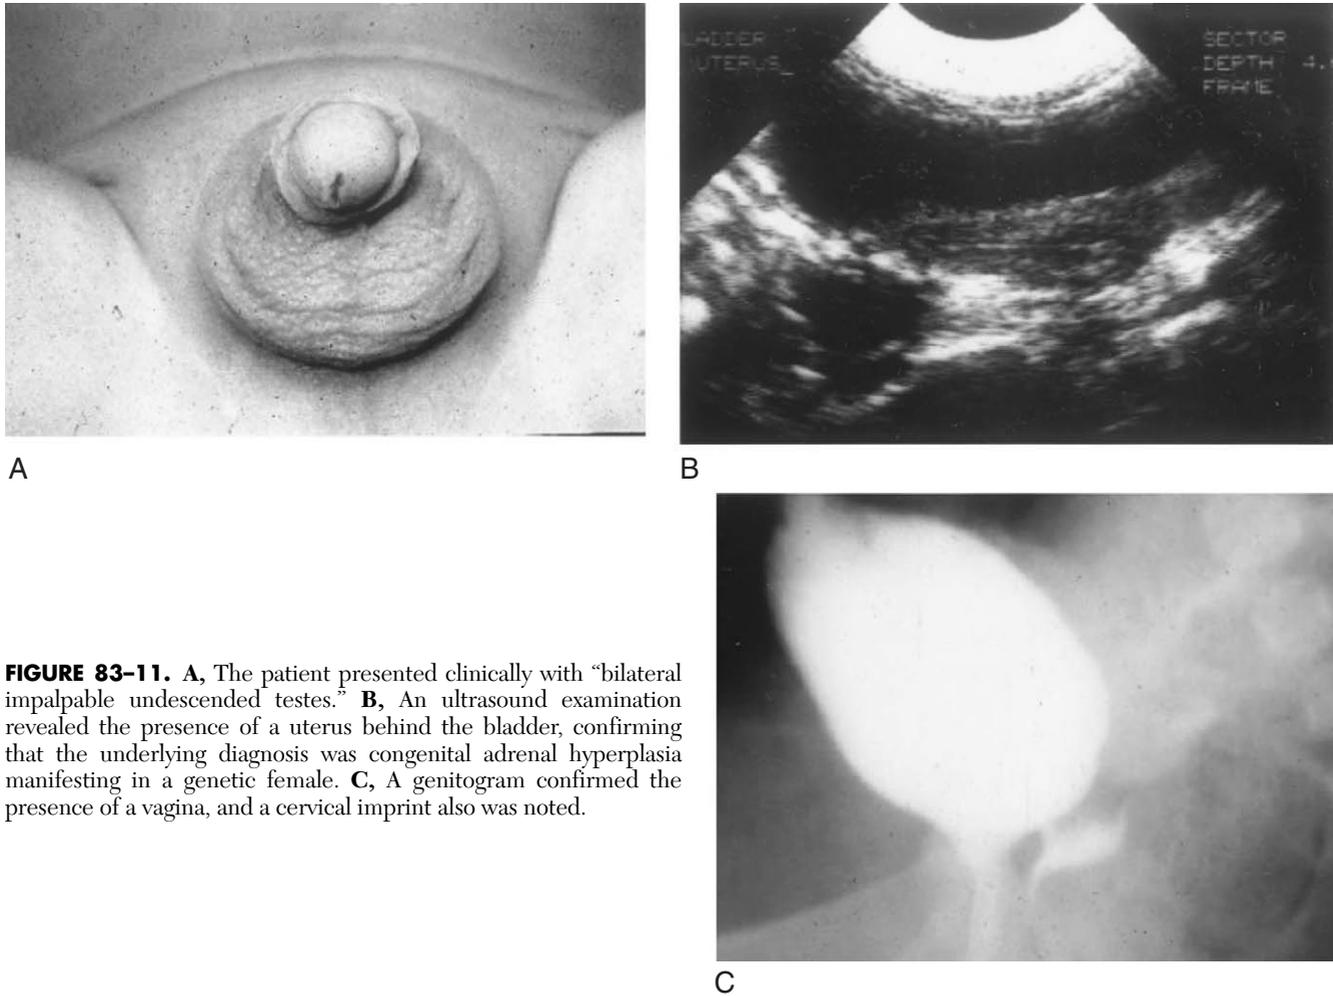

high in the inguinal canal also is a candidate for surgical intervention, because it is unlikely to descend on its own. If, however, the testis is near the scrotum, a repeat examination is prudent. A retractile testis may also present at this point, in which the testis may be pulled into the scrotal sac but will stay down only if there is a gentle overstretch of the cremasteric muscle fibers. Affected infants require close follow-up evaluation.

Long-term issues facing patients with cryptorchidism include a significantly increased risk of infertility and a slightly increased risk of testicular malignancy. Fertility rates vary greatly, depending on whether the cryptorchidism is unilateral or bilateral. Long-term follow-up studies looking at paternity have suggested that 90% of boys with unilateral cryptorchidism report paternity in later years (Cendron et al, 1989; Lee et al, 2001). However, for bilateral undescended testes, the paternity rate dropped to 50% for patients operated on in the first 3 years of life. As the patients' age at bilateral orchiopexy increases, the paternity rates decline (Lee et al, 2001). A number of centers have shown that cryptorchidism results in lower sperm counts despite surgical correction, and that the lowest counts are seen in those patients with bilateral cryptorchidism. Testicular biopsy at the time of orchiopexy may offer a potential to identify those patients at the greatest risk of infertility 20 and 30 years later (Huff et al, 1989). A histologic scoring system allowing for the prediction of a high-risk cohort of patients was recently validated with long-term follow-up semen analyses. The ability to predict low sperm counts using biopsy criteria also may allow for early hormonal treatment to enhance future fertility prospects in this group of patients. Although the timing of orchiopexy has been controversial, Lee and colleagues' (1996) long-term follow-up data suggest that, for bilateral undescended testes, an earlier age of surgery correlates with a better paternity rate.

There is an increased risk of malignancy for a child with an undescended testis, as the relative risk for testicular cancer in patients with an undescended testis increases anywhere from 9- to 40-fold over that in the normal population. This observation must be tempered, however, with the reality that testicular cancer is rare. This means that the overall lifetime risk of developing testicular cancer remains low for the individual patient. Orchiopexy is recommended, to place both testes in their proper scrotal position and to allow for monthly self-examination once the patient enters the pubertal years.

### Testicular Torsion

Torsion of the testes is a rare event in the neonatal period, but there is controversy as to its optimal management. The most important point in arriving at a management decision is a determination of what the scrotum looked like at birth. Was it blue, tense, and painless on initial exam in the delivery room? Was the scrotum normal initially, and then develop swelling accompanied by pain? The newborn that presents in the delivery room with an initially painless, blue, and tense hemiscrotum will be most likely to have an antenatal torsion. In this type of torsion, the entire tunica vaginalis and spermatic vessels

**FIGURE 83-11.** **A**, The patient presented clinically with “bilateral impalpable undescended testes.” **B**, An ultrasound examination revealed the presence of a uterus behind the bladder, confirming that the underlying diagnosis was congenital adrenal hyperplasia manifesting in a genetic female. **C**, A genitogram confirmed the presence of a vagina, and a cervical imprint also was noted.

are twisted in such a way as to occlude the vascular pedicle and render the testis ischemic. This may often occur during the last trimester, and thus what one is seeing in the delivery room is a late presentation of a process that has been ongoing for some time. In fact, if the antenatal torsion occurs early enough in gestation all inflammation will have resolved, and the neonate presents with an impalpable testis. Surgical findings include blood vessels and a vas deferens that end blindly at a common point where a small nubbin is occasionally found.

The controversy about management of torsion revolves around what to do for the infant who is born with a clinically apparent torsion. Immediate exploration in the hours after birth does not result in testicular salvage. However, there are several case reports documented in which bilateral metachronous torsions occurred, often with the initially normal testis subsequently undergoing a torsion (Kay et al, 1980). For this reason, some authors have advocated proceeding with an exploration to surgically tack down the normal testis and prevent a torsion in the remaining healthy gonad (Jerkins et al, 1983; Kaplan and Silber, 1989). Testes with antenatal torsion may also present as a firm mass in the neonatal period. The use of Doppler ultrasonography will help differentiate torsion

(no flow) from the more rare neonatal yolk sac tumor where testicular blood flow will be seen.

### Hydrocele

A hydrocele is nothing more than a collection of fluid between the tunica vaginalis, the liner of the scrotal sac, and the tunica albuginea, which covers the surface of the testes. In the neonate, this fluid will have its origin within the peritoneal cavity, which communicates with the scrotal sac via an evagination or extension of the peritoneum called a patent processus vaginalis. If the patency is small enough it may actually function as a one-way valve allowing fluid into, but not out of the scrotum. This explains the slow and progressive increases in scrotal size that may be seen in some cases. In other cases with a large patency, the fluid may move in and out of the scrotum with ease such that when the urologist arrives to examine the child, the swelling is gone. It is important to reassure families that these infants will often improve over time. Indeed, as for the frequency of a patent processus vaginalis, in autopsy series of men with no history of hernias or hydroceles, a 20% patency rate was found. Hydroceles may present

acutely following the placement of ventriculoperitoneal shunts or peritoneal dialysis catheters. In these instances, both sides should be repaired since there is a 30% chance that the contralateral side will also become symptomatic. Overly aggressive therapy of the neonatal hydrocele is to be avoided because many of these hydroceles will resolve on their own, and because the surgery always carries with it the attendant risk of damage to the vas deferens, and testicular vessels, and may result in testicular atrophy. The likelihood of such an iatrogenic injury is increased in the small neonate (Scherer and Grosfeld, 1993).

### **Hernia**

In cases where the patency of the processus vaginalis is large enough, it is possible that intestines and other viscera (including the bladder) may migrate into the scrotal sac. This, by definition, is a hernia, which may be easily reducible so that there is no urgency for repair (Scherer and Grosfeld, 1993). In contrast, if a hernia is difficult to reduce or incarcerated, this is cause for alarm and should prompt repair. If the neck of the sac is so tight that the hernia cannot be reduced, the blood supply to the intestine will be compromised and this is classified as a strangulated hernia, and represents a surgical emergency.

### **Hypospadias**

The diagnosis of hypospadias is established when the urethral meatus is not present in the normal glanular position; it may be present anywhere from the glans to the perineum. In addition, there is an asymmetrical or hooded foreskin, and the penis may be tethered, creating a significant bend (chordee). These infants must not undergo circumcision, because the foreskin is crucial for use in the urethral reconstruction and correction of the chordee. However, up to 10% of patients with a hypospadias may have an intact foreskin, and the diagnosis can be made only after circumcision. These cases constitute the megameatus-intact prepuce (MIP) variants. In such cases, the loss of foreskin does not compromise the hypospadias repair, which is carried out when the infant is 6 months old. It is important to be certain that both testes are descended into their proper scrotal positions; if a hypospadias is seen in conjunction with an undescended testis, the possibility of an intersex state exists (Rajfer and Walsh, 1976). This is particularly true if both testes are undescended and impalpable, in which case a diagnosis of congenital adrenal hyperplasia must be ruled out at once (see later section on ambiguous genitalia).

On making the diagnosis of hypospadias, the examining physician must immediately check to see if both testes are palpable. For an infant with a hypospadias and two testes that are properly placed in the scrotum, an outpatient evaluation with a urologist may be arranged within 1 month, to allay parental concerns, even though the reconstruction is deferred until the infant is 6 months of age. Completely elective outpatient surgery is felt to be safest after 6 months of age.

Hypospadias manifests with a wide spectrum of severity. The best results will be obtained in the simpler 90% of

cases, in which the meatus is present anywhere along the penile shaft. Snodgrass and Nguyen (2002) have developed a versatile repair that offers success rates of 98% to 99% for hypospadias with the meatus present along the penile shaft. Current hypospadias repairs offer functional improvement in terms of the quality of stream, as well as cosmetic results that are increasingly approaching those seen in normal males. Even the 10% of cases that constitute the most severe penoscrotal hypospadias may be reconstructed with good cosmetic and functional results. The key in all of these cases is the preservation of all genital skin that is to be used in the reconstruction—hence the need to avoid circumcision (Baskin and Duckett, 1996).

### **Circumcision**

Few topics arouse as much controversy, office visits, phone calls, and annoyance for families, pediatricians, and urologists as the issue of routine circumcision in the newborn male. Circumcision has been practiced for centuries, and despite all-out efforts in the late 1970s and early 1980s to discourage it, families have continued to clamor for this procedure. It is a fact that in the United States, nearly 80% of the male population is circumcised; thus, for many families, the concept that one could forgo this procedure is a surprise. For many families, the need for their children to fit in and look like their siblings or father is a major issue. It is reasonable to assume that the main reason most Americans seek routine circumcision is cosmetic. The other reason that families cite in their decision for circumcision is ease of maintaining hygiene. Superimposed on these notions are a number of other arguments including the “threat” of penile cancer and an “increased risk of sexually transmitted disease.” It is true that for patients with poor hygiene, a nonretractile foreskin will mask the onset of carcinoma of the penis. It also is true that this is a rare malignancy in the United States and a common malignancy in underdeveloped nations where circumcision is not practiced. However, this difference fails to explain why in Europe, where the overwhelming majority of men are not circumcised, penile cancer is rare. The reasons relate to access to regular bathing, basic hygiene, and the ability to retract the foreskin when sexual activity begins. The etiology of carcinoma of the penis is polyfactorial, and so long as the foreskin may be retracted to allow for good hygiene, the threat of malignancy is in and of itself a nonindication for circumcision. Likewise, the risk of sexually transmitted diseases is polyfactorial, and circumcision will not eradicate this family of diseases. Educational efforts on behalf of diminished promiscuity, condom use, and basic hygiene will produce a greater benefit for society as a whole than circumcision alone.

All of these rational arguments in favor of noncircumcision tend to fall short of their mark; the vast majority of American parents will request routine circumcision. Parents may cite a significant study reported by Wiswell and Geschke and colleagues, in several stages (Wiswell and Geschke, 1989; Wiswell et al, 1993), that identified a small but very real medical benefit to circumcision. By looking closely at the discharge data from U.S. Army

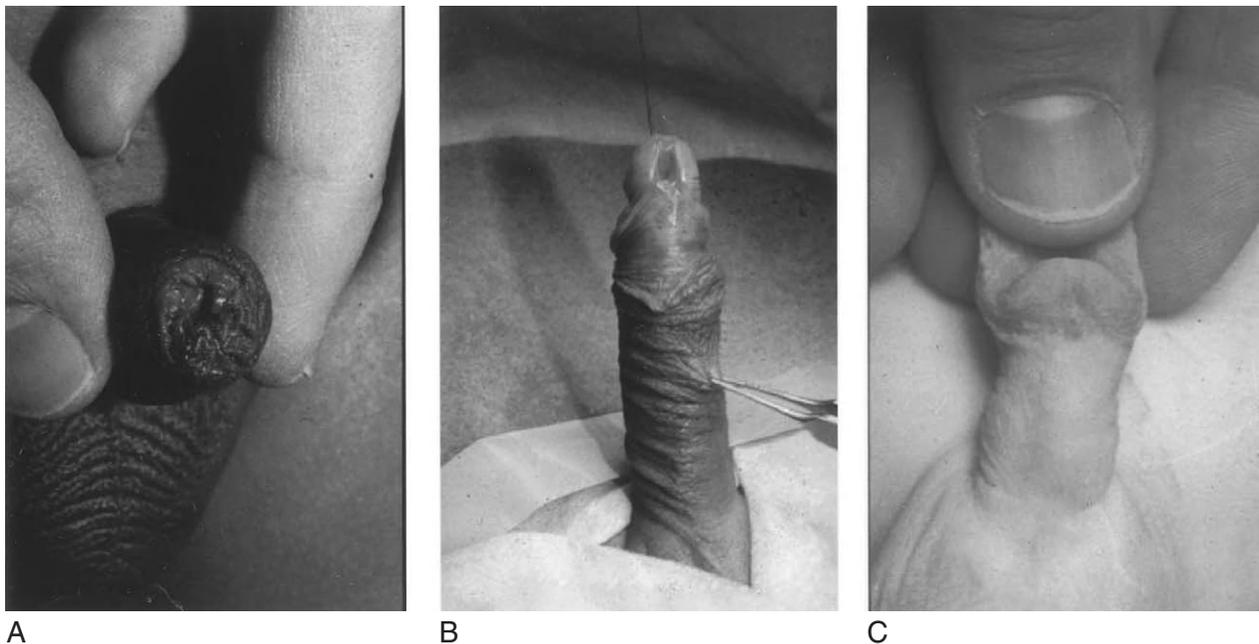

hospitals worldwide, these investigators were able to correlate the status of the foreskin with subsequent outcomes with regard to urinary tract infections. Their findings include that, within the first year of life, although only 20% of the males were not circumcised, this 20% accounted for 80% of all urinary tract infections. In other words, these investigators demonstrated that the presence of foreskin increased the chances of a urinary tract infection by approximately fourfold during the first year of life. It is estimated that 99 children have to undergo circumcision to avoid 1 episode of urinary tract infection in the 100th patient—a small but real medical benefit. Nevertheless, circumcision is to be encouraged for any neonate with an underlying congenital anomaly of the urinary tract such as reflux, posterior urethral valves, or megaureters, where the added burden of a urinary tract infection could have more serious consequences.

The three main techniques for circumcision are use of the Plastibell, the Gomco clamp, and the Mogen clamp. Each has benefits and drawbacks; each physician performing circumcisions will find the method with which he or she feels most comfortable and should use it repetitively. If there is any doubt about a child's particular anatomy, the procedure should be stopped, and urologic consultation obtained. The use of EMLA cream and a circumferential block is highly effective in minimizing the pain associated with the procedure.

The leading contraindication to circumcision is medical fragility of the infant. Circumcision in a premature baby may present a technical challenge related to the infant's

smaller size, because a proper fit between child and equipment is essential. In such instances, circumcision should be deferred until just before discharge from the NICU. In the child with a complex medical course, this timing also offers the physician a chance to carry out a circumcision with full cardiovascular and respiratory monitoring, which is not always available in an office-based setting. Circumcision must never be performed in any child with hypospadias or epispadias (Fig. 83-12), because as mentioned earlier, this skin is essential to the urethral reconstruction.

Bleeding after a routine circumcision may be seen in 10% to 20% of the cases, and this minor spotting is no cause for alarm. If the bleeding has passed onto the diaper, and a repositioning of the pressure dressing fails to stop the bleeding, the frenulum should be inspected, because this is where most bleeding vessels are found. If the bleeding persists, the clinician should not hesitate to obtain coagulation studies, because both hemophilia and von Willebrand disease may manifest in this manner. Rarely, there is injury to the glans and urethra. However, the most common problem arising after circumcision is penile adhesions, although this complication may be prevented by teaching parents to pull back on the penile shaft skin and apply petrolatum over the glans. Parents also should be warned that despite a nice skin fit in the neonatal period, the cosmetic appearance of the penis may change as the prepubic fat pad grows. The result may be that a perfect circumcision is obscured as the penis is pulled back into the fat pad; in such cases, reassurance, and not surgical revision, is indicated.

**FIGURE 83-12.** Hypospadias may not be discovered until the time of circumcision, because the foreskin has such a normal appearance, as in **A** and **B**. These cases represent the megameatus-intact prepuce variant, in which circumcision is not at all detrimental to future reconstruction. **C**, This photograph shows a more typical hypospadias with an asymmetrical foreskin and a meatus that is present at the glanular margin. In such cases, circumcision should be deferred because the hooded preputial skin may be required for subsequent reconstruction.

### Ambiguous Genitalia

The diagnosis and management of the child with ambiguous genitalia remain a medical and social emergency, and a complete discussion of this topic is beyond the scope of this section. Whereas in the past, this dilemma came as a total surprise in the delivery suite, today prenatal diagnosis has allowed for the discussions about genital ambiguity to begin in advance (Rintoul and Crombleholme, 2002). The widespread use of ultrasonography and increasing use of amniocentesis have allowed for the in utero diagnosis of virilizing congenital adrenal hyperplasia and complete androgen resistance syndromes. Such diagnosis is possible because the sonographic appearance of the genitalia will not match the karyotype obtained at amniocentesis. Still, the clinician must be prepared to deal with the situation in which no amniocentesis data are available and only one maternal sonogram was done in early gestation.

The most common presentation will be the female with congenital adrenal hyperplasia, which varies in its severity of presentation. Findings on physical examination range from severe clitoromegaly to a fully developed phallus with no palpable gonads (see Fig. 83–11). This virilization is caused by enzymatic deficiencies in the pathways of cortisol synthesis, leading to shunting into the androgen biosynthetic pathways (White, 2002). The family history is useful, as an older sibling or relative may have already been diagnosed with this condition. It is also useful to know if a karyotype was done during gestation. If a karyotype was not done or the results are not available, an ultrasound examination of the pelvis may be ordered to look behind the bladder for any müllerian remnants (see Fig. 83–11) and a karyotype should be ordered. Virilizing congenital adrenal hyperplasia is a rare diagnosis, and most males with bilateral impalpable testes will prove to be normal males. However, a delay in establishing this diagnosis is dangerous because replacement therapy with cortisol must be initiated. A delay in diagnosis also has profound implications for gender assignment. A genitogram (see Fig. 83–11) will delineate the extent of surgery required. The timing of surgery and the process of gender assignment are controversial at present, and these issues are addressed in the final paragraph.

Another common presentation is that of the child with androgen insensitivity who presents as a phenotypic female despite an amniocentesis showing an XY karyotype. This situation arises because for virilization to occur, the androgens must first bind to their receptors in the cytosol. Mutations in this receptor or at other points downstream then result in a phenotypic female who at subsequent laparotomy is found to have testes. Furthermore, these testes have continued to produce the müllerian inhibitory substance—hence, the uterus and the upper two thirds of the vaginal vault will be missing. There are no surgical management or gender assignment issues for these patients in the neonatal period.

Mixed gonadal dysgenesis (MGD) is seen in the neonatal unit as patients present with a severe hypospadias and a unilateral undescended testis. However, Rajfer and Walsh (1976) noted that MGD was one of the most common diagnoses made in patients with hypospadias and associated cryptorchidism. These patients may have a normal XY karyotype or a mosaic presentation. At exploratory laparotomy, the gonads are biopsied; a testis will be found

on one side and a primitive streak on the opposite side. Rudimentary müllerian structures may be seen on the side of the streak gonad and may include a hypoplastic uterus. Streak gonads are removed because of their malignant potential. Although in past years a female gender assignment was considered, the current trend favors maintaining a male gender of rearing, with subsequent application of now-available advanced hypospadias reconstruction techniques.

The traditional approach to the diagnosis and management of genital ambiguity has undergone a great deal of criticism and increasing scrutiny over the past several years. With the traditional approach, the emphasis was placed on assigning a gender of rearing as soon as possible, and initiating any surgical reconstructions in the neonatal period. In recent years, it has become apparent that there can be problems with such an approach. Physicians, together with the parents, can assign a sex and gender role to a neonate. However, the long-term question arises as to whether a child's own gender identity will be congruent with the assigned gender role. For years it was believed that gender identity was plastic and not fixed until a child was 2 years of age. Given the technical problems encountered in phallic reconstruction, it was believed that if a satisfactory phallus could not be reconstructed, a female sex should be assigned. The recent reports of several patients who, on reaching the teenage years, have reverted back to a male gender after early female gender assignment have challenged this practice (Diamond, 1999; Reiner, 2002). In light of these scientific and clinical concerns, some authors and patients have called for a moratorium on surgery in infancy for patients with genital ambiguity (Diamond, 1999). They propose that all diagnostic tests be performed to allow for a determination of what the best gender assignment will be for the child. However, no irreversible surgery would be performed until it becomes clear what the child's own gender identity is, and a pediatric assent could be obtained. It is important to note that many patients with an XY karyotype assigned to a female gender have compensated to their situation (Schober et al, 2002). However, because the brain is a sexually dimorphic organ, many of the structural differences between the two genders that exist do so on the basis of hormonal imprinting in utero (Gorski, 2002; Swaab et al, 2002).

## Acute and Chronic Renal Failure

Philippe S. Friedlich, Jacquelyn R. Evans,  
Tivadar Tulassay, and Istvan Seri

### DEFINITION OF NEONATAL ACUTE AND CHRONIC RENAL FAILURE

Neonatal acute renal failure (ARF) is defined as the sudden, severe derangement of glomerular filtration and tubular function and is diagnosed when serum creatinine is greater than 1.5 mg/dL regardless of the rate of urine output. ARF also should be suspected in the newborn if serum creatinine fails to decline below maternal levels by (at least) the fifth to seventh days postnatally or is rising by 0.3 mg/dL/day or faster (Karlłowicz and Adelman, 1992).

Neonatal ARF has conventionally been subdivided into prerenal, intrarenal (intrinsic), and postrenal (obstructive) renal failure according to the primary site of the disorder. The overall incidence of neonatal ARF is approximately 20% of all neonatal intensive care unit (NICU) admissions (Karlłowicz and Adelman, 1992; Stapleton et al, 1987). Greater than 70% of these cases represent prerenal ARF with the rest being intrinsic or obstructive ARF. It is important to remember that the conventional classification of neonatal *obstructive* renal failure as ARF is incorrect; this disorder rather represents the acute presentation of a chronic renal failure when separation from the placental circulation at birth occurs.

Neonatal chronic renal failure (CRF) develops when derangements of glomerular filtration and/or tubular function continue following the resolution of the acute phase of renal failure.

### PATHOPHYSIOLOGY OF NEONATAL RENAL FAILURE

#### Prerenal Acute Renal Failure

Prerenal ARF is the most common form of ARF in the newborn. The cause of prerenal ARF is renal hypoperfusion due to systemic hypotension or to selective decreases in renal blood flow in response to tissue hypoxia without significant systemic hypotension. Under these circumstances, renal autoregulation fails to maintain renal blood flow (RBF) and glomerular filtration rate (GFR) in the physiologic range. Correction of the underlying condition immediately restores normal renal function unless renal hypoperfusion has been so severe or prolonged that renal parenchymal damage has already developed. Once parenchymal damage occurs, prerenal ARF evolves into intrinsic ARF.

In prerenal ARF, despite the decrease in RBF, GFR is initially relatively preserved leading to enhanced tubular reabsorption of solutes and water. The increase in filtration fraction ( $GFR/RBF \times 100$ ) increases peritubular oncotic pressure, resulting in enhanced proximal tubular sodium and water reabsorption (Feld et al, 1986). Furthermore, vasopressin and endothelin secretion as well as the activity of the renin-angiotensin-aldosterone system and the renal sympathetic nerves increases, leading to further enhancement of renal tubular solute and water absorption. The net result of these renal hemodynamic and hormonal changes is oliguria, decreased urinary sodium losses, and increased urinary osmolality. In some newborns, however, oliguria does not develop, because pituitary release of or renal responsiveness to vasopressin is decreased (Dixon and Anderson, 1985), and because in these cases less significant alterations in the renal microcirculation may occur. Thus, the rate of urine output has a somewhat limited diagnostic value in newborns (see later). Urine output is an important prognostic factor, however, because morbidity and mortality in nonoliguric ARF are decreased compared with those in the oliguric form, even if features of intrinsic renal failure develop (Chevalier et al, 1984; Karlłowicz and Adelman, 1995).

Severe perinatal blood loss, perinatal asphyxia, respiratory distress syndrome, dehydration in the extremely immature preterm infant due to increased transepidermal free water losses, necrotizing enterocolitis, hydrops, septic shock, other severe illness associated with capillary leak syndrome, and the use of certain pharmacologic agents (see later) are the most frequent conditions associated with absolute or relative decreases of intravascular volume or renal hypoperfusion (or both) resulting in the development of prerenal ARF in the newborn (Table 84-1). In addition, decreases in renal perfusion may occur following primary surgical repair or surgical reduction of omphalocele, gastroschisis, or congenital diaphragmatic hernia. Finally, acute decreases in cardiac output during cardiac surgery or use of extracorporeal membrane oxygenation (ECMO) also may lead to the development of prerenal ARF. In addition, ECMO may result in impaired autoregulation of organ blood flow (Liem et al, 1995), leading to the development of a pressure-passive circulation. Thus, in newborns on ECMO, prerenal failure may develop rapidly unless blood pressure is tightly controlled in the normal range. If blood pressure cannot be appropriately maintained and renal blood flow remains compromised for a prolonged period of time, the prerenal failure may evolve into intrinsic renal failure with potentially permanent damage to the kidneys.

#### Intrinsic Acute Renal Failure

Approximately 6% to 8% of newborns admitted to NICUs have intrinsic ARF, with severe perinatal asphyxia being the most common cause (Stapleton et al, 1987). In contrast with prerenal ARF, the renal functional abnormalities in intrinsic ARF are not immediately reversible. The severity of intrinsic ARF ranges from mild tubular dysfunction to acute tubular necrosis, with or without oliguria and anuria, to renal infarction and corticomedullary necrosis with

TABLE 84-1

## Causes of Acute Renal Failure in the Newborn\*

Prerenal Acute Renal Failure	Intrinsic Acute Renal Failure	Obstructive Renal Failure
Loss of effective circulating blood volume	Acute tubular necrosis (long-lasting, severe renal ischemia, nephrotoxins)	Congenital malformations
Absolute loss		Imperforate prepuce
Hemorrhage		Urethral stricture
Dehydration	Congenital malformations	PUV
Relative loss	Bilateral renal agenesis	Urethral diverticulum
↑ Capillary leak (sepsis, NEC, RDS, asphyxia, ECMO)	Renal dysplasia	Primary VUR
Renal hypoperfusion	Polycystic kidneys	Ureterocele
All of the above	Infections	Megaureter
Congestive heart failure	Congenital infections (syphilis, toxoplasmosis)	UPJ obstruction
Cardiac surgery	Pyelonephritis	Extrinsic compression
Pharmacologic agents	Bacterial endocarditis	Sacrococcygeal teratoma
Indomethacin	Renal vascular causes	Hematocolpos
Tolazoline	Renal artery thrombosis	Intrinsic obstruction
ACE inhibitors	Renal vein thrombosis	Renal calculi
	DIC	Fungus balls
	Nephrotoxins	Neurogenic bladder
	Aminoglycosides	
	Indomethacin	
	Amphotericin B	
	Methicillin	
	Radiocontrast dyes	
	Intrarenal obstruction	
	Uric acid nephropathy	
	Myoglobinuria	
	Hemoglobinuria	

\*In many cases, a combination of several causative factors contributes to the development of acute renal failure. For instance, absolute hypovolemia, increased capillary leak-induced loss of effective circulating blood volume, and reflex renal vasoconstriction all may contribute to renal hypoperfusion and ensuing renal injury in newborns with severe forms of shock.

ACE, angiotensin-converting enzyme; COX-2, cyclooxygenase type 2; DIC, disseminated intravascular coagulation; ECMO, extracorporeal membrane oxygenation; NEC, necrotizing enterocolitis; PUV, posterior urethral valve; RDS, respiratory distress syndrome; UPJ, ureteropelvic junction; VUR, vesicoureteral reflux.

Data from Karlowicz and Adelman, 1992.

irreversible renal damage. It is of clinical importance that untreated and sustained prerenal or obstructive ARF eventually develops into intrinsic ARF (see earlier). Conditions most commonly associated with the development of intrinsic ARF in the newborn are listed in Table 84-1.

The term *acute tubular necrosis* has been used interchangeably with *acute renal failure*. Although extensive tubule injury is a frequent pathologic finding in ARF, acute tubular necrosis should be used only to refer to cases of intrinsic ARF secondary to renal ischemia or nephrotoxic substances, in which tubular necrosis is always one of the main mechanisms causing renal failure (Kon and Ichikawa, 1984).

The course of intrinsic ARF may be subdivided into initiation, maintenance, and recovery phases. The initiation phase includes the original insult and the associated events. The sustained low GFR, tubular dysfunction, and azotemia represent the maintenance phase. The duration of the maintenance phase depends, at least in part, on the severity and duration of the initial insult. The recovery phase is characterized by the gradual restoration of GFR and tubular functions. Recognition of the different phases of neonatal intrinsic ARF is helpful in the diagnosis, clinical management, and prognostication of the disorder.

Changes in renal hemodynamics brought about by the excessive production and release of vasoconstrictive hormones, including the renin-angiotensin system, epine-

phrine, norepinephrine, endothelin, adenosine, vasoconstrictive prostaglandins, and vasopressin, play an important role in the development and maintenance of intrinsic renal failure (Karlowicz and Adelman, 1992; Toth-Heyn et al, 2000). In addition, alterations in the function and ultrastructure of the nephron, including the decrease in the permeability and surface area of the glomerular capillary, intratubular obstruction to tubular flow by cellular debris, and tubular back-leak, contribute to the impairment of renal function in intrinsic ARF. Finally, the deterioration of hemodynamic and tubular functions is associated with intracellular events, such as enhanced free radical injury with reperfusion of the kidneys and accumulation and sequestration of intracellular calcium in mitochondria, resulting in phospholipase activation and the ensuing deterioration of mitochondrial structure and function. If the initiating insult is severe, sustained, or repeated, the intracellular events may lead to widespread epithelial cell death and irreversible tissue damage, resulting in the development of CRF.

### Ischemic-Hypoxic Injury

Despite being the best-oxygenated organ, the kidney is susceptible to ischemic-hypoxic injury because of the redistribution of its blood flow under pathologic circumstances to

the “vital” organs and also because of the unique vascular supply of the renal medulla. The presentation and course of the renal damage depend on the severity and duration of the insult. Mild ischemia results in transient loss of renal concentrating capacity, owing to the extreme sensitivity of the medullary thick ascending limb to tissue hypoxia (Brezis et al, 1984). The loss of concentrating capacity may be difficult to detect in immature preterm newborns with the developmentally regulated maturity of their renal concentrating capacity (see Chapter 80). More prolonged injury produces widespread tubular dysfunction, with significant impairments in sodium and water reabsorption and decreases in GFR. This degree of severity of intrinsic ARF is most frequently seen in full-term newborns with severe perinatal asphyxia, who present most commonly with the nonoliguric form of ARF (Karlłowicz and Adelman, 1995). Finally, prolonged or repeated insults may result in the irreversible form of intrinsic ARF, with oliguria and anuria and persistent tubular and glomerular damage leading to the development of CRF.

The primary pathomechanism of ischemic-hypoxic intrinsic ARF is the damage to the renal tubular epithelium, resulting in back-leak of the glomerular filtrate and intraluminal obstruction with necrotic cellular debris (Kon and Ichikawa, 1984). The latter results in an elevation of the pericapillary hydrostatic pressure in the Bowman space, leading to further decreases in GFR. The tubuloglomerular feedback mechanism also may be activated by the compensatory increases in the delivery of sodium and water to the distal parts of the nephron in the unobstructed tubules, resulting in a further loss in GFR (Myers and Moran, 1986). In addition, abnormalities in the ultrastructure of the glomerulus and decreases in the total filtering surface area occur (Feld et al, 1986; Kon and Ichikawa, 1984). The cumulative effect of these changes in the most severe cases of intrinsic ARF is the complete cessation of glomerular filtration.

The use of some medications, including captopril or enalapril (Rasoulpour and Marinelli, 1992) (see Chapter 87) and tolazoline (Guignard and Gouyon, 1988), may also lead to the development of ischemic intrinsic ARF in the sick newborn. The angiotensin-converting enzyme (ACE) inhibitors (captopril and enalapril) may induce unpredictable decreases in systemic blood pressure so that renal perfusion pressure drops below the autoregulatory range, leading to tissue hypoperfusion with subsequent hypoxic-ischemic damage to the renal epithelium. Although tolazoline is not available in the United States any more, it is worth mentioning that, in addition to causing systemic hypotension, this drug also may induce severe renal vasoconstriction, further compromising renal perfusion (Guignard and Gouyon, 1988).

### Nephrotoxic Injury

The predominant lesion in nephrotoxic ARF is the damage to the proximal tubule cells (Feld et al, 1986). In clinical practice, aminoglycoside administration to the newborn is one of the most common conditions in which such damage can occur. Aminoglycosides inhibit lysosomal phospholipases, leading to tubule cell phos-

pholipidosis and subsequent necrosis (Giuliano et al, 1984). Changes in the ultrastructure of the glomerulus also occur (Kon and Ichikawa, 1984). The immature kidney appears to be less susceptible to aminoglycoside toxicity than that of the adult (Pelayo et al, 1983). The clinician must also remember that aminoglycoside toxicity is usually *nonoliguri*; therefore, serial monitoring of serum creatinine values is necessary, especially during prolonged administration of these antibiotics, to detect their potential nephrotoxicity in the newborn. The mechanisms of aminoglycoside toxicity may be activated even when serum levels are in the accepted range for toxicity in the newborn (Adelman et al, 1987). The potential long-term consequences of this effect on neonatal renal function are unknown.

Finally, neonates and infants with mitochondrial cytopathies may present with renal dysfunction resembling nephrotoxic injury before the neurologic and neuromuscular symptoms become evident (Buemi et al, 1997). Renal tubulopathy (Fanconi syndrome) is frequently a leading presentation in newborns with mitochondrial cytopathies; affected infants may first present with tubulointerstitial nephropathy developing into terminal uremia.

### Combined Ischemic and Nephrotoxic Injury

Other medications, including amphotericin B and indomethacin, exert their renal side effects by causing both ischemic and direct nephrotoxic renal injury. Amphotericin B alters renal function by reducing RBF and GFR and by directly affecting tubular function, resulting in renal tubular acidosis and increased urinary potassium excretion. Although these nephrotoxic effects are most often reversible, cases of fatal neonatal renal failure due to amphotericin B toxicity have been reported (Baley et al, 1984). Serum creatinine and electrolytes should be closely monitored; the dosing interval should be prolonged if serum creatinine rises, and replacement therapy with potassium and bicarbonate should be provided if indicated. Finally, because liposomal or lipid complex amphotericin B-based products appear to be less nephrotoxic, their use should be considered in neonates at risk for renal insufficiency (Adler-Shobert et al, 2001; Friedlich et al, 1997).

Severe, although usually transient, nephrotoxicity can occur with indomethacin administration. The potentiation of the vasoconstrictive and sodium- and water-retaining effects of angiotensin II, norepinephrine, and vasopressin by the indomethacin-induced inhibition of renal prostaglandin production is the primary mechanism of the renal actions of the drug. Because neonatal renal function is more dependent on local prostaglandin production than that of the euvolemic adult (especially when intravascular volume is decreased as a result of fluid restriction, increased capillary leak, and transepidermal water losses in the preterm infant with patent ductus arteriosus), indomethacin administration is almost always associated with elevated serum creatinine concentrations, decreased urine output, and hyponatremia (Cifuentes et al, 1979). In addition, indomethacin may also exert a direct aldosterone-like effect on the distal tubule. Because the renal side effects of indomethacin are mostly transient, some

clinicians prefer to wait until spontaneous recovery of renal function occurs while maintaining a restricted fluid intake without additional sodium supplementation. Whether concomitant low-dose dopamine infusion aids in the recovery from the renal tubular side effects of indomethacin treatment remains to be determined (Baenzinger et al, 1999; Fajardo et al, 1992; Seri, 1995; Seri et al, 2002). If severe oliguria or anuria develops in the preterm infant, however, furosemide administration may become necessary to prevent the persistence of the ARF caused by indomethacin (Yeh et al, 1982). Serum creatinine and electrolytes as well as urine output should be closely monitored in these newborns. If gentamicin or other nephrotoxic medications are being concomitantly administered, the dosing interval for these medications should be prolonged in anticipation of the increases in serum creatinine.

A less common form of neonatal intrinsic ARF associated with hypoxia, perinatal asphyxia, or polycythemia is uric acid nephropathy (Karlłowicz and Adelman, 1992; Stapleton et al, 1987). In such cases, precipitation of uric acid or monosodium urate crystals results in obstruction of the renal tubules, causing intrinsic ARF. Because newborns normally excrete more uric acid, they may be prone to the development of uric acid nephropathy if severe and prolonged hyperuricemia develops (Stapleton et al, 1987). In addition, intrinsic ARF, partly as a result of intratubular obstruction, may develop with cases of rhabdomyolysis in severe perinatal asphyxia (Kojima et al, 1985) or with massive hemoglobinuria resulting from intravascular hemolysis. Radiopaque contrast agents also may cause intrinsic ARF, especially in newborns who already have compromised renal function, such as those with congenital heart disease undergoing cardiac catheterization (Karlłowicz and Adelman, 1992).

Finally, medications given to pregnant women may cause combined ischemic and nephrotoxic renal injury in the fetus, resulting in the clinical presentation of ARF after birth. A frequently used class of medications that fall into this category are the nonsteroidal anti-inflammatory drugs (NSAIDs) prescribed for tocolysis—both nonselective cyclooxygenase inhibitors such as indomethacin or ketoprofen (Bannwarth et al, 1999) and selective cyclooxygenase type 2 (COX-2) inhibitors such as nimesulide (Peruzzi et al, 1999). Because intrauterine nimesulide exposure may also lead to end-stage intrinsic ARF necessitating dialysis of the newborn (Balasubramanian, 2000; Peruzzi et al, 1999), COX-2 inhibitors must be used with caution in pregnant women.

### **Obstructive Renal Failure: Acute Presentation of Chronic Renal Failure**

Obstructive renal failure can be caused by a variety of congenital malformations of the kidneys and the urinary collecting system (see Table 84–1) (see also Chapters 82 and 83). Some of these newborns have reversible renal failure, whereas others have renal dysplasia with irreversible intrinsic renal failure at the time of diagnosis. Although prognostication of long-term outcome of renal

function in obstructive renal failure is extremely difficult, in newborns with prune-belly syndrome, a nadir serum creatinine greater than 0.7 mg/dL, bilateral renal abnormalities on renal ultrasound scan, and clinical pyelonephritis are prognostic for development of CRF (Noh et al, 1999).

### **DIAGNOSIS OF NEONATAL ACUTE AND CHRONIC RENAL FAILURE**

Despite its limitations, serum creatinine is the most widely used measure to evaluate glomerular filtration in the clinical setting and is more specific than blood urea nitrogen (BUN) (see Chapter 81, on clinical evaluation in renal/kidney disease). Because the production of BUN is increased by a high dietary protein intake, gastrointestinal bleeding, and hypercatabolic states, BUN levels are elevated out of proportion to changes in GFR under these conditions. Moreover, the renal excretion of urea also is influenced by tubular function, especially under conditions associated with alterations in tubular water reabsorption. Therefore, as a general rule, if the BUN-to-serum creatinine ratio exceeds 20, increased urea production or increased renal urea reabsorption (or both) should be suspected (Feld et al, 1986).

The major goal in the initial evaluation of neonatal ARF is to diagnose prerenal ARF and obstructive renal failure promptly to prevent their transition to intrinsic ARF and then CRF. The medical history of the pregnancy, the findings on prenatal tests and ultrasound studies, and the physical examination usually provide important clues in the newborn presenting with oliguria and anuria in the immediate postnatal period. If obstruction is suspected, a renal and bladder ultrasound study should be performed without delay (see Chapter 83). In cases in which oliguria and elevated serum creatinine values are associated with hematuria or hypertension (or both), the possibility of renal vascular disease should also be considered (see Chapter 87).

The clinically most reliable diagnostic tool to differentiate prerenal ARF from intrinsic ARF is the provision of an appropriate fluid challenge, unless the newborn is suspected of having a urinary outlet obstruction or renal hypoperfusion secondary to congestive heart failure. Isotonic solution (usually normal saline) should be given in a dose of 20 mL/kg or more over a period of 30 minutes to 2 hours. If urine output remains less than 1 mL/kg per hour after 2 hours and there are no clinical signs of intravascular volume deficit, 1 to 2 mg/kg of furosemide should be administered. Low-dose dopamine infusion may be used in addition to the volume challenge, especially if systemic blood pressure is labile or remains low after the volume challenge is completed. Low-dose dopamine improves renal perfusion, increases GFR, and increases renal sodium and free water excretion in the preterm and term infant (Seri, 1995; Seri et al, 1998). In addition, primarily along the proximal parts of the nephron, dopamine inhibits renal tubular Na<sup>+</sup>,K<sup>+</sup>-ATPase activity and decreases renal oxygen consumption when oxygen delivery is limited (Seri, 1995). However, the clinical importance of this effect of the drug remains to be demonstrated, and

because dopamine blunts the tubuloglomerular feedback and increases solute delivery to the distal parts of the nephron, oxygen consumption in the outer medulla may increase rather than decrease (Heyman et al, 1995). On the other hand, at least under pathologic conditions, dopamine restores the diminished outer medullary blood flow and ameliorates outer medullary hypoxia caused by indomethacin or by the inhibition of nitric oxide synthesis (Heyman et al, 1995). Therefore, the use of dopamine may be beneficial in the sick preterm and term infant with *prerenal ARF* caused by hypoxemia, acidosis, or indomethacin administration (Seri, 1995; Seri et al, 1998, 2002). Finally, although widely used in children and adults to diagnose *prerenal ARF*, the mannitol test is contraindicated in newborns with a predisposition to the development of intraventricular hemorrhage or periventricular leukomalacia because of the drug-induced sudden increase in serum osmolality.

Compared with intrinsic ARF, *prerenal ARF* is associated with a low urinary sodium excretion, fractional excretion of sodium (FENa), and renal failure index and with high urine-to-plasma osmolar and creatinine ratios (Table 84-2). Although these diagnostic indices are helpful in differentiating *prerenal ARF* from intrinsic ARF in older children and adults, there are important limitations to their use in the sick preterm and term newborn. Some newborns, especially immature preterm infants, with *prerenal ARF* have values overlapping those attributed to intrinsic ARF (Ellis and Arnold, 1982). Furthermore, FENa in preterm infants born at less than 32 weeks of gestation with normal renal function is usually higher than 3%, and there are no data of FENa in these infants with intrinsic ARF. Finally, because of the developmentally regulated limitation of their concentrating capacity and the effects of low protein intake and urea excretion on urine osmolality (Feld et al, 1986), the urine-to-plasma creatinine ratio instead of the urine-to-plasma osmolal ratio should be used in newborns to evaluate their renal tubular reabsorptive capacity.

Laboratory values to be monitored in ARF include serum sodium, potassium, chloride, bicarbonate, calcium,

phosphorus, magnesium, creatinine, uric acid, and glucose as well as BUN and blood gases; a complete blood count with platelets should also be included. If urine is available, a urinalysis, urine culture, and a spot urine sample for sodium, creatinine, and osmolality should be obtained. Findings in a given spot urine sample may significantly differ from those in another one, and repeat analyses or a timed urine collection may become necessary in selected cases to aid in the differential diagnosis.

Neonatal CRF is diagnosed when sustained derangements of glomerular filtration and/or tubular function occur with minimal to no resolution over time. In some cases, the acute phase of the renal compromise has not been detected or has occurred in utero, and the diagnosis of CRF is established without documented evidence of preexisting ARF.

## TREATMENT OF NEONATAL ACUTE AND CHRONIC RENAL FAILURE

### Prerenal Acute Renal Failure

The approach of diagnosing *prerenal ARF* with the provision of fluid boluses and diuretic treatment (if appropriate) also serves as the initial management of this condition. Most newborns admitted to NICUs with ARF have the *prerenal* form of ARF and respond to fluid therapy. If systemic hypotension develops despite adequate volume administration, early initiation of dopamine with the subsequent normalization of blood pressure often establishes appropriate renal perfusion (Seri et al, 1993, 1998). In cases of pressor/inotrope-resistant hypotension and shock, a brief course of low-dose hydrocortisone administration has been demonstrated to be effective in restoring systemic perfusion and renal function in preterm neonates (Seri et al, 2001). Other management goals include the maintenance of normoxemia and normal pH to avoid the recurrence of renal vasoconstriction and to improve capillary integrity as well as the replacement of blood and free water losses as needed.

TABLE 84-2

### Diagnostic Indices Suggestive of Prerenal or Intrinsic Renal Failure in the Newborn

	Prerenal Acute Renal Failure	Intrinsic Acute Renal Failure
Urine flow rate (mL/kg/hr)	Variable	Variable
Urine osmolality (mOsm/L)	>400	≤400
Urine-to-plasma osmolal ratio	>1.3	≤1.0
Urine-to-plasma creatinine ratio	29.2 ± 1.6 <sup>‡</sup>	9.7 ± 3.6 <sup>‡</sup>
Urine [Na <sup>+</sup> ] (mEq/L)	10-50	30-90
FENa* (%)	<0.3 (0.9 ± 0.6) <sup>‡</sup>	>3.0 (4.3 ± 2.2) <sup>‡</sup>
Renal failure index* <sup>†</sup>	<3.0 (1.3 ± 0.8) <sup>‡</sup>	>3.0 (11.6 ± 9.5) <sup>‡</sup>
Response to fluid challenge (± furosemide)	Increased urine output	No effect on urine output

\*Fractional excretion of sodium (FENa) = (urine [Na<sup>+</sup>]/serum [Na<sup>+</sup>])/(urine [Cr]/serum [Cr]) × 100.

<sup>†</sup>Renal failure index (RFI) = urine [Na<sup>+</sup>]/(urine [Cr]/serum [Cr]).

<sup>‡</sup>Mean ± SD.

Data from Feld et al, 1986; Karlowicz and Adelman, 1992; and Mathew et al, 1980. See text for details.

### Intrinsic Acute Renal Failure and Chronic Renal Failure

Whenever possible, newborns presenting with conditions potentially associated with the development of intrinsic ARF should be monitored closely and, if available, preventive measures applied before the onset of renal injury. In established intrinsic ARF of the newborn, management centers on providing appropriate *supportive care* until renal function recovers (see later). Additional *nonspecific therapy* includes the use of furosemide (Fildes et al, 1986) and dopamine (Karlłowicz and Adelman, 1992; Seri et al, 1993, 1998; Tulassay et al, 1983). Although there is no conclusive evidence that the attempt to provide selective renal vasodilatation and diuresis improves prognosis in intrinsic ARF, patients who respond to diuretic management with an increase in urine output early in the course of renal failure are more likely to survive (Fildes et al, 1986). In addition, the use of these medications may aid in ensuring an appropriate fluid and electrolyte balance. If dopamine is used, it should be started early in the course of the disease and at low doses (1 to 4  $\mu\text{g}/\text{kg}/\text{minute}$ ) to avoid unnecessary increases in systemic blood pressure and possible renal vasoconstriction (Karlłowicz and Adelman, 1992; Seri, 1995; Seri et al, 1993, 1998; Tulassay et al, 1983). The combined use of dopamine and furosemide may have a synergistic effect on inducing diuresis even in the preterm newborn (Tulassay and Seri, 1986). The potential toxicity of long-term and aggressive furosemide therapy, including ototoxicity, interstitial nephritis, osteopenia, nephrocalcinosis, hypotension, and persistence of patent ductus arteriosus, should be taken into consideration, especially in the preterm newborn (Karlłowicz and Adelman, 1992). Because continuous infusion of furosemide is less toxic and more effective than its bolus administration, continuous infusion of the drug should be used in neonates with intrinsic ARF.

There is no accepted *specific therapy* in clinical practice for intrinsic ARF. Experimental findings suggest that early administration of adenosine triphosphate–magnesium chloride (ATP-MgCl<sub>2</sub>) or thyroxine may decrease the extent of cellular damage in experimental intrinsic ARF (Karlłowicz and Adelman, 1992). Both agents exert their protective effects mainly by improving the recovery of renal cellular ATP (Boydston et al, 1995; Karlłowicz and Adelman, 1992). Because of its serious hemodynamic side effects, however, ATP-MgCl<sub>2</sub> is probably contraindicated in sick newborns. With regard to thyroxine, there is only one noncontrolled clinical study, in which the hormone was implicated in the recovery of renal function in eight children with ARF (Straub, 1976). The potential of thyroxine as well as adenine nucleotides and several growth factors to facilitate recovery in experimental ARF probably will be used in future clinical trials in an attempt to improve further recovery and survival of patients with intrinsic ARF (Wagener et al, 1995).

*Supportive care* includes prevention, early recognition, and aggressive management of complications of neonatal intrinsic ARF, including fluid overload, hypertension, electrolyte disturbances, nutritional deficiency, metabolic acidosis, and sepsis. Severe fluid restriction limiting intake to insensible and gastrointestinal and renal losses is required to avoid

fluid overload with the development of pulmonary edema, congestive heart failure, hypertension, and hyponatremia. Fluid restriction also mandates the placement of a central venous line and the use of high glucose concentrations with little or no sodium and no potassium in the infusate.

Hypertension usually develops as a consequence of fluid overload or hyperreninemia resulting from the renal damage. The evaluation, diagnosis, and treatment of neonatal hypertension are described in Chapter 87.

Hyponatremia, hyperkalemia, hyperphosphatemia, and hypocalcemia frequently develop and necessitate close monitoring and aggressive treatment when indicated. In cases of nonsymptomatic hyponatremia (serum sodium concentrations usually between 120 and 130 mEq/L), further restriction of free water intake is recommended. If hyponatremia at this level results in clinical signs and symptoms (lethargy, seizures) or serum sodium concentration falls below 120 mEq/L, 3% sodium chloride should be administered over 2 hours according to the following formula:

$$\text{Na}^+_{\text{required}} (\text{mEq}) = ([\text{Na}^+]_{\text{desired}} - [\text{Na}^+]_{\text{actual}}) \times \text{body weight (Kg)} \times 0.8$$

Possible complications of hypertonic saline administration, especially if infused over less than 1 to 2 hours, include congestive heart failure, pulmonary edema, hypertension, intraventricular hemorrhage, and periventricular leukomalacia. Care should be taken not to increase serum sodium concentration more rapidly than 0.5 mEq/hour.

Signs of progressive hyperkalemia on the electrocardiogram, in order of severity, consist of tall peaked T waves, heart block with widened QRS complexes, arrhythmia, the development of sine waves, and finally cardiac arrest. If diuretics are ineffective and all potassium intake has been abolished (including that in medications), with serum potassium levels between 6 and 7 mEq/L and associated electrocardiogram changes or with serum potassium greater than 7 mEq/L in the absence of characteristic electrocardiogram changes, additional treatment is necessary. Under these conditions, management of hyperkalemia includes the administration of calcium gluconate, sodium bicarbonate, and insulin with glucose (Table 84–3). Although sodium polystyrene may also be administered, it must be remembered that up to 6 hours may be required before any effect is seen, and the exchange resin may be ineffective in preterm infants born at less than 29 weeks of gestation (Malone, 1991). Hyperkalemia unresponsive to medical management is one of the most common indications for peritoneal and hemodialysis in the newborn with intrinsic ARF (Coulthard and Vernon, 1995; Karlłowicz and Adelman, 1992).

Hyperphosphatemia is common in ARF and should be treated with low phosphorus intake. Significant elevations in serum phosphate represent a risk of development of extraskeletal calcifications of the heart, blood vessels, and kidneys in the newborn, especially when the calcium-phosphorus product exceeds 70 (Lerner and Gruskin, 1990). Low-phosphorus formulas should be provided for those newborns who tolerate feeding. Soy formulas should be avoided because of their high aluminum content. Although calcium carbonate may be used as a phosphate-binding agent, severe hyperphosphatemia is best treated with dialysis.

TABLE 84-3

**Medical Management of Hyperkalemia in the Newborn**

Drug	Dose	Onset of Action	Duration of Action
Calcium gluconate (10%)	0.5-1.0 mL/kg (IV over 10 min)	1-5 min	15-60 min
Sodium bicarbonate (3.75% solution)	1.0-2.0 mEq/kg (IV over 10 min)	5-10 min	2-6 hr
Insulin	1 IU/5 g glucose (IV bolus or continuous infusion)	15-30 min	4-6 hr
Glucose	≤14 mg/kg/min (IV bolus or continuous infusion)	15-30 min	4-6 hr
Sodium polystyrene sulfonate	1 g/kg dose q6h as needed (orally/rectally)	1-2 hr*	4-6 hr

\*Onset of action may take up to 6 hours, and the drug may be ineffective in preterm infants born at less than 29 weeks of gestation (Malone, 1991). See text for details.

Although total calcium levels are frequently low in newborns with intrinsic ARF, ionized calcium is less commonly decreased, because of concurrent hypoalbuminemia and metabolic acidosis. If ionized calcium is decreased and the newborn is symptomatic, 100 to 200 mg/kg of calcium gluconate should be infused over 10 to 20 minutes and repeated every 4 to 8 hours as necessary. The usual maintenance doses of elemental calcium (50 to 100 mg/kg/day) also should be provided, in the form of calcium gluconate or calcium carbonate. If the newborn is being fed, dihydrotachysterol or calciferol may be administered to increase intestinal reabsorption of calcium.

Nutritional deficiency almost always develops in newborns with intrinsic ARF. The goal is to provide 100 kcal/kg/day with carbohydrates and fat, and 1 to 2 g/kg/day of high-biologic-value protein or an amino acid equivalent. Metabolic acidosis usually should be treated only when pH is less than 7.20, unless the newborn presents with associated pulmonary vascular reactivity and persistent pulmonary hypertension. The latter clinical scenario represents an extreme clinical challenge and may require the initiation of ECMO and hemofiltration to treat both the pulmonary vascular disease and the renal disease. Finally, because sepsis is a common cause of death in newborns with intrinsic ARF, infection control must be rigorously observed, and when sepsis is suspected appropriate diagnostic steps should be taken and non-nephrotoxic antibiotic therapy initiated. Because ARF alters the volume of distribution, protein binding, and renal excretion of many antibiotics, drug doses and dosing intervals should frequently be adjusted. Furthermore, many hepatically metabolized antibiotics still require renal excretion of their potentially toxic metabolites.

### **Obstructive Renal Failure: Acute-Onset Chronic Renal Failure**

Management of obstructive renal failure centers on the immediate relief of the obstruction, supportive medical care, and surgical correction of the underlying congenital malformation. Polyuria with electrolyte losses may occur following the relief of the obstruction, and close monitoring of serum electrolytes and appropriate fluid and electrolyte replacement therapy are necessary in the clinical care of such newborns.

## **Management of More Advanced Renal Failure**

### **Dialysis**

When renal failure is prolonged beyond 1 to 2 weeks, supportive therapy becomes unsuccessful and serious complications of intrinsic ARF develop. These complications may also develop in patients with worsening CRF and include severe fluid overload, electrolyte abnormalities (especially hyperkalemia or severe hyponatremia refractory to medical management), symptomatic uremia (tremors, vomiting, irritability), rising serum creatinine and BUN, and hypertension. When complications develop, dialysis should be initiated. However, dialysis should be started when the newborn is *still hemodynamically stable* so that this treatment modality can limit morbidity and mortality from ARF or CRF.

### **Peritoneal Dialysis**

Peritoneal dialysis has traditionally been preferred over hemodialysis in the newborn, but this may change with the use of cycling hemodialysis (see later). With peritoneal dialysis, the peritoneal catheter may be placed either percutaneously or surgically. One of the major problems with percutaneous catheters is the possibility of leakage around the catheter, rendering the dialysis virtually impossible. In patients with liver immaturity or dysfunction, bicarbonate dialysis may become necessary, because using the standard lactate-containing solution may result in significant metabolic acidosis owing to the inability of the liver to metabolize lactate adequately. Other, immaturity- and size-related technical problems with peritoneal dialysis include the need to deliver very small volumes, the high risk of infection (peritonitis) and bleeding complications, and the obstruction of the catheter by the sometimes very active omentum of the preterm infant (Coulthard and Vernon, 1995). Absolute or relative contraindications to peritoneal dialysis include necrotizing enterocolitis, abdominal wall defects, coagulopathy, hemodynamic instability, and the presence of an intra-abdominal foreign body, such as a ventriculoperitoneal shunt or diaphragmatic patch.

### **Hemodialysis**

Peritoneal dialysis is unlikely to be successful in cases with the foregoing contraindications. However, the small size of the neonatal arteries and veins restricts the use of

hemodialysis because, as described by Poiseuille's law, at any pressure, the rate of flow of a liquid through a tube varies with the fourth power of the radius. Thus, if the catheter that can be used for hemodialysis is half the size of the peritoneal catheter for the same patient, only  $1/16$  of the flow can be achieved at the same pressure. As for the type of catheters, use of a double-lumen catheter is preferred over use of two catheters for sampling and return, but the patient's size may again become a limiting factor. Hemodialysis is controlled by three factors: the membrane surface area, blood flow through the catheter, and dialysate fluid flow rate. Three different types of hemodialysis have been used in neonates and infants: continuous arteriovenous hemofiltration, continuous pumped hemodialysis, and cycling hemodialysis with a reservoir. *Continuous arteriovenous hemofiltration* uses the patient's cardiac output as the driving force for the hemofilter, which has a high ultrafiltration coefficient. The advantage of this technique is that it avoids rapid fluid shifts and the occurrence of hypotension by providing slow, continuous removal of an isotonic solute. *Continuous pumped hemodialysis* has all the limitations inherent to patient size and cannot be used in small or preterm neonates. Recently, *cycling hemodialysis with a reservoir* has been introduced (Coulthard and Sharp, 1995, 2001), allowing for the hemodialysis of preterm neonates weighing as little as 600 g using a manual syringe-driven circuit and a reservoir. This technique does not require priming of the circuit with blood and uses very small volumes. Effective hemodialysis is ensured by pushing the blood several times across the dialyzer in the reservoir before returning it to the neonate. However, more data are needed to assess safety and efficacy of this approach. It is important to note that these techniques require systemic heparinization, with activated clotting time usually kept at 180 to 200 seconds, rendering the technique relatively contraindicated in preterm newborns and others at high risk for intracranial bleeding. Furthermore, clotting of the catheters may occur, especially after prolonged use (Ronco et al, 1986).

### Transplantation

Renal transplantation is the definitive therapy for children with end-stage renal disease. Data on renal transplantation before 6 months of age or below a recipient weight of 6 kg are limited. However, recent data indicate that kidney transplantation results in young infants (<1 year of age) may be comparable to those in older pediatric age groups; the 5-year patient and/or graft survival rate is well over 80% (Humar et al, 2001). It also has been suggested that there is no need to set a minimum age for performing renal transplantation in very young infants (Humar et al, 2001). The patient's potential for growth and development, the primary renal disease, associated anomalies, urologic conditions, and family psychosocial status all are considered in determining eligibility for and the optimal time of transplantation. Although the overall postoperative complication rate is similar to that in older age groups, young infants may present with more vascular thrombotic complications. Long-term neurodevelopmental outcome in high-risk patients appears to be related to prematurity

at birth and the presence of brain infarcts, probably secondary to the higher rate of the early post-transplantation thrombotic complications in the young infant (Qvist et al, 2002). Outcome is more favorable if the neonatal and young infant recipients receive their primary transplants from living donors (Humar et al, 2001).

### CLINICAL COURSE OF NEONATAL ACUTE AND CHRONIC RENAL FAILURE

Derangement of glomerular and tubular function may last for up to 3 to 6 weeks in newborns with ARF. In the case of oliguric ARF, if recovery occurs, it is usually heralded by a gradual increase in the urine output over the course of several days and, in some cases, by the appearance of a polyuric phase. The free water and electrolyte losses associated with the polyuric phase of recovery mandate close monitoring of serum electrolytes and appropriate replacement therapy with sodium, potassium, and free water if indicated. Serum creatinine and BUN usually start decreasing later in the course of polyuria.

CRF is characterized by reduced GFR in cases with excessive nephron losses and tubular dysfunction. CRF with reduced GFR develops in approximately 40% of newborns in both acquired oliguric (Stapleton et al, 1987) and nonoliguric (Chevalier et al, 1984) ARF. Newborns with the history of ARF secondary to congenital malformation have the worst long-term prognosis; close to 80% of such infants later develop CRF (Reinold et al, 1977).

In cases of CRF in which renal tubular dysfunction is the dominating pathophysiologic abnormality, a permanent decrease in the concentrating capacity due to injury to the epithelium of the thick ascending limb (see earlier) is the most frequent finding. Other abnormalities include chronic hypertension, renal tubular acidosis, impaired renal growth, and, mostly in cases of renal cortical necrosis, nephrocalcinosis (Karlłowicz and Adelman, 1992).

### OUTCOME OF NEONATAL RENAL FAILURE

Overall long-term outcome for neonates with renal failure depends on the primary etiology, the extent of the insult in the acute phase of the renal failure, and associated anomalies. The mortality rate in newborns with ARF caused by congenital malformation or by acquired diseases is around 50% (Karlłowicz and Adelman, 1992; Stapleton et al, 1987), whereas newborns with nonoliguric ARF have a much better prognosis (Chevalier et al, 1984; Karlłowicz and Adelman, 1992). Although preliminary results appear encouraging, at present only limited data are available on long-term outcome of infants with CRF and renal transplantation.

# Glomerulonephropathies and Disorders of Tubular Function

Bernard S. Kaplan

## GLOMERULONEPHROPATHIES

Glomerulonephropathies generally manifest with features of the nephrotic syndrome and less often with those of the nephritic syndrome. Massive proteinuria, hypoalbuminemia, hyperlipidemia, and edema characterize the nephrotic syndrome. Newborns may have transient proteinuria without apparent glomerular injury, and serum albumin levels can be in the nephrotic range in normal premature infants. Therefore, the diagnosis of nephrotic syndrome should be made only in patients with persistent, massive proteinuria, severe hypoalbuminemia, hyperlipidemia not caused by hyperalimentation, and edema that is not the result of fluid overload or capillary leak, or both. Nephritis (hematuria, red blood cell casts, oliguria or anuria, hypertension, and azotemia) is uncommon in newborns.

The nephrotic syndrome can be inherited as an entity isolated to the kidneys (congenital nephrotic syndrome of the Finnish type [CNF]) or as part of a defined malformation syndrome (Denys-Drash syndrome, Galloway-Mowat syndrome, or nail-patella syndrome). Glomerulopathies that occur in newborns and infants also can be divided into primary glomerular conditions with nephrotic syndrome (e.g., CNF) and secondary glomerular conditions (e.g., congenital syphilis). Only CNF and congenital syphilis *typically* manifest with nephrotic syndrome at birth. Diffuse mesangial sclerosis (DMS), Denys-Drash syndrome, and Galloway-Mowat syndrome rarely manifest in the neonatal period. Minimal-change nephrotic syndrome, focal segmental glomerulosclerosis, membranous glomerulonephritis, collagen type III glomerulopathy and mercury toxicity do not occur in newborns but occasionally present in infants. However, lupus nephritis and congenital toxoplasmosis have been reported in a neonate (Lam et al, 1999). Renal vein thrombosis can be a consequence of the nephrotic syndrome but is not a cause of the syndrome. There is no convincing evidence that intrauterine infections with cytomegalovirus (Batsky et al, 1993), rubella virus (Beale et al, 1979), or *Toxoplasma* (Shahin et al, 1974) are causes of neonatal nephrotic syndrome. In reports of *unique* family syndromes, congenital nephrotic syndrome occurred in association with congenital anomalies, such as buphthalmos. Finally, there are reports of congenital glomerular injury that elude classifi-

cation and reports of spontaneous remission of apparent congenital nephrotic syndrome (Haws et al, 1992).

## Congenital Nephrotic Syndrome (CNS) of the Finnish Type

In CNF (NPHS1) [McKusick #256300], inheritance is autosomal recessive and the locus is assigned to 19q12-q13.1 (Kestila et al, 1994). The *NPHS1* gene that is mutated in NPHS1 codes for nephrin, a cell-surface podocyte protein. Two mutations, Fin-major and Fin-minor, are found in over 90% of Finnish patients (Patrakka et al, 2000). CNF occurs in all population groups, but the highest prevalence is in Finland, with an incidence of 12.2 per 100,000 newborns (Huttunen, 1976). There is minor intrafamilial and interfamilial variability in the severity and age at onset of the nephrotic syndrome. Absence of a history of Finnish ancestry does not exclude the diagnosis. Proteinuria is detected within the first week of life in 71% of cases and by 2 months in all affected infants (Huttunen, 1976). Early onset of hypertension and renal failure are uncommon. Infants are often premature and small for gestational age. Although there are no typical dysmorphic features, large anterior fontanelles, limb deformations, and pyloric stenosis do occur (Sibley et al, 1986). Maternal serum and amniotic fluid alpha-fetoprotein levels are elevated (Seppala et al, 1976), and increased concentrations of albumin are detected in the amniotic fluid in some cases. The diagnosis may be made coincidentally by the finding of a low thyroxine level during screening for hypothyroidism (Finnegan et al, 1980). Most of these patients have a primary form of hypothyroidism characterized by low thyroxine and high thyroid-stimulating hormone (TSH) levels caused by urinary losses of thyroxine and iodine (McLean et al, 1982). The placenta is large, with a mean placenta-to-neonate weight ratio of 0.43 (normal ratio is around 0.18).

Echodense kidneys are symmetrically enlarged on ultrasonography. Proximal tubules are dilated in 74% of cases, and glomeruli initially appear normal. Ultrastructural studies show the effacement (*fusion*) of epithelial cell foot processes and, later in the course, interstitial fibrosis, lymphocytic and plasma cell infiltration, periglomerular fibrosis, and glomerular sclerosis (Habib, 1993).

The course is characterized by nephrotic syndrome complicated by failure to thrive, recurrent infections, and eventual chronic renal failure. Renal vein thrombosis may occur in utero or post partum. The nephrotic syndrome is resistant to treatment. Aggressive feeding by nasogastric or gastrostomy tube can ensure weight gain. Massive edema is treated with intravenous albumin. Furosemide is added if the patient is not volume depleted. Hypothyroidism is treated with thyroxine. Bilateral nephrectomies and dialysis are indicated if edema, volume depletion, and inanition cannot be controlled. Long-term peritoneal dialysis is difficult but feasible in small infants. The results with living-related-donor renal transplantation are encouraging, and CNF does not recur after transplantation (Mahan et al, 1984). Unfortunately, a unique post-transplantation glomerular lesion resembling transplant glomerulopathy occurs in a quarter of the patients and is resistant to treatment (Laine et al, 1993).

### Diffuse Mesangial Sclerosis

DMS can be inherited as an autosomal recessive condition or occur sporadically, and it is a component of the Denys-Drash syndrome (see later) (Habib, 1993). DMS has been reported in an 18-week fetus (Spear et al, 1991) and occasionally can manifest in the neonatal period (Scott and Rochefort, 1992). Maternal and fetal alpha-fetoprotein concentrations and placental size are usually normal (Scott and Rochefort, 1992). Most patients present with nephrotic syndrome and chronic renal failure between 3 and 6 months and are hypertensive. There are no dysmorphic features. The kidneys are seen to be enlarged and echodense by ultrasound examination. The fully developed renal lesion consists of mesangial sclerosis, collapsed tufts, embedded mesangial cells, thick glomerular basement membranes, and tubulointerstitial lesions (Habib, 1993).

There is no specific treatment. Hypertension is treated with angiotensin-converting enzyme (ACE) inhibitors, but several additional agents often are required. Treatment of DMS includes optimization of caloric intake, peritoneal dialysis, and transplantation. DMS does not recur after transplantation. It is important to determine whether there is a mutation in the *WT1* gene on chromosome 11p to rule out Denys-Drash syndrome. If that cannot be done, renal ultrasound examinations may be warranted every few months to monitor for Wilms tumor.

### Denys-Drash Syndrome

Early onset of nephrotic syndrome with DMS can also occur in the Denys-Drash syndrome. The syndrome consists of overlapping features of ambiguous genitalia, nephrotic syndrome with DMS (Habib, 1993), Wilms tumor, and a zinc finger mutation on chromosome 11p (Schumacher et al, 1998). Occasionally, patients present with nephrotic syndrome in the neonatal period (Maalouf et al, 1998). Siblings are not affected. Most patients die by 4 years of age unless they receive a kidney transplant.

### Galloway-Mowat Syndrome

Galloway-Mowat syndrome is a rare condition that consists of abnormal central nervous system development and nephrotic syndrome (Cooperstone et al, 1993). Inheritance is autosomal recessive, and there may be variable expression in a family (Cohen et al, 1994). Patients may be small for gestational age. The nephrotic syndrome usually manifests before the age of 3 years and often develops before 3 months. There are no consistent glomerular histopathologic changes. The pathogenesis has not been determined. Neurologic findings are microcephaly, wide sulci, abnormal gyral patterns, developmental retardation, and seizures (Kucharczuk et al, 2000). Large floppy ears, a receding forehead, and hiatal hernia are features in some cases (Cooperstone et al, 1993). Death usually occurs before 6 months of age. The nephrotic syndrome does not respond to treatment. Renal transplantation is not encouraged because of the progressive nature of the severe neurologic disorder. Increased values on maternal

serum and amniotic fluid alpha-fetoprotein assays and abnormal renal ultrasonographic findings may prove useful for prenatal diagnosis (Palm et al, 1986).

### Congenital Syphilis

Clinical features of nephrotic syndrome predominate over those of nephritis. The diagnosis must be suspected in an infant who has edema, proteinuria, and signs of congenital syphilis (McDonald et al, 1971). The glomerular findings implicate an immune pathogenesis with subepithelial deposits that contain immunoglobulin G (IgG) and treponema antigen (O'Regan et al, 1976). Treatment with penicillin results in permanent remission of the glomerulopathy.

## DISORDERS OF RENAL TUBULAR FUNCTION

The diagnosis of a renal tubular disorder cannot be made without an appreciation of normal renal maturation. Premature newborns (and even full-term newborns) can exhibit sodium and chloride wasting and have variable combinations of aminoaciduria, glucosuria, phosphaturia, impaired potassium excretion, reduced reabsorptive capacity for sodium bicarbonate, and inability to concentrate the urine maximally. In healthy newborns, these are transient aberrations that tend to be isolated and that do not cause problems except for the low bicarbonate threshold in preterm infants. This derangement can lead to mild metabolic acidosis during the first few months of life. Very low-birth-weight newborns may have nonoliguric hyperkalemia, in part secondary to decreased  $\text{Na}^+, \text{K}^+$ -ATPase activity, which increases with maturation. Therefore, except in specific circumstances, it is not necessary to embark on a full-scale evaluation.

Some renal tubular disorders may be suspected and confirmed in utero. A prenatal diagnosis, however, requiring chorionic villus sampling or amniocentesis can be made only after the diagnosis of the condition in an older sibling. Postnatally, the possibility of a tubular disorder may arise when abnormal blood gas and electrolyte results are obtained. The initial manifestations of a renal tubular disorder may not include all of the findings associated with the disorder.

Three constellations of fluid and electrolyte imbalances should alert the neonatologist to the possibility of a disorder of renal tubular function. (1) The combination of *metabolic acidosis*, *hyperkalemia*, and *hyponatremia* is seen in renal dysplasias, obstructive uropathy (especially if complicated by a urinary tract infection), and pseudohypoaldosteronism. Furthermore, congenital adrenal hyperplasia can manifest with these abnormalities. (2) *Metabolic acidosis*, *hypokalemia*, and *hypophosphatemia* are the characteristic findings seen in patients with the renal tubular Fanconi syndrome. (3) *Metabolic alkalosis*, *hypokalemia*, and *hyponatremia* occur in the Bartter syndromes.

Important clinical clues to the presence of a renal tubular disorder are poor feeding, unexplained vomiting, dehydration, failure to thrive, drowsiness, irritability, tetany, seizures, and unexplained icterus. Isolated proximal renal tubular acidosis (RTA) is uncommon, and the need for large quantities of bicarbonate to correct a hyperchloremic

metabolic acidosis is a clue to the diagnosis. Fructose intolerance and galactosemia must be considered in a jaundiced newborn who has Fanconi syndrome. Hypophosphatemia and renal phosphate wasting are manifestations of X-linked hypophosphatemic rickets, but it is uncommon for this disorder to be diagnosed in a newborn. Hyperchloremic metabolic acidosis with a decrease in the unmeasured anion gap and in the absence of diarrhea raises the possibility of distal RTA. Distal RTA rarely manifests in the neonatal period, however. Pseudohypoaldosteronism, Bartter syndromes, and renal adysplasias must be considered in newborns with severe hyponatremia and renal salt wasting. Infants with Bartter syndrome are hypokalemic, whereas those with renal adysplasia, pseudohypoaldosteronism, and the renal tubular hyperkalemia syndromes are hyperkalemic. Hematuria, renal calculi, and nephrocalcinosis with hypercalciuria can occur in newborns with and without prolonged use of furosemide. Primary hyperoxaluria type 1 may manifest in the newborn period with acute renal failure and nephrocalcinosis (Ellis et al, 2001).

### **Renal Fanconi Syndrome of Proximal Tubular Dysfunction**

The renal Fanconi syndrome is characterized by generalized proximal renal tubular dysfunction with impaired net reabsorption of amino acids, bicarbonate, glucose, phosphate, urate, sodium, potassium, magnesium, calcium, and low-molecular-weight proteins. Renal excretion of these solutes and water is increased, and the serum concentrations of some are variably reduced. Hypophosphatemia results in vitamin D-resistant rickets, and bicarbonaturia causes a hyperchloremic metabolic acidosis. In newborns, the clinical manifestations of renal Fanconi syndrome may include polyuria, dehydration, metabolic acidosis, and glycosuria. These features are often asynchronous. Growth retardation and rickets mostly occur later in infancy.

### **Hereditary Fructose Intolerance**

Hereditary fructose intolerance (HFI) [McKusick #229600] manifests only in newborns fed sucrose or fructose in formula, antibiotics, fruit juices, or honey. The symptoms are poor feeding, vomiting, and failure to thrive (Gitzelman et al, 1989). The diagnosis can be made by molecular analysis of the aldolase-B gene in blood (Brooks and Tolan, 1993). Inheritance is autosomal recessive. Fructose-containing foods must be withdrawn from the diet as soon as the condition is suspected.

### **Galactosemia**

Classic galactosemia [McKusick #230400] can manifest in neonates with vomiting, diarrhea, hyperbilirubinemia with jaundice, hepatomegaly, ascites, and *Escherichia coli* sepsis a few days after starting milk ingestion. Cataracts are occasionally detectable by slit-lamp examination in neonates. This autosomal recessive disease is caused by deficient activity of galactose-1-phosphate uridylyltransferase (GALT) as a result of mutations at the *GALT* gene on chromosome

17q (Tyfield et al, 1999). Two other autosomal recessively inherited disorders of galactose metabolism—transferase and epimerase deficiency—occur more rarely. Newborn screening programs include tests for detection of galactosemia. The diagnosis is suggested by demonstrating increased concentrations of galactose in blood and urine and confirmed by demonstrating deficient red blood cell GALT (or galactokinase). Milk and milk-containing products must be withdrawn from the diet.

### **Cytochrome-c Oxidase Deficiency**

Cytochrome-c oxidase deficiency (Biervliet et al, 1977), a fatal infantile cytopathy with variable manifestations in brain, skeletal and cardiac muscle, and liver, and occasionally also manifesting with renal Fanconi syndrome, is one of the “mitochondrial cytopathy” syndromes associated with defects in complex IV of the respiratory chain (cytochrome-c oxidase; EC 1.9.3.1). Inheritance appears to be autosomal recessive. Clinical features include neonatal onset of hypotonia; hyporeflexia; respiratory failure; elevated levels of lactic and pyruvic acids in blood, cerebrospinal fluid, or urine; and renal Fanconi syndrome (Lombes et al, 1996). There is no treatment; prognosis is dismal, and most patients die in infancy.

### **Cystinosis**

Infants affected with cystinosis [McKusick #219800] appear normal at birth and develop manifestations of the renal Fanconi syndrome between 6 and 12 months. The diagnosis should be considered if there are features of the renal Fanconi syndrome in a neonate. Inheritance is autosomal recessive, and there is defective lysosomal transport of cystine. The cystinosis gene, *CTNS*, maps to chromosome 17p13 and encodes an integral membrane protein, cystinosisin (Town et al, 1998). Cystinosis can be diagnosed in utero using cystine measurements in chorionic villi by 9 weeks (Smith et al, 1987). Early and adequate treatment with oral cysteamine retards progression to end-stage renal failure (Markello et al, 1993), and administration of 0.55% cysteamine eyedrops from 1 year of age dissolves the corneal cystine crystals (Gahl et al, 2000).

### **Tyrosinemia Type 1**

Type 1 tyrosinemia [McKusick #276700] is caused by deficiency in the gene for fumarylacetoacetate hydrolase on chromosome 15q23-q25. Although type 1 tyrosinemia is an important cause of renal Fanconi syndrome and hepatocellular carcinoma, this condition rarely manifests in the neonate (Vanden Eijnden et al, 2000).

### **Renal Glycosuria**

Isolated forms of renal glycosuria rarely manifest in the newborn and are benign. Intermittent or constant renal glycosuria can be detected in newborns who have the rare and possibly autosomal recessive condition of glucose and galactose malabsorption (Markello et al, 1993).

## Renal Tubular Acidosis

Primary RTA is characterized by chronic hyperchloremic metabolic acidosis associated with an inability to acidify the urine. It may be a primary disorder or secondary to acquired renal injury. Primary RTA is not associated with the renal Fanconi syndrome. Primary RTA is separated into three main types: proximal RTA (pRTA) (type 2); distal RTA (dRTA) or “classic” RTA (type 1), and hyperkalemic RTA (type 4) (Rodriguez-Soriano, 2002).

### Primary Proximal Renal Tubular Acidosis

Proximal RTA is an integral feature of the renal Fanconi syndrome, and primary pRTA is extremely uncommon. Proximal RTA is the result of an inability to reabsorb filtered bicarbonate in the proximal tubule, with bicarbonate wasting and hyperchloremic metabolic acidosis and normal distal tubular acidification. Therefore, when the filtered bicarbonate is reclaimed up to the maximal renal tubular reabsorptive capacity for a patient with pRTA, the urine pH is appropriate for the severity of the metabolic acidosis, with values below 5.3. When pRTA occurs as an isolated defect, it is usually transient (Nash et al, 1972).

### Distal Renal Tubular Acidosis

Clinical manifestations of dRTA are anorexia, failure to thrive, hypotonia, a persistently low serum bicarbonate, elevated serum chloride, inappropriately high urine pH, and, in some cases, nephrocalcinosis. Additional findings are decreased urinary excretion of titratable acid, ammonium ( $\text{NH}_4^+$ ), and citrate. Some patients have congenital high-frequency nerve deafness. Untreated patients develop rickets (Caldas et al, 1992). Distal RTA is often considered in the differential diagnosis of a neonate with a non-anion gap acidosis, but there are few reports of dRTA in neonates (Caldas et al, 1992; McSherry et al, 1978). The possibility of dRTA can be inferred from calculating the rate of excretion of ( $\text{NH}_4^+$ ). This can be determined indirectly by calculating the urinary net charge or urine anion gap (Goldstein et al, 1986):

The kidney is not the cause of the acidosis if the chloride ( $\text{Cl}^-$ ) is greater than the sum of the  $\text{Na}^+$  (sodium) +  $\text{K}^+$  (potassium). If the sum of  $\text{Na}^+ + \text{K}^+$  is greater than  $\text{Cl}^-$ , then the urinary ( $\text{NH}_4^+$ ) may be less than 80 mmol per day, in keeping with dRTA (Carlisle et al, 1991). The diagnosis of dRTA is often made erroneously in patients with a hyperchloremic metabolic acidosis who have an “inappropriate” urine pH over 6 but who have diarrhea (Izraeli et al, 1990).

Regardless of whether a transient or permanent form of dRTA is suspected, adequate amounts of alkali, as either bicarbonate or citrate, in doses of 2 to 3 mEq/kg/day are required to maintain a normal serum bicarbonate concentration (Igarashi et al, 1992). This can be withdrawn after several months to challenge the diagnosis, or the infant can be allowed to outgrow the dose. Challenge with an ammonium chloride loading test is not necessary because the diagnosis can be inferred from indirect tests such as the urine anion gap.

At least two autosomal recessively inherited forms of dRTA exist. In dRTA *without* nerve deafness, the mutated gene is located on chromosome 7q33-34; the gene product is the 116-kD  $\beta$  subunit of the apical pump (ATP6 $\beta$ 1) (Smith et al, 2000). Distal RTA *with* nerve deafness (Karet et al, 1999) is caused by mutations in ATP6 $\beta$ 1, located on chromosome 2p13, encoding the  $\beta$  subunit of the apical proton pump, which mediates distal nephron acid secretion.

### Renal Tubular Acidosis Caused by Maternal Sniffing of Toluene

Maternal toluene abuse from paint or glue sniffing during pregnancy causes severe RTA in mother and neonate (Lindemann, 1991).

### Bartter Syndromes: Inherited Hypokalemic Renal Tubular Disorders

The Bartter syndromes are a group of congenital chronic tubular disorders characterized by hypokalemic metabolic alkalosis, polyuria, salt wasting, hyperkaliuria, hyperaldosteronism, resistance to the pressor effect of angiotensin, juxtaglomerular apparatus hyperplasia, increased renal renin production, and, in some patients, hypercalciuria and nephrocalcinosis. Similar features occur with loop diuretic treatment and congenital chloride diarrhea. At least three clinical subtypes of the Bartter syndromes, with marked phenotypic variations within each subtype, are known: the *antenatal hypercalciuric variant*, or hyperprostaglandin E syndrome (HPS/aBS); *classic Bartter syndrome* (cBS); and the *Gitelman variant of Bartter syndrome* (GS). The common characteristics of each subtype are hypokalemic metabolic alkalosis and renal salt wasting.

### Antenatal Hypercalciuric Variant

Antenatal hypercalciuric variant (hyperprostaglandin E syndrome) (HPS/aBS) is a life-threatening neonatal disorder. Features include polyhydramnios, premature delivery, hypokalemia, hypercalciuria, metabolic alkalosis, fever, vomiting, diarrhea and failure to thrive, hyposthenuria, and nephrocalcinosis. The inheritance is autosomal recessive with mutations in the gene for either the furosemide-sensitive Na-K-2Cl cotransporter, NKCC2 (*SLC12A1*), or the inwardly rectifying potassium channel, subfamily J, member 1, ROMK (*KCNJ1*) on chromosome 11q24 (Jeck et al, 2001a). Classic Bartter syndrome also may be caused by a mutation in either of these genes, suggesting that the antenatal and classic forms are different manifestations of severity of the same disorder. In addition, neonates have been identified who have homozygous gene mutations linked to chromosome 1p31, who do not respond to indomethacin treatment, and who have a more severe variant with marked delays in growth and motor development, chronic renal failure, and congenital deafness (Jeck et al, 2001b). There is no cure for Bartter syndrome, but treatment with inhibitors of prostaglandin synthesis improves the polyuria, corrects the biochemical abnormalities, and permits satisfactory growth and development. However, the nephrocalcinosis may not improve (Mourani et al, 2000).

### **Classic Bartter Syndrome**

In classic Bartter syndrome (cBS) [McKusick #241200], the clinical phenotype varies from episodes of neonatal severe volume depletion with hypotension and hypokalemia to mild symptoms in a patient diagnosed in adolescence. Serum magnesium levels are normal. Several reported cases involved mutations in one of three genes encoding ascending limb of Henle transporters: (1) Na-K-2Cl cotransporter (basolateral chloride channel), *CLCNKB*, on chromosome 1p36; (2) Na-K-2Cl cotransporter gene, *NKCC2* (*SLC12A1*), on chromosome 15q13; or (3) the gene encoding the inwardly rectifying K<sup>+</sup> channel, subfamily J, member 1, *ROMK* (*ROMK1/KCNJ1*) on chromosome 11q24. *CLCNKB* mutations also may cause congenital Bartter (HPS/aBS) or a Gitelman-like phenotype.

### **Gitelman Variant of Bartter Syndrome**

The Gitelman variant of Bartter syndrome (GS) [McKusick #263800] usually does not manifest in neonates (Bettinelli et al, 2000). Hypocalciuria and hypomagnesemia are specific clinical features of Gitelman syndrome. The Gitelman variant is caused by mutations in the gene for the thiazide-sensitive Na-Cl cotransporter NCCT (*SLC12A3*) of the distal tubule, on chromosome 16q13.

### **Renal Tubular Hyperkalemia**

The causes of neonatal renal tubular hyperkalemia (RTH) are marked prematurity, renal dysplasia, urinary tract obstruction, urinary tract infection, pseudohypoaldosteronism, and congenital adrenal hyperplasia (Rodriguez-Soriano et al, 1995). Features of RTH include an inappropriately low urine potassium concentration, renal salt wasting, and metabolic acidosis. The serum creatinine concentration is often increased because of volume depletion (pseudohypoaldosteronism, congenital adrenal hyperplasia), reduced nephron mass (renal dysplasia), or obstruction (posterior urethral valves).

### **Pseudohypoaldosteronism**

Two syndromes of aldosterone resistance exist: pseudohypoaldosteronism type I and pseudohypoaldosteronism type II (Hanukoglu, 1991). Furthermore, there are two clinically and genetically distinct types of type I pseudohypoaldosteronism: the renal pseudohypoaldosteronism and the multiple-organ pseudohypoaldosteronism. Pseudohypoaldosteronism may be inherited as an autosomal dominant or as an autosomal recessive trait. In the dominant form of pseudohypoaldosteronism type I, mutations in the gene *MLR* encoding the mineralocorticoid receptor have been recognized. In the recessive form of pseudohypoaldosteronism type I there are mutations in the genes *SNCC1A*, *SNCC1B*, and *SCNN1G*, which encode subunits of the epithelial Na<sup>+</sup> channel (Rodriguez-Soriano, 2000).

### **Renal Pseudohypoaldosteronism Type I**

Renal pseudohypoaldosteronism type I usually starts in early infancy and is characterized by diminished renal tubular responsiveness to aldosterone, with hyponatremia,

hyperkalemia, markedly elevated plasma aldosterone, and hyperreninemia. The clinical expression ranges from that in severely affected patients who die in infancy to an asymptomatic state. Symptomatic patients are treated with sodium supplementation, which usually is no longer necessary by 2 years of age.

### **Multiple Organ Pseudohypoaldosteronism Type I**

With multiple organ pseudohypoaldosteronism type I, there is impaired responsiveness to aldosterone in salivary and sweat glands, renal tubules, and colonic mucosal cells. The course is protracted, with life-threatening episodes of salt wasting.

### **Pseudohypoaldosteronism Type II (Gordon Hyperkalemia-Hypertension Syndrome)**

Features of pseudohypoaldosteronism type II (Gordon hyperkalemia-hypertension syndrome) are hyperkalemia despite a normal glomerular filtration rate, hypertension, variable mild hyperchloremia, metabolic acidosis, and suppressed plasma renin activity (Schambelan et al, 1981). The metabolic abnormalities are corrected by treatment with thiazide diuretics. There are no reports of neonatal presentation.

### **Congenital Nephrogenic Diabetes Insipidus**

Nephrogenic diabetes insipidus (NDI) can result from congenital or acquired insults to the kidneys including electrolyte abnormalities (hypokalemia, hypocalcemia), drugs (aminoglycosides), tubular interstitial inflammation, obstruction, and dysplasia. In the congenital or inherited forms of NDI, insensitivity of the distal nephron to the antidiuretic effect of vasopressin results in an inability to concentrate urine, resulting in the excretion of large quantities of hypotonic urine (Bichet et al, 1997; van Lieburg et al, 1999). Affected neonates may be irritable, feed poorly, fail to gain weight, and have unexplained dehydration and fevers. Serum concentrations of sodium, chloride, creatinine, and blood urea nitrogen (BUN) are elevated, and serum levels of vasopressin are normal or increased. There is a blunted response of plasma factor VIII, von Willebrand factor, and plasminogen activator after administration of 1-desamino-8-D-arginine vasopressin (DDAVP). Treatment with hydrochlorothiazide (3 mg/kg/day) and amiloride (0.3 mg/kg/day three times a day) may be preferable to hydrochlorothiazide and indomethacin because indomethacin can cause bleeding. Treatment can prevent dehydration, electrolyte imbalances, cerebral calcification and seizures, and result in normal growth but patients continue to have polydipsia and polyuria.

About 90% of patients with inherited NDI are males with the X-linked form caused by mutations in the arginine vasopressin receptor 2 gene (*AVPR2*) located in chromosomal region Xq28 (Morello and Bichet, 2001) that codes for the V2 receptor. In less than 10% of the families, the inheritance of NDI is autosomal recessive or autosomal dominant. In these cases, mutations have been identified in the aquaporin-2 gene (*AQP2*) on chromosome 12q13 that codes for the vasopressin-sensitive water channel (Goji et al, 1998). The reliability of prenatal diagnosis of the X-linked form of NDI is about 96%.

## Urinary Tract Infections and Vesicoureteral Reflux

Stephen A. Zderic

This chapter provides an overview of the epidemiology, pathophysiology, radiographic evaluation, and management of urinary tract infections in the neonate. Although the focus here is on the management of vesicoureteral reflux as one of the congenital conditions frequently associated with urinary tract infection, other congenital urologic anomalies also may manifest with urinary tract infection. Of several key points emphasized in this chapter, one of the most important is that reflux itself does not cause urinary tract infection. Therefore, many children may have reflux without any symptoms, and the neonates who develop bladder infections and have reflux will be the ones who present clinically. It also is important to remember that biologic susceptibility plays a major role in the etiology of neonatal urinary tract infections. Finally, it has been recognized that not all damage to the kidneys associated with reflux reflects scarring from infection. Indeed, some kidneys with high-grade reflux have elements of dysplasia and scarring at the time of initial presentation and in the absence of infection.

### URINARY TRACT INFECTIONS

#### Epidemiology

Within the first several months of postnatal life, urinary tract infections are more common in boys. After the first 6 months, the incidence in girls increases steadily as that in boys declines (Shortliffe, 1992). Some studies have suggested that the incidence of urinary tract infections is anywhere from 10- to 15-fold higher in girls than in boys between 1 and 3 years of age. A major risk factor for urinary tract infection was delineated by Wiswell reporting alone (1992) and with Geschke (1989), who noted that although only 20% of males were uncircumcised, this group accounted for 80% of all urinary tract infections in boys. These data suggests that circumcision offers protection against urinary tract infections in the first year of life. Wiswell and Geschke's findings offer support for encouraging circumcision in males with congenital structural or functional abnormalities placing them at high risk for pyelonephritis and sepsis, such as patients with posterior urethral valves or reflux.

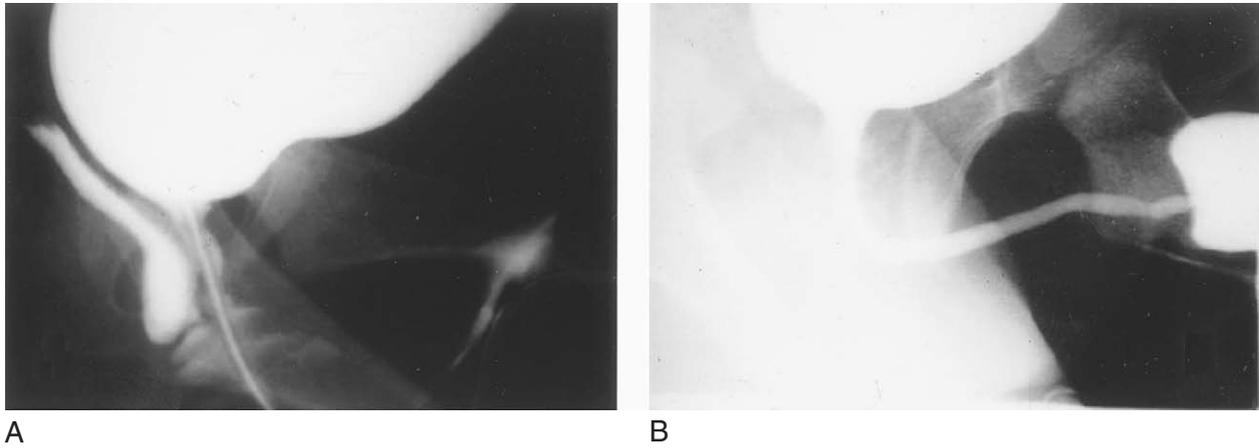

#### Diagnosis

The diagnosis of a urinary tract infection in a young infant is not always straightforward, and a high index of suspicion is required because the symptoms are so generalized. In one series of 100 infants, all infants were

febrile with temperatures above 38° C (70% had temperatures above 39° C), 60% were irritable, 50% were feeding poorly, and 40% had vomiting or diarrhea (Ginsburg and McCracken, 1982). The index of suspicion must rise when these aforementioned symptoms are present with no localizing source. In such instances, obtaining a urine specimen for analysis and culture must be included in the evaluation.

Much has been said and written about the procurement of specimens by the techniques of clean catch (not applicable in neonates), use of a bag, catheterization, or suprapubic puncture. Results of studies on bag or clean-catch specimens are valid only if cultures are truly negative. It is intuitively obvious why these collection methods are susceptible to contamination in girls and, especially, in the uncircumcised male (Fig. 86-1). Knowledge of the composition of the preputial or vaginal flora is of little use in managing the febrile child; what matters most is the composition of the urine within the bladder itself. This problem is compounded when bagged specimens are obtained at home and arrive "fresh" at the office only to be sent to a central laboratory before plating. Another problem arises with the definition of what a negative urine culture means. In many instances the reports say the results are negative but only because the presence of 100,000 colony-forming units (CFUs) is used as a cutoff point to define a positive culture. Hoberman and colleagues (1994) have looked at the frequency distribution of the voided or bag specimens and compared the findings with those in post-void specimens obtained by catheterization of febrile infants. The authors found that 10,000 to 49,000 CFUs/mL usually represented contamination, whereas counts in excess of 50,000 CFUs/mL were more characteristic of a true positive. Still, there were overlaps between these groups, and numeric quantitation remains an inexact tool.

The gold standard for specimen collection remains suprapubic aspiration, which is accurate and can be safely performed in a neonate because the bladder is a pelvic organ. A 21-gauge needle may be inserted into the palpable bladder just above the pubic symphysis in the midline to collect an aspirate. However, even urologists rarely use this method of collection; a catheterized specimen is easy to obtain and provides accurate results, especially if the first 2 to 3 mL of urine, which may contain urethral contaminants, is discarded. For a febrile child presenting to an emergency room with possible urosepsis, or requiring hospital admission, documentation of a urinary tract infection should be established on the basis of a catheterized specimen (or a suprapubic aspirate). *Voided clean-catch or bag methods may be used early on in an evaluation before the urinary tract is considered a source.* However, the increased incidence of false-positive findings seen with these collection methods means that more patients will undergo antibiotic therapy and a costly and invasive radiographic work-up. The greatest diagnostic yield from doing these expensive and invasive studies will be in the population of patients whose urinary tract infection was most accurately diagnosed by using catheterized or suprapubic specimens.

**FIGURE 86-1.** These VCUG findings demonstrate how bagged specimens may lead to false-positive results in infant females or uncircumcised males. Vaginal reflux allows for contaminants in the bagged specimen from an infant female (**A**). In the uncircumcised male, urine may pool underneath the foreskin and acquire contaminating flora (**B**).

### Treatment

The neonate with suspected urosepsis should receive broad-spectrum antibiotic coverage until results of sensitivity testing dictate a shift to single-antibiotic coverage. Ampicillin and gentamicin provide excellent coverage for the most common pathogens that are likely to be present. The most likely pathogen is *Escherichia coli*, but there is always a possibility of *Pseudomonas*, especially in an infant who was just discharged to home following a stay in the neonatal intensive care unit (NICU). The duration of intravenous antibiotic therapy for pyelonephritis can be debated, but parenteral therapy at least avoids the concern of compliance issues. Experimental evidence demonstrates that reflux-associated pyelonephritis in piglet confirmed by technetium 99m dimercaptosuccinic acid (DMSA) scan can be successfully treated with only oral macrodantin (Risdon et al, 1995). Given the expense of hospitalization or home-based intravenous antibiotic therapy, the mandatory duration of parenteral therapy will continue to be debated, especially in the older child (Hoberman et al, 1999). However, in the more susceptible neonate, parenteral therapy should be instituted in a hospital setting and continued until results of a follow-up urine culture become negative (AAP Committee, 1999). At that point, oral antibiotic therapy may be started for a total course of 10 to 14 days.

Once the acute infection has been treated, antibiotic prophylaxis should be instituted until the child is ready for radiographic imaging studies. The use of amoxicillin (12.5 mg/kg) in neonates, or trimethoprim-sulfamethoxazole in infants, is accepted for prophylaxis. The use of trimethoprim-sulfamethoxazole in urology patients for suppression is based on the classic work of Stamey (1980), who demonstrated that low-dose antibiotic treatment does not produce shifts in the fecal flora. In contrast, high doses of trimethoprim-sulfamethoxazole and especially of broad-spectrum antibiotics have been shown to produce greater and more concerning shifts in the fecal flora. This finding is especially significant because the feces serve as

the origin for most (>90%) of the bacteria that colonize the perineum and vagina and thus ultimately produce a urinary tract infection.

### The Radiographic Work-up

Once a diagnosis of urinary tract infection has been established and treated, it is important to initiate a radiographic work-up to look for any underlying structural anomalies (AAP Committee, 1999). It has been stated that up to 30% of children with a urinary tract infection have aberrant urinary tract anatomy or function. The radiographic evaluation should consist of an ultrasound study of the *kidneys and bladder*, followed by a carefully done voiding cystourethrogram (VCUG) (Lebowitz and Mandell, 1987). Most often, a 2- to 4-week period is allowed between infection and the radiographic imaging, but this interval is arbitrary. It is more important is to ensure that the urine is sterile before performance of the VCUG. A patient should be maintained on antimicrobial prophylaxis until imaging rules out any urinary tract pathology. On sonography, obtaining both kidney and bladder views is stressed because sometimes the kidneys alone are imaged and shown to be normal, and the work-up is terminated. Then, several infections later, a bladder ultrasound study shows a stone, ureterocele, or diverticulum. Even if a VCUG is being done on the same day of the renal ultrasound examination, a small ureterocele may be missed at the fluoroscopy that would have been seen on the bladder sonogram.

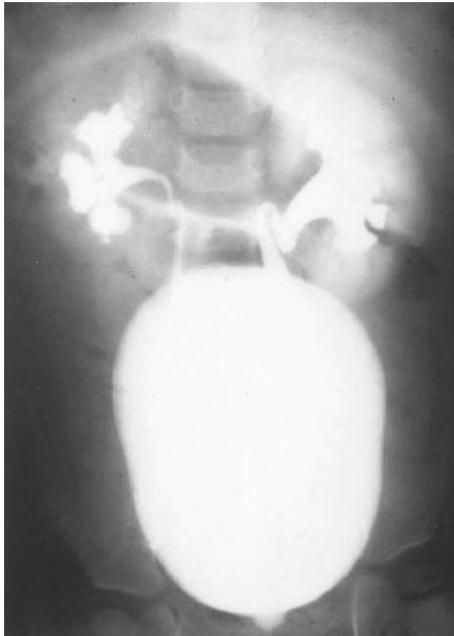

The VCUG must be done carefully and requires patience on the part of all concerned. Because the act of voiding is required to demonstrate reflux in 20% to 30% of reflux cases, such cases would be missed if the child were anesthetized for a static cystogram. The policy at the author's institution is to obtain a classic fluoroscopic study first, to define the anatomy and accurately grade the reflux if it is present. Some groups have advocated that radionuclide VCUG be used as the initial screening study.

However, to appropriately define the anatomy, the contrast VCUG remains the gold standard. As discussed later in the section on reflux, the cornerstone of accurate management is grading of the reflux, which can be provided only by a well-executed VCUG study.

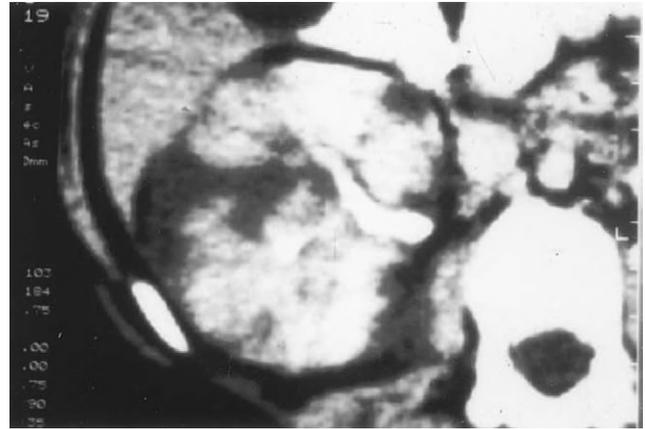

In recent years there has been a growing support in the literature for the use of DMSA scanning to identify patients with acute pyelonephritis. However, it is this author's bias that an *accurately collected* urine specimen showing signs of infection in a febrile patient is adequate. The DMSA scan is very helpful in assessing the patient with abnormal anatomy secondary to exstrophy or spina bifida, whose chronic catheterization regimens result in chronic urinary colonization and a urine culture that will always be positive.

### Pathophysiology

Urinary tract infections are multifactorial in their etiology and clearly represent an altered balance between host and pathogen. Abnormal anatomy serves to exacerbate the effects of a urinary tract infection. The reader is referred to several excellent reviews regarding this issue (Lebowitz and Mandell, 1987; Shortliffe, 1992; Stamey, 1980). Hematogenous spread of bacteria to the urinary tract may occur but is very rare. Most urinary tract infections will start in the bladder and then *ascend* to produce pyelonephritis. This ascent of infected urine from the bladder to the kidney may take place via two major mechanisms: (1) the bacteria may be extremely virulent and produce pili that allow the bacteria to attach themselves to the ureter and migrate upstream, or (2) the patient may have reflux that showers the renal pelvis, allowing for intrarenal reflux and seeding of the renal parenchyma (Fig. 86-2). Once bacteria are injected into the renal parenchyma under high pressures, areas of

**FIGURE 86-2.** High-grade bilateral vesicoureteral reflux with evidence of pyelotubular backflow within the left kidney is demonstrated on this VCUG in a neonate.

**FIGURE 86-3.** This CT scan of an infant with right pyelonephritis and associated grade II reflux shows the signs of lobar nephronia. Areas within the right kidney function well and excrete contrast—others show signs of poor perfusion.

focal infection and inflammation develop (Fig. 86-3), and a series of complex steps in the inflammatory cascade take place (Roberts, 1992). If this process is not interrupted by treatment, it can produce severe renal injury or scarring. Furthermore, if repeated infectious insults such as these continue without adequate therapy, the long-term result is significant renal scarring, which in its extreme produces reflux nephropathy, leading to end-stage renal disease.

Equally important in the pathogenesis of urinary tract infections is the biology of the patient (or host). It is accepted that many patients are more susceptible to bacterial urinary tract infections because their bladder mucosa expresses cell surface proteins that have a high affinity for the cell surface antigens on the bacterial cell wall. A great deal is known about the bladder mucosal expression of these complex glycoproteins, with some being mannose sensitive. In these cases, the receptor-ligand interaction between pathogen and host is based on the molecular recognition of mannose-6-phosphate (Schaeffer et al, 1984).

### Urinary Tract Infections Complicated by Obstructive Uropathy

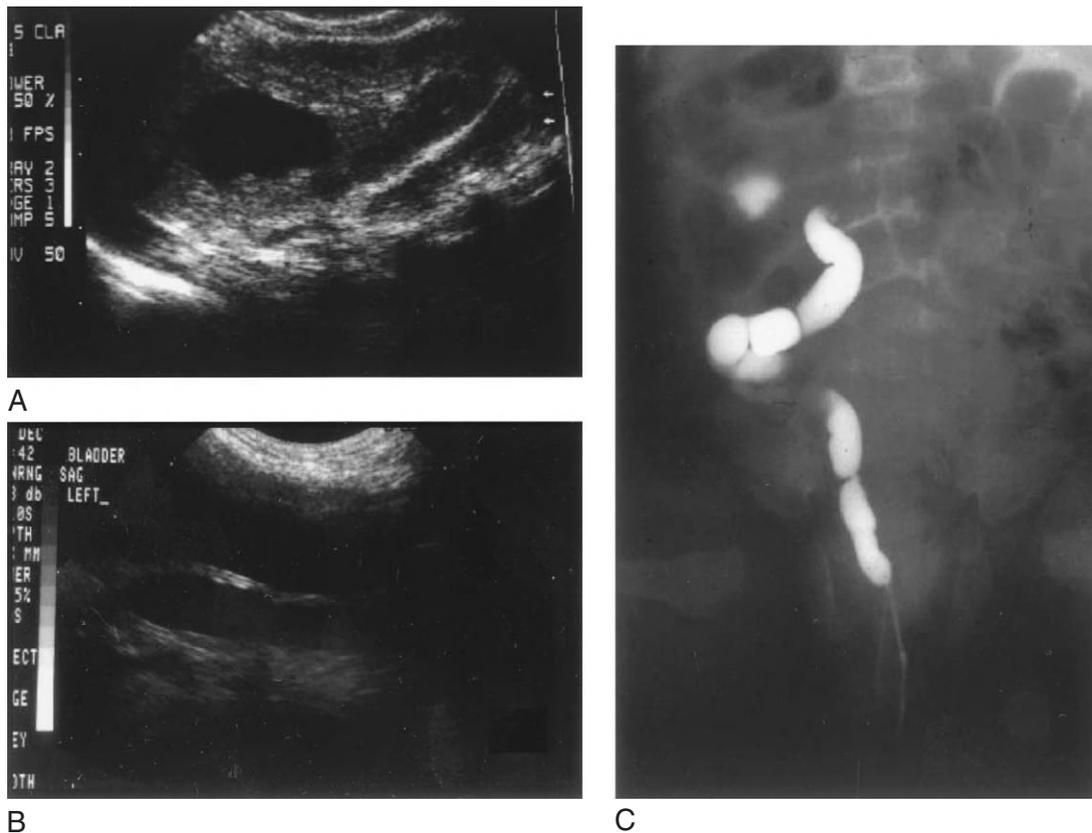

An important consideration is what happens when urinary tract infections develop in a newborn with an abnormal urinary tract. It used to be extremely common for obstructive uropathies to present after urosepsis had developed. With the widespread use of prenatal sonography, however, most neonates with an obstructive uropathy are identified at birth, and antibiotic prophylaxis is initiated. However, on occasion even today, a neonate may still present with urosepsis secondary to an obstructive uropathy. In such cases, the obstructive uropathy may have developed after the initial early normal prenatal ultrasound examination, or the problem went undiscovered because of a lack of access to prenatal care.

The most common pathologic factor associated with a febrile urinary tract infection in a neonate or infant is vesicoureteral reflux. However, on occasion, an obstructed system will be discovered during the work-up. The presence of obstruction produces a dangerous combination of bacteria, urinary stasis, and a warm environment with a near-ideal culture broth. Thus, one must always consider the possibility of an infection developing in an obstructed system. Keeping this possibility in mind is important because the management may be altered by the use of surgical drainage (by either ureterostomy or percutaneous nephrostomy). During treatment for acute pyelonephritis, the patient may not defervesce for 48 to 72 hours. *However, beyond 72 hours, underlying obstruction must be suspected if fever persists or the neonate's condition worsens.* Under these circumstances, an ultrasound study to rule out obstruction is warranted. Infections may become established in primary megaureters, ureterocele, or ectopic ureters (Fig. 86-4) and, on rare occasions, in ureteropelvic junction (UPJ) obstructions. Urine production allows for some antibiotic to reach these bacteria, and a good response may be seen if the patient receives treatment early in the course of the infection. In advanced cases, especially in those associated with poor renal func-

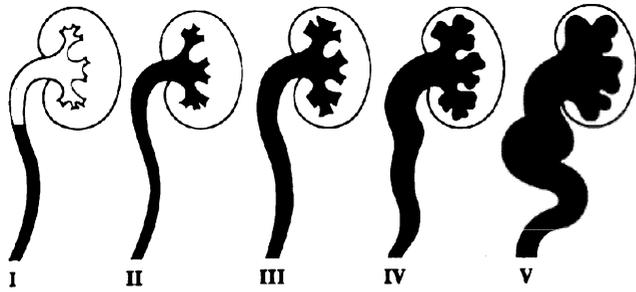

tion, temporary drainage procedures such as percutaneous nephrostomy will allow for eradication of the infection and for the patient's condition to stabilize before definitive repair.

## VESICoureTERAL REFLUX

Vesicoureteral reflux exists when urine flows from the bladder back toward the kidney; this reverse flow may occur during bladder filling or emptying (voiding). Using the contrast VCUG, it is possible to grade reflux from I through V (Fig. 86-5). Grading reflux allows physicians to communicate findings quickly and to understand what the chances of spontaneous resolution are. Many additional findings appear on the VCUG images besides just the grade. Was there reflux on filling, and did it start at the beginning or at the end of the filling phase? How much contrast was added to the bladder prior to the initiation of voiding? Was there evidence of a pyelotubular backflow? (See Fig. 86-2.) By evaluating the findings in detail, a better understanding of the severity, potential treatment modalities, and outcome can be achieved and utilized for the benefit of the patient.

**FIGURE 86-4.** Ectopic ureter and urosepsis. This 3-month-old infant presented with a high fever and a positive urine culture that failed to respond to parenteral antibiotic therapy. **A** and **B**, The ultrasound showed signs of right hydronephrosis and hydroureter; **C**, a retrograde pyelogram confirmed a diagnosis of ectopic ureter. Most such cases are identified by fetal sonography. However, in this instance, the young parents did not seek prenatal care. Following a cutaneous diversion of this ectopic ureter, the infant became afebrile, and ureteral reimplantation was successfully performed 6 months later.

**FIGURE 86-5.** Grading scale for reflux. The International Reflux Study used this grading scale, which is based on the findings on a conventional fluoroscopic voiding cystourethrogram.

The etiology of reflux remains debated, but there is growing agreement that reflux constitutes a syndrome. Some patients with reflux have a congenital anatomic basis for the reflux. The normal course of the ureter travels through the bladder wall and underneath the mucosal layer to create a flap valve mechanism, which prevents vesicoureteral reflux. Reflux due to anatomic abnormalities in bladder insertion of the ureter is referred to as *primary reflux*. In other patients, reflux occurs secondary to increases in bladder pressure, a condition referred to as *secondary reflux*. For example, many patients with posterior urethral valves may have reflux, which disappears once the valves are resected. This distinction is important because the rules for primary reflux resolution do *not* apply to cases of reflux secondary to obstructing lesions such as posterior urethral valves or the neurogenic bladder seen with spina bifida.

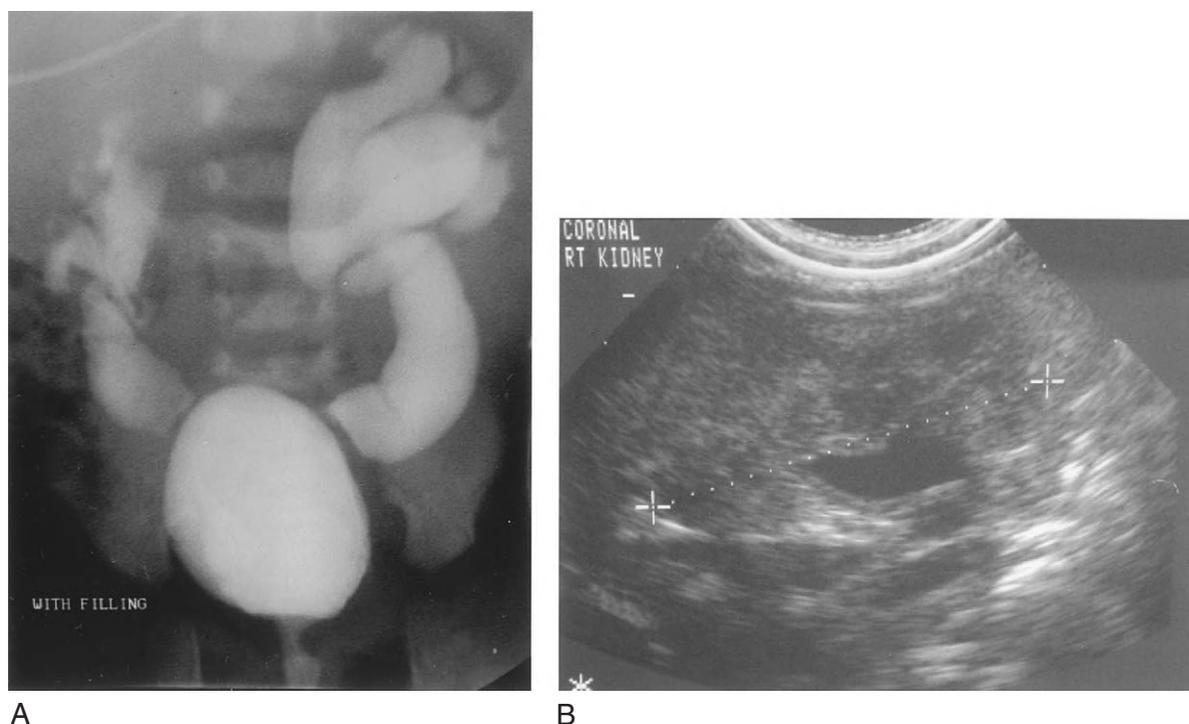

Growing clinical (Sillen et al, 1992, 1996a, b) evidence suggests that voiding pressures are dramatically increased in infants with reflux, especially in boys. Sillen (2001) has shown that, even in normal males, voiding pressures are elevated in the neonatal period and decline dramatically during the first 2 years of life. Sillen's data demonstrate that voiding pressures in boys with high-grade reflux are often three- to fourfold higher than those seen in older children. In these boys, the reflux often resolves in a surprisingly short period of time, implying that with maturation of bladder function, the pressures drop. Of interest, female newborns do not fare as well with regard to the resolution of neonatal reflux on a grade-for-grade basis, nor are their voiding pressures as elevated. These clinical observations are supported by experimental findings suggesting that there are gender-related differences in bladder neck function. The key concept is that voiding pressures are elevated, especially in the male neonate with reflux, and that these pressures diminish over time. These observations have a great bearing on how reflux resolution rates should be interpreted in the newborn.

However, outcomes for reflux resolution in neonates must be studied further (Sillen, 1999a, b). This should be made easier by the increased number of cases detected by prenatal ultrasonography. Evidence from a multicenter study suggests that reflux detected in the first months of life as part of a work-up for prenatal hydronephrosis has a better chance for spontaneous resolution, grade for grade, than that diagnosed in the child presenting at 2 to

4 years of age (Herndon et al, 1999). Given this information, recommendations that can be made about neonatal reflux management will be altered by the mode of presentation and social circumstances (compliance issues). For a newborn with prenatally diagnosed grade IV or V reflux, expectant observation with antibiotic prophylaxis seems most reasonable. However, this course of action demands that parents comply with antibiotic prophylaxis and understand that a breakthrough infection rate as high as 20% is possible (Herndon et al, 1999). This series also pointed out the benefit for circumcision in males with known reflux (Herndon et al, 1999). The case can be made for a more aggressive surgical approach if a neonate presents with *urosepsis and high-grade (IV or V) reflux*. It is absolutely crucial for any parent and referring physician to understand that successful reimplantation surgery diminishes but does not eradicate the likelihood of pyelonephritis. A child with innate susceptibility will still experience bladder infections despite the absence of reflux.

Several studies have shown that siblings of patients with reflux also have a higher likelihood of having reflux (Jerkins and Noe, 1982; Noe, 1995). Sibling screening studies in the first year of life have shown that anywhere from 20% to 50% of the siblings will have a VCUG that is positive for reflux (Noe, 1995; Parekh et al, 2002). It can be argued that all siblings should be screened, perhaps even up to the age of 9 years. Several studies have shown an increased incidence of renal scarring in siblings whose reflux was discovered by screening (Sweeney et al, 2001; Wan et al, 1996). Parekh and colleagues (2002) suggest that sibling reflux follows a more benign course and noted no renal scarring following antibiotic prophylaxis. On the other hand, would the cohort of patients in their study have done just as well if undiagnosed and left off antibiotic prophylaxis? It behooves us to remember that many asymptomatic infants have undiagnosed reflux, never develop urinary tract infections, resolve their reflux, and live normal lives. The extent to which screening averts renal complications will be best answered by prospective trials.

It is clear that identifying neonates with reflux and starting antibiotic prophylaxis offer benefit in terms of reducing the number of episodes of pyelonephritis. Clearly, episodes of pyelonephritis and the associated renal inflammation that results (see Fig. 86-3) can do harm if left untreated. It is estimated that each episode of febrile urinary tract infection may lead to a 5% risk of formation of a new renal scar per episode. All authorities agree that repeated and untreated infection does harm to the kidney. It is, however, very important to note that not all of the renal insufficiency in patients with reflux reflects damage by infection. This case is demonstrated in Figure 86-6, in which a VCUG was done for antenatal reflux and demonstrated massive grade V reflux. In the patient, a newborn child, urinary tract infection had never been noted, yet the creatinine was already abnormal and the ultrasound findings demonstrated increased echogenicity and a loss of corticomedullary differentiation. In this setting, the high-grade reflux is associated with renal dysplasia at the onset, and renal failure will be progressive.

**FIGURE 86-6.** Dysplasia and high-grade reflux. This case demonstrates the association of bilateral grade V reflux with renal dysplasia. The voiding cystourethrogram (A) and ultrasound scan (B) shown here were performed within the first 2 weeks of life, and the child had never had a diagnosed urinary tract infection during this interval. Despite sterile urine, the creatinine was elevated, and the renal sonogram showed increased echogenicity and poor corticomedullary differentiation. This case points out that renal insufficiency associated with reflux often is present at the outset and is not always secondary to infection.

## Renal Vascular Disease in the Newborn

Tivadar Tulassay, Rangasamy Ramanathan,  
Jacquelyn R. Evans, and Istvan Seri

For the pediatric patient population, the neonatal period represents the time of greatest risk for thromboembolic complications, with neonates presenting with 5.1 symptomatic thromboses per 100,000 live births (Nowak-Göttl et al, 1997). This high incidence decreases significantly after the first year of life. Neonatal hemostasis is characterized by a decrease in both the concentration and the function of the procoagulant and anticoagulant proteins. In addition, there is a decreased response of neonatal platelets to physiologic agonists, although, by affecting blood rheology and offering an additional source for adenosine diphosphate (ADP) release, the higher hematocrit may partially compensate for the immaturity of platelet function (Israels et al, 2001). However, under pathologic conditions, such as hypoxia, hypovolemia, hypotension, maternal diabetes, infection, and polycythemia, this delicate balance is easily disrupted, leading to an increased incidence of bleeding or thrombosis in the sick newborn. Among the recently recognized genetic conditions, hereditary thrombophilia with the G1691A mutation in the factor V gene (factor V Leiden) is the most commonly found prothrombotic risk factor for early spontaneous thrombosis during infancy (Nowak-Göttl et al, 2001; Schobess et al, 1999). In addition to the pathologic conditions, the placement of an indwelling arterial or venous catheter resulting in endothelial injury plays a major role in thrombus formation in neonates. This notion is supported by the observation that 44% to 89% of all major vessel thromboses in the newborn are associated with catheter placement (Nowak-Göttl et al, 1997; Schmidt and Andrew, 1995). Symptomatic thromboembolic complications with umbilical artery catheters alone are estimated at 1% to 9% (Weiner et al, 1998); placement of an umbilical vein catheter in sick neonates is associated with portal vein thrombosis in 1.3% of the cases (Schwartz et al, 1997). The incidence of asymptomatic aortic and ductus venosus, inferior vena cava, and right atrial thrombosis associated with umbilical catheters is in the 17% to 31% range (Horgan et al, 1987; Oppenheimer et al, 1982, Roy et al, 2002). It has recently been found that Doppler echocardiography is less sensitive than contrast venography in detecting asymptomatic thrombosis associated with umbilical vein catheter placement (Roy et al, 2002). Finally, although relatively rarely reported, neonatal thromboembolism may result in death or severe organ failure as a consequence of irreversible tissue damage.

The neonatal kidney is especially at high risk for thrombus formation. In addition to the use of umbilical artery

catheters (see later), the low renal blood flow, the relatively small caliber of the renal vessels, high catecholamine levels, and the enhanced renal vasoconstrictive and angioproliferative effects of endothelin and angiotensin II contribute to the increased risk of thrombogenesis in the neonatal kidney. The incidence of renovascular thrombosis in the newborn is unknown. In the past, renal venous thrombosis was more common. Since the introduction of umbilical arterial catheters in the routine care of the sick newborn, however, aortic and associated renal arterial thrombosis has become more frequent. Although renal vascular events usually manifest with the development of renal dysfunction, the function of other organs also may be affected, leading to the development of adrenal hemorrhage, necrotizing enterocolitis, congestive heart failure, systemic hypertension, inadequate perfusion of the lower extremities, and multiorgan failure.

### RENAL ARTERIAL OBSTRUCTION

#### Etiology and Incidence

In the vast majority of the cases, renal arterial obstruction is the consequence of intra-arterial thrombus formation. Before the introduction of umbilical artery catheterization, only a few cases of renal artery thrombosis were reported, with shock, coagulopathy, and congestive heart failure being the principal causative factors (Adelman, 1988). The introduction of umbilical artery catheterization in the early 1970s resulted in a significant increase in the incidence of neonatal aortic thrombosis. Because the presence of a catheter-related aortic thrombus is associated with involvement of one or both of the renal arteries in 30% to 50% of affected newborns, umbilical artery catheter placement also increases the incidence of renal artery thrombosis (Schmidt and Andrew, 1995; Seibert et al, 1987). Ultrasonographic findings suggest that catheter-related asymptomatic aortic thrombi are present in 17% to 31% of newborns (Horgan et al, 1987; Oppenheimer et al, 1982), although the Doppler ultrasound technique may underestimate the real incidence (Roy et al, 2002; Schmidt and Andrew, 1995). The incidence of *severe symptomatic thrombosis* after umbilical artery catheter placement is much lower and is reported to be around 1% (O'Neill et al, 1981). Because the trauma to the vessel wall inflicted at the time of the placement of the catheter appears to play the most important role in aortic thrombus formation (Goetzman et al, 1975; Rasoulpour and Marinelli, 1992), the procedure should be done carefully to minimize endothelial injury and the attendant risk of thrombus formation. Because continuous infusion of low-dose heparin prolongs the patency of umbilical artery lines (Rajani et al, 1979), its use has been recommended and practiced in most intensive care units. However, the reports are conflicting regarding the effect of low-dose heparin infusion on the incidence of thrombotic sequelae (Ankola and Atakent, 1993; Horgan et al, 1987). On the other hand, heparin bonding of catheters has been shown to be clearly associated with significantly fewer thrombotic complications (Krafte-Jacobs et al, 1995). Owing to the possible relationship between heparin use and systemic fungal

infections in extremely low-birth-weight (ELBW) neonates, however, the routine use of heparin may have to be reassessed, at least for this patient population (Stephenson, 2001).

In addition to the endothelial injury caused by catheter placement, several other risk factors for aortic and renal arterial thrombosis have been identified. Systemic infection, birth weight less than 1500 g, perinatal asphyxia, polycythemia, intrauterine cocaine exposure, maternal diabetes mellitus, maternal lupus, congenital heart disease, hypercoagulability, dehydration (especially hypernatremic dehydration), and infusion of calcium salts, hyperalimentation solutions, or intravenous fat preparations through the umbilical arterial catheter are the most important additional risk factors for aortic and renal artery thrombosis in the newborn (Schmidt and Andrew, 1995; Seibert et al, 1987; Vailas et al, 1986).

Finally, resistance to activated protein C has been identified as a risk factor for thrombotic disease, even in the absence of umbilical catheter placement (Manco-Johnson et al, 1988). In over 90% of cases, the basis for the activated protein C resistance is a mutation in the coagulation factor V gene (factor V Leiden) that renders factor V Leiden more resistant to inactivation by activated protein C. The prevalence of factor V Leiden mutation in neonates with arterial thrombosis reaches 23% (Hagstrom et al, 1998). In cases of homozygous congenital protein C deficiency with associated thrombosis, in addition to anticoagulant therapy, the administration of supplemental protein C is necessary to correct the hypercoagulable prothrombotic condition (Dreyfus et al, 1991).

### Thromboembolic Complications of Umbilical Artery Catheters in Neonates

Umbilical artery catheters are extensively used for blood pressure monitoring, blood gas sampling, and fluid administration in critically ill newborn infants. As mentioned earlier, however, there are significant variations in the type and size of catheter used, catheter tip position, presence of end or side holes in the catheter, type of fluids or drugs infused, duration of catheterization, and heparinization of the infusate.

Catheter materials used include polyvinyl chloride, polyurethane, Silastic or silicone-based polymer, and heparin-coated or heparin-bonded catheters. The soft Silastic catheters may cause less intimal tear at the time of insertion, and Silastic or heparin-coated catheters may be less thrombogenic. However, a randomized study comparing polyvinyl chloride and heparin-bonded polyurethane catheters in 125 infants without additional heparin in the infusate showed no difference in the incidence of aortic thrombosis (Jackson et al, 1987). Of interest, heparin-coated catheters may reduce infections by inhibiting bacterial adherence to the catheter (Applegren et al, 1996; Mermel et al, 1993). Finally, although the use of antiseptic-impregnated catheters has not yet been studied extensively in newborns, silver-impregnated catheters have been shown to reduce catheter-related sepsis in adults.

Umbilical artery catheter tip positioning may also influence the risk of aortic and/or renal artery thrombosis,

ischemic events, intraventricular hemorrhage, and necrotizing enterocolitis. However, there are conflicting data on clinically significant complications associated with high versus low umbilical artery lines. In an earlier study, high umbilical artery catheters placed at a T6 to T10 vertebral level have been reported to be associated with a lower incidence of clinically significant vascular complications, without an increase in hypertension, intraventricular hemorrhage, or necrotizing enterocolitis (Harris and Little, 1978). However, another study found that newborns with a high umbilical artery catheter in place more frequently develop aortic and renal thrombosis (Seibert et al, 1987). Finally, a recent meta-analysis comparing the complications associated with high versus low positioning of the umbilical artery line suggests a probable reduction in aortic thrombosis and a longer catheter life with high line positioning (Barrington, 2002).

Position of the hole at the tip of the catheter also may influence the incidence of aortic thrombosis, because the use of side-hole catheters has been associated with a higher incidence of this complication than is seen with end-hole catheters (Weststrom et al, 1979). No data regarding about the optimal size of the catheter are available. The authors' preference is to use a 3.5 French catheter in infants weighing less than 1000 g and a 5.0 French catheter in infants weighing greater than 1000 g. In addition to the short-term side effects, long-term complications have been reported following neonatal umbilical catheterization including acquired coarctation of abdominal aorta and renal artery stenosis (Adelman and Morrell, 2000).

### Clinical Presentation and Laboratory Findings

The symptoms of aortic and renal artery thrombosis depend on the severity and extension of thrombus formation. Some infants may remain asymptomatic for a longer period of time, whereas others may show severe symptoms immediately after thrombus formation. Thrombosis of the abdominal aorta and the renal arteries should be suspected in newborns with a history of umbilical artery catheterization who exhibit signs of congestive heart failure, hypertension, oliguria, renal failure, bowel ischemia or frank necrotizing enterocolitis (secondary to obstruction of the superior or inferior mesenteric artery), or decreased femoral pulses with lower limb ischemia (Schmidt and Andrew, 1995; Vailas et al, 1986). The finding that symptoms of arterial or renal vein thrombosis occur sooner in term (within the first few postnatal days) than in preterm neonates (at a median postnatal age of 8 days) implies that increased vigilance of monitoring for potential signs of thromboembolic complications, for a longer time period, is indicated in the preterm patient population (Nowak-Göttl et al, 1997). Aortic and renal artery thrombosis may be classified according to the severity of the clinical findings. *Minor thrombosis* manifests with mildly decreased limb perfusion, hypertension, and hematuria; *moderate thrombosis* is present when decreased limb perfusion, hypertension, oliguria, and congestive heart failure occur; and *major thrombosis* is characterized by hypertension and signs of multiorgan failure. Laboratory abnormalities most commonly associated with aortic thrombosis are thrombocytopenia, hypofibrinogenemia,

elevated fibrin split products, variable prothrombin and thromboplastin times, conjugated hyperbilirubinemia, elevated blood urea nitrogen and serum creatinine, hyperreninemia, and hematuria.

### Diagnosis

Because ultrasonography fails to detect small intra-arterial renal thrombi (Roy et al, 2002, Schmidt and Andrew, 1995; Seibert et al, 1987; Vailas et al, 1986) and, in some cases, even larger asymptomatic venous thrombosis (Roy et al, 2002), the “gold standard” imaging technique for the diagnosis of neonatal thrombosis remains angiography. However, in clinical practice, the diagnosis of aortic and main renal artery thrombosis is most frequently made by real-time and Doppler ultrasonography (Schmidt and Andrew, 1995). Radionuclide imaging also may be useful in cases of suspected catheter-related renal artery thrombosis if the ultrasonographic findings are inconclusive (Molteni et al, 1993; Schmidt and Andrew, 1995). In cases in which intrathrombotic fibrinolytic therapy or surgical intervention is considered, aortography performed through the umbilical artery line should confirm the diagnosis (Richardson et al, 1988; Schmidt and Andrew, 1995).

### Treatment

Prospective studies have shown that a large number of newborns with umbilical artery catheters may develop asymptomatic aortic thrombosis (Oppenheimer et al, 1982; Seibert et al, 1987, 1991; Vailas et al, 1986). Because most of these thrombi resolve spontaneously, only supportive care, removal of the umbilical artery catheter, and close ultrasonographic follow-up evaluation are recommended for management of the asymptomatic or the minimally symptomatic newborn (Schmidt and Andrew, 1995; Vailas et al, 1986). In more severe cases, when fibrinolytic therapy is considered, the umbilical artery line may be left in place (see later).

In the symptomatic patient with stable thrombosis of the aorta and renal arteries and only mild signs of organ dysfunction, supportive medical management consists of treatment of systemic hypertension and of the usually transient renal insufficiency and mild congestive heart failure. At present, heparin is the anticoagulant of choice in these newborns (Payne et al, 1989; Richardson et al, 1988; Schmidt and Andrew, 1995). The initial loading dose is 75 to 100 IU/kg followed by 28 IU/kg/hour continuous infusion (Andrew et al, 1994). Laboratory monitoring to avoid excessive heparinization and close follow-up of the clinical response by Doppler flow measurements and real-time ultrasonography are obligatory. Heparin has a large volume of distribution in newborns, resulting in faster drug clearance (Schmidt and Andrew, 1995). Newborns at high risk for intracranial bleeding and those with established intracranial bleeding or with active bleeding elsewhere may not be candidates for systemic heparinization. The duration of heparin therapy depends on the clinical response measured by the improvement in organ function and should be at least 7 days (Schmidt and Andrew, 1995). It is important to note that in some newborns, a resistance to heparin therapy secondary to inherited or acquired antithrombin III deficiency may occur. In such cases, the administration of supplemental antithrom-

bin III may be necessary to restore the effectiveness of heparin treatment. Recently, the use of low-molecular-weight heparins (LMWHs) has been advocated in the management of neonatal thrombosis because of the potential advantages LMWHs offer over unfractionated heparin. These advantages include a longer half-life with predictable pharmacokinetics, better bioavailability, ease of subcutaneous administration, decreased risk of osteopenia and heparin-induced thrombocytopenia, lack of interference by concurrent medications, and decreased risk for hemorrhagic complications. LMWHs also have a greater activity against factor Xa when compared with heparin. In adults and in children, LMWHs have been proved to be safe and effective in the treatment of venous and arterial thrombosis (Weitz, 1997), and in a recent prospective cohort study, 48 neonates also were successfully treated with the LMWH enoxaparin (Dix et al, 2000). Finally, there is no evidence that long-term oral anticoagulation therapy is necessary after the resolution of neonatal aortic and renal thrombosis.

Medical management of cases with potential life-threatening complications of aortic or renal thrombosis includes systemic (Schmidt and Andrew, 1995) or intrathrombotic (Schmidt and Andrew, 1995; Strife et al, 1988) application of fibrinolytic therapy and aggressive supportive care directed at organ dysfunction. The intrathrombotic infusion of the fibrinolytic agent reduces cumulative dose requirements and possibly the untoward systemic effects of fibrinolytic therapy. Close ultrasonographic or angiographic follow-up is considered mandatory to evaluate the thrombolytic response to these agents. The fibrinolytic agents used in the clinical management of newborns with major thrombosis have been streptokinase, urokinase, and tissue plasminogen activator (Schmidt and Andrew, 1995). These fibrinolytic agents act by directly or indirectly converting plasminogen to plasmin, thus activating fibrinolysis. Streptokinase forms a protein complex with plasminogen, which in turn converts other plasminogen molecules to plasmin (Holden, 1990). The theoretical drawbacks of streptokinase use are depletion of the substrate and possible toxic reactions. However, it is primarily because of the antigenicity and systemic side effects of streptokinase that its use has been abandoned (Hartmann et al, 2001). Urokinase, a nonantigenic protein, directly converts plasminogen to plasmin in both the systemic circulation and the thrombus (Holden, 1990). Laboratory responses to urokinase include a decrease in fibrinogen concentration and an increase in fibrin split products. In cases with poor laboratory and clinical responses, supplementation of plasminogen by the administration of fresh frozen plasma has been recommended. Although urokinase has been the most frequently used fibrinolytic agent in newborns (Schmidt and Andrew, 1995), owing to its potential contamination with reovirus, the Food and Drug Administration (FDA) has recently recommended to consider other treatment options before urokinase is administered until the problem with the viral contamination has been solved. The third fibrinolytic agent, tissue plasminogen activator (tPA), is a fibrin-specific plasminogen activator that binds poorly to circulating plasminogen or fibrinogen (Haire, 1992). This agent offers several theoretical advantages in the newborn, including a short half-life,

minimal antigenicity, direct activation of plasminogen, lack of inhibition by  $\alpha_2$ -antiplasmin, and localization of fibrinolytic activity (Kennedy et al, 1990). Thus, at least in theory, the use of this agent minimizes systemic proteolysis, with maximal fibrinolytic activity on the surface of the thrombus. Indeed, several investigators have recently reported the use of recombinant tissue plasminogen activator (r-tPA) in neonates to treat life- or limb-threatening neonatal arterial thrombosis (Dillon et al, 1993; Weiner et al, 1998; Hartmann et al, 2001). The published data indicate that successful lysis with r-tPA occurs in most patients and that hemorrhagic complications are unusual although may happen. An absolute contraindication to the use of r-tPA in neonates is the presence of intraventricular hemorrhage and/or significant cerebral ischemic changes. The protocol for r-tPA therapy in neonates should include monitoring for the presence of intraventricular hemorrhage and/or cerebral ischemic changes before and during therapy, normalizing blood pressure prior to r-tPA administration, limiting its dose to 0.4 mg/kg/hour, maintaining the fibrinogen level at greater than 150 mg/dL, and performing sonographic evaluations of thrombus during and after r-tPA administration to assess lysis and long-term outcome (Weiner et al, 1998). Recently, r-tPA at 0.7 mg/kg given as an initial bolus over 30 to 60 minutes followed by 0.2 mg/kg/hour along with low-dose heparin at 4 to 10 IU/kg/hour was used successfully in treatment of catheter-related thrombosis in neonates (Hartmann et al, 2001). This protocol appears to be effective and safe without apparent increases in the risk of intracranial bleeding. According to the available and limited information comparing the use of urokinase and r-tPA in neonates, there is probably no real difference between them in effectiveness and toxicity (Nowak-Göttl et al, 1999). However, more information is needed to appropriately address this question. Finally, it is unclear at present if concomitant systemic heparinization offers any benefit without increasing the risk of bleeding complications.

The major complication of fibrinolytic therapy is the occurrence of intracranial hemorrhage, especially in the sick preterm infant (Strife et al, 1988). Therefore, intrathrombotic rather than systemic fibrinolytic therapy with radiologic imaging studies including serial head ultrasound examinations and laboratory monitoring of the appropriate coagulation parameters before, during, and after treatment constitute the suggested specific management of the newborn at high risk for intracranial bleeding who presents with a life-threatening aortic or renal arterial thrombosis. Although surgical thrombectomy has been successfully performed in newborns (Payne et al, 1989; Schmidt and Andrew, 1995), guidelines for the indication and timing of surgical management of neonatal aortic and renal thrombosis are not well established. Moreover, it must be emphasized that there is also no validated approach at present for the use of anticoagulant or fibrinolytic agents in newborns with aortic and renal thrombosis owing to the lack of scientific evidence concerning optimal management strategies. The above-described empiric approach to medical management has summarized, in the absence of well-designed controlled clinical studies, the most recent recommendations based on the results of case reports.

### Prognosis

Gestational and postnatal age, underlying pathologic conditions of the newborn, and the age, size, and location of the thrombus all have an impact on the outcome of neonatal aortic and renal arterial thrombosis. The overall mortality rate lies between 9% and 20% (Nowak-Göttl et al, 1997; Schmidt and Andrew, 1995). Mortality rates with major aortic and renal arterial thrombosis, however, are higher (Vailas et al, 1986), whereas most newborns with minor or moderate thrombi recover. Concerning the recovery of blood flow through the affected vessel, a complete resolution or partial vessel patency occurs in approximately 60% of the cases following neonatal thromboembolism (Nowak-Göttl et al, 1997).

The most frequent long-term morbidity in the affected newborn is renovascular hypertension. Although hypertension may persist for months or sometimes years, blood pressure eventually becomes normal, and the majority of the patients remain normotensive even after the antihypertensive treatment has been discontinued. It is not known, however, whether these children will have a higher incidence of hypertension or renal failure in adulthood. Chronic renal insufficiency develops less frequently during infancy and early childhood and is always the consequence of severe aortic and bilateral renal arterial thrombosis causing irreversible renal parenchymal damage.

## RENAL VEIN OBSTRUCTION

Although renal vein thrombosis may occur at any age, newborns are particularly at risk for the development of this vascular event, because 60% to 75% of the patients with renal vein thrombosis are younger than 1 month of age. Prenatally demonstrated renal vein thrombosis has also been reported, mainly in fetuses of diabetic mothers (Duncan et al, 1991; Sanders and Jaquier, 1989).

### Incidence

Earlier autopsy findings indicate that the incidence of renal vein thrombosis is 1/40 to 1/300 in newborns who died (Arneil et al, 1973). A more recent estimate of the minimal incidence of renal vein thrombosis in term neonates is 2.2 cases per 100,000 live births, with a sixfold higher rate in preterm neonates (Böbenkamp et al, 2000).

### Etiology

The anatomy of the renal vasculature and the differences between the left and the right renal venous drainage determine the response of the renal venous system to injury. The drainage of the left adrenal vein into the left main renal vein explains why ipsilateral adrenal hemorrhage more frequently accompanies left-sided than it does right-sided renal vein thrombosis. The lack of venous collaterals in the right kidney is responsible for the more rapid and severe occurrence of clinical symptoms of venous thrombosis on this side. In the primary and most frequent form of renal vein thrombosis in the newborn, clotting starts in the small intrarenal veins when venous stasis occurs. As a result of the free anastomoses within the renal venous system, microthrombi spread distally and involve the renal cortex and medulla extending into larger

veins (Arneil et al, 1973). In the secondary form of renal vein thrombosis, a thrombus in the inferior vena cava extends into the renal vein.

Renal vein thrombosis in the newborn has been frequently associated with known risks—catheters, surgery, trauma, and infection. Genetic factors also may predispose the infant to develop thrombosis, and the pathogenic role of inherited prothrombotic states (i.e., activated protein C resistance, factor V Leiden) has now been well demonstrated (Hangstrom et al, 1998). Association of factor V Leiden with methyltetrahydrofolate reductase and platelet glycoprotein IIIa (GPIIIa) polymorphisms also may result in renal vein thrombosis (Giordano et al, 2001). In addition to prethrombotic or hypercoagulable prothrombotic states, conditions associated with decreases in renal blood flow are important factors frequently involved in the pathogenesis of renal vein thrombosis in the newborn. The normally low venous blood flow in the newborn may be further reduced by intravascular volume loss (from bleeding or dehydration), hypoxia, infection, polycythemia, or cyanotic congenital heart disease. The ensuing venous stasis and hemoconcentration, especially when accompanied by disturbances in fluid and electrolyte homeostasis and acid-base balance, result in sludging and thrombosis in the small interlobular veins. The microthrombi in the small veins then spread distally to involve the larger vessels. In thromboembolic states, subsequent renal vein involvement occurs with the proximal extension of the thrombus from the pelvic/iliac veins and from the inferior vena cava. In the newborn, renal vein thrombosis most frequently occurs after a central line placement through the femoral vein or if hemorrhagic shock develops. Finally, infants of diabetic mothers are at an especially high risk for renal vein thrombosis as a result of a combination of several risk factors, including their hypercoagulable state and relatively low extracellular water content as well as the often associated polycythemia, perinatal asphyxia, and respiratory distress.

#### Thromboembolic Complications of Umbilical Venous Catheters In Neonates

Umbilical venous catheterization is an alternative initial option for central venous access, especially in infants weighing less than 1000 g. As mentioned earlier, this route allows for administration of hypertonic nutrient fluids, drugs, and pressors, and for continuous infusion of medications. Verification of catheter tip position by radiography is extremely important and should be done before using the line. The tip should lie in the inferior vena cava, 0.5 to 1.0 cm above the diaphragm, avoiding hepatic and portal veins. Placing the catheter tip in the right atrium increases the risk for cardiac tamponade via perforation of the atrial wall by the catheter or transudation of the infusate through the thin atrial wall into the pericardial space. Potential complications of umbilical venous catheter placement include portal vein, hepatic vein, or inferior vena cava thrombosis; thrombotic endocarditis; obstruction of pulmonary venous return in infants with infradiaphragmatic total anomalous pulmonary venous return; air embolism; and infection.

#### Clinical Presentation and Laboratory Findings

The classic diagnostic triad of a palpable abdominal mass, gross hematuria, and thrombocytopenia is infrequently seen in the neonate. The development of a unilateral or bilateral flank mass in association with a sudden deterioration of clinical status, however, should raise the possibility of renal vein thrombosis in the newborn. Other clinical signs and laboratory findings consistent with renal vein thrombosis include oliguria or anuria, gross hematuria, thrombocytopenia, hemolytic anemia, metabolic acidosis, and azotemia. Prothrombin time and partial thromboplastin time may be prolonged because of consumption of coagulation factors. At the beginning of the clinical course, blood pressure often is low. Although hypertension may develop later in the course, the increase in blood pressure usually does not reach the level seen in cases of renal artery thrombosis. Some newborns, however, whose early clinical symptoms are mild or overlooked, may present with hypertension days or weeks after the development of the renal vein thrombosis.

#### Diagnosis

The diagnosis of renal vein thrombosis in the newborn is suspected based on the clinical presentation and laboratory findings, as just described, and confirmed by the results of real-time and Doppler ultrasonography (Nowak-Göttl et al, 1997; Schmidt and Andrew, 1995; Slovis et al, 1993; Weiner et al, 1998). Sonography confirms the diagnosis with approximately 92% accuracy (Ricci and Lloyd, 1990), and performance of additional studies such as angiography is infrequently needed. The real-time ultrasonographic features are nonspecific and include renal enlargement and evidence of edema causing distortion of the renal architecture with an inhomogeneous appearance of the parenchyma and loss of corticomedullary differentiation. The findings on color Doppler sonography are more specific, making the diagnosis relatively easy once the thrombus has reached the larger renal veins. Using high-frequency transducers (7.0 to 10 MHz), a hypoechoic apex and renal papilla can be identified, with a ring of reduced echogenicity seen around the affected pyramids 1 to 2 weeks after the acute phase (Wright et al, 1996). Among the survivors, characteristic calcification of intrarenal veins is detected in 60% of the cases (Slovis et al, 1993).

Renal vein thrombosis should always be differentiated from renal artery thrombosis. The latter occurs mostly in newborns with catheterization of the umbilical artery, it does not present with renal enlargement, and the subsequent systemic hypertension is usually more severe than that in renal vein thrombosis.

#### Treatment

Initial treatment is directed at correcting the abnormalities in the fluid, electrolyte, and acid-base balance. The use of hypertonic infusions, nephrotoxic medications, and hyperosmolar radiographic contrast agents should be avoided. Diuretics are of limited value, and their use may further perpetuate hemoconcentration. If hemoconcentration cannot be corrected by infusion therapy, peritoneal dialysis may be indicated.

Although the correction of hemoconcentration and hyperviscosity in most patients prevents further propagation of the thrombus, intravenous heparin may be of value in preventing extension of the thrombus (Ricci and Lloyd, 1990). According to findings in earlier studies, heparin treatment does not prevent the development of renal dysfunction (Mocan et al, 1991; Nuss et al, 1994). More recently, however, anticoagulation with heparin and/or LMWH in neonates with renal vein thrombosis showed significant improvement in long-term renal outcome (Zigman et al, 2000). Successful thrombolytic therapy with urokinase infused through a lower extremity vein also has been reported (Duncan et al, 1991). It is important to note that the combined use of thrombolytic and anticoagulation therapy in preterm neonates may be complicated by severe intracranial bleeding and without the resolution of the renal vein thrombosis (Weinschenk et al, 2001). Because active bleeding and the risk for intraventricular hemorrhage are the main contraindications to anticoagulant and thrombolytic therapy, their use is recommended mostly in the full-term newborn with life-threatening thromboembolic complications (see earlier).

The role of surgical intervention in the treatment of renal vein thrombosis has been extensively debated. Theoretically, in the primary form of renal vein thrombosis, thrombectomy precludes extension of the thrombus into the vena cava or opposite kidney and prevents infections and the development of hypertension caused by renal ischemia. Because the smaller intrarenal veins are almost always occluded, however, extraction of thrombus from the main renal vein does not alleviate renal infarction in most cases of renal vein thrombosis. Moreover, an advantage of early thrombectomy or nephrectomy has not been demonstrated, even with bilateral involvement (Ricci and Lloyd, 1990).

### Prognosis

The survival rate for newborns with renal vein thrombosis has improved during the past decade and is around 80% to 95% (Ricci and Lloyd, 1990; Schmidt and Andrew, 1995). Most deaths are due to the underlying disease and not the renal vein thrombosis or the ensuing renal dysfunction. The extent of recovery of the involved kidney after renal vein thrombosis varies, ranging from complete restoration of renal function to the development of a nonfunctioning shrunken kidney, partially fibrous kidney, renal hypertension, nephrotic syndrome, or chronic renal tubular dysfunction. Kidney atrophy is already present at 1 year of age in two thirds of the patients with a sonographic diagnosis of neonatal renal vein obstruction (Böbenkamp et al, 2000). Although long-term follow-up data on survivors of neonatal renal vein thrombosis are limited, at a follow-up period of 5 to 12 years, blood pressure, glomerular filtration rate, and urinary concentration ability remained within normal limits in a majority of affected children (Keidan et al, 1994; Mocan et al, 1991). Because persistent renal imaging abnormalities were present in more than 80% of these patients (Mocan et al, 1991), however, the long-term outcome of renal function in patients with neonatal renal vein thrombosis remains uncertain, and continuing follow-up is absolutely necessary.

## RENAL CORTICAL AND MEDULLARY NECROSIS

Renal cortical necrosis, renal medullary necrosis, and combined cortical and medullary necrosis are uncommon disorders in the newborn. They occur only in critically ill newborns who, in most of the cases, present with irreversible shock. Therefore, renal cortical and medullary necrosis is the manifestation of an end-organ insult to the kidney caused most frequently by extreme perinatal or postnatal stress, and it is seldom recognized while the newborn is alive.

### Incidence and Etiology

Autopsy findings indicate that the incidence of renal cortical and medullary necrosis is around 5% in infants who die at less than 3 months of age (Lerner et al, 1992). Risk factors for the development of renal cortical and medullary necrosis include prematurity, congenital heart disease associated with low renal perfusion or poor tissue oxygenation, perinatal asphyxia, sepsis, bleeding diathesis or coagulopathy, and respiratory distress resulting in cardiovascular compromise. In addition, the use of contrast agents during cardiac catheterization also appears to be a risk factor.

### Pathomechanism and Clinical Presentation

The clinical manifestations of renal cortical and medullary necrosis (hematuria, oliguria or anuria, and renal enlargement) are nonspecific and are present in several more common neonatal renal abnormalities. Because renal cortical and medullary necrosis occurs only in newborns with shock caused by a life-threatening condition, its recognition is often delayed or the diagnosis is never even considered. It is unclear why some affected newborns preferentially develop medullary necrosis, whereas others present with cortical necrosis of the kidney. The severity of the intrarenal arteriolar vasoconstriction and the magnitude of the underlying resistance of the capillary bed in the renal cortex and medulla may have a major impact on the primary localization of the necrotic process.

Increased local production of vasodilator prostaglandins attenuates renal vasoconstriction occurring with acute circulatory collapse (Gleason, 1987). Because inhibition of prostaglandin synthesis by indomethacin enhances renal ischemia under these circumstances, administration of the drug may contribute to the development of renal cortical and medullary necrosis in premature newborns with severely compromised cardiovascular status.

Hyperosmotic radiocontrast agents also may produce marked and protracted medullary vasoconstriction and hypoxia, probably by affecting renal medullary prostaglandin synthesis (Gruskin et al, 1974; Nygren et al, 1988). Their use in newborns with congenital heart disease during cardiac catheterization may contribute to the development of renal cortical and medullary necrosis in this patient population. Whether the use of isosmotic contrast agents results in similar renal response is unknown.

### Diagnosis, Management, and Prognosis

There are no specific clinical, laboratory, or imaging findings to aid in the diagnosis of neonatal renal cortical and medullary necrosis, and no specific therapy is available. In

all critically ill newborns with shock or thrombosis of the renal vessels, or after the administration of a hyperosmolar contrast agent during cardiac catheterization, the clinician should maintain a high degree of suspicion until the presence of a major renal insult can safely be ruled out. Considerations in the differential diagnosis include all causes of neonatal acute renal failure, including bilateral renal artery or renal vein thrombosis, autosomal recessive polycystic kidney disease, and bilaterally multicystic or hydronephrotic kidneys. During the acute phase, renal scintigraphy and magnetic resonance imaging (MRI) may be of value in the diagnosis. The decreased ability of the critically ill newborn to tolerate transport in the acute phase of the disease, however, renders these studies impractical.

The prognosis for neonatal renal cortical and medullary necrosis depends on the underlying disease. Excretory urography in survivors shows characteristic bizarre-appearing dilated calices with a variable amount of scarring. These morphologic changes are most frequently associated with reduced glomerular filtration rate, renal concentrating defect, hypertension, and segmental hypoplasia. As in the cases of renal artery and vein thrombosis, the long-term effects of neonatal cortical and medullary necrosis on renal function remain to be determined.

## ADRENAL HEMORRHAGE

### Incidence

The incidence of detected neonatal adrenal hemorrhage ranges from 1.7 to 2.1 per 1000 births (Marino et al, 1990). Because adrenal bleeding may remain asymptomatic, the real occurrence is probably higher. Among newborns who die, the incidence of adrenal hemorrhage is around 10%. In a majority of the cases, the bleeding locates to one side, and only 5% to 8% of adrenal hemorrhages are bilateral (Marino et al, 1990).

### Pathomechanism

The fetal and neonatal adrenal glands are relatively large and are more vascularized than later in life, which may predispose them to bleeding. Risk factors associated with adrenal hemorrhage in the newborn include birth trauma, perinatal asphyxia, shock, infection, thrombosis of the inferior vena cava and left renal vein, and hemorrhagic disorders.

### Clinical Presentation

Clinical symptoms are nonspecific and most frequently include unexplained and persistent jaundice, mild anemia, and abdominal distention associated with an abdominal mass. In the case of bilateral adrenal hemorrhage, hypoglycemia and hypotension may be the presenting findings. In boys, neonatal adrenal hemorrhage may present with the clinical manifestation of a scrotal hematoma (Miele et al, 1997; Putnam, 1989). The simultaneous occurrence of adrenal bleeding and incomplete rotation of the colon leading to early duodenal obstruction also has been reported (Cheves et al, 1989). Finally, some infants remain completely asymptomatic, and the diagnosis is made only incidentally.

### Diagnosis

Suprarenal masses in the newborn that should be considered in the differential diagnosis of neonatal adrenal hemorrhage include abscesses; neuroblastoma; renal duplication; hydronephrosis; Wilms tumor; enteric duplications; and renal, pancreatic, hepatic, ovarian, and choledochal cysts. If adrenal hemorrhage is suspected, laboratory tests including a complete blood cell count, serum bilirubin, serum glucose, and urinary excretion of catecholamines and their metabolites aid in establishing the diagnosis. In typical cases, the diagnosis is confirmed by ultrasonography. Usually the whole gland is affected, but occasionally an uninvolved adrenal limb may be detected adjacent to the suprarenal mass. Because hemorrhage into the adrenal gland usually is followed by necrosis and later resolution with fibrosis and calcification, the evolution of these signs is characteristic on the sonographic follow-up examinations. Calcification of the adrenal gland is usually noted about 2 weeks after the hemorrhage. Despite the high resolution of ultrasound imaging, the use of MRI, computed tomography, or radionuclide renal scan sometimes is necessary to differentiate between an atypical adrenal hemorrhage and neuroblastoma or a renal mass. Surgical exploration is seldom needed.

In utero adrenal bleeding of the fetus should be considered if a cystic mass in the suprarenal area is detected on prenatal ultrasonography (Marino et al, 1990). It is extremely difficult, however, to distinguish between fetal adrenal hemorrhage and cystic neuroblastoma without histologic examination. Because adrenal hemorrhage shows progressive changes within 2 weeks, whereas neuroblastoma usually remains unchanged during this time, a repeat prenatal ultrasound study may be helpful in establishing the diagnosis. A hemorrhage into an adrenal neuroblastoma may also cause progressive cystic changes on repeat ultrasonographic examinations, making the prenatal differential diagnosis extremely difficult. In such cases, intrauterine evaluation of the suprarenal mass by MRI may be informative.

The occurrence of benign hemorrhagic adrenocortical cysts also has been reported in Beckwith-Wiedemann syndrome, a condition also associated with a high incidence of adrenocortical carcinoma (McCauley et al, 1991). The differentiation of these benign hemorrhagic lesions of the adrenals from common adrenal hemorrhage may be difficult by imaging studies alone.

### Outcome

In a majority of cases, the prognosis for neonatal adrenal hemorrhage is excellent. The disease is self-limiting and except for the rare bilateral cases requires no specific treatment.

## HYPERTENSION IN THE NEWBORN

The first reported blood pressure measurement in the newborn was performed in the late 19th century by the direct determination of the pressure in the umbilical artery (Ribemont, 1879). Since then, the ever-increasing body of information on arterial blood pressure in the newborn has generated many new and as-yet unanswered

questions. For example, because the physiologic blood pressure range in the neonatal period, especially in the immature preterm infant, remains unknown, hypotension and hypertension cannot be adequately defined in this patient population.

### Blood Pressure Measurement Techniques

The requirements for the techniques of blood pressure measurement include that the method should be simple, painless, and reliable with an acceptable risk-to-benefit ratio, and it should give information continuously or at least in frequent intervals without disturbing the newborn.

#### *Invasive Measurement*

The most widely used method of blood pressure measurement in the critically ill newborn is by means of an indwelling umbilical or peripheral artery catheter connected to a transducer. Three sources of error are of importance when this method is used. First, if the catheter is too small in diameter, it underestimates the systolic pressure because of loss of higher frequencies. Second, the position of the catheter tip too close to the wall of the vessel or the presence of a clot at the tip of the catheter may result in damping of the pressure waves, leading to an underestimation of the blood pressure. Finally, the presence of even small air bubbles in the system generates a resonant frequency, which then alters the measured systolic, diastolic, and, to a lesser extent, mean blood pressure values (Weindling, 1989). The position of the umbilical arterial catheter tip in the aorta (high versus low) does not influence the measured value. Occasionally, both peripheral and umbilical artery lines are placed and transduced in extremely labile, critically ill full-term newborns. In these cases, the peripheral artery catheter may read higher systolic pressures than the umbilical line (Adelman, 1988).

#### *Noninvasive Measurement*

Three noninvasive methods are used in clinical practice. The traditional methods using auscultation, palpation, or the flush technique are insensitive, especially when the stroke volume is low. The Doppler ultrasound method is reliable for the measurement of systolic values, but it cannot accurately detect the diastolic pressure (Emery and Greenough, 1992). Automatic oscillometry is the most commonly used noninvasive technique that provides an accurate, reproducible, and convenient estimate of blood pressure (including the mean blood pressure) in most newborns, provided that the appropriate size cuff is used with a cuff width-to-arm circumference ratio of 0.44 to 0.55 (Low et al, 1995; Sonesson and Broberger, 1987). Oscillometry is the only noninvasive method that actually measures mean blood pressure instead of calculating it. In very low-birth-weight (VLBW) newborns, however, as well as in cases of extreme hypotension, some inaccuracy is possible (Rasoulpour and Marinelli, 1992).

### Definition and Incidence

Despite the large body of information on blood pressure values in the neonatal period, there is no accurate definition of pathologic blood pressure values for the newborn

and, in particular, for the VLBW infant (see earlier). In the clinical practice, the infant's blood pressure and tissue perfusion generally are considered to be adequate as long as urine output and capillary refill are within normal limits in the absence of metabolic acidosis. Although this approach may be an appropriate clinical approximation for hypotension, it does not allow for prompt detection of mild systemic hypoperfusion. In addition, the indirect clinical assessment is not at all useful to determine the blood pressure values representing hypertension because there are no specific clinical or laboratory signs to indicate the level of systemic blood pressure elevation that has the potential of causing end-organ damage in the given newborn. In the pediatric population, hypertension is defined as the average systolic or diastolic blood pressure (or both) at the 95th percentile or greater for age and gender when measured on at least three occasions. This definition, however, cannot be applied to neonatal hypertension because it presupposes an accurate definition of normal neonatal blood pressure (see earlier). Therefore, neonatal hypertension remains arbitrarily defined as systolic blood pressure greater than 90 mm Hg and diastolic blood pressure greater than 60 mm Hg in the full-term newborn and systolic blood pressure greater than 80 mm Hg and diastolic blood pressure greater than 50 mm Hg in the preterm infant (Adelman, 1988). At present, this arbitrary definition is widely accepted and referred to in the literature. On the basis of these criteria, the reported incidence of neonatal hypertension ranges from 0.7% to 3.2% (Adelman, 1988; Rasoulpour and Marinelli, 1992; Singh et al, 1992; Numtnarumit et al, 1999). In the ELBW infant (weighing less than 1000 g), however, even the arbitrary limits of hypertension are not agreed on (Spinazzola et al, 1991). Obviously, additional well-designed studies are needed to follow the normal changes in neonatal blood pressure with time, to provide more appropriate 95% confidence limits for use in the diagnosis of neonatal hypertension.

Factors directly associated with increases in blood pressure in the newborn include maternal smoking during pregnancy (Beratis et al, 1996); maternal age (Gillman et al, 2001); gestational and postnatal age (Georgieff et al, 1996; Rasoulpour and Marinelli, 1992; Spinazzola et al, 1991; Versmold et al, 1981; Zubrow et al, 1995); route of delivery (Engle, 2001); stress; agitation; application of topical mydriatics; crying; upright position; and, provided that the newborn is euvoletic, abdominal compression. Endotracheal suctioning results in a biphasic blood pressure response, with an initial brief drop followed by a greater rise of longer duration (Perry et al, 1990). It has been suggested that neonatal blood pressure is higher in preterm infants whose mother received antenatal steroids (Demarani et al, 1999; Moise et al, 1995). Conversely, some investigators reported no increases in blood pressure in neonates whose mothers received steroids antenatally (LeFlore et al, 2000; Omar et al, 1999).

### Blood Pressure Standards

The determination of normal values for blood pressure in newborn infants has been attempted by numerous investigations, and there is good agreement on several principles. Mean blood pressure increases with postnatal age

by 1 to 2 mm Hg per day during the first week and by approximately 1 mm Hg per week during the first 6 weeks of life. Because blood pressure is affected by gestational age and birth weight, it is lower in premature infants than in full-term newborns (Emery and Greenough, 1992; Hegyi et al, 1994; Nuntnarumit et al, 1999; Versmold et al, 1981; Weindling, 1989). Small-for-gestational age infants may have lower blood pressure than that in larger babies with comparable gestational age. Among premature infants, however, the limits of systolic and diastolic blood pressure appear to be less dependent on weight and gestational age if they do not require mechanical ventilation and have a stable cardiovascular status (Hegyi et al, 1994). Systolic blood pressure in newborn infants usually stabilizes at a mean of 92 mm Hg (95% confidence interval [CI] 72 to 112) at a postconceptional age of 44 to 48 weeks, irrespective of gestation at birth (Northern Neonatal Nursing Initiative, 1999).

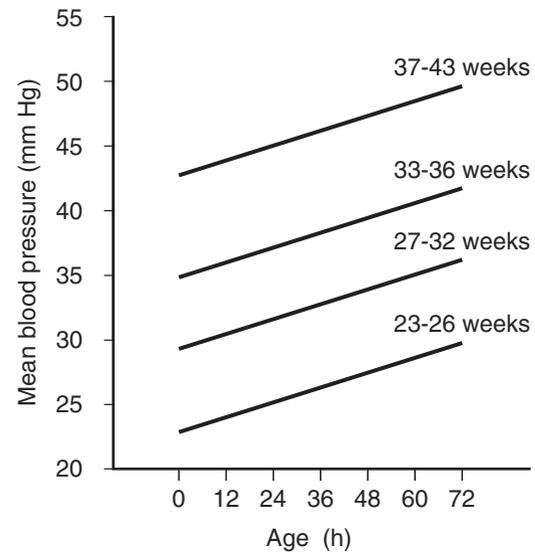

As mentioned earlier, there is a paucity of data on the reference values for arterial blood pressure in the newborn period. Normative data for blood pressure in the newborns, including VLBW neonates, may be influenced by management protocols used in the given institution (Al-Aweel et al, 2001; Nuntnarumit et al, 1999; Nwankwo et al, 1997). The Joint Working Group of the British Association of Perinatal Medicine has recommended that mean arterial blood pressure be maintained at or above the gestational age of the infants in weeks during the first day of life (Report of the Joint Working Group, 1992). Although this approach seems to be practical, its safety requires further investigation. Moreover, recent data suggest that 90% of extremely preterm neonates not receiving pressor or inotrope support will have a mean arterial blood pressure higher than 30 mm Hg by the end of the third postnatal day (Nuntnarumit et al, 1999) (Fig. 87-1). Table 87-1 describes the normal blood pressure values in healthy term newborns during the first year of life, and Table 87-2 depicts the increase in systolic blood pressure in preterm infants during the first postnatal week.

### Etiology

Neonatal hypertension is associated with certain congenital malformations and acquired diseases (Table 87-3). The most common causes of hypertension seen in neonatal intensive care units are thrombosis of the renal artery due to umbilical arterial catheterization, bronchopulmonary dysplasia, extracorporeal membrane oxygenation, and coarctation of the aorta (Flynn, 2000; Rasoulpour and Marinelli, 1992; Seibert et al, 1991).

### Clinical Signs

Approximately one third of patients with neonatal hypertension remain asymptomatic (Adelman, 1987). In those who develop clinical signs, the findings are rather nonspecific, and the presence or severity of the signs and symptoms is not related to the magnitude of the blood pressure elevation. The clinical manifestations of neonatal hypertension include signs of dysfunction of the cardiovascular system (congestive heart failure, decreased or unequal pulses, cardiomegaly, hepatomegaly, vasomotor instability), the respiratory system (tachypnea, cyanosis), the cen-

**FIGURE 87-1.** Gestational age- and postnatal age-dependent nomogram for mean blood pressure values in neonates during the first 3 days of life. The nomogram is derived from continuous arterial blood pressure measurements obtained from 103 neonates with gestational ages between 23 and 43 weeks. Each line represents the lower limit of 80% confidence interval of mean blood pressure for each gestational age group. Thus, 90% of infants for each gestational age group are expected to have a mean blood pressure equal to or greater than the value indicated by the corresponding line (the lower limit of confidence interval). (From Nuntnarumit P, Yang W, Bada-Ellzey HS: Blood pressure measurements in the newborn. *Clin Perinatol* 26:981-996, 1999.)

tral nervous system (tremors, seizures, lethargy, coma, apnea, abnormal muscle tone, opisthotonos, asymmetrical reflexes, facial palsy, hypertensive retinopathy, cerebral edema and hemorrhage), and the kidneys (dehydration, sodium wasting, oliguria or anuria, renal enlargement). In addition, nonspecific general symptoms of hypertension (abdominal distention, edema, fever, and failure to thrive) also may be encountered. Most infants develop hypertension during the first 2 weeks of life, with a range of 1 to 45 days (Adelman, 1988). Approximately 50% of newborns with hypertension exhibit signs of hypertensive retinopathy, including a decreased ratio of the arterial to venous caliber, vascular tortuosity, and exudate formation (Skalina et al, 1983).

### Evaluation of Neonatal Hypertension

After the thorough review of the history and the findings on physical examination, appropriate laboratory and imaging studies should be performed according to the suspected cause. In the hypertensive newborn with an indwelling umbilical artery catheter, a urinalysis and the evaluation of serum electrolytes, creatinine, and blood urea nitrogen should be immediately followed by real-time and Doppler ultrasonographic studies of the kidneys, perirenal regions, renal arteries and veins, aorta, and inferior vena cava. Dynamic (technetium 99 m diethylenetriaminepenta-acetic acid) and static (technetium 99 m dimercaptosuccinic acid) renal radionuclide scans are additional valuable tests in

newborns with suspected renovascular hypertension, providing information about renal blood flow and its intrarenal distribution as well as about renal function. Aortography performed through the umbilical artery catheter is seldom indicated. Evaluation of the role of pain sensation or agitation in the cause of hypertension and four-extremity blood pressure measurements also should be part of the initial work-up. A more detailed cardiac evaluation, including an electrocardiogram, a chest radiograph, and an echocardiographic study, is necessary in cases in which a cardiac cause of the hypertension is suspected. In most newborns, the usual work-up as described previously is sufficient for the diagnosis. If the clinical or laboratory

findings so indicate, however, further studies may be warranted to rule out other, less frequent conditions associated with neonatal hypertension, including endocrine disorders and pheochromocytoma.

**Treatment**

As a result of inability to define neonatal hypertension accurately and the lack of information about the short-term and long-term side effects of antihypertensive medications in the newborn, firm clinical guidelines regarding the treatment of neonatal hypertension cannot be postulated. In asymptomatic newborns, with only mild to moderate elevation of blood pressure and without an identified cause, close observation, with no aggressive antihypertensive treatment, is recommended, unless clinical or echocardiographic evidence of hypertension develops. The definitive therapy of neonatal hypertension is to treat the primary cause whenever possible (e.g., removal of the umbilical catheter, discontinuation of an offending medication). In asymptomatic newborns with severe hypertension and in all symptomatic newborns even with only mild to moderate blood pressure elevation, treatment of the hypertension with antihypertensive agents is the presently accepted clinical practice (Table 87-4).

For mild hypertension with a component of fluid retention, diuretic therapy using furosemide or a thiazide diuretic with or without spironolactone is recommended. In the long-term diuretic treatment of neonatal hypertension, thiazide diuretics are preferred over furosemide because long-term furosemide treatment is associated with potentially detrimental side effects, including severe electrolyte imbalance resulting in failure to thrive, calcinuria, nephrocalcinosis, and osteopenia.

TABLE 87-2

**Systolic Blood Pressure in Preterm Infants with Birth Weight <1500 g During the First Week of Life**

Age (days)	n	Systolic Blood Pressure (mm Hg)	+2 SD* (mm Hg)
1	44	39.2 ± 7.6	54.4
2	37	45.3 ± 7.8	60.9
3	33	45.2 ± 7.8	60.8
4	27	46.0 ± 8.9	63.8
5	23	46.0 ± 8.7	63.4
6	22	47.5 ± 9.9	67.3
7	19	51.1 ± 9.9	70.9

\*In children, mean pressure plus 2 standard deviations is considered as the upper limit of normal (see text for details).

**Other**

Drugs (corticosteroids, theophylline, pancuronium, intrauterine cocaine exposure, phenylephrine eye drops)  
 Extracorporeal membrane oxygenation  
 Bronchopulmonary dysplasia  
 Increased intracranial pressure/seizures  
 Fluid and electrolyte overload  
 Following closure of an abdominal wall defect

For the initial treatment of moderate to severe hypertension, the direct-acting vascular smooth muscle relaxant hydralazine is used frequently. Hydralazine also may decrease pulmonary vascular resistance in infants with bronchopulmonary dysplasia. Hydralazine may be given alone or in combination with a beta blocker. Among the beta blockers, the nonselective agent propranolol has been used most widely because it appears to increase the efficacy of hydralazine while decreasing thiazide-induced tachycardia. Propranolol may precipitate heart failure, however, and cause hypoglycemia and bronchospasm.

The use of an angiotensin-converting enzyme (ACE) inhibitor, primarily captopril, has become the treatment of choice in severe neonatal renovascular hypertension not responding to other medications. Mostly because of the higher postnatal renin levels and the immaturity of their renal function, newborns are extremely sensitive to the antihypertensive effects of captopril. When it was given at

the originally recommended higher doses (0.3 mg/kg), unpredictable decreases in the systemic blood pressure occurred in some of the newborns, resulting in renal failure (Rasoulpour and Marinelli, 1992) and neurologic complications (Perlman and Volpe, 1989). Therefore, captopril should be started at lower doses, and the dose should be titrated so that the lowest effective dose is administered long-term (see Table 87-4). The intravenous ACE inhibitor enalaprilat also has been used successfully for the treatment of severe neonatal renovascular hypertension (Mason et al, 1992).

Hypertensive emergencies in the newborn are usually managed with hydralazine, diazoxide, sodium nitroprusside, or nicardipine. To avoid a rapid and substantial drop in blood pressure and thus tissue perfusion, stepwise dose increases are recommended. Diazoxide, a direct arteriolar smooth muscle relaxant, must be given rapidly because it avidly binds to protein. Side effects with repeated use include sodium and water retention and hyperglycemia. Sodium nitroprusside acts via the generation of nitric oxide, and thus its effect is dependent on the intact function of the endothelium. This photosensitive agent is an extremely potent vasodilator and must be administered in titrated continuous infusion while being shielded from light. Owing to its mechanism of action and metabolism, it may cause methemoglobinemia and cyanide toxicity. Because its administration to newborns in doses of 0.2 to 6  $\mu\text{g}/\text{kg}/\text{minute}$  for up to 4 days has been found safe, routine monitoring of thiocyanate levels may not be necessary if the drug is administered in the aforementioned dose range and for a short period only (Benitz et al, 1985). The development of an unexplained metabolic acidosis with increased mixed venous oxygen content must prompt the discontinuation of the drug infusion and the measurement of plasma cyanide levels. Nicardipine is a dihydropyridine calcium channel-blocking agent that, when administered by intravenous infusion, has a powerful, titratable antihypertensive effect. In a dose of 0.8 to 1.8  $\mu\text{g}/\text{kg}/\text{minute}$ , nicardipine effectively lowers blood pressure also in the neonatal period (Flynn et al, 2001). However, since the immature myocardium is more dependent on the transport of extracellular calcium for its function, more data are needed to establish the safety and long-term efficacy of calcium channel blockers in the neonatal patient population.

In hypertensive infants with stenosis of the renal artery, a balloon angioplasty or surgical reconstruction of the renal artery may be attempted. Only the poorly functioning, sclerotic, and shrunken kidney with established hypertension represents an indication for nephrectomy.

**Prognosis**

In a majority of the cases of neonatal hypertension, systemic blood pressure can be adequately controlled by pharmacologic management, and the hypertension eventually resolves (Adelman, 1987; Rasoulpour and Marinelli, 1992). The long-term outcome, however, remains unclear. Newborns with hypertension of renovascular or renoparenchymal origin and those with persistent abnormalities of renal size and function, especially with concurrent bronchopulmonary dysplasia, require close and long-term follow-up,

TABLE 87-4

## Antihypertensive Agents Used in the Treatment of Hypertension in Newborns

Medication	Route	Dose	Comments
<b>Diuretics</b>			
Furosemide	IV, oral (q8h, q12h, q24h)	1-2 mg/kg/dose	Hyponatremia, hypokalemia, hypochloremia, hypercalciuria, nephrocalcinosis, osteopenia, ototoxicity, growth retardation
Chlorothiazide	IV, oral	5-50 mg/kg/day (q12h)	Hyponatremia, hypokalemia, hypochloremia, calcium sparing
Spironolactone	Oral	1-3 mg/kg/day	Weak diuretic, hyperkalemia
<b>Adrenergic blockers</b>			
Beta-adrenergic blockers			
Propranolol	Oral	0.5-2 mg/kg/day	Precipitation of heart failure, bronchospasm, hypoglycemia, decreased renin release, recommended in combination with hydralazine
Alpha <sub>1</sub> /beta-adrenergic blockers			
Labetalol	IV	0.25-1 mg/kg/hr	Limited experience in neonatal hypertensive emergencies
<b>Vasodilators</b>			
Hydralazine*	IV	0.1-2 mg/kg/dose (q6-12h)	Reflex tachycardia, paroxysmal atrial tachycardia, emesis, diarrhea, positive ANA assay (SLE-like syndrome)
Diazoxide*	Oral	0.25-1 mg/kg/dose (q6-12h)	Hypotension, hyperglycemia, sodium and water retention
	IV	1-3 mg/kg/dose	
Nitroprusside*	IV	0.2-10 µg/kg/min	Thiocyanate and cyanide toxicity, methemoglobinemia; drug must be protected from light due to increased photochemical degradation
<b>Angiotensin-Converting Enzyme Inhibitors</b>			
Captopril	Oral	10-50 µg/kg/dose (q8-24h) May titrate to 0.5 mg/kg/dose	Oliguria, renal failure, hyperkalemia, apnea, seizures, cough
Enalaprilat	IV	5-15 µg/kg/dose (q8-24h)	Oliguria, renal failure, hyperkalemia, cough

\*Recommended in neonatal hypertensive emergencies.

ANA, antinuclear antibody; SLE, systemic lupus erythematosus.

because the scars and atrophic regions in the kidney carry the possibility of recurrence of hypertension as well as that of the development of renal insufficiency at a later age.

# ENDOCRINE DISORDERS

Editor: H. WILLIAM TAEUSCH

CHAPTER

## 88

### Embryology, Developmental Biology, and Anatomy of the Endocrine System

Lewis P. Rubin

#### ENDOCRINE AND NEUROENDOCRINE DEVELOPMENT IN THE FETUS AND PERINATAL TRANSITION

The endocrine system consists of a number of interacting effector–target organ feedback pathways. The placental-fetal endocrine tissues sustain the intrauterine milieu and promote adaptation for postnatal life. During this perinatal transition, the organism shifts from dependence on the placenta to independent homeostatic regulation (Gluckman et al, 1999). The functional development of the endocrine glands and hormonal responsiveness of target tissues are influenced by fetal genotype, maternal genotype, maternal prepregnancy and pregnancy health and nutrition, and pregnancy-associated and other maternal stresses.

Much of the understanding about the developmental biology of the endocrine system is derived from large-animal fetal physiology models and gene manipulation in mice. An important caveat in comparing ontogenic studies in different species, however, is to consider the similarities with and differences from human fetuses and newborns. A critical point for interspecies comparisons is the relationship between birth and the maturational state of the neonate. Different species (and different organ systems of a single species) may be classified either as immature (altricial) or more developed (precocial). The human newborn has a relatively mature (precocial) brain and lung and mature neuroendocrine and parathyroid-renal pathways but is relatively clumsy—that is, motorically immature (altricial).

The human fetal endocrine system develops more or less independently of maternal endocrine influences. This separation is possible because the placenta is an efficient barrier to fetal access to most maternal hormones including steroids, sterols, peptides, glycoproteins, and catechols. Nevertheless, transplacental passage of even minute

amounts of several maternal hormones can be essential for normal fetal development. For example, in human fetuses with congenital hypothyroidism (Chapter 92, on thyroid disorders), maternal-fetal transfer of thyroid hormone ( $T_4$ ) may result in neonatal plasma levels 25% to 50% of those in normal newborns (Vulsma et al, 1989). Therefore, the outcome in congenital hypothyroidism is generally good when  $T_4$  replacement is initiated within the first 2 weeks after birth. In contrast, maternal hypothyroidism during pregnancy adversely affects neurodevelopmental outcome in the offspring (Haddow et al, 1999), and the combination of severe maternal and fetal hypothyroxinemia results in profound neurodevelopmental disability (Yasuda et al, 1999).

Disturbances in transplacental substrate transfer, such as that of calcium (Chapter 89) and glucose (Chapter 93), also may modify the development of fetal and neonatal hormonal pathways. Maternal immunoglobins and certain therapeutic agents also are transported to the fetus. In the example of Graves disease, transplacental transfer of maternal thyroid-stimulating antibodies may cause fetal hyperthyroidism, and maternal antithyroid medications (propylthiouracil, methimazole) in sufficient doses suppress fetal thyroid function (Chapter 92).

#### MOLECULAR DETERMINANTS OF ENDOCRINE DEVELOPMENT

Genotyping studies have shown that functional mutations in a single gene, usually encoding a transcription factor, can produce endocrine organ hypoplasia or aplasia. Important clinical examples include mutations in *HESX1* in septo-optic dysplasia with pituitary hypoplasia (Dattani et al, 1998), *IPF1* in pancreatic agenesis (Stoffers et al, 1997), *PAX8* in congenital hypothyroidism associated with thyroid hypoplasia (Congdon et al, 2001), or *DAX-1* in X-linked adrenal hypoplasia congenita and hypogonadotropic hypogonadism (Achermann et al, 2001).

Congenital (non-neoplastic) endocrine hyperfunction also is often caused by single-gene mutations that in this case lead to gene inactivation (*CaR*, *SURI*, *Kir6.2*) or activation (*TSHR*, *LHR*, *GK*, *GLUD1*) (Table 88–1). All proteins currently known to cause fetal and neonatal non-neoplastic endocrine hyperfunction disrupt hormone exocytosis or cell sensing of an extracellular regulator of hormone exocytosis (Marx, 1999).

A second important genetic mechanism for developmental endocrinopathies involves genomic imprinting. In mammals, some (imprinted) genes are expressed solely from either the paternally or the maternally inherited allele.

TABLE 88-1

## Features of Nonneoplastic Endocrine Hyperfunction Disorders

Tissue Expressing Hyperfunction	Syndrome	Gene Mutated	Typical Age at Onset (yr)	Treatment
Parathyroid cells	FHH	<i>CaR</i>	0	None
	NSHPT	<i>CaR</i>	0	Excision*
Pancreatic islet beta cells	PHHI-1	<i>SUR1</i>	0	Excision†
	PHHI-2	<i>Kir6.2</i>	0	Excision†
	PHHI-3	<i>GK</i>	15	Diazoxide
	PHHI-4	<i>GLUD1</i>	0	Diazoxide
Thyrocytes	Congenital thyrotoxicosis	<i>TSHR</i>	0-10	Medical or ablative
Leydig cells	Testotoxicosis	<i>LHR</i>	3	Medical

\*Total excision of all tissue.

†Near-total excision.

*CaR*, calcium receptor gene; FHH, familial hypocalcemic hypercalcemia; *GK*, glucokinase gene; *GLUD1*, glutamate dehydrogenase type 1 gene; *Kir6.2*, beta cell ATP-binding subunit of inward-rectifying potassium channel gene; *LHR*, luteinizing hormone receptor gene; NSHPT, neonatal severe hyperparathyroidism; PHHI, persistent hyperinsulinemic hypoglycemia of infancy (types 1 to 4); *SUR1*, beta cell-specific sulfonylurea receptor (component of potassium channel) gene; *TSHR*, thyroid-stimulating hormone receptor gene.

Data from Marx, 1999.

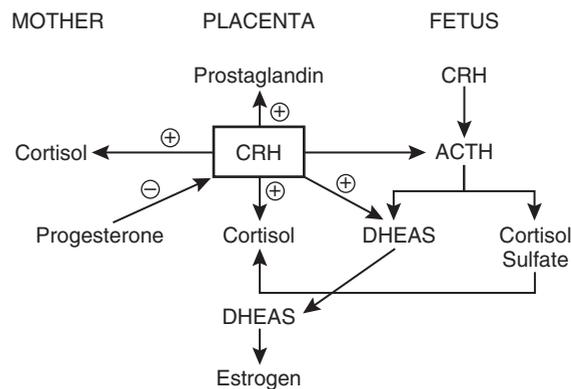

Maternal and paternal imprints are established, respectively, in dividing diplotene oocytes and prospermatogonia. Lack of imprinting of specific chromosomes or chromosome segments occurs as a result of uniparental disomy or deletions of imprinted centers. Imprinting defects can cause distinct developmental abnormalities according to the chromosome involved (Tilghman, 1999). The chief mechanism involves differential methylation of specific sites in or near imprinted genes. These methylation marks are maintained throughout development and are only erased and reestablished in the germ line. Human endocrinopathies caused by imprinting defects include transient neonatal diabetes mellitus (Chapter 93) and Albright hereditary osteodystrophy (*GNAS1* imprinting defect) (Chapter 89). The single-copy *GNAS1* gene coding for the  $G_s$   $\alpha$  subunit is the only  $G$  protein  $\alpha$  subunit yet shown to produce human disease.

### STEROIDOGENESIS AND THE MATERNAL-PLACENTAL-FETAL UNIT

During pregnancy, the mother, fetus, and placenta function in concert as a steroidogenic unit for estrogen and progesterone production. Maternal cholesterol is the principal substrate for placental synthesis of progesterone precursors for fetal androgen production. Although the placenta lacks 17-hydroxylase and 17,20-desmolase (*CYP17*) activities for estrogen synthesis, the human fetal adrenal compensates with a considerable output of  $\Delta^5$ -steroids (17-hydroxylated precursors), particularly dihydroepiandrosterone sulfate (DHEAS) (Fig. 88-1). In primates, estrogen plays an integrative role in modulating placental-fetal communication and intrauterine development (Albrecht and Pepe, 1999). Estrogen promotes placental trophoblast differentiation into syncytiotrophoblast and up-regulates key enzymes in progesterone biosynthesis and cortisol-cortisone conversion.

Throughout most of gestation, protection from hypercortisolism is crucial for normal neuroendocrine develop-

ment. Late in gestation, with activation of the fetal hypothalamic-pituitary-adrenal (HPA) axis, fetal cortisol acts as a trigger for parturition; lung, gastrointestinal, brain, and adrenal medullary maturation; induction of numerous metabolic pathways; and increased beta-adrenergic receptor density in heart, lung, and brown fat. In fact, studies on the role of glucocorticoids in preterm labor and fetal maturation have led to the successful, widespread use of antenatal glucocorticoids to accelerate fetal, especially lung, maturation (Liggins and Howie, 1972) (see also Chapter 6). On the other hand, chronic or repetitive fetal

**FIGURE 88-1.** Schematic representation of the interrelationships among the mother, placenta and fetus in the upregulation of placental CRH production in response to stress. Maternal and/or fetal cortisol stimulates placental CRH expression. Placental CRH, in turn, stimulates the fetal HPA axis and secretion of DHEAS from the fetal zone of adrenal cortex. ACTH, adrenocorticotropic hormone; CRH, cortisol-releasing hormone; DHEAS, dehydroepiandrosterone sulfate; HPA, hypothalamic-pituitary-adrenal. (Adapted from Challis JRC, Sloboda D, Matthews SG, et al: *The fetal placental hypothalamic-pituitary-adrenal [HPA] axis, parturition and postnatal health. Mol Cell Endocrinol 185:135, 2001.*)

exposure to antenatal glucocorticoid has a profound, sometimes deleterious influence on postnatal adaptation and activity of the endocrine pancreas, pituitary-adrenal axis, and cardiovascular activity (Challis et al, 2001) (see later section, “The ‘Fetal Origins of Adult Disease’ Hypothesis”).

Therefore, it is not surprising that in all species studied, including humans (Beitins et al, 1973), fetal access to maternal glucocorticoid is restricted and fetal glucocorticoid levels (cortisol or corticosterone) are low. This maternal-to-fetal gradient is maintained by the enzyme 11 $\beta$ -hydroxysteroid dehydrogenase (11 $\beta$ HSD). The type 1 enzyme isoform is bidirectional. The type 2 isoform (11 $\beta$ HSD2) unidirectionally converts cortisol and corticosterone to inactive cortisone and 11-dehydrocorticosterone, respectively. The low cortisol-to-cortisone ratio (approximately 0.3) in the fetal circulation reflects a low fetal cortisol production and high placental 11 $\beta$ HSD2 activity. The cortisol-to-cortisone ratio rises after birth.

As pregnancy progresses, the maternal-placental-fetal steroidogenic unit activates the fetal HPA axis. This is a central mechanism for the fetus to exert an influence on gestation. For example, placental production of corticotropin-releasing hormone (CRH) is correlated with the length of gestation. A CRH/adrenocorticotropic hormone (ACTH)/cortisol surge occurs near term that induces involution of the fetal adrenal cortex, increased adrenal 3 $\beta$ -hydroxysteroid dehydrogenase (3 $\beta$ HSD) activity, and a relative reduction in the placental 11 $\beta$ HSD2-to-11 $\beta$ HSD1 ratio. In humans, the fall in placental 11 $\beta$ HSD2 mRNA expression and rise in fetoplacental cortisol levels lead to a rise in placental prostaglandin (PGE<sub>2</sub> and PGF<sub>2 $\alpha$</sub> ) synthesis that, in turn, stimulates uterine contractility and further CRH expression (see Fig. 88–1). The increased fetal adrenal cortisol production and decreased placental cortisol clearance in preparation for parturition synchronize the maturation of critical organs (lung, liver, intestine, adrenal, brain). In effect, term birth may be viewed as an escape mechanism from this intrauterine environment of increasing hypercortisolemia. In primates, the postnatal transition is promoted by disconnection from this robust placental steroid production.

A critical aspect of intrauterine endocrinology is the opposite effects of the increase in late fetal cortisol levels on hypothalamic and placental CRH expression. Specifically, cortisol inhibits hypothalamic CRH production via the HPA-negative feedback loop but stimulates placental CRH production, an effect mediated via the cAMP response element in the CRH promoter (Cheng et al, 2000). Positive feedback loops are intrinsically unstable and, in this instance, terminate in birth.

It is possible that placental CRH in humans may have evolved to meet the need for high fetal adrenal production of estrogen precursors such as DHEAS (Majzoub et al, 1999). Fetoplacental 17 $\beta$ -estradiol (E<sub>2</sub>) and progesterone plasma levels are quite high and fall approximately 100-fold during the first day after birth. From this perspective, birth may have adverse endocrine consequences for the preterm newborn. In extremely preterm infants, the consequences of E<sub>2</sub> and progesterone withdrawal so early in development are largely unknown. Extremely preterm infants have different steroid hormone profiles from the norms for infants born at term. Whether these

“abnormal” hormone levels are maladaptive and related to morbidity is controversial. One pilot study of E<sub>2</sub> and progesterone supplementation in extremely low-birth-weight (ELBW) infants showed trends toward increased bone mineral accretion and a decreased incidence of chronic lung disease (Trotter et al, 1999). Randomized clinical trials of “physiologic replacement” in extremely preterm newborns may answer these important clinical questions.

## HYPOTHALAMIC-PITUITARY-ADRENAL AXIS

The HPA system maintains homeostasis in a stable environment, facilitates adaptation to environmental stresses, and regulates somatic growth, reproduction, and lactation. Advancing pregnancy is associated with HPA axis maturation.

The hypothalamus forms an interface between the endocrine and autonomic systems and regulates thermoregulation, blood pressure, energy balance, and behavioral responses. Early specification signals are required before or during gastrulation for forebrain induction. Later in embryogenesis, ventralizing and rostralizing signals from the axial mesoderm (e.g., Sonic Hedgehog [Shh]) are required to induce the cell types of the presumptive hypothalamus (Michaud, 2001). The fetal hypothalamus begins to form soon after the appearance of the hypothalamic sulcus in the 32-day embryo. Between 6 and 12 weeks, the basal hypothalamus differentiates into distinct nuclei and fiber tracts and produces hormones detectable by immunohistochemistry or immunoassay. Portal vascular connections to the anterior pituitary are established by about 12 weeks (Thliveris and Currie, 1980), although the definitive hypothalamo-hypophyseal portal system develops primarily in the third trimester. Failure of ventral forebrain induction causes holoprosencephaly (see Chapter 63). Endocrine deficiencies caused by hypothalamic and/or pituitary dysfunction may be the only clinical sign in milder forms of (lobar) holoprosencephaly.

Neuropeptide secretion from hypothalamic neurons and negative and positive feedback loops from target organs regulate the synthesis and secretion of distinct pituitary hormones. The anterior pituitary gland (adenohypophysis) derives from ectodermal thickening of the diencephalon and roof of the oral pit. The pituitary diverticulum (Rathke’s pouch) bulges into the floor of the prosencephalon by week 4. In week 6, sphenoidal mesenchyme pinches off the pituitary diverticulum from the oral pit. The precursor cells of the anterior pituitary begin to differentiate by week 8. These distinct pituitary cell types arise in a temporally and spatially specific pattern and in tandem with their inputs from hypothalamic nuclei. Development of the hypothalamo-hypophyseal portal veins permits the local circulation of releasing hormones, including thyrotropin-releasing hormone (TRH), growth hormone-releasing hormone (GHRH), CRH, and somatostatin (SS).

During the second trimester, the anterior pituitary differentiates into the five endocrine cell types that secrete six hormones: (1) pro-opiomelanocortin (POMC), which is proteolytically cleaved to ACTH in corticotropes and melanocyte-stimulating hormone (MSH $\alpha$ ) in melanotropes;

(2) thyroid-stimulating hormone (TSH) in thyrotropes; (3) growth hormone (GH) in somatotropes; (4) prolactin (PRL) in lactotropes; and (5) follicle-stimulating hormone (FSH) and (6) luteinizing hormone (LH) in gonadotropes (Fig. 88–2). Serum GH concentrations peak at 20 to 24 weeks (Suganuma et al, 1989) and decline steadily thereafter, perhaps as a result of hypothalamic-pituitary maturation and increased interaction between GHRH and somatotropin release-inhibiting hormone (SRIH).

Anterior pituitary organogenesis illuminates how mutation of a single regulatory gene can cause multiple hormone deficiencies—in this case, multiple pituitary hormone deficiencies (MPHD), or panhypopituitarism—even though the genes encoding those hormones are dispersed throughout the genome. Transient embryonic morphogenetic signaling gradients induce overlapping expression patterns of transcription factors (repressors, activators) and coregulators and direct the positional fates of specific cell types. These pituitary and hypothalamic transcription factors coordinate gland formation, differentiation, expansion, and definitive function of the distinct pituitary cell types (Parks et al, 1999). Pituitary development and hormone expression require Pit-1, a pituitary-specific transcription factor. *PIT1* gene expression directs differentiation and proliferation of somatotrophs, lactotrophs, and thyrotrophs and transactivation of the genes encoding GH, PRL, and TSH. Several *PIT1* mutations have been shown to be responsible for a phenotype of multiple congenital pituitary hormone deficiencies involving GH, PRL, and TSH (Vallette-Kasic et al, 2001). The repressor *HESX1* (“homeobox gene expressed in embryonic stem cells,” or Rpx for “Rathke pouch homeobox”) is expressed early in the anterior region of the embryo and is involved in the initial determination of the optic nerves and anterior pituitary (see Fig. 88–2). *HESX1* mutations cause some recessive and autosomal forms of hypopituitarism and septo-optic dysplasia.

The neural component of the pituitary, the posterior pituitary gland or neurohypophysis, grows from an infundibular sac projecting from the floor of the diencephalon (at 5 to 8 weeks). Magnocellular neurons from the hypothalamus synapse with posterior lobe neurosecretory cells. Two hormones, oxytocin and vasopressin, are secreted directly into the general circulation.

The mammalian adrenal (or suprarenal) glands develop as a fusion of two distinct embryologic tissues, the cortex and the medulla (Fig. 88–3). The adrenal cortex arises bilaterally from coelomic mesothelium between the base of the mesentery (mesogastrium) medially and the mesonephros and undifferentiated gonad (urogenital ridge) laterally. The close proximity of these embryonic structures explains why ectopic cortical tissue may be located below the kidneys and sometimes is associated with the ovaries or testes. In week 6, coelomic cells become embedded in the underlying mesoderm, where they meet and envelop neural crest cells migrating from the sympathetic chain.

This migration of neuroblasts (neuroectoderm) forms the ganglia of the sympathetic trunk and sympathetic plexuses as well as the catecholamine-secreting paraganglia (chromaffin tissue). In the human embryo, the sympathetic trunk arises by about week 7. After weeks 10 to 12, chromaffin tissue develops along the aorta and subse-

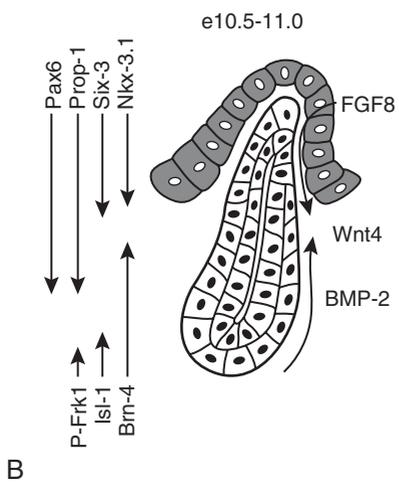

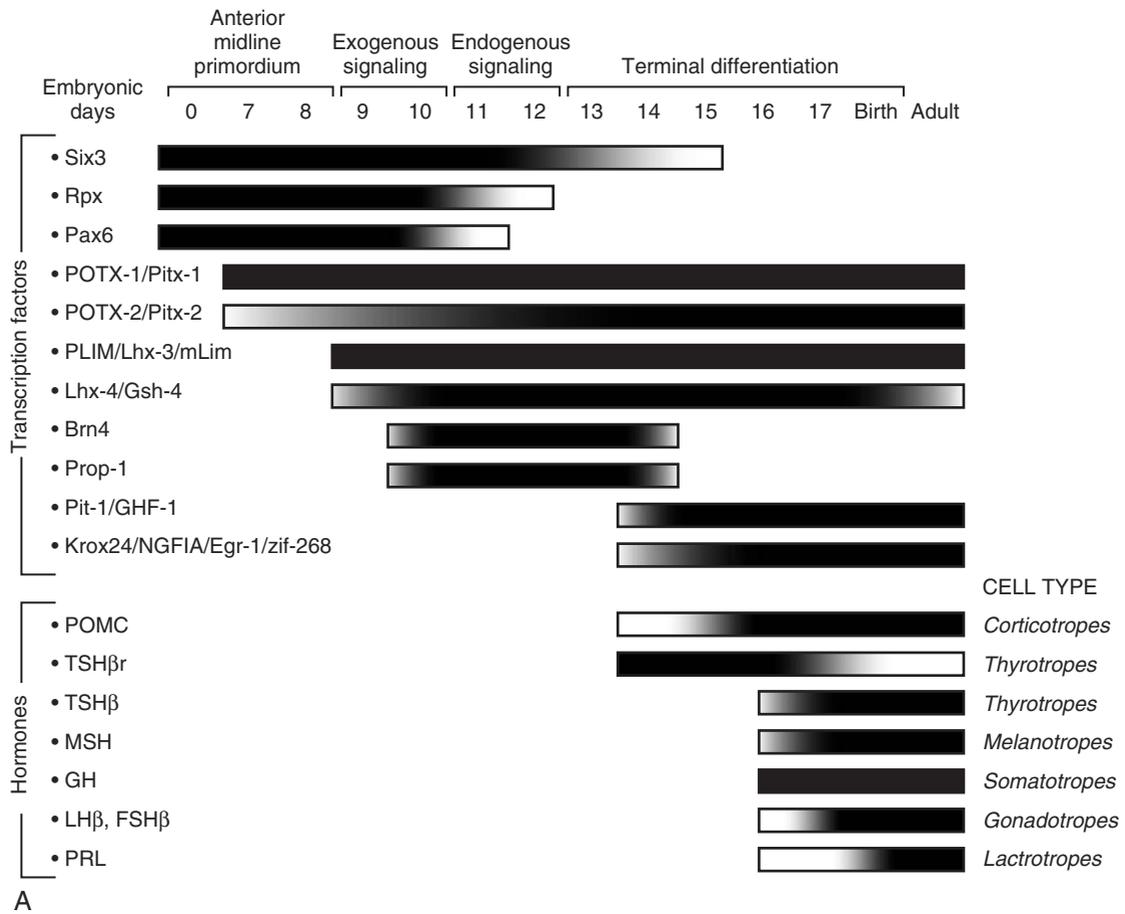

quently differentiates into paraganglia and the adrenal medulla. Most of the paraganglia reach a maximal size by about 28 weeks; however, the organ of Zuckerkandl ventral to the aortic bifurcation continues to enlarge until term (Lagerkrantz, 1998). Usually, paraganglionic sites of chromaffin tissue involute with age, but they may develop into extra-adrenal pheochromocytomas.

The adrenal medulla functions as a classic endocrine tissue; that is, it secretes hormones directly into the blood stream. The medulla also participates in sympathetic control via preganglionic sympathetic nerve fibers. Pheochromocytoblasts give rise to the medullary pheochromocytes, which are epinephrine- and norepinephrine-secreting homologues of sympathetic postganglionic cells. Medullary cells are chromaffin (stain brown with chromium salts) and argyrophilic (stain with silver salts). By 3 months, adrenal pheochromocytes secrete epinephrine and norepinephrine into the medullary sinusoids and then into the systemic circulation. In the human fetus, the hypothalamic-pituitary-medullary adrenal axis becomes sufficiently functional by midgestation so that fetal stress responses can be independent of those of the mother (Gitau et al, 2001). This fetal stress response contrasts to fetal cortisol output. The fetal adrenal cortex minimally secretes cortisol before midgestation and fetal cortisol surges are determined by placental transfer from the mother.

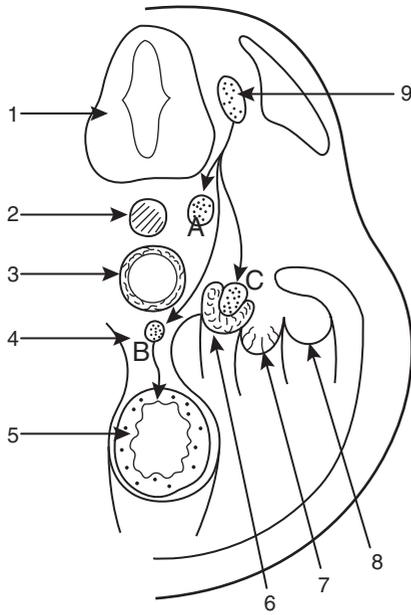

From the third month, the superficial shell of adrenal cortical cells forms the precursor of the postnatal zona glomerulosa and zona fasciculata, that is, the definitive or adult cortex. The more superficial zona glomerulosa has a pseudoglomerular histologic appearance and secretes the mineralocorticoid aldosterone. The zona fasciculata contains large cells packed in radiate columns alternating with sinusoids and arterioles and secretes cortisol. The third definitive cortical layer, a network of cell cords called the zona reticularis, is absent at birth and develops from 3 years onward. It is an extragonadal source of sex steroids.

Deep to the presumptive definitive layer, cells proliferate inward, forming the impermanent fetal cortex. The outer (transitional) zone of the fetal cortex contains smaller (10- to 20- $\mu\text{m}$ -diameter) basophilic cells. This transitional zone, between the inner (fetal) and outer (definitive) zones, expresses CYP17 and  $3\beta\text{HSD}$  only relatively late in gestation, so that adrenal cortisol production also increases only relatively late in normal gestation. Most of the inner fetal zone consists of large (20- to 50- $\mu\text{m}$ ) eosinophilic cells that are the primary site for steroidogenesis, including abundant secretion of  $\Delta^5$ -steroid substrates for placental estrogen production (see earlier section, “Steroidogenesis and the Maternal-Placental-Fetal Unit”). The fetal zone accounts for about 80% of fetal adrenal mass, or about 8 g at birth. During the first year, the fetal cortex regresses, and the adrenal mass diminishes to 2 to 3 g.

Evaluation of the HPA axis in infants is used to test for primary adrenal suppression as well as for secondary adrenal insufficiency, either in preterm neonates who are thought to be cortisol deficient (Watterberg et al, 2001) or following dexamethasone treatment. In the latter case, a CRH test may more reliably indicate suppressed cortisol secretion than the short ACTH(1-24) test (Karlsson et al,

**FIGURE 88-2.** Expression of transcription factors and hormones during pituitary gland development in the mouse. **A**, Pituitary gland commitment has been divided into three phases. Phase 1, encompassing embryonic days 6 to 8.5 (e6-e8.5), is characterized by development and differentiation of stomodeum and oral ectoderm and the expression of *Rpx*, *Six-3*, *Pax6*, *Pitx-1*, and *Pitx-2*. Phase 2 (e8.5-e10.5), induction from exogenous signals, and phase 3 (e10.5-e12.5), induction from endogenous signals, are characterized by appearance of Rathke’s pouch and expression of *PLIM* and *Lhx-4*. The pituitary gland cell lineage determination involves phase 3 (e12.5-adult) and the expression of *Pit-1*. POMC in corticotropes is the first hormone to appear (e12.5); TSH $\beta$  appears on e13.5, MSH on e14.5, GH on e15.5 and LH $\beta$ , FSH $\beta$ , and PRL before birth. **B**, Ventral-dorsal gradient of expression of transcription factors and signaling molecules in e10.5-e11 pituitary gland. FSH $\beta$ , follicle-stimulating hormone- $\beta$ ; GH, growth hormone; LH $\beta$ , luteinizing hormone- $\beta$ ; MSH, melanocyte-stimulating hormone; POMC, pro-opiomelanocortin; PRL, prolactin-releasing hormone; TSH $\beta$ , thyroid-stimulating hormone- $\beta$ . (From Kioussi C, Carriere C, Rosenfeld MG: A model for the development of the hypothalamic-pituitary axis: Transcribing the hypophysis. *Mech Dev* 81:23, 1999.)

**FIGURE 88-3.** Transverse cross section of human adrenal development: neural tube (1), chorda (2), aorta (3), base of the mesentery (4), digestive tube (5), adrenal cortex (6), undifferentiated gonad (7), mesonephros (8). Migration of neuronal cells (arrows) from the neural crest (9) forms the sympathetic trunk ganglia (A), sympathetic plexuses (B), and the medulla and paraganglia (C). (From Avisse C, Marcus C, Patey M, et al: *Surgical anatomy and embryology of the adrenal glands*. *Surg Clin North Am* 80:403, 2000.)

2000). It is not yet clear whether the low circulating cortisol levels in ELBW infants reflect clinically relevant glucocorticoid deficiency (Chrousos, 2001).

### HYPOTHALAMIC-PITUITARY-THYROID AXIS

Maturation of the thyroid axis occurs in three phases: hypothalamic, pituitary, and thyroidal. At 10 to 20 weeks of gestation, secretory granules can be identified in differentiating pituitary thyrotropes, and TSH is detectable by bioassay and immunoassay.

The thyroid is the first endocrine gland to develop in the embryo. It forms at about 24 days from a pharyngeal outpouching, the thyroid diverticulum; as the anterior embryo grows, it migrates ventrally to the developing hyoid bone and laryngeal cartilages. By 7 weeks, the thyroid gland has assumed its definitive lobar shape and reached its final location in the neck. By 10 to 11 weeks, clusters of endodermal epithelial cells form single layers around lumens, the thyroid follicles, in which colloid begins to appear. Umbilical blood sampling has demonstrated that fetal TSH and  $T_4$  are already detectable by 12 weeks and increase gradually through pregnancy to about 7 mU/L for TSH and 19.9 pmol/L for  $T_4$  by term (Thorpe-Beeston et al, 1991). The fetal pituitary-thyroid feedback mechanism appears to be fully responsive by 18 to 20 weeks (Fisher, 1997). By that time, in pregnant women with Graves disease, transplacental passage of

maternal thyroid-stimulating autoantibodies can induce fetal hyperthyroidism (Rakover et al, 1999).

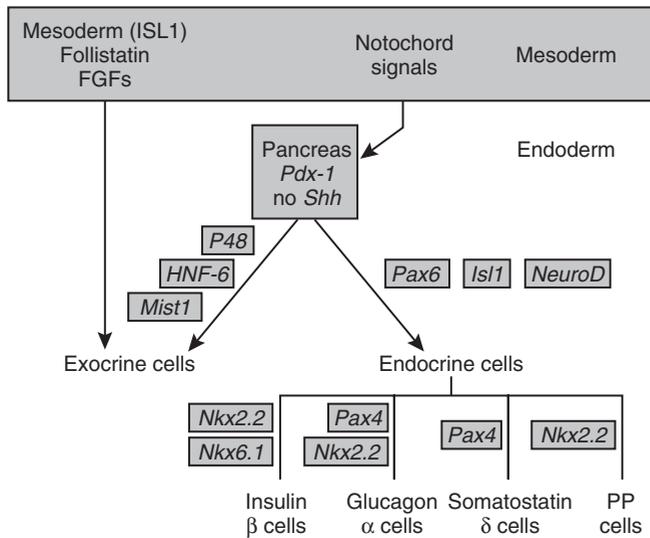

Because pituitary and thyroid differentiation are contemporaneous, it has been suggested that the controlling events are independent. During the second half of gestation, fetal thyroid gland function is believed to mature under the influence of increased hypothalamic TRH secretion, pituitary TSH secretion, thyroid cell sensitivity to TSH, and pituitary sensitivity to negative feedback by  $T_4$  (Chapter 92). However, as described previously (under “Endocrine and Neuroendocrine Development in the Fetus and Perinatal Transition”), small amounts of maternal thyroid hormones cross the placenta; adequate functioning of both maternal and fetal thyroid glands is important for normal fetal development. In congenital hypothyroidism due to defects in glandular ontogenesis (athyreosis), maternal thyroid hormones lessen the impact on fetal neurological development. Early neonatal diagnosis and  $T_4$  treatment permit normalized growth and development. In contrast, when the mother is hypothyroid throughout gestation, the fetal consequences are more severe (Glinoe and Delange, 2000).

### ENDOCRINE PANCREAS

During the first 4 weeks of gestation, the ventral and dorsal pancreatic anlage arises from evaginations of the embryonic foregut. After rotation of the stomach and duodenum, the ventral pancreatic bud migrates and fuses with the dorsal bud. By branching morphogenesis, the ductal pluripotential epithelial cells give rise to endocrine and acinar cells under the influence of locally acting signals and activation of lineage-specific transcription factors (Hill and Duvillie, 2000; Peters et al, 2000). Beginning by week 7, scattered endocrine cells produce somatostatin, pancreatic polypeptide (PP), glucagons, and, by week 9, insulin. Pax and Ndx family transcription factors control the further fate determination of alpha, beta, delta, and PP endocrine cells (Fig. 88-4). Ongoing beta cell proliferation and differentiation are dependent on insulin-like growth factor-I (IGF-II) gene expression in the islets.

In the human, islet formation begins by week 12. Polyclonal clusters of endocrine cells aggregate in response to developmental expression of cell adhesion molecules (e.g., N-CAM and cadherins). In 24-week fetuses, islets generally remain in direct contact with the ducts, whereas by term, the islets have separated from the ducts; in adults, the islets are dispersed throughout the lobule (Watanabe et al, 1999). Islet volume also increases from about 4% to 13% of total pancreatic tissue by term (Peters et al, 2000). Endodermal differentiation into pancreatic endocrine cells, like other epithelial differentiation, depends on inductive signals derived from surrounding mesenchyme. Targeted gene deletion studies in mice have demonstrated critical roles for several transcription factors in pancreatic endocrine development (Sander and German, 1997) (see Fig. 88-4).

Human postnatal insulin kinetics and end-organ sensitivity to insulin appear to be established during the third trimester in preparation for extrauterine fuel metabolism. Recent observations indicate that both the

**FIGURE 88-4.** Molecular control of cell fate choices in the pancreas. *Pax6* and *Isl1* are expressed early, and their disruption leads to the reduction or absence of endocrine differentiation, which suggests that they could be expressed in endocrine progenitors able to give rise to all cell types. In *Isl1* mutant mice, *Pax6* is not expressed, which suggests *Pax6* is downstream of *Isl1*. Although *Pax4*, *NeuroD*, *Ndx2.2* and *Ndx6.1* are expressed as early as *Pax6* and *Isl1*, they affect the differentiation of only a subset of lineages. *Pax4* is required for glucagon- and somatostatin-producing cell differentiation. *Ndx2.2* is expressed in all islet cells, except somatostatin-producing cells, and its inactivation leads to the absence of the cell types where it is expressed. *Ndx6.1* is itself required for insulin cell differentiation. Although *Mist1* and *HNF-6* are expressed in endocrine cell lineages, their function has not yet been assessed by inactivation experiments. FGFs, fibroblast growth factors; PP, pancreatic peptide. (From Grapin-Botton A, Melton DA: Endoderm development: From patterning to organogenesis. *Trends Genet* 16: 124, 2000.)

maternal environment and the fetal genome influence the number and/or function of pancreatic beta cells in early life, with lifelong implications for postnatal diabetes (Hill and Duvillie, 2000; Hoet and Hanson, 1999). In contrast, insulin gene knockout mice (Duvillie et al, 1997) and human newborns with pancreatic agenesis (Stoffers et al, 1997) show severe intrauterine growth restriction/retardation (IUGR), which is consistent with insulin's role in mitogenesis and growth.

### PARATHYROID-RENAL AXIS

The parathyroid-renal (parathyroid hormone [PTH]–vitamin D) axis is the principal regulatory pathway in mammalian mineral and bone homeostasis (Chapter 89). The parathyroid glands arise from the dorsal parts of pharyngeal or branchial (“gill”) pouches 3 and 4. These paired endodermal cell masses migrate ventrally and come to rest and differentiate in the back of the thyroid lobes as the superior (fourth pouch) and inferior (third pouch) parathyroid glands. The presence of immunoreactive PTH-containing cells can be detected in the human fetal parathyroids at

10 weeks. Defects in neural crest cell migration, such as DiGeorge syndrome (Chapter 89), result in embryonic field defects including parathyroid aplasia or hypoplasia. The caudal pharyngeal complex (pouches 4 and 5) develops into the calcitonin-secreting C cells in the thyroid gland. Calcitonin is detectable in fetal thyroidal C cells as early as 14 weeks. The fetal renal tubules can synthesize the active hormonal form of vitamin D, 1,25-dihydroxyvitamin D [1,25(OH)<sub>2</sub>D], at least as early as the second half of gestation. Fetal plasma 1,25(OH)<sub>2</sub>D levels remain low, however, as a result of high placental clearance.

### GONADAL AXES

Human reproductive system development is regulated by complex genetic, endocrine, and environmental signals. Gender-specific organogenesis begins in the early embryo, and sexual dimorphism results in the development of either ovaries or testes by birth. Further sexual maturation occurs in the perinatal period and at puberty (Chapter 91).

In mammals, genetic sex is determined by inheritance of either an X or a Y chromosome from the male gamete. The initial stages of gonadal and genital development in male and female embryos are morphologically indistinguishable. The gonads arise from thickening of the ventrolateral surface of the embryonic mesonephros (the genital ridge). At least four genes are required for testicular induction of the bipotential gonads: the orphan nuclear receptor steroidogenic factor-1 gene (*SF-1*), the Wilms tumor–associated gene (*WT1*), and the homeobox genes *Lhx1* (*Lim1*) and *Lhx9*. The two pituitary gonadotropins, LH and FSH, play a key role in cell fate determination and maturation of the sexual organs. Mutations in gonadotropin subunit or gonadotropin receptor genes have been associated with various types of hypogonadism in males and females.

In females, the müllerian ducts give rise to the uterus, fallopian tubes, and proximal vagina. The fetal ovarian germ cells are maintained in early meiotic arrest. The fetal ovary is characterized by late expression of the LH receptor (compared with that in the testis), late onset of aromatase activity, and low E<sub>2</sub> content. The postnatal ovarian follicles are prominent, and serum E<sub>2</sub> levels in female neonates remain low.

In males, wolffian ducts develop into epididymis, vas deferens, seminal vesicles, and prostate. Divergence from the female developmental pathway toward male sexual differentiation requires secretion of several testicular hormones. After gonad formation, expression of the *SRY* (“sex-determining region of the Y chromosome”) gene initiates the male developmental cascade. *SRY* contains a high-mobility group (HMG) box, a conserved transcription factor motif that, in this instance, targets testicular Sertoli cell differentiation. Mutations in the HMG box are associated with 46,XY pure gonadal dysgenesis and sex reversal. Early events in testis development are differentiation of Sertoli cells and androgen-producing Leydig cells, LH receptor and steroid enzyme expression, autonomous steroid secretion, and high testosterone content. In contrast, germ cell maturation occurs later in gestation. Postnatally,

testicular Leydig and Sertoli cells are prominent, and serum testosterone levels are high.

Müllerian-inhibiting substance (MIS) produced by Sertoli cells induces müllerian duct regression. LH and placental human chorionic gonadotropin induce Leydig cell androgen synthesis. In turn, testosterone and dihydrotestosterone promote development of the wolffian duct derivatives (male internal reproductive tract) and the virilization of the external genitalia. Therefore, inadequate fetal and neonatal testosterone secretion (e.g., due to hypogonadotropic hypogonadism or panhypopituitarism) impairs normal phallus and scrotum development. Leydig insulin-like 3 hormone (INSL3) may mediate transabdominal testicular descent into the scrotum (Nef and Parada, 2000). Female embryonic differentiation continues when the absence of MIS permits persistence of the müllerian structures, a lack of androgens permits wolffian duct degeneration, and the absence of INSL3 maintains the gonads in the abdomen.

### FETAL AND NEONATAL CIRCADIAN RHYTHMS

Neuroendocrine rhythmicity is an essential aspect of normal physiology and behavior. Certain rhythms occur in response to light-dark cycles. *Ultradian rhythms* have a periodicity shorter than 1 day but longer than 1 hour. Others, termed *circadian rhythms*, occur with a periodicity roughly matching the earth's rotation (24 hours) and persist even in the absence of environmental stimuli. Currently, little is known about either the maturational onset of ultradian or circadian hormonal secretion or the effects of perturbing factors such as prematurity or intrauterine and neonatal hormone treatment on endocrine periodicity.

In mammals, the master clock or pacemaker that controls circadian rhythms is located in oscillating neurons of the hypothalamic suprachiasmatic nuclei (SCN). The molecular mechanisms of rhythmogenic SCN function involve pulsed expression of specific transcription factors that induce the oscillatory secretion of neuropeptides including somatostatin, vasoactive intestinal peptide (VIP), arginine vasopressin (AVP), and neurotensin. Efferent pathways project from the SCN to other nuclei, such as the paraventricular nucleus (PVN). SCN efferents to the PVN stimulate secretion of CRH, which results in circadian adrenal cortisol secretion (see earlier section, "Hypothalamic-Pituitary-Adrenal Axis"), and pineal gland expression of melatonin.

Regulation and entrainment of the circadian clock(s) occur by transcriptional negative feedback loops and post-transcriptional controls. In the human fetus, heart rate, fetal movements, and some other outputs may be entrained to maternal rhythms. However, by late pregnancy the fetus establishes a circadian rhythm of cortisol secretion, presumably controlled by the fetal hypothalamic pacemaker (Seron-Ferre et al, 2001). ELBW infants (birth weight less than 1000 g and gestational age less than 28 weeks) show little short-term pulsatility in circulating cortisol levels over time (Jett et al, 1997). Nevertheless, available data suggest that the adult pattern of circadian cortisol secretion is established by 2 to 4 months after birth, irrespective of gestational age. In contrast, the

onset of circadian melatonin secretion is related to post-conceptual age, not postnatal age.

The influence of the neonatal intensive care unit (NICU) environment on biologic rhythms of preterm infants is, as yet, poorly understood. Gene profiling experiments and clinical trials in newborns probably will yield a more detailed perspective on the developmental regulation and entrainment of circadian clocks.

### THE "FETAL ORIGINS OF ADULT DISEASE" HYPOTHESIS

Research from a wide range of disciplines has shown that endocrine function in adult life is determined, in part, by environmental influences acting at different stages of development spanning conception into infancy. Programming is a process by which environmental stimuli during critical periods of growth and development have lasting effects on the structure or function of tissues and physiologic systems. Intrauterine stresses can have an impact on HPA axis development and can program distinct autonomic, neuroendocrine, and behavioral responses into adulthood.

The "fetal origins" or so-called thrifty phenotype hypothesis proposes that the fetus adapts to a limited supply of nutrients in a manner that permanently alters its physiology and metabolism, with increased risk of disease in later life (Hales and Barker, 1992). The Dutch famine of 1944 to 1945 provided a unique opportunity to examine the long-term effects of intrauterine malnutrition in humans. The famine was imposed for a defined period on a previously well-nourished population. Extensive and reliable records have permitted unprecedented analysis of a birth cohort exposed to this discrete intrauterine insult. Additionally, David Barker and colleagues in Southampton, United Kingdom, have exploited detailed obstetric records in British hospitals to establish that IUGR is a strong predictor of adult metabolic and cardiovascular disease (e.g., Barker, 1998). For example, the relative risk for insulin resistance and "syndrome X" (the metabolic syndrome), consisting of type 2 diabetes, hypertension, and hyperlipidemia, is significantly higher in persons who were thin at birth with a low ponderal index. Clinical studies also uphold the association of maternal psychosocial or other stress in pregnancy with qualitative and quantitative changes in birth outcome and fetal and neonatal neuroendocrine activity (Wadhwa et al, 1996).

Increased fetal access to glucocorticoids during critical developmental periods may be a common mechanism explaining how these diverse maternal and uteroplacental stresses, including maternal undernutrition, psychosocial stress, and uteroplacental hypoxemia, induce fetal programming. Increased fetal glucocorticoids and stress both program specific effects in the brain, notably the HPA axis and dopaminergic-motor systems (Matthews, 2000; Welberg and Seckl, 2001), and can induce IUGR. The principal stress-mediated catecholamines (norepinephrine, epinephrine) transcriptionally repress placental trophoblast 11 $\beta$ HSD2 expression via alpha-adrenergic pathways (Sarkar et al, 2001), thereby increasing transplacental transfer of maternal cortisol to the developing fetus.

IUGR and metabolic programming interact with the genotype to influence the onset of endocrine, metabolic and cardiovascular disease in later life (e.g., Ibanez et al, 2001). Intrauterine stress producing low birth weight is associated with altered basal and stimulated cortisol levels as an early marker of HPA responsiveness, followed by glucose intolerance (insulin resistance) and hypertension (Levitt et al, 2000).

IUGR also results in a reduced beta cell population at birth (Van Assche et al, 1977). Fetal beta cell growth and development may be more sensitive to ambient amino acid than to glucose concentrations, suggesting a role for intrauterine protein availability for normal insulin homeostasis. In IUGR due to fetal malnutrition, altered expression of IGF-II (an islet cell survival factor) or IGF-binding proteins may severely alter beta cell ontogeny, resulting in a population of beta cells poorly suited for responding to subsequent metabolic stress (Hill and Duvillie, 2000). Fetal hypercortisolism also can decrease expression of IGFs and IGF receptors in late gestation (Price et al, 1992).

### THE ENVIRONMENTAL ENDOCRINE HYPOTHESIS

Recent environmental changes appear to have potentially important effects on the development of the endocrine system. Specifically, industrial and agricultural chemicals, through their actions on endocrine function, may be responsible for a number of reproductive and developmental abnormalities in a wide range of species, including humans (Cooper and Kavlock, 1997; Krinsky, 2000). These exogenous agents, or “endocrine disruptors,” can interfere with the synthesis, storage and release, transport, metabolism, binding, action, or elimination of natural hormones. This importance of environmental endocrine-disrupting chemicals for public health and ecology, first stressed by Theo Colborn in the late 1980s, prompted passage in the United States of the Food Quality Protection Act and the Safe Drinking Water Estrogenic Substances Screening Act of 1996.

Three independent lines of research have provided the initial evidence for the importance of environmental agents on human endocrine development: recognition of the adverse effects of the potent synthetic estrogens—specifically, diethylstilbestrol (DES) and related compounds—on female and male reproductive tract development; field and laboratory studies associating wildlife reproductive malformations with chemical pollutants; and research linking xenoestrogens to declines in human sperm counts (Krinsky, 2000). Structural abnormalities of the reproductive tract including hypospadias and cryptorchidism, which have potential hormone-mediated origin and a critical developmental component, show upward secular trending.

During development, reproductive tract tissues are especially sensitive to low concentrations of sex steroids. Androgens secreted by a maternal adrenal tumor can virilize a female fetus (Kirk et al, 1992). Increased placental estradiol production has been associated with cryptorchidism in male newborns (Hadziselimovic et al, 2000). One mechanism is estrogenic down-regulation of insulin-3 (Insl3) expression by embryonic Leydig cells

(Nef et al, 2000). Similarly, endocrine disruptors with antiandrogenic or estrogenic activity can have feminizing effects in the developing male fetus. Estrogens may induce adverse reproductive changes in female fetuses, but antiandrogens have little effect (Toppari and Skakkebaek, 1998). Changes induced by intrauterine exposure to endocrine disruptors may be irreversible, in contrast with the reversible changes induced by transient hormone exposure in the adult (Bigsby et al, 1999).

Endocrine disruptors such as organochlorines (e.g., the pesticide DDT) can alter normal gonadal ontogeny. In female fetuses, the onset of meiosis is delayed, and in male fetuses, testosterone synthesis is increased (Rhind et al, 2001). Prenatal exposure to the estrogenic agent DES increases risk of reproductive teratogenicity in female and male offspring. Exposure of the conceptus to antiandrogenic pharmaceuticals such as the androgen receptor antagonist flutamide and the 5 $\alpha$ -reductase inhibitor finasteride generally affects males, causing hypospadias, cryptorchidism, reduced testicular mass, or decreased sperm production. Exposure to polychlorinated biphenyl (PCB) congeners, either in utero or via breast-feeding, has structural, functional, and behavioral influences, particularly on thyroidal axis development and differentiation of the male reproductive tract (Brouwer et al, 1998). It is evident that the endocrine system presents a number of target sites for adverse effects of environmental agents. Much more information is needed about the specific ecologic and public health risks.

# Disorders of Calcium and Phosphorus Metabolism

Lewis P. Rubin

## HOMEOSTATIC CONTROL OF CALCIUM AND MAGNESIUM

Calcium plays two important physiologic roles. Calcium salts in bone provide structural integrity. Regulation of calcium ions present in the cytosol and extracellular fluid (ECF) is essential for maintenance and control of many biologic processes, including cell-cell communication, cell aggregation and division, coagulation, neuromuscular excitability, membrane integrity and permeability, enzyme activity, and secretion. This diversity of functions is made possible by the maintenance of a large electrochemical gradient between the ECF  $\text{Ca}^{2+}$  concentration, which is in the 1 mmol/L range, and resting intracellular (cytosolic)  $\text{Ca}^{2+}$  concentration, which is about 0.1  $\mu\text{mol/L}$ .

Significant alterations in serum calcium concentration occur frequently in the neonatal period. It is important to evaluate these alterations in light of the normal dynamic changes that take place during the perinatal transition. After the first 2 to 3 extrauterine days, normal serum calcium concentrations vary only slightly with age, range between 8.8 and 10.6 mg/dL, and average about 10 mg/dL. In the United States, serum or plasma calcium levels usually are reported as mg/dL, which may be converted to molar units by dividing by 4 (e.g., 10 mg/dL is equivalent to 2.5 mmol/L).

Approximately 55% to 60% of the total plasma calcium is diffusible (or ultrafilterable), and the rest is protein bound. Most diffusible calcium is ionized, but about 5% of total circulating calcium is complexed to plasma anions, such as phosphates, citrate, and bicarbonate. Ionized calcium ( $\text{Ca}^{2+}$ ) is the only biologically available fraction of ECF calcium. It is subject to precise metabolic control.

Hypoalbuminemia leads to a decline in total serum calcium, but proportionate increases in the ionized fraction usually maintain serum  $\text{Ca}^{2+}$  within the normal range. Acute alkalosis (e.g., hyperventilation or bicarbonate infusion) or rapid administration of citrate-buffered blood (e.g., during exchange transfusion, initiation of extracorporeal membrane oxygenation [ECMO], cardioplegia, or organ transplantation) may acutely lower serum  $\text{Ca}^{2+}$  by increasing albumin binding or citrate chelation, respectively. These conditions can produce transient clinical manifestations of hypocalcemia but do not lower the total serum calcium concentration. Electrocardiogram Q-Tc intervals and algorithms for correcting serum total calcium for alterations in serum albumin concentration and/or pH or for calculating “free” calcium concentration

have not proved to be reliable compared with actual measurement of  $\text{Ca}^{2+}$  using ion-selective electrodes (Clase et al, 2000). For routine clinical purposes, measuring total serum calcium often suffices.

Although the intestine has considerable absorptive capacity for calcium, renal tubular calcium reabsorption usually exceeds intestinal absorption by at least 40-fold. Most of the tubular  $\text{Ca}^{2+}$  load is reabsorbed in the proximal tubule and thick ascending limb of the loop of Henle via paracellular, passive flux (coupled with sodium reabsorption) driven by the existing electrochemical gradient. A transcellular pathway in the distal nephron tightly regulates the rest of urinary  $\text{Ca}^{2+}$  reabsorption. Calcitropic hormones regulate the distal  $\text{Ca}^{2+}$ -selective,  $\text{Na}^+$ -independent channels.

More than 98% of total body calcium is deposited in the skeleton as hydroxyapatite [ $\text{Ca}_5(\text{OH})(\text{PO}_4)_3$ ]; the ECF and soft tissues contain the remainder. A small fraction of skeletal calcium freely exchanges with the ECF and serves as an important buffer of circulating calcium. Consequently, decreased skeletal calcium is a hallmark of most chronic metabolic bone diseases.

Magnesium homeostasis also is largely renally mediated. Approximately 80% of total plasma magnesium is filtered through the glomerulus and is reabsorbed mainly in cortical segments of the thick ascending limb of the loop of Henle. Once the maximal tubular reabsorption is exceeded, filtered magnesium is excreted into the urine. Hormones regulate magnesium reabsorption by changing the transepithelial voltage and paracellular permeability of tubular cells.

## HOMEOSTATIC CONTROL OF PHOSPHORUS

Blood inorganic phosphate ( $\text{P}_i$ ) concentration varies with age. It is highest during infancy and gradually declines to adulthood. Approximately 10% of plasma  $\text{P}_i$  is noncovalently bound to protein, whereas 90% circulates as  $\text{HPO}_4^{2-}$  and  $\text{HPO}_4^-$  ions or as complexes with sodium, calcium, or magnesium. About 80% to 85% of total body phosphorus is contained in the hydroxyapatite lattice of bone, where it contributes to mechanical support. The remainder is distributed in the ECF, largely as inorganic ions or complexes, and in soft tissues as phosphate esters. Intracellular phosphate esters and phosphorylated intermediates regulate cell metabolism and gene expression (via phosphorylase, kinase, and phosphatase activities) and generate and transfer cellular energy (e.g., via adenosine triphosphate [ATP]). Cytosolic and ECF phosphorus levels (approximately 0.1 mmol/L and 0.2 mmol/L, respectively) are less stringently regulated than are levels of  $\text{Ca}^{2+}$  and  $\text{Mg}^{2+}$ .

Dietary phosphate generally is absorbed in proportion to its content in food. Although phosphorus and calcium can be absorbed along the entire length of the small intestine, most phosphate transport takes place in the jejunum and ileum, whereas most calcium absorption occurs in the duodenum. The renal proximal tubule is the principal regulatory site for phosphorus homeostasis. Renal regulation is accomplished primarily by varying the threshold for

phosphate reabsorption (the tubular maximum for  $P_i$ /glomerular filtration rate, or  $TmP/GFR$ ). Hormones (parathyroid hormone [PTH], parathyroid hormone-related protein [PTHrP], growth hormone) and dietary phosphate reset this theoretical threshold by regulating apical tubular  $Na^+-P_i$  cotransporters (Murer and Biber, 1995). Essentially, the  $TmP/GFR$  is the “set point” that defines the fasting serum phosphorus concentration. At lower serum phosphorus levels, most filtered phosphorus is reabsorbed; at higher levels, most filtered phosphorus is excreted. To assess the  $TmP/GFR$ , a fasting urine specimen is obtained for measurement of phosphorus and creatinine along with simultaneous determination of serum phosphorus and creatinine. A nomogram has been constructed so that  $TmP/GFR$  can easily be derived from these values (Walton and Bijvoet, 1975).

The higher serum phosphate levels in infants (e.g., 4.5 to 9.3 mg/dL) compared with those in adults (3.0 to 4.5 mg/dL) reflect infants' greater tubular phosphate reabsorption. This adaptation permits avid tubular phosphate conservation despite high ambient serum phosphate levels. For this reason, neonatal disorders of chronic hypophosphatemia and/or phosphorus depletion usually result from inadequate dietary supply (as in preterm infants) or intrinsic (e.g., familial hypophosphatemic rickets) or extrinsic (e.g., hyperparathyroidism) alterations in  $TmP/GFR$ . Similarly, chronic hyperphosphatemia usually implies either intrinsic (e.g., renal insufficiency) or extrinsic (e.g., hypoparathyroidism) abnormalities in  $TmP/GFR$ .

### THE PARATHYROID-RENAL HORMONAL AXIS

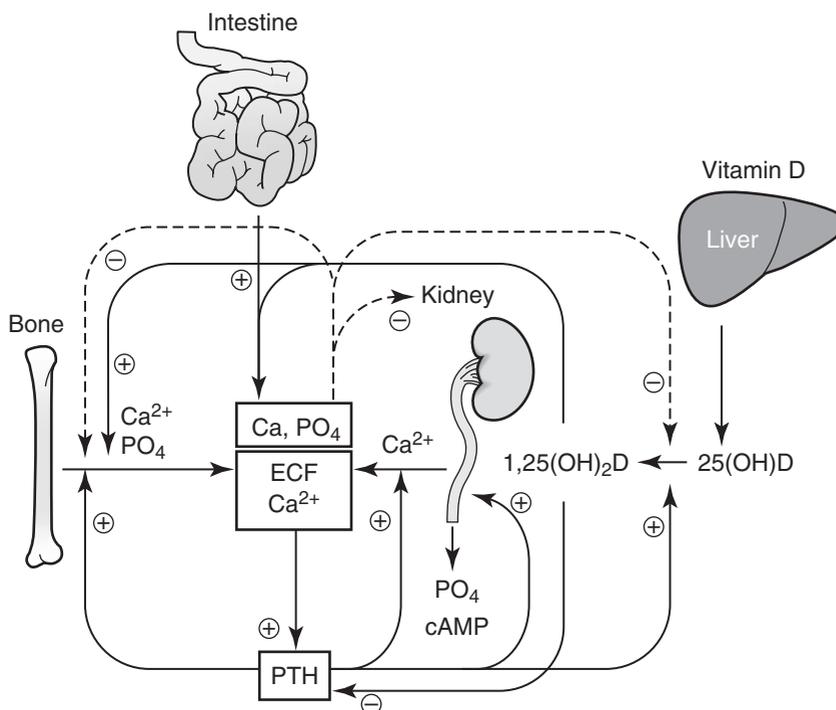

In mammals, calcium and phosphate homeostasis is controlled by a parathyroid-renal hormonal axis involving PTH and 1,25-dihydroxyvitamin D [ $1,25(OH)_2D$ ]. The

influence of these two hormones on bone deposition, mobilization of mineral, and regulation of intestinal and renal absorption is depicted in Figure 89-1. Deficiency or excess of either hormone causes hypocalcemia or hypercalcemia, respectively.

### Parathyroid Hormones

PTH is a 9500-dalton, single-chain polypeptide. PTH is synthesized by the four parathyroid glands, which are derived from the embryonic third and fourth pharyngeal pouches. The messenger RNA (mRNA) for PTH (pre-proPTH) encodes the 84 amino acids of the mature peptide, an N-terminal “pre” sequence of 25 amino acids, and a basic “pro” hexapeptide, which is clipped intracellularly. Following secretion, the intact PTH molecule [PTH (1-84)] is further metabolized and rapidly cleared from the circulation, with a half-life of less than 4 minutes. The N-terminal region of the PTH molecule [PTH(1-34)] binds the PTH receptor and shows full biologic activity, whereas the C terminus has specific, albeit poorly understood activities in osteoclasts and osteoclastic precursors.

Secretion of PTH fragments by the parathyroid glands and prolonged clearance of C-terminal PTH metabolites add considerable immunoheterogeneity to circulating PTH. The numerous inconsistencies found in reports on PTH pathophysiology until the late 1980s are due to use of earlier-generation “C-terminal” and “mid-molecule” PTH assays. In contrast, current two-site “intact PTH” assays are sufficiently sensitive and specific to detect physiologic levels of biologically active PTH(1-84) and to distinguish hypoparathyroid from euparathyroid states. The normal circulating levels of intact PTH range from approximately 10 to 60 pg/mL; the maximally stimulated

**FIGURE 89-1.** Hormonal regulation of calcium and phosphate by PTH and  $1,25(OH)_2D$ . Decreased  $Ca^{2+}$  stimulates PTH and  $1,25(OH)_2D$  secretion. Renal, gastrointestinal, and skeletal mechanisms increase  $Ca^{2+}$ , inhibiting PTH secretion and closing the negative feedback loop.  $Ca^{2+}$ , ionized calcium; cAMP, cyclic adenosine monophosphate; ECF, extracellular fluid;  $25(OH)D$ , 25-hydroxyvitamin D;  $1,25(OH)_2D$ , 1,25-dihydroxyvitamin D;  $PO_4$ , inorganic phosphate; PTH, parathyroid hormone; (From Brown EM, MacLeod RJ: Extracellular calcium sensing and extracellular calcium signaling. *Physiol Rev* 81:239, 2001.)

(hypocalcemic) and maximally suppressed (hypercalcemic) levels for normal parathyroid function are about 100 to 150 pg/mL and 2 to 5 pg/mL, respectively.

Parathyroid cells are exquisitely responsive to changes in ambient  $\text{Ca}^{2+}$ . PTH secretory dynamics may be described as an inverse sigmoid hysteretic relationship between serum PTH and  $\text{Ca}^{2+}$  with a parathyroid cell “set point” (the  $\text{Ca}^{2+}$  at which PTH secretion is half-maximal) of 1.2 to 1.25 mmol/L. The parathyroid “calciostat” detects perturbations of blood  $\text{Ca}^{2+}$  of as small as 0.025 to 0.05 mmol/L and promptly adjusts PTH secretion. The molecular mechanism that enables certain cells (e.g., parathyroid cells, thyroidal C cells, renal tubular cells, osteoblasts) to sense these minute changes in ECF  $\text{Ca}^{2+}$  involves a heptahelical G protein-coupled receptor (GPCR), the  $\text{Ca}^{2+}$ -sensing receptor (CaR). ECF  $\text{Ca}^{2+}$  (and, at lower potency,  $\text{Mg}^{2+}$ ) binds the CaR, activates several intracellular effector pathways, and ultimately leads to oppositely directed changes in PTH secretion and altered renal cation handling (Brown and MacLeod, 2001). As described later, loss-of-function (or inactivating) mutations in the *CaR* gene are responsible for neonatal hyperparathyroidism and familial hypocalciuric hypercalcemia, whereas gain-of-function *CaR* mutations result in autosomal dominant neonatal hypocalcemia.

PTH mobilizes calcium and phosphorus from bone, stimulates calcium reabsorption, inhibits phosphorus reabsorption by reducing  $\text{TmP/GFR}$ , and stimulates the renal synthesis of  $1,25(\text{OH})_2\text{D}$ , which participates with PTH in reabsorbing bone mineral and also increases efficiency of intestinal absorption of calcium and phosphorus. Therefore, PTH secretion causes the serum calcium concentration to rise and the serum phosphorus concentration to be maintained or decline.

PTH-related protein (PTHrP) is a second member of the PTH family, first identified as the cause of humoral hypercalcemia of malignancy. The amino acid sequences of PTHrP and PTH are homologous at the N terminus, and 8 of the first 13 amino acids are identical. Beyond this region, the sequences have little in common. PTHrP is a multifunctional molecule, like neuropeptides such as pro-opiomelanocortin (the precursor of corticotropin, endorphins, and melanocyte-stimulating hormones). The three PTHrP isoforms (139, 141 and 173 amino acids) give rise to several secreted peptide fragments. PTHrP is widely expressed, especially in fetal tissues, and has important local functions in morphogenesis and differentiation. The normal circulating levels of PTHrP are considerably lower than the levels of PTH, and it is doubtful that PTHrP has a major role in calcium homeostasis. Two important exceptions are in the fetus and lactating woman, for whom PTHrP appears to be an important calcitropic hormone.

The principal PTH receptor (type 1 PTH/PTHrP receptor) is a GPCR belonging to a newly recognized receptor subfamily that includes receptors for calcitonin, secretin, and corticotropin-releasing hormone. This versatile PTH/PTHrP receptor mediates actions of its two physiologic ligands in multiple tissues and signals through several second messenger pathways. The best-characterized effector of PTH action is cyclic adenosine monophosphate (cAMP).

## Vitamin D

Vitamin D is a secosteroid synthesized in the skin or absorbed from the diet. Exposure to sunlight (wavelength of 290 to 320 nm) cleaves the B ring of 7-dehydrocholesterol (7-DHC), or provitamin D, the immediate precursor of cholesterol, to form a sterol, previtamin D. Previtamin D in the skin undergoes isomerization to the biologically inert vitamin D. Vitamin D enters the circulation bound to vitamin D-binding protein and is transported to the liver, where a mitochondrial cytochrome P450 vitamin D-25-hydroxylase produces 25-hydroxyvitamin D [ $25(\text{OH})\text{D}$ ].  $25(\text{OH})\text{D}$  (provitamin D) is the major circulating vitamin D metabolite. Because activity of hepatic 25-hydroxylase is not tightly regulated, measurement of serum  $25(\text{OH})\text{D}$  is a useful assessment of vitamin D stores. In renal proximal tubule cells, mitochondrial cytochrome P450 25(OH)D- $1\alpha$ -hydroxylase metabolizes  $25(\text{OH})\text{D}$  to the biologically active hormone,  $1,25(\text{OH})_2\text{D}$ . The normal circulating level of  $25(\text{OH})\text{D}$  is approximately 10 to 50 ng/mL. The normal circulating concentration of  $1,25(\text{OH})_2\text{D}$  ranges from 30 to 75 pg/mL, or about 1/1000 that of  $25(\text{OH})\text{D}$ .

Serum  $25(\text{OH})\text{D}$  levels are increased by sunlight exposure and by vitamin D ingestion and are decreased in vitamin D deficiency and in hepatobiliary disorders. Circulating  $1,25(\text{OH})_2\text{D}$  levels are increased by hyperparathyroidism and phosphate depletion and are reduced in hypoparathyroidism.  $1,25(\text{OH})_2\text{D}$  is biologically inactivated through a series of reactions beginning with 24-hydroxylation.  $1,25(\text{OH})_2\text{D}$  induces the 24-hydroxylase in vitamin D target cells, whereas hypocalcemia, by increasing PTH levels, suppresses this enzyme. 24-Hydroxylase metabolizes  $25(\text{OH})\text{D}$  as well as  $1,25(\text{OH})_2\text{D}$ . In vitamin D-sufficient states, the kidney preferentially 24-hydroxylates the prohormone,  $25(\text{OH})\text{D}$ , to  $24,25(\text{OH})_2\text{D}$ . In contrast, when vitamin D action is required,  $25(\text{OH})\text{D}$ - $1\alpha$ -hydroxylase is preferentially activated for  $1,25(\text{OH})_2\text{D}$  synthesis.

A chief biologic function of  $1,25(\text{OH})_2\text{D}$  is to increase intestinal absorption of calcium and phosphorus. During low calcium intake, PTH levels increase and stimulate the renal conversion of  $25(\text{OH})\text{D}$  to  $1,25(\text{OH})_2\text{D}$ , which in turn stimulates osteoclast differentiation and bone resorption. Most of the identified biologic actions of  $1,25(\text{OH})_2\text{D}$  are mediated via binding to the vitamin D receptor (VDR), a member of the intracellular receptor superfamily, and via VDR interaction with specific response elements (VDREs) in promoters of vitamin D-responsive genes.

The parathyroid-renal [ $\text{PTH}$ - $1,25(\text{OH})_2\text{D}$ ] axis, reminiscent of the hypothalamic-pituitary-adrenal axis, is the principal means for systemic response to a prolonged or major hypocalcemic challenge. In this long-loop feedback system,  $1,25(\text{OH})_2\text{D}$ -mediated calcium absorption provides the ultimate feedback on PTH secretion. PTH secreted in response to hypocalcemia is the principal regulator of renal production of  $1,25(\text{OH})_2\text{D}$  that, in turn, feeds back to suppress PTH gene expression (see Fig. 89-1). Maximal adjustments of intestinal calcium absorption via the PTH- $1,25(\text{OH})_2\text{D}$  axis require 1 to 2 days to become fully operative, so  $1,25(\text{OH})_2\text{D}$  effects come into play only when a hypocalcemic stress persists. In contrast, PTH regulates the minute-to-minute perturbations of ECF [ $\text{Ca}^{2+}$ ].

## Calcitonin

Calcitonin, a peptide hormone synthesized by thyroid parafollicular C cells, has an antihypercalcemic effect, that is, an effect opposite that of the actions of PTH. Human calcitonin is a 32-amino-acid chain with a 1,7-disulfide bridge and a C-terminal prolinamide. Alternative splicing of several transcripts from the single calcitonin gene produces several polypeptide products. These peptides have uncertain calcitropic importance. The primary stimulus for calcitonin secretion is a rise in circulating calcium concentration. Calcitonin lowers serum calcium and phosphorus chiefly by inhibiting bone resorption.

Currently, there is no compelling evidence that the calcitonin-like calcium-lowering hormones are critical regulators of calcium homeostasis in nonpregnant adult humans, perhaps because the low prevailing rates of bone turnover blunt the impact of the antiresorptive actions. However, calcitonin may have important calcitropic functions in pregnant and lactating women and in the fetus and neonate, and in other mammals, particularly rodents, whose bones are constantly growing. In human newborns, the C cell population and serum calcitonin concentrations are much greater than in adults.

## PERINATAL MINERAL METABOLISM

During human pregnancy, approximately 30 g of calcium and more than 16 g of phosphorus are transferred transplacentally from the maternal circulation to the growing fetus, the bulk during the third trimester when fetal calcium accretion is approximately 140 to 150 mg/kg per day. A mid-molecule PTHrP hormone (Kovacs et al, 1996) that is expressed principally by placenta regulates this transplacental calcium pump. In humans, a doubling of maternal intestinal calcium absorption and a net increase of calcium accretion into bone compensate for the formidable demand on maternal calcium.

## Pregnancy

Pregnancy constitutes a unique hormonal milieu that promotes a state of “physiologic absorptive hypercalciuria” (Gertner et al, 1986). Maternal total serum calcium declines slightly during pregnancy, reaches a nadir in the mid-third trimester, and then increases slightly toward term. The maternal serum phosphorus and magnesium profiles are similar to that of calcium. Maternal serum 25(OH)D varies with the season and with vitamin D intake, but the vitamin D transport protein (DBP) increases during pregnancy. Serum 1,25(OH)<sub>2</sub>D concentrations increase early in pregnancy and continue to rise through gestation (Seely et al, 1997). The calculated concentration of free 1,25(OH)<sub>2</sub>D also rises. For many years, it was believed that PTH levels also increased steadily through pregnancy. However, use of newer immunometric “sandwich” assays indicates that PTH actually declines during the course of pregnancy (Davis et al, 1988; Saggese et al, 1991; Seely et al, 1997). PTHrP levels, in contrast, may be higher in pregnant than in nonpregnant women (Bertelloni et al, 1994). The role of circulating calcitonin in pregnancy is uncertain.

1,25(OH)<sub>2</sub>D drives the maternal enhanced intestinal mineral absorption. Following parturition, 1,25(OH)<sub>2</sub>D concentrations and calcium absorption rates (Kent et al, 1991) fall to prepregnancy levels. The interplay of calcitropic and progestational hormones in pregnancy protects the maternal skeleton from demineralization. In contrast, during the relatively low estrogen state of lactation, calcium is mobilized from bone stores, possibly under the influence of PTHrP (Dobnig et al, 1995).

In the third trimester, total and ionized calcium and phosphorus levels in fetal plasma are higher than maternal levels, and there is a state of “physiologic fetal hypercalcemia” (Rubin et al, 1991). Fetal plasma PTH is low, and calcitonin and PTHrP levels are relatively high. Even these low circulating PTH levels may be functionally important in fetal calcium and magnesium metabolism (Kovacs et al, 2001). There also is a close correlation between maternal and fetal serum 25(OH)D levels, consistent with transplacental transfer of this metabolite. Low levels may be found in infants born to women with low circulating 25(OH)D resulting from poor dietary intake of vitamin D and lack of sunlight exposure. Fetal plasma 1,25(OH)<sub>2</sub>D also is relatively low, despite robust renal 25(OH)D-1 $\alpha$ -hydroxylase activity, whereas concentrations of 24,25(OH)<sub>2</sub>D are high. In fact, the major function of the fetal kidneys in calcium homeostasis may be production of 1,25(OH)<sub>2</sub>D, rather than renal tubular regulation of calcium excretion. The high circulating concentrations of calcitonin may support this stimulated fetal 25(OH)D-1 $\alpha$ -hydroxylase activity. In contrast, the relatively low circulating fetal 1,25(OH)<sub>2</sub>D concentrations are a consequence of enhanced placental clearance (Ross et al, 1989). Constitutively activated placental 24-hydroxylase activity (Rubin et al, 1993) also preferentially hydroxylates maternally derived 25(OH)D to 24,25(OH)<sub>2</sub>D. This placental capacity to metabolize 25(OH)D and 1,25(OH)<sub>2</sub>D probably accounts for the enhanced clearance of fetal 1,25(OH)<sub>2</sub>D, limits access of placentally synthesized 1,25(OH)<sub>2</sub>D to the fetal and maternal circulations, and, in effect, partitions the maternal and fetal vitamin D pools.

## The Neonate

Placental transfer of calcium ceases abruptly at birth. In healthy term newborns, total calcium concentration and [Ca<sup>2+</sup>] decline from nearly 11 mg/dL and 6 mg/dL, respectively, in umbilical cord blood to serum levels of 8 to 9 mg/dL and 5 mg/dL by 24 to 48 hours. The nadir of [Ca<sup>2+</sup>] may range from 4.4 to 5.4 mg/dL. Concomitant rises in PTH and 1,25(OH)<sub>2</sub>D stabilize serum calcium as the newborn adapts to extrauterine mineral homeostasis and dietary calcium intake. In preterm infants, calcium absorption from the intestine is nonsaturable and may be vitamin D independent (Bronner et al, 1992). Serum calcitonin levels increase sharply during the first day and remain elevated compared with those in adults. In the mother, prolactin helps stimulate PTHrP expression in lactating breast tissue. PTHrP is secreted into milk at concentrations 10,000-fold higher than its serum concentration. It is likely that the abundant milk PTHrP content ingested by the neonate also is important for mineral regulation. By 2 weeks of life, serum calcium rises to the mean values observed in older children and adults.

During the first week of life, urinary phosphate excretion is significantly higher in preterm than in term infants but then approximates that of term infants, possibly owing to accelerated postnatal renal maturation. Calcium excretion is low during the first week, when the newborn must compensate for the postpartum fall in serum calcium. After the first several days, calcium excretion increases with a magnitude inversely proportional to gestation. The high urinary calcium-to-creatinine ratio (UCa/Cr) of young infants then steadily declines with age (Sargent et al, 1993). However, in preterm breast-fed infants who are more than 2 weeks old, the UCa/Cr can exceed 2.0 (Karlen et al, 1985). These changes may reflect the relative phosphate deficiency in many preterm infants, which results in an adaptively low urinary phosphate excretion, decreased bone mineralization, and, consequently, relatively high urinary calcium excretion.

## CALCIUM METABOLISM IN THE NEWBORN

### Neonatal Hypocalcemia

*Neonatal hypocalcemia* has been variously defined as a serum calcium level of less than 8 mg/dL, less than 7.5 mg/dL, or less than 7.0 mg/dL and as a  $\text{Ca}^{2+}$  level of less than 4.0 mg/dL. Under conditions of normal acid-base status and normal serum albumin, serum total calcium and  $\text{Ca}^{2+}$  levels are linearly correlated, so total serum calcium measurements remain useful as a screening test. However, because  $\text{Ca}^{2+}$  is the physiologically relevant fraction, in sick infants it may be preferable to assay  $[\text{Ca}^{2+}]$  directly in freshly obtained blood samples. A precise definition of hypocalcemia, like hypoglycemia, in preterm infants is particularly difficult to formulate. Preterm hypocalcemia is probably best defined with reference to  $[\text{Ca}^{2+}]$ .

A useful approach to the classification of neonatal hypocalcemia is by time of onset. “Early”- and “late”-occurring hypocalcemia (Table 89–1) have different causes, usually occur in different clinical settings, and should prompt different approaches to evaluation and management.

### Clinical Findings

Because  $\text{Ca}^{2+}$  couples excitation and contraction in skeletal and cardiac muscle, increased neuromuscular excitability (tetany) is a cardinal feature of hypocalcemia. However, hypocalcemic signs in neonates are variable and may not correlate with the magnitude of the decline in  $[\text{Ca}^{2+}]$ . Although some infants are severely affected, others having equally depressed serum calcium levels may be asymptomatic.

Tetanic infants are jittery and hyperactive and frequently exhibit muscle jerking and twitching. Generalized or focal clonic seizures may occur at any time during the calcium derangement. Hyperacusis may be detected as an exaggerated response to environmental noises (e.g., a “spontaneous” Moro reflex). Occasionally, respiratory or gastrointestinal signs, rather than neurologic findings, predominate. Laryngospasm with inspiratory stridor, sometimes severe enough to cause cyanosis or anoxia, or wheezing due to bronchospasm may be a presenting manifestation. Vomiting, possibly related to pylorospasm, sometimes causes hematemesis or melena. At times, the

gastrointestinal signs are severe enough to mimic those of intestinal obstruction. Other signs of neonatal tetany include extensor hypertonia, apnea, tachycardia, tachypnea, and edema. Carpopedal spasm and Chvostek sign are not as reliably elicited in hypocalcemic newborns as in older children or adults.

### Early Neonatal Hypocalcemia

Hypocalcemia occurring during the first 3 days of life, usually between 24 and 48 hours postpartum, is termed *early neonatal hypocalcemia*. It is a pathologic exaggeration of the normal decline in circulating calcium. Early neonatal hypocalcemia is characteristically seen in any of four circumstances: prematurity, severe stress or asphyxia, maternal diabetes, and significant intrauterine growth restriction (IUGR). Typically, in preterm infants, there is a steeper and more rapid postnatal decline in serum calcium than in term newborns; the magnitude of the depression is inversely proportional to gestational age. Untreated, many low-birth-weight (LBW) infants and essentially all extremely low-birth-weight (ELBW) infants exhibit total calcium levels of less than 7.0 mg/dL by day 2. However, the fall in  $[\text{Ca}^{2+}]$  is not proportional to the fall in total calcium concentration, and the ratio of ionized to total calcium in these newborns is higher. This “sparing” of  $\text{Ca}^{2+}$  may be related to the lower serum protein concentration and pH in prematurity. The sparing effect on  $[\text{Ca}^{2+}]$  also, in part, explains the frequent absence of hypocalcemic signs in preterm infants.

The neonatal parathyroid glands, regardless of degree of prematurity, can mount an appropriate PTH response to hypocalcemia. In fact, hypocalcemia in extremely preterm newborns (Rubin et al, 1991) or infants undergoing cardiac bypass (Robertie et al, 1992) stimulates increases in serum PTH at least as great as those seen in adults during citrate-induced hypocalcemia (Grant et al, 1990). Resistance to PTH action plays an uncertain role in early neonatal hypocalcemia. A several day delay in the phosphaturic and renal cAMP responses to PTH has inconsistently been reported, suggesting that there might be a maturational delay in renal responses to PTH. High renal sodium excretion in preterm infants also probably aggravates calciuric losses. In addition, the preterm infant's exaggerated rise in calcitonin may promote hypocalcemia. Currently, there is no convincing evidence that abnormalities in vitamin D metabolism are involved in the etiopathogenesis of hypocalcemia in preterm infants. Like fetuses, even ELBW newborns efficiently synthesize  $1,25(\text{OH})_2\text{D}$  when vitamin D stores are adequate.

Early neonatal hypocalcemia with hyperphosphatemia is frequently observed in severely stressed or asphyxiated infants. The causes are probably multifactorial and may include, to varying degrees, renal insufficiency, tissue catabolism, and acidosis. There is an exaggerated serum calcitonin response and elevated PTH levels. Low serum  $\text{Ca}^{2+}$  and elevated serum magnesium levels have been correlated with severity of hypoxic-ischemic encephalopathy and poor outcome (Ilves et al, 2000).

Infants of diabetic mothers (IDMs) show an exaggerated postnatal drop in circulating calcium levels compared to

TABLE 89-1

**Causes of Neonatal Hypocalcemia**

Early-onset hypocalcemia (<48 hr of age)	Abnormal vitamin D [1,25(OH) <sub>2</sub> D] production or action (“hypocalcemic rickets”)
Prematurity	Vitamin D deficiency (secondary to maternal vitamin D deficiency)
Perinatal distress/asphyxia	Acquired or inherited disorders of vitamin D metabolism
Infants of diabetic mothers	Resistance to the actions of vitamin D
Intrauterine growth restriction	Hyperphosphatemia
Late-onset hypocalcemia (1st week of life)	Excessive dietary phosphate
High phosphate load ± hypoparathyroidism or vitamin D deficiency	Phosphate-containing enemas
Neonatal hypoparathyroid syndromes	Rhabdomyolysis-induced acute renal failure
Parathyroid agenesis	Hyperphosphatemic renal insufficiency
DiGeorge syndrome (22q11.2 deletions)	“Hungry bones syndrome” (mineralization outpacing osteoclastic bone resorption)
Familial isolated hypoparathyroidism	Other causes
PTH gene mutations	Metabolic or respiratory alkalosis
Autosomal dominant hypocalcemic hypocalciuria (ADHH)	Phototherapy
Activating mutations of the Ca <sup>2+</sup> -sensing receptor	Long chain 3-hydroxyacyl-CoA dehydrogenase deficiency (LCHAD)
Neonatal hypoparathyroidism secondary to maternal hyperparathyroidism	Pancreatitis
Autoimmune–candidiasis–ectodermal dystrophy (APECED or APS1)	Sepsis, septic shock
Hypoparathyroidism associated with skeletal dysplasias	Rotavirus gastroenteritis
Kenny-Caffey syndrome	Osteopetrosis and other skeletal dysplasias
Sanjad-Sakati (hypoparathyroidism-retardation-dysmorphism [HRD]) syndrome	Pseudohypocalcemia (hypoalbuminemia)
Osteogenesis imperfecta type II	Medications
PTH resistance (transient neonatal pseudohypoparathyroidism)	Bicarbonate
Hypomagnesemia ± distal renal tubular acidosis	Rapid transfusion or plasmapheresis with citrated blood
Primary hypomagnesemia	Furosemide-induced
Renal tubular acidosis type 1	Lipid infusions

CoA, coenzyme A; 1,25(OH)<sub>2</sub>D, 1,25-dihydroxyvitamin D.

gestational age controls. The course usually is similar to that of early neonatal hypocalcemia in preterm infants, although hypocalcemia sometimes persists for several additional days. Maternal and neonatal hypomagnesemia (Mimouni et al, 1986) and low fetal PTH/PTHrP biologic activity (Rubin et al, 1991) may be causative factors. The greater bone mass and relative undermineralization typical of macrosomic IDMs also may increase the neonatal demand for calcium, producing a more profound and prolonged decline in postnatal serum calcium levels. Similar mechanisms may come into play in the transient hypocalcemia often observed in small-for-gestational-age (SGA) infants. Hypercalcitonemia, hypoparathyroidism, abnormalities in vitamin D metabolism, and hyperphosphatemia all have been implicated, but none has been consistently found.

Historically, symptomatic neonatal hypocalcemia in IDMs has been associated with the severity of maternal diabetes (e.g., White classification) and inadequate glycemic control. Not surprisingly, preterm IDMs who have sustained IUGR and asphyxia as a result of uteroplacental insufficiency invariably become quite hypocalcemic. In recent years, improved metabolic control for pregnant diabetic women has markedly diminished the occurrence and severity of early neonatal hypocalcemia in IDMs (Demarini et al, 1994). Healthy IDMs who are able to begin milk feedings on the first day do not require serum calcium monitoring unless suspicious signs (e.g., jitteriness, stridor) are noted.

**Late Neonatal Hypocalcemia**

Late neonatal hypocalcemia, or hypocalcemia developing after 3 to 5 days of life, occurs more frequently in term than in preterm newborns and is not correlated with maternal diabetes, birth trauma, or asphyxia. Historically associated with cow milk or cow milk formula feedings, it also occasionally occurs in breast-fed infants. The entity of “late infantile tetany” seen in infants fed whole cow’s milk has become a rarity with adjustment of phosphorus content in humanized cow milk and soy infant formulas.

The hyperphosphatemia that is a prominent feature of late neonatal hypocalcemia may result from varying combinations of dietary phosphate load, immature renal tubular phosphate excretion, transiently low levels of circulating PTH, hypomagnesemia, and marginal maternal vitamin D intake. A relatively high dietary phosphate load coupled with a low GFR leads to an increase in serum phosphate levels and a reciprocal decline in serum calcium levels. The normal response to hypocalcemia is an increase in PTH secretion, leading to increased urinary phosphate excretion and tubular calcium resorption. It is relevant, therefore, that low circulating PTH levels have sometimes been observed in infants with late neonatal hypocalcemia. Serum calcium levels frequently increase when these infants are placed on a low-phosphate formula and calcium supplements. After several days to weeks, serum PTH usually increases, and the infants then can

tolerate more dietary phosphate. The pathogenesis of this “transient hypoparathyroidism” in late neonatal hypocalcemia is not readily apparent. Some of these infants show a persistent or recurrent inability to mount an adequate PTH response to a hypocalcemic challenge, indicating partial hypoparathyroidism (see later).

In other infants, maternal vitamin D deficiency can cause late (or occasionally an “early”) neonatal hypocalcemia. This possibility is investigated by assaying maternal and neonatal serum 25(OH)D levels. A role for maternal vitamin D deficiency also is implicated by the increased incidence of late neonatal hypocalcemia in winter. The high prevalence of enamel hypoplasia of incisor teeth reported in affected infants indicates a defect in mineralization during the third trimester of pregnancy.

Hypocalcemia and hyperphosphatemia after the first 2 to 3 days always should prompt a thorough investigation for underlying cause(s) (see Table 89–1). Hypocalcemia in this setting usually implies primary or secondary dysregulation of the parathyroid-renal [PTH-1,25(OH)<sub>2</sub>D] axis, hypomagnesemia, or renal insufficiency. The primary hormonal and end-organ disturbances that cause neonatal hypoglycemic syndromes are described in a later section. As a cautionary note, earlier observations of generally favorable neurologic outcomes in newborns with hypocalcemic or hypomagnesemic seizures (which may have been related to a nutritional metabolic disturbance) may be less relevant to the current neonatal population, in which hypocalcemia or hypomagnesemia due to dietary phosphate overload seldom is observed. In this group, neurologic prognosis may be more closely related to the causative disorder (Lynch and Rust, 1994).

### **Hypocalcemia Caused by Hypoparathyroid Syndromes**

Improved clinical assays have increased recognition of PTH deficiency manifesting during the first weeks of life. Cytogenetic and molecular genetic diagnosis also permits characterization of several types of congenital hypoparathyroidism. The biochemical hallmarks of hypoparathyroidism are hypocalcemia and hyperphosphatemia in the presence of normal renal function. Serum PTH concentrations are inappropriately low or undetectable.

Isolated hypoparathyroidism is usually sporadic but may show X-linked, autosomal recessive or autosomal dominant inheritance. Congenital hypoparathyroidism may be part of the DiGeorge syndrome (DGS), which comprises hypoparathyroid hypocalcemia, thymic hypoplasia with T-cell incompetence, conotruncal cardiac defects, and dysmorphic facies. The DGS phenotype results from defects in cervical neural crest cell migration into the derivatives of the third and fourth pharyngeal (branchial) pouches. More than 90% of persons with a clinical diagnosis of DGS have deletions (monosomy or partial monosomy) of chromosome region 22q11.2 detectable by fluorescence in situ hybridization (FISH) using 22q11 probes or by high-resolution G band karyotyping. Recent studies suggest that haploinsufficiency of the *UFD1* gene within the 22q11.2 region results in the

DGS phenotype (Yamagishi et al, 1999). However, the rare identification of other cytogenetic abnormalities suggests that several distinct molecular defects can lead to disturbed cranial neural crest cell migration.

DGS is sporadic in about 90% of cases. In many familial clusters the variable phenotype behaves as an autosomal dominant trait. In familial transmission, there appears to be a strong tendency for 22q11.2 deletions to be maternal in origin (Demczuk et al, 1996). In members of the same family, the 22q11 deletion may be associated with different phenotypic features, depending on whether endocrinologic, cardiac, craniofacial, or palatal abnormalities are the focus of attention. The clinical spectrum in DGS encompasses features previously categorized as Shprintzen (velocardiofacial) syndrome, conotruncal anomaly face (Takao) syndrome, and isolated cardiac outflow tract defects. Even transient congenital hypoparathyroidism in the absence of a DGS phenotype can be associated with a 22q11 deletion, so these infants should be evaluated and monitored for recurrence of hypocalcemia. The incidence of DGS may be at least 1 case per 5000 live births (Ryan et al, 1997).

DGS often manifests in the first week of life with hypocalcemic tetany or seizures. Craniofacial features include microretrognathia, submucous cleft palate, low-set and abnormal pinnae, telecanthus with short palpebral fissures, short philtrum, and a relatively small mouth. The presence of cardiac outflow tract or aortic arch abnormalities (especially pulmonary atresia/tetralogy of Fallot, type B interrupted aortic arch, truncus arteriosus, anomalies of aortic arch laterality, or abnormal branching of the brachiocephalic vessels), even in the absence of other DGS features, should prompt investigation with a standard karyotype to exclude major rearrangements and with FISH using DGS probes to detect microdeletions. Parents of an infant with DGS should be screened for carrier status. These infants require close anticipatory monitoring for the onset of hypocalcemia. Absence of a thymic shadow on chest radiograph is not a reliable indicator. A variety of T-cell and B-cell disorders is relatively common in DGS but severe T-cell immunodeficiency is rare. Nevertheless, because of the potential for inducing graft-versus-host disease, until T-cell immunocompetence has been demonstrated, irradiated red blood cell transfusions may be preferred.

A normal serum PTH obtained when an infant is relatively normocalcemic also does not exclude the diagnosis of DGS. Infants with DGS may show resolution of hypoparathyroidism by early childhood, although PTH reserves may remain inadequate for defense against hypocalcemic stresses.

Hypoparathyroidism is a prominent feature of several rare skeletal dysplasias. Kenny-Caffey syndrome is an autosomal recessive (sometimes dominant) skeletal dysplasia featuring transient neonatal hypoparathyroidism and dwarfism, macrocephaly, delayed fontanel closure, dysmorphic facies, and cortical thickening of tubular bones (Fanconi et al, 1992). In Sanjad-Sakati syndrome (Sanjad et al, 1991), or hypoparathyroidism-retardation-dysmorphism (HRD) syndrome, hypoparathyroidism is associated with IUGR and poor postnatal growth, characteristic facies (deep-set eyes, depressed nasal bridge,

beaked nose, long philtrum, thin upper lip, micrognathia, large and floppy earlobes), small hands and feet, skeletal defects, and developmental delay. This autosomal recessive disorder has been described in persons of Gulf Arab and Bedouin ancestry. The gene for Sanjad-Sakati syndrome (*hrd* locus) maps to chromosome 1q42-q43, which also is the autosomal recessive Kenny-Caffey locus, suggesting that these are allelic disorders (Diaz et al, 1999).

Although osteogenesis imperfecta (OI) type II usually is perinatally lethal, some infants have prolonged survival. Knisely and colleagues (1988) showed that acute parathyroid hemorrhage (“parathyroid apoplexy”) is a common event in OI II and may contribute to early death. Autoimmune-candidiasis-ectodermal dystrophy (APECED), also known as autoimmune polyglandular syndrome type I (APS 1), is a rare autosomal recessive disorder characterized by hypoparathyroidism, adrenal insufficiency, and chronic mucocutaneous candidiasis. In afflicted persons, the development of chronic active hepatitis, malabsorption, juvenile-onset pernicious anemia, alopecia, and primary hypogonadism is frequent. APECED results from inheritance of mutations in an autoimmune regulator gene (*AIRE*). When APECED is diagnosed in early infancy, which is rare, hypocalcemia (with or without candidiasis) typically is the presenting sign.

A major breakthrough in the last decade has been the association of several forms of autosomal dominant and autosomal recessive congenital hypoparathyroidism, with allelic variants of the *preproPTH* and calcium-sensing receptor (*CaR*) genes. Affected infants have subnormal or undetectable serum PTH levels but do not have congenital anomalies or developmental field defects, DGS locus deletions, candidiasis or autoimmune polyglandular failure, or antiendocrine antibodies. Autosomal dominant and autosomal recessive forms of familial isolated hypoparathyroidism have been related to mutations in the *preproPTH* gene (Sunthornthevarakul et al, 1999). Activating *CaR* gene mutations cause autosomal dominant hypocalcemic hypocalciuria (ADHH) or “CaR hyperfunction.” The parathyroid and renal calcistat is reset downward, so that hypocalcemia does not elicit normal compensatory PTH secretion or renal calcium reabsorption. Because de novo *CaR* mutations producing CaR hyperfunction may account for many cases of so-called sporadic idiopathic hypoparathyroidism (D’Souza-Li et al, 2002; Lienhardt et al, 2001), mutational analysis of the *CaR* gene should be considered in the work-up of isolated hypoparathyroidism in infants, especially when hypocalcemia manifests with inappropriately normal urinary calcium excretion (relative hypercalciuria). In fact, hypercalciuria and nephrocalcinosis can develop even when serum calcium remains below the normal range. Therefore, these patients require close monitoring of urinary calcium excretion for adjusting therapy with 1,25(OH)<sub>2</sub>D analogues (Lienhardt et al, 2001).

Resistance to PTH comes in three forms. Deletion of the PTH/PTHrP receptor is embryologically or perinatally lethal. Loss of one allele for *GNAS1*, which encodes G<sub>s</sub>α, the G protein α subunit required for

receptor-stimulated cAMP generation, produces pseudohypoparathyroidism type 1a (PHP1a). PHP1a is characterized by PTH-resistant (pseudo)hypoparathyroidism and characteristic somatic features (short stature, brachydactyly, and subcutaneous ossification), which collectively are known as Albright hereditary osteodystrophy. Isolated PTH resistance in the absence of this somatic phenotype is called pseudohypoparathyroidism type 1b (PHP1b). This disorder was recently shown to be an imprinting defect in which both *GNAS1* alleles have an unmethylated (paternal) pattern (Liu et al, 2000). Although persons eventually diagnosed with a PTH resistance syndrome usually do not show hypocalcemia during the first month of life, transient neonatal pseudohypoparathyroidism has occasionally been reported (Minagawa et al, 1995). Neonatal PTH resistance, which has an unknown frequency, manifests as hypocalcemic seizures with hyperphosphatemia and an elevated PTH. Molecular characterizations have not been performed.

### Neonatal Hypocalcemia Associated with Maternal Hyperparathyroidism

Hypocalcemia is commonly observed in newborns of hyperparathyroid mothers. These infants frequently show increased neuromuscular irritability during the first 3 weeks of life but occasionally may do so much later as limited PTH reserve and latent hypoparathyroidism emerge under stress or with time (Cuneo et al, 1996). The serum calcium levels usually range from 5.0 to 7.5 mg/dL, and the serum phosphate levels are often greater than 8.0 mg/dL. Hypocalcemic signs may be exacerbated by high-phosphate diets. In some instances, the signs of hypocalcemia can be quite severe and resistant to therapy. Calcium supplementation, which in some instances must be continued for several weeks, produces eventual improvement.

In maternal hyperparathyroidism, the increased maternal serum calcium facilitates transplacental calcium transport, producing fetal hypercalcemia greater than the moderate elevations of serum calcium normally observed in the third trimester. As a result, fetal PTH secretion is suppressed more than it is in normal pregnancy. The suppressed parathyroids are unable to maintain normal serum calcium levels post partum. The reason for the hypomagnesemia observed in some infants born to hyperparathyroid mothers is uncertain, but this derangement may be due to (1) maternal magnesium depletion as a complication of hyperparathyroidism; (2) transient neonatal hypoparathyroidism; or (3) hyperphosphatemia, which may result from transient hypoparathyroidism or high dietary phosphate intake, or both.

Maternal serum calcium and phosphorus should be assayed whenever this diagnosis is suspected. Hypocalcemic tetany occurring in the infant may lead to diagnosis of hyperparathyroidism in an asymptomatic mother. Maternal serum calcium values in the upper normal range can be falsely reassuring if the samples were obtained during pregnancy, a time when serum calcium levels normally decline.

### Neonatal Hypocalcemia Associated with Hypomagnesemia or Renal Tubular Acidosis

Hypomagnesemia causes hypocalcemia by interfering with the parathyroid cell CaR-mediated release of PTH and blunting end-organ PTH response. Depression of serum magnesium levels in newborns may be chronic, sometimes as primary hypomagnesemia with secondary hypocalcemia, or transient.

Hypomagnesemia with secondary hypocalcemia (HSH) can manifest within the first weeks of life with persistent hypocalcemia, tetany, and seizures uncontrollable by anti-convulsants or calcium gluconate. Delay in establishing the diagnosis may lead to permanent neurologic impairment. This rare autosomal recessive disorder results from defective intestinal magnesium absorption and renal magnesium leak. HSH is caused by mutations in the gene encoding TRPM6, a member of the transient receptor potential (TRP) channel family that is expressed in intestinal epithelia and renal tubules (Schlingmann et al, 2002; Walder et al, 2002). In contrast, in the intestinal defect of primary familial hypomagnesemia, serum magnesium is low despite a normal renal fractional excretion of magnesium (<5%) (Shalev et al, 1998).

Several forms of primary renal hypomagnesemia have been described, including autosomal recessive familial hypomagnesemia with hypercalciuria and nephrocalcinosis caused by mutations in the claudin-like paracellin-1 gene (*PCLN1*, *CLDN16*) (Simon et al, 1999) and a genetically heterogeneous autosomal dominant “isolated renal magnesium wasting” (Kantorovich et al, 2002). The clinical spectrum includes polyuria, hyposthenuria, moderate metabolic acidosis with an inappropriately high urine pH and a positive urine anion gap, low citrate excretion, renal magnesium and calcium wasting, secondary renal potassium wasting, nephrocalcinosis, muscle weakness, persistent tetany, seizures, and sometimes abnormal facies and sensorineural hearing loss. The partial distal acidification defect, which is probably secondary to a medullary interstitial nephropathy, can be functionally distinguished from primary distal renal tubular acidosis (RTA1) (Rodríguez-Soriano and Vallo, 1994). In primary hypomagnesemia, the serum magnesium is frequently less than 0.8 mg/dL (normal 1.6 to 2.8 mg/dL), and the magnesium deficiency leads to parathyroid failure and peripheral PTH resistance, despite hypocalcemia. High-dose enteral magnesium leads to spontaneous parallel increases in serum PTH and calcium levels and renal phosphate clearance. Renal transplantation normalizes serum magnesium and urinary calcium.

A transient hypomagnesemia in newborns often occurs in association with hypocalcemia. Less commonly, the serum calcium level may be normal. In transient hypomagnesemia, the decrease in serum magnesium level typically is less severe (0.8 to 1.4 mg/dL) than in magnesium transport defects. In many infants with transient hypomagnesemia, the serum magnesium level increases spontaneously as the serum calcium level returns to normal following the administration of calcium supplements. However, in other cases, the hypocalcemia responds poorly to calcium therapy, but when magnesium salts are given, both serum calcium and magnesium levels rise.

Secondary hypomagnesemia from renal magnesium wasting can be caused by administration of loop diuretics, aminoglycosides, or amphotericin B or by urinary tract obstruction, or may occur in the diuretic phase of acute renal failure. The disorder also may be mistaken for neonatal hypoparathyroidism because of the tetany and hypocalcemia, or as Bartter syndrome (hypokalemic alkalosis with hypercalciuria) because of secondary potassium wasting. The clinician's index of suspicion should be raised whenever hypomagnesemia occurs in one of these situations. Finding low serum magnesium levels with inappropriately high urinary magnesium excretion confirms the diagnosis of renal magnesium wasting. A common laboratory feature of magnesium depletion, regardless of cause, is hypokalemia. Attempts to replete the potassium deficit with potassium therapy alone usually is not successful without concurrent magnesium therapy.

The distal type of renal tubular acidosis, RTA1, is characterized by hypocalcemia, hypercalciuria, varying degrees of hypomagnesemia, hyperchloremia, low serum bicarbonate, and a fixed urinary specific gravity and urinary pH (about 5.0). The mineral excretion defect leads to nephrocalcinosis and metabolic bone disease. RTA1 sometimes manifests during early infancy, when the hypocalcemia may precede the RTA. Lewis (1992) proposed that Tiny Tim in Dickens' *A Christmas Carol* had RTA1, which would account for Tim's growth failure, osteomalacia, fractures, and neuromuscular weakness.

### Hypocalcemia Resulting from Vitamin D Disorders

In older children and adults, hypocalcemia rarely occurs as an isolated finding that results from disorders of vitamin D intake or metabolism. Most persons with abnormalities in either the production or the action of 1,25(OH)<sub>2</sub>D present with rickets or osteomalacia. In contrast, young infants may exhibit hypocalcemic tetany before rachitic features become very conspicuous. Abnormalities in vitamin D metabolism can be divided into three broad categories: vitamin D deficiency, acquired or inherited disorders of vitamin D metabolism, and resistance to the actions of vitamin D.

Maternal vitamin D deficiency is the major risk factor for neonatal vitamin D deficiency presenting as hypocalcemia. Maternal vitamin D deficiency has become unusual in countries where vitamin D supplementation of dairy products and other foods is common. It does occur, however, when both sunlight exposure and dietary intake of vitamin D are inadequate. Female immigrants from the Middle East or South Asia who continue to wear traditional dress *and* have inadequate dietary vitamin D intake are particularly at high risk (Shaw and Pal, 2002), especially during pregnancy. Breast-fed infants of lactovegetarian mothers also are susceptible to early-onset hypocalcemic rickets. Nutritional rickets in newborns can be prevented by daily supplementation of 400 IU for infants and 400 IU daily for mothers during pregnancy and lactation or 1000 IU daily if begun in the third trimester.

Intestinal absorption of fat-soluble vitamin D requires a functioning exocrine pancreas, biliary tract, and bowel mucosa. Consequently, pregnant women with malabsorption

syndromes may be vitamin D deficient. Anticonvulsant therapy (e.g., with phenobarbital or diphenylhydantoin) during pregnancy, which increases hepatic catabolism of 25(OH)D, also can induce maternal and fetal vitamin D deficiency. Pregnant women who take anticonvulsants should receive vitamin D supplementation (800 to 1000 IU/day).

### Phosphate-Induced Hypocalcemia

Hypocalcemia is the systemic response to hyperphosphatemia. Conditions conducive to phosphate-induced neonatal hypocalcemia are excessive dietary phosphate, rhabdomyolysis-induced acute renal failure, and hyperphosphatemic renal insufficiency. Phosphate-containing enemas can produce significant phosphate absorption. Their use is hazardous and contraindicated for infants.

### Other Causes of Neonatal Hypocalcemia

It is important to recognize that hypocalcemia may be precipitated whenever skeletal mineralization significantly outpaces the rate of osteoclastic bone resorption. Examples of this type of hypocalcemia occur with overzealous vitamin D replacement in infants with rickets or hypoparathyroidism. Pancreatitis can cause hypocalcemia and tetany through the action of pancreatic lipase on retroperitoneal and omental fat to release free fatty acids (FFAs). FFAs avidly chelate calcium and remove it from the ECF. Pancreatitis also may release pancreatic calcium-lowering factors (Tomomura et al, 1995). Sepsis and septic shock cause hypocalcemia by unknown mechanisms. Neonatal or infantile hypocalcemia and hypocalcemic seizures may accompany long-chain 3-hydroxyacyl-coenzyme A (CoA) dehydrogenase deficiency (LCHAD) (Ibdah et al, 1999) and severe cases of rotavirus gastroenteritis (Foldenauer et al, 1998). Hypocalcemic jitteriness or seizures can be the presenting sign of infantile osteopetrosis (Srinivasan et al, 2000). Prompt recognition permits early evaluation for bone marrow or hematopoietic stem cell transplantation. Certain other skeletal dysplasia syndromes are associated with neonatal hypocalcemia, which may be severe.

Several common therapeutic interventions can induce hypocalcemia. Bicarbonate therapy, as well as any form of metabolic or respiratory alkalization, decreases both ionized calcium levels and bone resorption of calcium. Blood transfusion or plasmapheresis can promote calcium complexes with the infused citrate, decreasing  $\text{Ca}^{2+}$ . Hypocalcemia after initiation of ECMO is related to composition of the circuit-priming solution and to acute citrate loading and may lead to hemodynamic instability (Meliones et al, 1995). Furosemide therapy promotes calciuresis and nephrolithiasis. Phototherapy for hyperbilirubinemia may be associated with mild hypocalcemia. This effect has been attributed to decreased melatonin secretion, which potentiates glucocorticoid actions on bone metabolism. Lipid infusions may elevate serum FFAs, which form insoluble complexes with calcium. Most of these effects are transient, and cessation of therapy is followed by a return to normal serum calcium levels. The major exception is aggressive furosemide therapy, which when prolonged may lead to bone demineralization and renal dysfunction (Downing et al, 1992).

### Treatment

The decision to treat hypocalcemia in an infant depends on the severity of the hypocalcemia and the presence of clinical signs and symptoms. The morbidity associated with calcium treatment must be weighed against the potential benefits. Hypocalcemic preterm infants who have no symptoms and are not ill from any other cause probably do not need specific treatment. Early neonatal hypocalcemia should resolve by day 3. Some clinicians begin treatment in preterm newborns once serum calcium levels have dropped to 6.0 to 6.5 mg/dL or after  $[\text{Ca}^{2+}]$  has decreased to 2.5 to 3.0 mg/dL. Another reasonable approach is to initiate prophylactic calcium infusions (or calcium-containing parenteral nutrition) for all ELBW infants within the first 24 hours. There is no role for prophylaxis or treatment with pharmacologic doses of vitamin D. For newborns who exhibit cardiovascular compromise (e.g., severe respiratory distress, pulmonary hypertension, asphyxia, sepsis) or who require cardiotoxic drugs or blood pressure support, monitoring blood  $[\text{Ca}^{2+}]$  is particularly helpful, with the aim of preventing the onset of significant hypocalcemia.

The mainstay of treatment for neonatal hypocalcemia is intravenous administration of calcium salts. Calcium gluconate is preferred over calcium chloride (which, in sufficient doses, produces hyperchloremic acidosis) or calcium lactate. A 10% solution of calcium gluconate contains 9.4 mg Ca/mL. A constant infusion of approximately 45 to 75 mg/kg/day usually produces a sustained increase in serum calcium level (7 to 8 mg/dL). Bolus infusions are hazardous and only transiently effective.

The risks associated with calcium infusions can be minimized by attention to detail. Rapid intravenous infusion of calcium can cause sudden elevation in serum calcium, leading to bradyarrhythmias. Bolus infusion of calcium should be reserved for treating hypocalcemic tetany and seizures. Extravasation of calcium solutions into subcutaneous tissues may cause necrosis and subcutaneous calcification. Therefore, meticulous care of peripheral intravenous catheter sites is particularly important when calcium-containing solutions are infused. Inadvertent intrahepatic infusion of calcium through an umbilical vein catheter (due to failure to reach the inferior vena cava) can cause hepatic necrosis. Rapid intra-aortic infusion via an umbilical artery can cause arterial spasm and, at least experimentally, intestinal necrosis.

**Hypocalcemic Crisis.** For emergency treatment of hypocalcemic crisis with seizures, tetany, or apnea, 1 to 2 mL/kg of a 10% solution of calcium gluconate should be administered over 5 to 10 min. The initial serum calcium level may be less than 5.0 mg/dL. Careful observation of the infant and of the infusion site is essential, and the infusion should be discontinued if there is bradycardia or when the desired clinical result is obtained. The intravenous dose of calcium gluconate necessary to stop convulsions is usually 1 to 3 mL/kg. Toxic reactions are avoided if the maximum intravenous dose of calcium gluconate given at any one time does not exceed 2 mL/kg; doses above 3 mL/kg should be administered with caution. If necessary, intravenous calcium therapy may be repeated 3 or 4 times in 24 hours to help control acute symptoms.

**Nonemergency Treatment.** After acute symptoms have been controlled, calcium therapy should be continued as needed to maintain serum calcium above 7.0 mg/dL. In part, the level of serum calcium to be achieved depends on serum total protein, particularly albumin. In hypoalbuminemic infants, lower levels of total serum calcium are normally present. In preterm and sick infants for whom oral intake is limited, 5 to 8 mL/kg of 10% calcium gluconate (45 to 75 mg Ca/kg) may be infused with intravenous fluids over a 24-hour period. The lower dose range is preferred whenever there is hyperphosphatemia. If oral feedings are tolerated, 10% calcium gluconate may be given in the same daily dose divided into 4 to 6 feedings. Alternatively, calcium glubionate (Neo-Calglucon), which contains 23.6 mg Ca/mL, may be given in a dose of 2 mL/kg/day divided into feedings. Oral calcium gluconate is better tolerated by young infants because the high sugar content and osmolality of calcium glubionate may cause gastrointestinal irritation or diarrhea. Intravenous or oral calcium supplements should be continued until the serum calcium level stabilizes.

Dietary factors and hypoparathyroidism are important in the pathogenesis of late neonatal hypocalcemia. Therefore, therapy is often directed at reducing the phosphate load and increasing the calcium-to-phosphorus ratio of feedings to 4:1. This can be accomplished by the use of low-phosphorus feedings such as human milk or Similac PM 60/40 Low Iron in conjunction with calcium supplements. These measures inhibit intestinal absorption of phosphorus. Phosphate binders generally are not necessary. Serum calcium and phosphorus levels should be monitored at least once to twice weekly and the calcium supplements discontinued in a stepwise fashion after several weeks.

**Magnesium Administration.** When hypomagnesemia contributes to (or causes) hypocalcemia, administration of magnesium salts is indicated. Magnesium may be given intramuscularly as a 50% solution of magnesium sulfate (50% MgSO<sub>4</sub> • 7H<sub>2</sub>O contains 4 mEq/mL of magnesium). The suggested intramuscular or intravenous dose of 50% magnesium sulfate is 0.1 to 0.2 mL/kg. Intravenous infusions should be administered slowly using electrocardiographic monitoring to detect acute rhythm disturbances, which may include prolonged atrioventricular conduction time and sinoatrial or atrioventricular block. The magnesium dose may be repeated every 12 to 24 hours, depending on the clinical and serum magnesium response. Serum magnesium levels should be carefully monitored to guard against hypermagnesemia. Many infants with transient hypomagnesemia will respond sufficiently to one or two magnesium injections. Infants with primary hypomagnesemia have permanent magnesium wasting and low serum magnesium levels and require lifelong treatment with magnesium supplements.

**Vitamin D Treatment.** Infants with normal intestinal absorption who develop late hypocalcemia with vitamin D deficiency rickets usually respond within 4 weeks to 1000 to 2000 IU/day of oral vitamin D. These infants should receive at least 40 mg/kg/day of elemental calcium in

order to prevent hypocalcemia because the unmineralized osteoid may avidly incorporate calcium once vitamin D is provided ("hungry bones" syndrome). The PTH-dependent renal production of 1,25(OH)<sub>2</sub>D is deficient in all hypoparathyroid states. Therefore, in persistent congenital hypoparathyroidism, long-term treatment with vitamin D or a shorter-acting vitamin D analogue is indicated.

## Neonatal Hypercalcemia

Hypercalcemia usually is defined as total serum calcium concentration greater than 11.0 mg/dL and [Ca<sup>2+</sup>] greater than 5.0 mg/dL. Neonatal hypercalcemia is found in association with several clinical entities (Table 89–2). It may be asymptomatic and discovered incidentally or may manifest dramatically (especially if serum calcium is 14.0 mg/dL or greater) and be life-threatening, requiring immediate intervention. The clinical findings may include poor feeding, vomiting, constipation, polyuria, hypertension, tachypnea, dyspnea, hypotonia, lethargy, and seizures. Polyuria is due to an impaired renal response to vasopressin (nephrogenic diabetes insipidus) and may lead to dehydration. The hypertension is probably due to a direct vasoconstrictive effect of the elevated ECF calcium as well as to increased activity of the renin-angiotensin system resulting from renal arteriolar constriction. The central nervous manifestations result from

TABLE 89–2

### Causes of Neonatal Hypercalcemia

Iatrogenic (calcium salts)
Parathyroid hyperfunction
Neonatal severe primary hyperparathyroidism (NSPHP)
Ca <sup>2+</sup> -sensing receptor mutation homozygosity
Familial (benign) hypercalcemic hypocalciuria (FBHH)
Ca <sup>2+</sup> -sensing receptor mutation heterozygosity
Neonatal hyperparathyroidism associated with multiple endocrine adenomatosis
Renal tubular acidosis with secondary hyperparathyroidism
Neonatal hyperparathyroidism secondary to maternal hypoparathyroidism
Williams syndrome (elastin gene locus deletions)
Idiopathic infantile hypercalcemia ("Lightwood-type")
Phosphate depletion
Hypervitaminosis D
Vitamin D intoxication
Subcutaneous fat necrosis
Blue diaper syndrome
Hypercalcemia associated with skeletal dysplasias
Infantile hypophosphatasia
Jansen metaphyseal chondrodysplasia (activating mutations of the PTH/PTHrP receptor)
Other causes
Tumor-associated hypercalcemia
Congenital lactase deficiency
Acute adrenal insufficiency
Hypervitaminosis A
Thyrototoxicosis
Prolonged ECMO

ECMO, extracorporeal membrane oxygenation; PTH, parathyroid hormone; PTHrP, parathyroid hormone–related protein.

direct neuronal effects of calcium, hypertensive encephalopathy, and cerebral ischemia. Persistent hypercalcemia may produce extraskelatal calcification in the kidney, skin, subcutaneous tissue, falx cerebri, arteries, myocardium, lung, or gastric mucosa. Nephrocalcinosis, nephrolithiasis, diffuse bone undermineralization (and occasionally osteitis fibrosa) are well-recognized hypercalcemic complications. In infants, the predominant manifestation of chronic, moderate elevations of serum calcium may be failure to thrive. The physical examination usually is otherwise normal, except in those infants with subcutaneous fat necrosis, Williams syndrome, or skeletal dysplasias.

Normally, the parathyroid-renal axis prevents hypercalcemia via inhibition of PTH secretion and  $1,25(\text{OH})_2\text{D}$  synthesis, which reduces calcium absorption from the intestine, mobilization from bone, and reabsorption from the kidney. (The physiologic role of calcitonin is uncertain.) An elevated serum calcium, therefore, indicates that there is inappropriate calcium influx to the ECF from one or more of these pools. Because the kidney is the principal organ for stoichiometric calcium balance, hypercalcemia usually means the renal capacity to excrete calcium has been exceeded. In fact, abnormalities in distal tubular resorption are involved in the pathogenesis of many hypercalcemic conditions (e.g., hyperparathyroidism) and renal impairment frequently accompanies many hypercalcemic syndromes.

### Neonatal Hyperparathyroid Syndromes and Familial Hypocalciuric Hypercalcemia

Neonatal severe primary hyperparathyroidism (NSPHP) is a rare, life-threatening disorder. The enlarged parathyroid glands are resistant to regulation by  $\text{Ca}^{2+}$ , resulting in marked hypercalcemia, although milder clinical expression also occurs. These infants usually appear normal at birth but may have a narrow thorax, depressed sternum, or thoracolumbar kyphosis. Signs of hypercalcemia usually develop during the first days of life. Serum calcium levels may range between 15 and 30 mg/dL, serum phosphorus concentration is frequently less than 3.5 mg/dL with significant hyperphosphaturia, and PTH levels are very elevated. Anemia, hepatomegaly, and splenomegaly have been reported. Skeletal radiographs may show generalized undermineralization, irregular metaphyses (subperiosteal erosions), and multiple pathologic fractures of the long bones and ribs. Nephrocalcinosis is common. The bone findings initially may be mistaken for osteogenesis imperfecta (Bai et al, 1997).

Inheritance studies have long suggested a connection between NSPHP and a milder disease, familial (benign) hypocalciuric hypercalcemia (FBHH) as well as a relationship of both to PTH-independent “resetting” of parathyroid  $\text{Ca}^{2+}$  sensing and renal calcium handling. Sequencing of the parathyroid and renal CaR has clarified these relationships. Partial or total inactivating *CaR* mutations cause increased renal tubular calcium reabsorption (hypercalciuria) and persistent PTH secretion despite hypercalcemia. Homozygosity for inactivating *CaR* mutations causes NSPHP, whereas heterozygosity results in the autosomal dominant FBHH. Addi-

tionally, certain de novo or inherited heterozygous *CaR* mutations account for some cases of NSPHP.

Newborns (and older children and adults) with FBHH have mild (often asymptomatic) and intermittent hypercalcemia without hypercalciuria. In distinction to neonatal hyperparathyroidism, circulating levels of PTH, phosphorus, and  $1,25(\text{OH})_2\text{D}$  tend to be normal. Persons who have FBHH are at risk for having a child with NSPHP. Conversely, parents of an infant with hyperparathyroidism should be screened with serum calcium and phosphorus levels and a urinary UCa/Cr. A UCa/Cr below 0.01 supports the diagnosis. Early diagnosis and parathyroidectomy have been necessary for survival in fulminant NSHPT. However, conservative management may be warranted in less severe cases, which can be self-limiting and are often due to heterozygous *CaR* mutations.

Neonatal hyperparathyroidism occasionally occurs as part of the syndrome of multiple endocrine adenomatosis. There also have been reports of sporadic and familial forms of renal tubular acidosis with secondary hyperparathyroidism manifesting as hyperchloremia, hypercalcemia, elevated serum PTH, and severe metabolic acidosis (Nishiyama et al, 1990; Savani et al, 1993). Serum calcium and PTH may promptly revert to normal values after initiation of alkali therapy. Often, the acidification defect is transient (Igarashi, 1992). As the hyperparathyroidism and ECF volume contraction are corrected, serum calcium normalizes.

### Neonatal Hyperparathyroidism Associated with Maternal Hypoparathyroidism

Fetal and neonatal hyperparathyroidism may occur in infants born to mothers with poorly controlled (hypocalcemic) hypoparathyroidism. Maternal hypocalcemia leads to impaired transplacental calcium transfer and causes chronic stimulation of the fetal parathyroid glands. In contrast with infants with NSPHP, these newborns are frequently of low birth weight and have depressed or normal (rather than elevated) serum calcium levels and normal to mildly elevated (rather than depressed) serum phosphorus levels. The reasons for these differences between the two groups are unknown.

Mortality rates are high in infants born to poorly or untreated hyperparathyroid mothers, especially if there is significant IUGR. In survivors, the skeletal abnormalities usually regress and bone radiographs normalize by 4 to 7 months. Correction of hypocalcemia in hypoparathyroid women during pregnancy using calcium and vitamin D supplements prevents the development of fetal hyperparathyroidism.

### Williams Syndrome and Idiopathic Infantile Hypercalcemia

Williams syndrome (WS) (or Williams-Beuren syndrome) is an autosomal dominant disorder that, in fully expressed form, includes transient hypercalcemia in infancy, supra-aortic stenosis, multiple peripheral pulmonary arterial stenoses, “elfin” facies, mental and height deficiency, and dental malformations. The typical facial features include supraorbital fullness with a broad forehead,

short palpebral fissures with a medial flare to the eyebrows, a flat nasal bridge with a full tip and anteverted nostrils, ocular hypertelorism, strabismus, stellate iris, malar hypoplasia with a wide mouth and a full lower lip, and hypoplastic teeth with malocclusion. Hallux valgus with a small curved fifth digit is common. Pectus excavatum and umbilical or inguinal hernia are less commonly noted.

Two thirds of newborns with WS are small for gestational age, and many are born post-dates. The frequency of WS is estimated to be about 1/10,000 to 1/20,000. Hemizygoty for elastin gene mutations and deletions are responsible, at least in part, for the manifestations. WS often results from a contiguous gene deletion in which up to 2.5 Mb of genomic DNA distal to the elastin gene locus may be missing (Urban et al, 1996). Deletion of several specific genes in the WS region (7q11.23) appears to account for the distinct physiognomic and cognitive features. Expression of the full WS phenotype may be related to the size of the deletion. FISH for the detection of elastin locus deletions is the appropriate initial diagnostic assay.

Although the hypercalcemia is often diagnosed after the first month, the child with WS sometimes comes to clinical attention in the neonatal period (Shimizu et al, 1994). Heightened awareness of the syndrome should increase the frequency of neonatal diagnosis. The hypercalcemia rarely persists beyond several months and generally resolves spontaneously, but hypercalciuria may persist. The pathogenesis of hypercalcemia in WS remains unknown. Elevated serum calcium associated with normal or increased serum phosphorus levels and characteristic radiographic findings differentiate WS from primary hyperparathyroidism. In some older infants, the serum calcium level is normal, but the presence of nephrocalcinosis and other soft tissue calcifications suggests that hypercalcemia occurred earlier. Increased calcium absorption has been demonstrated, but enhanced vitamin D sensitivity or other disorders of specific calcitropic hormones have not been consistently found. A cautionary note is that many of these children were studied after their hypercalcemia had resolved. A low-calcium diet usually controls the hypercalcemia.

In the early 1950s in England, Lightwood (1952) reported a series of infants with severe hypercalcemia. Hypervitaminosis D was suggested by the findings of osteoporosis and dense bands of mineralization at the metaphyseal ends of long bones. Epidemiologic investigations revealed that a majority of these infants were born to mothers who ingested foods heavily fortified with vitamin D. Some infants also had received 3000 to 4000 IU of vitamin D daily in an effort to prevent nutritional deficiencies. With reduction of vitamin D supplementation, the incidence of infantile hypercalcemia has declined dramatically. However, in other instances, no known previous exposure to excessive maternal vitamin D intake has occurred. The incidence of this milder (Lightwood-type) "idiopathic" infantile hypercalcemia (IIH) without WS phenotypic features has remained relatively fixed over time. Further distinction between these conditions probably awaits more extensive genetic analysis and definition of the mineral metabolic derangement(s). In contrast with

those in WS, serum calcium levels remain elevated for a prolonged period in severely affected infants with IIH. There may be an exaggerated increase in serum  $1,25(\text{OH})_2\text{D}$  in response to exogenous PTH administration (Pronicka et al, 1988). Therefore, in addition to dietary calcium restriction and avoidance of vitamin D, glucocorticoid therapy to reduce gastrointestinal calcium absorption is sometimes warranted.

### Neonatal Hypercalcemia Associated with Subcutaneous Fat Necrosis

Hypercalcemia is an occasional, severe complication of subcutaneous fat necrosis in newborns. The erythematous to violaceous, indurated subcutaneous nodules and plaques often overlie bony prominences on the buttocks, thighs, trunk, cheeks, or arms and may appear up to several weeks after delivery. The lesions may resemble those of sclerema neonatorum. Frequently, there is a history of difficult delivery, trauma, hypothermia, or asphyxia. Hypercalcemic infants may present with poor weight gain despite adequate energy intake or with nephrocalcinosis. Hypercalcemia should be sought for in all infants with subcutaneous fat necrosis. Laboratory evaluation shows high blood  $1,25(\text{OH})_2\text{D}$  levels and usually normal phosphorus and alkaline phosphatase. Radiographs of the long bones also are usually normal, although periosteal elevation, features similar to those of WS, or ectopic calcification may be present. Skin and subcutaneous tissue punch biopsy specimens show lobular panniculitis with necrotic adipocytes, abundant histiocytes, and giant cells with radial crystals. Distinctive, needle-shaped clefts in the fat lobules are pathognomonic findings (Hicks et al, 1993). Magnetic resonance imaging (MRI) may point to the correct diagnosis without biopsy.

Unregulated production of  $1,25(\text{OH})_2\text{D}$  by activated macrophages induces hypercalcemia (Kruse et al, 1993) similar to the hypercalcemia encountered in sarcoidosis and other granulomatous diseases. Lesion prostaglandin E release also may contribute to hypercalcemia and osteoclastic bone resorption. Hypercalcemia associated with subcutaneous fat necrosis may persist for days to weeks. Prognosis depends on its duration. Treatment consists of glucocorticoids, intravascular volume expansion, furosemide diuresis, and a low-calcium, low-vitamin D diet.

### Blue Diaper Syndrome

Blue diaper syndrome is a rare familial disease in which hypercalcemia and nephrocalcinosis are associated with a defect in the intestinal transport of tryptophan (Drummond et al, 1964). Bacterial degradation of tryptophan in the intestine leads to excessive indole production, which is converted to indican in the liver. Oxidative conjugation of indican in the urine forms the water-insoluble dye indigo blue (indigotin), with a consequent peculiar bluish discoloration of the diaper. The clinical course is characterized by failure to thrive, recurrent unexplained fever, infections, marked irritability, and constipation. The mechanism of the hypercalcemia is uncertain, although oral tryptophan loading in human subjects and experimental

animals also elevates serum calcium. Treatment consists of glucocorticoids and a low-calcium, low-vitamin D diet.

### **Hypercalcemia Associated with Skeletal Dysplasias**

Several skeletal dysplasia syndromes are associated with hypercalcemia. Their distinctive phenotypes suggest appropriate diagnosis.

Hypophosphatasia is a rare autosomal recessive condition caused by deficiency of tissue-nonspecific alkaline phosphatase. The perinatal and early infantile onsets are characterized by defective bone mineralization. Prominent features are craniosynostosis, severe rickets, and hypercalcemia. More than 50% of patients with the infantile form have not survived the first year. Attempts to control the hypercalcemia, hypercalciuria, and chronic bone demineralization using chlorothiazide, calcitonin, and bisphosphonates have been disappointing (Deeb et al, 2000).

Jansen metaphyseal chondrodysplasia manifests in newborns with hypercalcemia and skeletal radiographs that mimic rachitic changes. This severe autosomal recessive disorder results from gain-of-function mutations in the PTH/PTHrP receptor leading to ligand-independent receptor activation (Schipani et al, 1996). PTH and PTHrP levels are low or undetectable. The functional consequences are premature chondrocyte maturation, accelerated endochondral bone formation, and hypercalcemia.

### **Hypercalcemia Associated with Phosphate Depletion**

Neonatal hypercalcemia due to phosphate depletion is most often seen in very-low-birth-weight (VLBW) infants who are fed unsupplemented human milk. The low phosphate content of human milk leads to hypophosphatemia, which stimulates renal 1,25(OH)<sub>2</sub>D synthesis, leading to increased intestinal calcium absorption. When phosphate is limited, little calcium can be deposited in bone, leading to rickets, hypercalcemia, and hypercalciuria. Extremely high serum calcium levels (greater than 15 mg/dL, with serum phosphorus less than 2 mg/dL and suppressed PTH) may be observed in VLBW infants in this setting. These infants respond to cautious phosphate replenishment. The condition is preventable by anticipatory monitoring of serum calcium and phosphorus levels in high-risk infants. Hypophosphatemic bone disease in VLBW infants is discussed later (see section “Osteopathy of Prematurity”).

### **Vitamin D Toxicity**

Excessive supplementation with vitamin D will cause hypercalcemia in newborns and infants. In preterm infants, prolonged feeding with premature formula (Nako et al, 1993) or mineral- and vitamin D-supplemented human milk fortifiers also has led to mild to significant hypercalcemia. Infants respond to discontinuation of vitamin D supplements. These occurrences have prompted vitamin reformulation of premature nutritional products.

Laboratory studies of hypervitaminosis D typically show elevation of 25(OH)D but not of 1,25(OH)<sub>2</sub>D. Serum PTH usually is suppressed by the hypercalcemia. Biochemical resolution may be protracted because vitamin D accumulates in body fat.

### **Other Causes of Neonatal Hypercalcemia**

Hypervitaminosis A and thyrotoxicosis also accelerate bone turnover and can induce hypercalcemia. Tumor-associated hypercalcemia in neonates is extremely rare. Most cases have been associated with congenital mesoblastic nephroma, the most common renal tumor of early infancy. Congenital lactase deficiency is associated with rapid onset of hypercalcemia, hypercalciuria, and medullary nephrocalcinosis (Saarela et al, 1995). The calcium derangements are well managed by a lactose-free diet. Modest hypercalcemia may occur in acute adrenal insufficiency. The pathogenesis is uncertain. Iatrogenic hypercalcemia may be induced, especially in VLBW infants, by administration of parenteral calcium supplementation in association with indomethacin treatment for patent ductus arteriosus (Rodd and Goodyer, 1999). Prolonged ECMO support has been associated with hypercalcemia (greater than 11 mg/dL) in some infants (Fridriksson et al, 2001). The cause is not known.

### **Treatment**

The first principle in the medical management of hypercalcemia is to increase the urinary calcium excretion by maximizing glomerular filtration rate (GFR) and urinary sodium excretion. In the normal kidney, sodium and calcium clearances are very closely linked during water or osmotic diuresis. Two-thirds normal to isotonic saline containing 20 to 30 mEq of potassium chloride per liter may be infused intravenously at a rate to correct dehydration and maximize GFR. After rehydration, furosemide (1 mg/kg) may be given intravenously at 6- to 8-hour intervals to inhibit tubular reabsorption of calcium.

When severe hypercalcemia is associated with hypophosphatemia, 30 to 50 mg/kg/day of oral or intravenous phosphorus as a phosphate salt may be given. Unlike sodium, phosphate does not remove calcium from the body but causes a redistribution of calcium. The goal of phosphate therapy is to maintain serum phosphorus levels in a range of 3 to 5 mg/dL. The oral route is preferable because of the potential for serious complications with intravenous phosphate treatment. Therapy usually results in a significant reduction in serum calcium concentration over 1 to 2 days. In more severe and resistant cases, glucocorticoids (e.g., prednisone, 2 mg/kg per day) may be added. Glucocorticoids suppress intestinal calcium absorption and increase renal excretion. Although glucocorticoids are effective in several types of hypercalcemia, they are relatively ineffective for the treatment of hypercalcemia associated with primary hyperparathyroidism. Experience with use of other antihypercalcemic agents (e.g., calcitonin or bisphosphonates) is limited in newborns.

The mainstays of the nonacute treatment of milder neonatal hypercalcemia are restriction of dietary calcium, elimination of vitamin D supplements, and limiting sunlight exposure.

### Neonatal Disorders of Serum Magnesium

Neonatal hypomagnesemia is discussed in a preceding section, “Neonatal Hypocalcemia Associated with Hypomagnesemia or Renal Tubular Necrosis.”

Neonatal hypermagnesemia usually is due to maternal magnesium sulfate administration for preeclamptic seizure prophylaxis or for tocolysis of premature uterine contractions. Later-onset neonatal hypermagnesemia can result from use of magnesium hydroxide-containing antacids (“milk of magnesia”). The hypermagnesemic newborn may exhibit varying degrees of flaccidity, unresponsiveness, respiratory insufficiency and apnea, ileus, or delayed passage of meconium. The signs may be mistaken for those of perinatal asphyxia. Occasionally, temporizing endotracheal intubation and mechanical ventilation are required. Feedings should be deferred until normalization of bowel function occurs. Prolonged fetal hypermagnesemia also increases the risk of meconium obstruction. Aside from this latter possibility, the neonatal effects of hypermagnesemia appear to be transient and usually disappear within several hours. Generally, newborns effectively excrete a magnesium load, and serial monitoring of serum levels usually is not necessary. However, in preterm newborns, who have limited renal excretory capacity for magnesium, hypermagnesemia may persist for more than 48 hours. No magnesium should be added to parenteral nutrition solutions until serum magnesium falls. Early hypermagnesemia in preterm infants also may suppress PTH secretion (Rantonen et al, 2001). Infusion of calcium salts may antagonize some of the adverse effects of excess magnesium.

### METABOLIC BONE DISEASE IN NEWBORNS AND INFANTS

Forms of metabolic bone disease manifesting in infants and children are listed in Table 89-3. The following definitions are presented as a background for the discussions of specific entities in this section.

*Osteopenia* is defined as radiographic evidence of diminished bone density. Osteopenia is present in rickets, osteomalacia, and osteoporosis.

*Rickets* is a disorder of the bone matrix, or osteoid, in growing bone resulting from undermineralization of cartilage; it involves both the growth plate (physis) and newly formed trabecular and cortical bone. In infancy, the most rapidly growing bones are the skull, upper limbs, and ribs. Early development of rickets, therefore, leads to craniotabes (“Ping-Pong ball” sign), widened cranial sutures, frontal bossing, swollen epiphyses of the wrists, costochondral beading (“rachitic rosary”), and Harrison’s sulcus (caused by diaphragmatic depression of the lower thorax on inspiration). There is an increased risk of pneumonia. Manifestations of muscle weakness (myopathy) may include dilated cardiomyopathy and ventricular dysfunction, which respond to vitamin D therapy (Mustafa et al, 1999). The radiographic features in rickets reflect expansion of the cartilaginous growth plate and delayed mineralization and include lucency and widening of the gap between metaphysis and epiphysis (the zone of provisional calcification); irregularity, cupping, or fraying of the metaphyseal margin; and

TABLE 89-3

#### Forms of Metabolic Bone Disease Manifesting in Newborns and Infants

Vitamin D deficiency
Maternal vitamin D deficiency (congenital rickets)
Inadequate intake of dietary vitamin D
Lack of adequate sunlight exposure + dietary inadequacy
Vitamin D malabsorption
Hepatic disease (steatorrhea)
Short gut syndrome
Pancreatic insufficiency
Vitamin D metabolic defects
Hepatic rickets (inadequate vitamin D 25-hydroxylation)
Vitamin D–dependent rickets (VDDR1)—defects in 1 $\alpha$ -hydroxylation
Renal insufficiency (renal osteodystrophy)
Antoconvulsants (increased 25(OH)D metabolism)
Vitamin D receptor defects
Vitamin D–resistant rickets (VDRRII)
Phosphate deficiency rickets
Osteopathy of prematurity
X-linked hypophosphatemic rickets
Fanconi syndrome
Antacid-induced osteopathy (aluminum hydroxide)
Tumor (including hemangioma)-associated rickets
Calcium deficiency rickets
Osteopathy of prematurity
Inadequate intake of dietary calcium after weaning
Inadequate calcium in TPN solution

25(OH)D, 25-hydroxyvitamin D; TPN, total parenteral nutrition.

osteopenia. Serum phosphorus or serum calcium or both characteristically are depressed, and serum alkaline phosphatase is elevated. An exception is the hyperphosphatemia of renal osteodystrophy.

*Osteomalacia* is rickets that occurs in the absence of linear growth. This is the typical pattern in adults, but it also can occur in poorly nourished preterm infants. In osteomalacia, the radiographic features of rickets at the cartilage-shaft junction are generally absent.

*Osteoporosis* in adults is defined as a state of reduced bone mass per unit volume with a normal ratio of mineral to matrix. Unlike in rickets and osteomalacia, where mineralization defects predominate, the primary abnormality in osteoporosis is either a decrease in matrix formation or an increase in matrix and mineral resorption. There is no generally accepted pediatric definition for osteoporosis (Rauch and Schoenau, 2002).

### Osteopathy of Prematurity

In preterm infants, osteopenia with or without rachitic changes at the cartilage-shaft junction may be observed between 3 and 12 weeks of age. This metabolic bone disorder has also been called “rickets of prematurity” and “osteopenia of prematurity.” Its incidence and severity increase with decreasing gestation and birth weight and it is more common in preterm infants with a complicated medical course and delayed nutrition. On the other hand,

osteopathy usually is not a problem for healthier, larger preterm infants. In osteopathic VLBW babies, postnatal bone mineralization lags significantly behind the expected intrauterine bone mineralization rate. The pathogenesis of this disorder is increased endosteal resorption rather than decreased bone formation; that is, it is a high-turnover osteopathy (Beyers et al, 1994).

The clinical findings in VLBW infants with severe osteopathy, as in older, term infants with rickets, include a widened anterior fontanel, craniotabes, bony expansion of the wrists, costochondral beading, and rib or long bone fractures. Undermineralization, softening, or fractures of the ribs can lead to respiratory distress (especially tachypnea), atelectasis, or pneumonia. In most premature infants, osteopathy is self-limiting. However, long-term effects of osteopathy of prematurity may include delayed dental maturation (Seow, 1996) and reduced stature into school age (Fewtrell et al, 2000). Bone mineral content later in childhood for these preterm newborns also is influenced by polymorphisms in multiple bone regulatory genes (Backstrom et al, 2001).

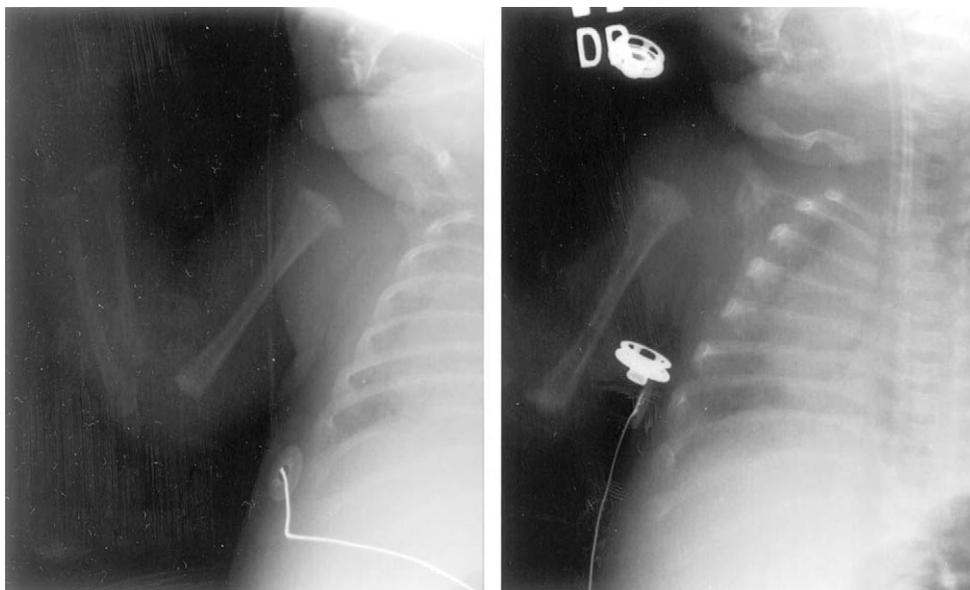

Although the clinical features of nutritional rickets in term infants and osteopathy of prematurity are similar, the latter has a distinctive pathogenesis. Preterm osteopathy is caused chiefly by deficiencies in dietary phosphate and calcium, rather than by vitamin D deficiency. Eighty percent of bone mineralization in the fetus occurs during the third trimester, when fetal calcium and phosphorus requirements are at least 100 to 120 mg/kg/day and 60 to 75 mg/kg/day, respectively. Diets particularly low in mineral (and especially phosphorus) content predispose preterm infants to osteopathy. The greatest risks for phosphate deficiency result from feeding unsupplemented human milk or milk formulas not designed for use in preterm infants and from prolonged parenteral nutrition.

Typically, neither hyperparathyroidism nor vitamin D deficiency is present in phosphate-deficient osteopathy of prematurity. In contrast, the pathogenesis of calcium deficiency rickets and that of vitamin D deficiency are similar

in that hypocalcemia causes hyperparathyroidism. The elevated PTH increases bone resorption and enhances renal  $1,25(\text{OH})_2\text{D}$  synthesis, which in turn increases intestinal calcium and phosphorus absorption. Individual preterm babies may exhibit predominantly phosphate depletion, but mixed phosphate and calcium deficiency is more common; isolated calcium deficiency is rare. In dual mineral deficiency, laboratory values may show low, normal, or slightly elevated serum calcium and low to low-normal phosphorus. In severe or complicated bone disease, serum  $25(\text{OH})\text{D}$  is a useful screen for evaluating the sufficiency of vitamin D stores; levels less than 6 ng/mL indicate severe vitamin D deficiency. For evaluating bone mineral status in preterm neonates, measurement of cortical thickness and visual inspection of the humerus on a chest radiograph probably constitute the simplest and best method (Fig. 89-2).

Serum alkaline phosphatase, a marker of osteoblastic bone formation, is frequently used to monitor skeletal metabolism in preterm infants. However, the magnitude of elevations in alkaline phosphatase (or osteocalcin) concentrations is not a good predictor of the extent of the bone mineral deficits (Ryan et al, 1993; Pittard et al, 1992). Serial urinary biochemical markers of bone metabolism (e.g., pyridinoline, deoxypyridinoline) have not yet been useful in predicting severe osteopathy, because levels are related to bone volume and normative data for growing preterm infants are lacking. Longitudinal assessment of bone mineral content by dual x-ray absorptiometry (DXA) or quantitative ultrasonography is not widely available.

Phosphate depletion and rickets occur in rapidly growing preterm infants fed unsupplemented human milk, which has low phosphate content. Characteristically, these infants develop hypophosphatemia, hypophosphaturia, hypercalcemia, and hypercalciuria. Serum PTH may be low or normal,  $25(\text{OH})\text{D}$  is normal, and  $1,25(\text{OH})_2\text{D}$  is elevated. The hypophosphatemia stimulates the production of  $1,25(\text{OH})_2\text{D}$ , which in turn increases intestinal calcium

**FIGURE 89-2.** Chest radiographs from a 700-g-birth-weight, 25-week-gestation infant with bronchopulmonary dysplasia and osteopathy of prematurity. **Left panel,** At 34 weeks of postconceptional age, mild osteopenia and metaphyseal changes (especially in right arm and wrist) are evident. **Right panel,** Two weeks later, signs of rachitic healing can be seen in ribs and long bones.

absorption. However, in the presence of hypophosphatemia, only limited amounts of calcium can be deposited in bone, leading to hypercalcemia and hypercalciuria. The hypercalcemia inhibits PTH secretion.

This form of rickets does not respond to vitamin D therapy. In fact, vitamin D supplementation without prior correction of the underlying dietary phosphate deficiency may aggravate the hypercalcemia and hypercalciuria by enhancing intestinal calcium absorption. The bone disease in these infants does respond to increased dietary phosphate, accomplished by adding a human milk supplement designed for preterm infants or switching to a preterm milk formula; both diets provide additional calcium as well as phosphorus. Addition of 20 to 25 mg/kg/day of potassium phosphate also will increase serum phosphorus levels. However, because phosphate repletion promotes bone mineralization, serum calcium may fall to subnormal levels (“hungry bones” syndrome) unless supplemental calcium (e.g., 30 mg/kg/day) also is provided. Recommended intakes of calcium and phosphorus (Atkinson, 1994; Schanler and Rifka, 1994) allow normalized bone growth and mineralization in preterm infants. For VLBW infants, it is important to maintain a mineral-enriched diet and to perform serial laboratory monitoring for several weeks to months after hospital discharge.

Human milk has a total antirachitic sterol activity of only 25 to 50 IU/L (Reeve et al, 1982), which may be insufficient for maintaining normal 25(OH)D levels in preterm infants. Therefore, preterm infants fed unsupplemented human milk also should receive 400 to 600 IU daily of vitamin D. There is no apparent benefit for additional vitamin D intake for VLBW infants who are receiving standard high-calcium, high-phosphorus preterm infant formulas.

Additional, non-nutritional risk factors for osteopathy in ill preterm infants are the early withdrawal of placental estradiol and progesterone (Trotter et al, 1999), lack of mobility (Moyer-Mileur et al, 2000), and therapy with dexamethasone (Kamitsuka et al, 1995), methylxanthines (Zanardo et al, 1995), or aminoglycosides (Giapros et al, 1995), any of which can increase urinary calcium excretion and contribute to serum mineral imbalance, nephrocalcinosis, and osteopenia. The importance of mechanical stimulation in preterm infants and term newborns with muscle weakness or paralysis is gaining better appreciation in neonatology. Glucocorticoids decrease bone formation by inhibiting osteoblast growth and increasing cell death of osteoblasts and osteocytes (Ng et al, 2002; Weinstein et al, 1998) and, at least over several months, increase osteoclastogenesis and bone resorption. Copper deficiency is a rare contributor to osteopenia in preterm infants (Tanaka et al, 1980).

### Nutritional (Vitamin D Deficiency) Rickets

In North America, Europe, and northern Asia, rickets most often occurs in exclusively breast-fed infants who also have little exposure to sunlight. Historically, a marked rise in prevalence in nutritional rickets has accompanied industrialization and urban crowding. Clinical rickets often manifests at 4 months of age or later, but onset in

early infancy is not uncommon. In the United States, there has been a recent apparent increase in the incidence of nutritional rickets. Because deeply dark-skinned infants who are breast-fed or are not exposed much to sunlight are at greatest risk, vitamin D supplementation for these babies is warranted (Kreiter et al, 2000; Shaw and Pal, 2002). Recent data also suggest vitamin D supplementation of breast-fed infant girls during the first year of life increases bone mineral mass in later childhood (Zamora et al, 1999). This author and others (Welch et al, 2000) advocate a simple approach of universal vitamin D supplementation for all breast-fed babies. Stoss therapy, which occasionally is used to treat rickets, consists of a single intramuscular large dose (150,000 to 500,000 IU) of vitamin D.

In tropical areas, the daily requirements for vitamin D usually are met by skin exposure to sunlight, and vitamin D deficiency rickets is less common. Instead, recent reports suggest dietary insufficiency of calcium contributes to the development of rickets in Africa and Asia. As a consequence, in tropical populations, rickets usually occurs later than at higher latitudes, between 1 and 2 years of age, after weaning and with introduction of a low-calcium diet.

Congenital rickets should always prompt an investigation for maternal vitamin D deficiency. Rickets, hypercalciuria, and hypophosphatemia also occur in Fanconi renotubular syndrome. Prolonged treatment with aluminum-containing antacids can induce hypophosphatemia and rickets (Pattaragarn and Alon, 2001). These antacids should be avoided or used with caution during infancy.

### Renal Osteodystrophy

Because normal renal function is essential for physiologic mineral and bone metabolism, renal insufficiency induces hyperphosphatemia and bone disease. Renal osteodystrophy can be predominantly a high- or low-bone-turnover form, or the two forms may alternate predominance during the clinical course in an individual infant. High bone turnover or osteitis fibrosa is a manifestation of secondary hyperparathyroidism. Parathyroid hyperfunction often occurs early in the course of renal failure. Contributing factors include phosphate retention, impaired renal 1,25(OH)<sub>2</sub>D synthesis, hypocalcemia, parathyroid gland hyperplasia, and skeletal resistance to PTH actions. Low-turnover osteodystrophy (adynamic bone or osteomalacia) results from suppressed bone formation; in older children and adults, it is more common among dialyzed patients. The relative incidences of these forms of renal osteodystrophy in newborns are not known.

A principal goal of therapy is to lower serum phosphate, in order to prevent hypocalcemia and severe hyperparathyroidism. Phosphate restriction is accomplished with feeding breast milk or Similac PM 60/40. Hypocalcemia and metabolic acidosis should be treated with appropriate supplements. If serum 1,25(OH)<sub>2</sub>D is low, 1,25(OH)<sub>2</sub>D therapy will increase intestinal calcium absorption, transcriptionally suppress *PTH* gene expression, and decrease parathyroid hyperplasia. Serum calcium, phosphorus, and PTH levels, as well as linear

growth and bone radiographs, should be serially monitored. Management of severe renal osteodystrophy in neonates is particularly complicated by the increased phosphate requirements for growth. Calcium supplementation and use of potent vitamin D metabolites also may produce an “oversuppression” of PTH. As with any complex disorder, effective clinical management requires close monitoring and an integrated team approach.

### Inherited Metabolic Bone Disease in Infancy

Three major forms of metabolic bone disease or rickets have been described that can present in newborns and infants. Vitamin D–dependent rickets (VDDR1), also called vitamin D pseudodeficiency or Prader-type rickets, is caused by mutations in the vitamin D 1 $\alpha$ -hydroxylase gene. This autosomal recessive disorder is most common in French Canadian kindreds. Muscle weakness and rickets appear shortly after birth. Treatment with 1 $\alpha$ -hydroxylated vitamin D analogues induces remission.

The autosomal recessive form of 1,25(OH)<sub>2</sub>D-resistant rickets (VDRRII) is caused by a wide range of mutations in the vitamin D receptor (VDR). Affected infants show early-onset rickets, hypocalcemia, elevated serum 1,25(OH)<sub>2</sub>D levels, secondary hyperparathyroidism, and often alopecia. Depending on the genotype, there is a variable response to supraphysiologic doses of 1,25(OH)<sub>2</sub>D analogues.

X-linked dominant hypophosphatemia (XLH), also known as familial hypophosphatemic rickets or vitamin D–resistant rickets, is a disorder of phosphate homeostasis. Its prevalence is 1/20,000. XLH is characterized by poor linear growth, rickets, and hypophosphatemia associated with a low TmP and renal tubular phosphate leak. Defective regulation of vitamin D metabolism results in inappropriately normal 1,25(OH)<sub>2</sub>D concentrations in the face of hypophosphatemia. The responsible gene is designated *PHEX* (“phosphate-regulating gene with homology to endopeptidases on the X chromosome”). The role that *PHEX* plays in the pathophysiology of XLH and renal phosphate transport currently is unresolved.

Neonatal rickets with increased bone density rather than osteopenia can occur in infantile osteopetrosis, a rare autosomal recessive disorder of osteoclast formation. Diagnosis may be obscured by concurrent maternal vitamin D deficiency (Popp et al, 2000).

## Disorders of the Adrenal Gland

Kathleen E. Bethin and Louis J. Muglia

Normal adrenal function is critically important for maintenance of intrauterine homeostasis, promotion of organ maturation, and adaptation to extrauterine life. As further testimony to the importance of the adrenal in perinatal adaptation, in some species, fetal glucocorticoid production serves as the trigger for parturition (Challis and Lye, 1994; Gross et al, 2000). Failure to recognize adrenal disease in the newborn, analogous to adrenal insufficiency in adults, has dire, often life-threatening consequences.

The mature adrenal consists of cortical steroidogenic cells and medullary chromaffin catecholamine-producing cells. The catecholamine-producing cells of the adrenal medulla arise from neural crest cells that migrate during intrauterine development from their paraspinal site of origin into the primitive adrenocortical condensation and serve as an endocrine arm of the sympathetic nervous system. This chapter focuses on the development, function, and pathophysiology of the steroidogenic adrenal cortex.

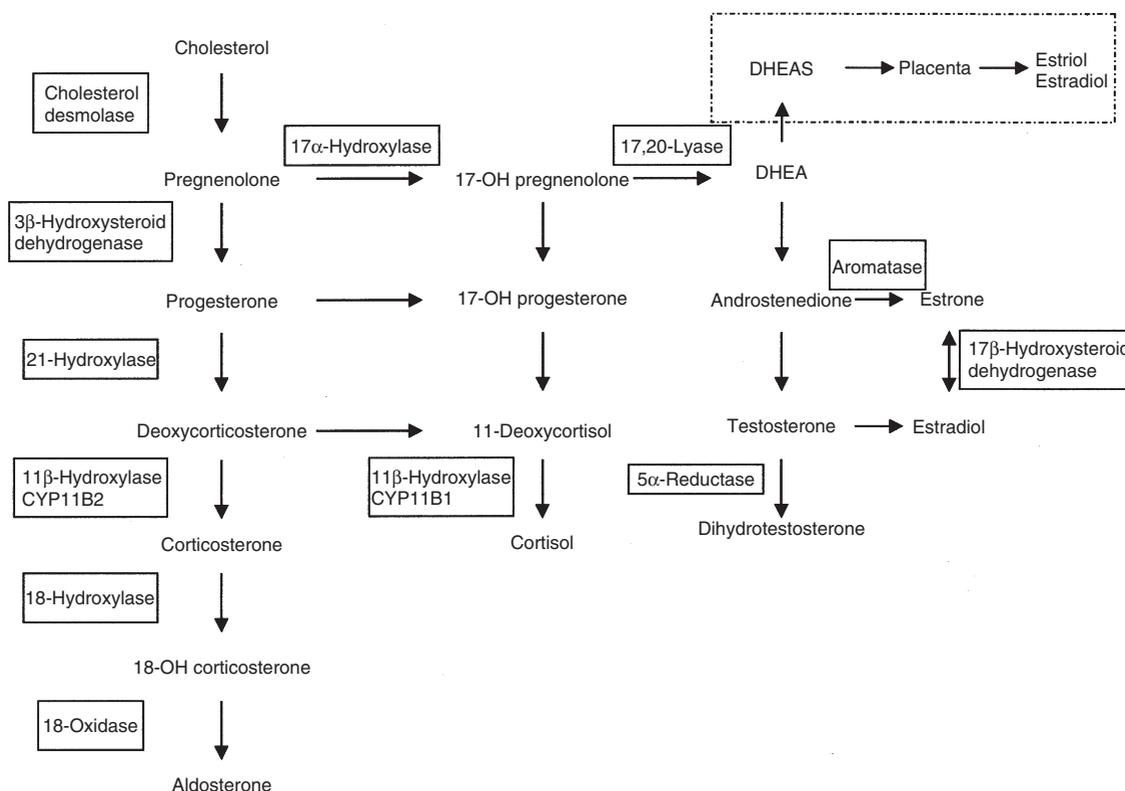

In the neonate, as in the adult, the adrenal cortex produces glucocorticoids and mineralocorticoids as its primary functional products. The fetal adrenal additionally must generate copious amounts of dehydroepiandrosterone sulfate (DHEAS) to serve as a substrate for placental estradiol and estriol production during pregnancy (Mesiano and Jaffe, 1997). The mammalian adrenal has accomplished the ability to preferentially produce a given steroid as its main product by the presence or absence of steroidogenic enzymes in discrete compartments. The DHEAS-producing fetal cortex lacks  $3\beta$ -hydroxysteroid dehydrogenase (Mesiano and Jaffe, 1997); the aldosterone-producing zona glomerulosa of the adult cortex lacks 17-hydroxylase but produces a unique form of 11-hydroxylase that also possesses aldosterone synthase activity (White et al, 1994); and the glucocorticoid-producing zona fasciculata of the adult cortex lacks aldosterone synthase activity but produces 17-hydroxylase/17,20-lyase for generation of glucocorticoids and androgens, respectively (Fig. 90–1). The zona reticularis does not appear as a discrete histologic region of the adrenal until the middle of the first decade of life and is associated with increased adrenal androgen production (adrenarche).

Cortisol and aldosterone, the primary glucocorticoid and mineralocorticoid, respectively, in humans, modulate cellular function by interaction with high affinity receptors located in the cytoplasm in the non-ligand-bound state (Truss and Beato, 1993). Products of two different genes exhibit high-affinity glucocorticoid binding: the mineralo-

corticoid (type I) receptor and the glucocorticoid (type II) receptor. When ligand is bound, the receptor undergoes a conformational change such that the chaperone proteins that normally mask the receptor's nuclear translocation sequence are exposed, allowing dimerization and subsequent entry into the nucleus, where specific genes are either activated or repressed by a variety of recently elucidated mechanisms (Collingwood et al, 1999). Primary adrenal insufficiency often combines defects in mineralocorticoid and glucocorticoid production and subsequent actions through their receptors in target tissues. Defects in mineralocorticoid action may result in dramatic salt-wasting crises in the first week of life; isolated glucocorticoid deficiency as occurs in secondary and tertiary hypoadrenalism (defects of the pituitary and hypothalamus, respectively) causes substantial morbidity as well. Glucocorticoids regulate carbohydrate metabolism (Van Cauter et al, 1992), free water excretion (Green et al, 1970), vascular tone (Munck and Guyre, 1984), and the inflammatory response (Chrousos, 1995), although the essential actions of glucocorticoids remain uncertain. Recent studies in mice deficient in the glucocorticoid receptor (Cole et al, 1995) or corticotropin-releasing hormone (CRH) (Muglia et al, 1995; Muglia et al, 1999) have demonstrated an essential role for glucocorticoids in promoting lung maturation. Of interest, CRH-deficient offspring of heterozygous parents survive normally, but CRH-deficient offspring of CRH-deficient parents die on the first day of life due to abnormal lung development. The placenta possesses a significant amount of  $11\beta$ -hydroxysteroid dehydrogenase and is capable of metabolizing glucocorticoid to inactive products (Pepe and Albrecht, 1990). The findings in CRH-deficient mice, however, implicate the ability of maternal glucocorticoid to cross the placenta and maintain appropriate tissue maturation if the fetus is glucocorticoid deficient and may explain why infants with congenital adrenal hyperplasia (CAH) or other states of inadequate glucocorticoid production do not exhibit overt pulmonary insufficiency.

### CONTROL OF GLUCOCORTICOID AND MINERALOCORTICOID PRODUCTION

Two distinct regulatory circuits control adrenal glucocorticoid and mineralocorticoid secretion. The hypothalamic-pituitary-adrenal (HPA) axis determines the set point for circulating glucocorticoid (cortisol) concentration. The neuropeptide corticotropin-releasing hormone (CRH) and arginine vasopressin are synthesized in the hypothalamic paraventricular nucleus and released into the hypophysial portal circulation at the median eminence in response to stress (Aguilera, 1994) and, beginning at approximately 6 months of age (Onishi et al, 1983), to circadian cues. These neuropeptides stimulate release of adrenocorticotropin—adrenocorticotrophic hormone (ACTH)—from anterior pituitary corticotrophs. ACTH released into the systemic circulation augments adrenocortical secretion of DHEAS and cortisol by acting on the ACTH receptor (Clark and Cammas, 1996), a member of the melanocortin receptor family. The ACTH receptor is present on

**FIGURE 90-1.** Steroid biosynthetic pathways. The synthesis of cortisol, aldosterone, testosterone, and estrogen from cholesterol is shown. The enzymes that catalyze the reactions are indicated in boxes. The dashed box outlines the pathway of estriol and estradiol synthesis by the placenta from dehydroepiandrosterone sulfate (DHEAS) produced by the fetal adrenal. DHEA, dehydroepiandrosterone.

steroidogenic cells of the fetal zone and transitional zone of the fetal adrenal as well as the adult cortex. The resulting increase in plasma cortisol concentration limits further release of hypothalamic neuropeptides and ACTH by negative feedback through glucocorticoid receptors at central nervous system and pituitary sites. As a corollary, if glucocorticoid production is impaired by intrinsic adrenal dysfunction, neuropeptide and ACTH release are augmented.

The components of the HPA axis are present early in human development (Mesiano and Jaffe, 1997). As detailed later on, the fetal adrenal begins to develop at the fourth week of gestation, a time similar to that for initial evagination of the pituitary primordium (Conklin, 1968). ACTH-producing pituitary cells can be detected at 7 weeks of gestation, and an intact hypophysial portal vascular system by 12 weeks (Baker and Jaffe, 1975; Thliveris and Currie, 1980). Nerve terminals containing CRH can be detected in the hypothalamus by approximately 16 weeks of gestation. Because virilization due to increased production of adrenal androgens in females with congenital adrenal hyperplasia occurs before 12 weeks of gestation, the ACTH-producing corticotrophs probably undergo cortisol-mediated feedback modulation at the initial stages of hypothalamic-pituitary development.

Mineralocorticoid (aldosterone) release by the zona glomerulosa of the adrenal is determined by the renin-

angiotensin system, with acute modulation of lower magnitude also by ACTH (Dzau, 1988). Decreases in vascular volume result in increased secretion of renin by the renal juxtaglomerular apparatus. Renin, a proteolytic enzyme, cleaves angiotensinogen to angiotensin I. Angiotensin I is then cleaved and activated by angiotensin-converting enzyme (ACE) in the lung and other peripheral sites to angiotensin II. Angiotensin II and its metabolite angiotensin III possess vasopressor and potent aldosterone secretory activity. Although angiotensin II receptors are present on cells of the definitive zone at 16 weeks of gestation, significant aldosterone production by the fetal adrenal does not occur until the third trimester of pregnancy (Mesiano and Jaffe, 1997).

## ADRENAL DEVELOPMENT

The development of the human adrenal gland begins at approximately the fourth week of gestation and continues through adolescence and young adulthood, as recently reviewed in detail (Mesiano and Jaffe, 1997). The developing adrenal cortex can first be identified as a thickening of coelomic epithelium between the primitive urogenital ridge and the dorsal mesentery. By the eighth week of gestation, the rudimentary adrenal cortex, or adrenal blastema, consists of functionally distinct

zones: the fetal zone, definitive zone, and transitional zone (Fig. 90–2) (Mesiano and Jaffe, 1997). It is unclear whether these zones arise from a single progenitor population. During most of embryogenesis, 80% to 90% of the adrenal cortex is made up of the fetal zone, with the remainder consisting of the definitive and transitional zones, destined to become the adult cortex. The fetal zone produces mainly DHEAS due to limited  $3\beta$ -hydroxysteroid dehydrogenase activity, and the definitive and transitional zones primarily produce corticoids in response to ACTH (Mesiano and Jaffe, 1997). A distinct adrenal medulla does not start to form until the first week of postnatal life and an adult-like medulla is not apparent until 12 to 18 months of life.

Beginning at 8 to 10 weeks of gestation, the fetal adrenal cortex produces significant levels of DHEAS. Production of DHEAS by the fetal adrenal increases throughout pregnancy to very high levels at term. The adrenal-derived DHEAS serves as the critical substrate for placenta estradiol and estriol synthesis. The measurement of these estrogens in maternal serum thus provides a valuable index of steroid-producing function of the fetoplacental unit (Yen, 1991). Cortisol, corticosterone and aldosterone

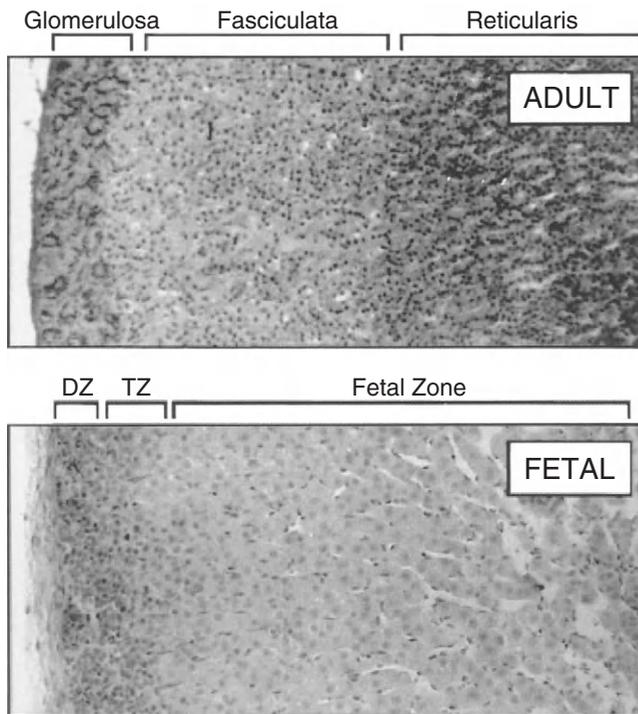

production can be detected by 10 to 20 weeks from the fetal adrenal (Partsch et al, 1991).

By 16 to 20 weeks of gestation, the fetal adrenal is dominated by the large steroid-secreting cells of the fetal zone and a narrow band of proliferative cells that represent the definitive zone. By late gestation, the definitive zone resembles the adult zona glomerulosa. A third zone called the transitional zone exists between the fetal and definitive zones. These cells are thought to produce cortisol and, by 30 weeks of gestation, resemble the zona fasciculata (Mesiano and Jaffe, 1997). Postnatally, the adrenal gland undergoes extensive remodeling with the expansion of the preexisting zona glomerulosa and zona fasciculata and apoptosis of the fetal zone.

By 20 weeks of gestation, the adrenal is the size of the fetal kidney, and between 20 and 30 weeks, its size doubles to 10 to 20 times the relative size of the adult adrenal (Mesiano and Jaffe, 1997). This growth is dependent on ACTH, as evidenced by failure of the fetal zone to increase beyond the size of a 15-week embryo in infants with anencephaly and the markedly enlarged fetal zone in infants with CAH. Furthermore, mice and humans with pro-opiomelanocortin (POMC) deficiency demonstrate severe adrenocortical atrophy. Despite this dependence on ACTH for growth of the fetal adrenal gland, plasma ACTH levels fall by almost 50% during the period of most rapid adrenal growth. The explanation for this apparent discrepancy is that the fetal adrenal gland becomes more responsive to ACTH during the second and third trimesters as a result of increased expression of the ACTH receptor. Although ACTH is the principal regulator of fetal adrenal growth, several other factors must be involved in adrenal growth (Mesiano and Jaffe, 1997). In anencephalic infants, the definitive zone is normal and development of the fetal zone is normal until 10 to 15 weeks of gestation (Gray and Abramovich, 1980). Additionally, the fetal zone rapidly involutes once the newborn is delivered and the uterine cord clamped, despite continued ACTH exposure (Gray and Abramovich, 1980).

The molecular basis of adrenal development has recently begun to be elucidated. Several transcription factors are critically important for normal adrenal development. Steroidogenic factor-1 (SF-1), or adrenal 4-binding protein, is a member of the nuclear receptor superfamily (Parker, 1998). SF-1 knockout mice lack adrenals and gonads, and subsequent identification of SF-1 mutations in humans with adrenal insufficiency confirms the essential role of SF-1 in development (Parker, 1998). SF-1 expression is found in the early urogenital ridge of the mouse in cells that give rise to both the bipotential gonad and adrenal cortex. Expression of SF-1 remains high throughout embryogenesis and postnatal and adult life (Parker, 1998).

DAX1 (dosage-sensitive sex reversal–adrenal hypoplasia congenita critical region on the X chromosome) is an orphan nuclear receptor that co-localizes with SF-1 in the cells of the adrenals, gonads, gonadotropes, and ventral-medial lateral nucleus of the hypothalamus. Deletion of DAX1 results in adrenal hypoplasia congenita. Although the exact role of DAX1 in adrenal development is not known, it has been shown to interact with SF-1 (Ikeda et al, 2001). Normally, DAX1 recruits the nuclear corepressor N-CoR to SF-1 and represses SF-1 (Crawford et al, 1998).

**FIGURE 90-2.** Upper panel, Morphology of the human adult adrenal cortex. The cortex is composed of the zona glomerulosa, zonal fasciculata, and zona reticularis. The adrenal medulla (not shown) is medial to the zona reticularis. Lower panel, Morphology of the fetal (midgestation) adrenal cortex. The fetal adrenal cortex is composed primarily of the inner large fetal zone (FZ) and the smaller outer definitive zone (DZ). The transitional zone (TZ) is at the outer edge of the fetal zone. (Reproduced with permission from Mesiano S, Jaffe RB: *Developmental and functional biology of the primate fetal adrenal cortex*. *Endocr Rev* 18:378-403, 1997. Copyright 1997 by The Endocrine Society.)

Similarly, the *WT1* (Wilms tumor gene) protein has been shown to interact with SF-1. *WT1* encodes 24 different protein isoforms that act as transcription factors. *WT1* is detected in the urogenital ridge of the mouse embryo but is not detected in adult or fetal adrenals. Mutations in *WT1* have resulted in abnormal development of the adrenal in the mouse but have not been clearly correlated with abnormal human adrenal development (Vidal and Schedl, 2000).

### ASSESSING ADRENAL FUNCTION IN THE NEWBORN

The spectrum of adrenal steroid production changes significantly over the first days and months of life. In determining whether steroidogenic function in the newborn adrenal is “normal,” special attention must be given to the age-related changes in adrenal steroid intermediates and circulating cortisol and aldosterone concentrations that reflect ongoing adrenal maturation. The third-trimester fetal zone, the predominant component of the adrenal cortex in the fetus, preferentially produces DHEA and DHEAS as a result of absent 3 $\beta$ -hydroxysteroid dehydrogenase activity. Rapid loss of the fetal zone in the days following birth results in a dramatic fall in circulating DHEA concentration over the first week to 1 month postnatally. DHEA concentrations above 1000 ng/dL are common in healthy newborn males and females on day 1 of life (de Peretti and Forest, 1976; Lee et al, 1989). The variable pattern of decline in the ensuing weeks probably reflects variation in remodeling of the fetal zone and emergence of the zona fasciculata of the adult cortex. In addition to impaired 3 $\beta$ -hydroxysteroid dehydrogenase activity, preterm infants have sustained elevations in 17-hydroxyprogesterone and the 17-hydroxyprogesterone-to-cortisol ratio, suggesting a reduction in 21-hydroxylase activity (Al Saedi et al, 1995; Lee et al, 1989). Because blood-spot 17-hydroxyprogesterone concentration is used as a newborn screen for CAH in many states (Mitchell et al, 1990), many preterm infants initially test abnormal. Subsequent follow-up testing is then required to determine whether CAH is present. Plasma aldosterone concentrations tend to be higher in preterm infants than in term infants also, both of which are higher than in older children and adults (Doerr et al, 1988; Kotchen et al, 1972).

In the ill newborn with hypotension or other evidence of cardiovascular instability, the question often arises as to whether these manifestations reflect underlying glucocorticoid insufficiency. Random plasma cortisol measurement is often inadequate to answer this question, as up to 10% of stressed newborns have low or undetectable cortisol levels but subsequently are capable of mounting an adequate cortisol response to exogenous ACTH administration (Thomas et al, 1986). In these infants, cosyntropin [(1-24)ACTH] testing should be performed for establishing adrenal function. The standard 0.25-mg cosyntropin dose with sampling at 30 or 60 minutes after administration has been widely employed for this purpose, although lower dose cosyntropin testing has been favored in some studies to reveal more subtle deficits in adrenal responsiveness (Korte et al, 1996). In a study by Hingre and

colleagues, all prematurely born infants (less than 30 weeks of gestation) that were sick had plasma cortisol levels that were comparable with healthy term infants (Hingre et al, 1994). The failure of stressed newborns, particularly those born prematurely, to mount a cortisol response of the same magnitude as older children and adults may reflect inadequate maturation of steroidogenic enzymes, or could represent the human counterpart of the stress-hyporesponsive period that has been extensively documented in studies of newborn animals (Dent et al, 2000; Sapolsky and Meaney, 1986). In the stress hyporesponsive period, the pituitary releases minimal ACTH in response to stress resulting in little adrenocortical activity.

## DISORDERS OF ADRENAL INSUFFICIENCY

### Neonatal Primary Adrenal Insufficiency

#### Biosynthetic Defects

#### Congenital Adrenal Hyperplasia

Enzymatic defects of steroid metabolism are one of the most common causes of neonatal adrenal insufficiency. The most frequent of these are the enzyme defects that cause CAH. This disorder occurs with any enzyme defect involved in the biosynthesis of cortisol from cholesterol that results in impaired production of cortisol. Loss of negative feedback by cortisol leads to increased secretion of ACTH from the pituitary and hyperplasia of the adrenal cortex. Females with CAH often are recognized at birth because of ambiguous genitalia due to virilization from adrenal androgens produced in excess. The phenotypic features of affected females range from mild clitoromegaly and posterior labial fusion to male-appearing genitalia without palpable testes in the scrotum. Genitalia of males with CAH are not affected unless the enzyme defect leads to decreased testosterone production, as seen with 3 $\beta$ -hydroxysteroid dehydrogenase deficiency. In this case, inadequate virilization occurs. Newborns with CAH may also present with hyperpigmentation, hypoglycemia, or acidosis. Depending on the degree of enzyme activity, patients with CAH may have either simple virilizing CAH or salt-wasting CAH. Infants with salt-wasting CAH do not exhibit salt-wasting until 5 to 15 days of life. Accordingly, males with undiagnosed salt-wasting CAH often present in adrenal crisis 1 to 2 weeks after birth (New, 1995; White and Speiser, 2000).

The most common form of CAH is 21-hydroxylase deficiency, inherited as an autosomal recessive trait, with an incidence of approximately 1/15,000 worldwide. The incidence may be as high as 1/300 in certain ethnic populations, such as the Yupik Eskimos of Alaska. A defect in 21-hydroxylase results in abnormally high levels of its substrate, 17-hydroxyprogesterone, and the androgens androstenedione and DHEA. These excess androgens result in virilization of affected female infants (Miller, 1991; New, 1995; White, 2001; White and Speiser, 2000).

The molecular biology of the 21-hydroxylase locus has been extensively characterized. There are two homologous genes within the class III region of the major histocompatibility locus on chromosome 6p21.3 that encode

21-hydroxylase and a related pseudogene. *P450c21B*, or *CYP21*, is the active gene; the pseudogene *P450c21A*, or *CYP21P*, contains at least nine different mutations. *CYP21P* and *CYP21* are 98% identical and therefore frequently recombine, resulting in most of the known mutations that cause CAH. Gene deletions and gene conversions in the homozygous form all cause the salt-losing form of CAH, although many point mutations also cause salt-losing CAH. Approximately 20% of mutations are a deletion of the 3' end of *CYP21P*, *C4B*, which encodes the fourth component of complement, and the first 3 to 7 exons of *CYP21*, resulting in a nonfunctional hybrid gene composed of the 5' end of *CYP21P* and the 3' end of *CYP21*. Another 20% to 25% of mutations are a point mutation in intron 2 of *CYP21*, resulting in an abnormally spliced product (Miller, 1991; White, 2001; White and Speiser, 2000). If there is an affected proband, defects in *CYP21* can be detected by polymerase chain reaction (PCR) analysis of polymorphic microsatellite markers based on linkage analysis (New et al, 2001; White and Speiser, 2000). Postnatally, a defect in 21-hydroxylase activity can be detected by measuring elevated 17-hydroxyprogesterone and adrenal androgens after day 2 of life. Many states measure 17-hydroxyprogesterone levels on the standard newborn screen.

Although biochemical evaluation is required for diagnosis of CAH, imaging methods can be useful in the evaluation of suspected adrenal disorders. In an infant with genital ambiguity, a pelvic ultrasound examination to look for the presence of a uterus is helpful in identifying a virilized female. Ultrasonography also is the preferred imaging modality for evaluation of the adrenals in the neonate. The adrenals of the neonate are easier to visualize by ultrasound examination than the adult glands, because the adrenals relative to the kidneys are much larger, there is decreased perirenal fat, and the adrenals are more superficially located (Ghiacy et al, 1985). Neonates with CAH tend to have longer and wider adrenals than those in normal infants (Sivit et al, 1991). In addition, neonates with CAH tend to have abnormal surface characteristics and echogenicity of their adrenals when compared with neonates with ambiguous genitalia of other causes. When all three characteristics are studied, adrenal ultrasound examination has a specificity of 92% and sensitivity of 100% in detecting CAH (Al-Alwan et al, 1999).

Although far less common than 21-hydroxylase deficiency, 11 $\beta$ -hydroxylase or 3 $\beta$ -hydroxysteroid dehydrogenase deficiency also needs to be considered in an infant suspected of having CAH. Mutations in *CYP11B1* (*P450c11*) cause 11 $\beta$ -hydroxylase deficiency. *CYP11B1* is a mitochondrial enzyme that catalyzes the 11 $\beta$ -hydroxylation of 11-deoxycortisol to cortisol. *CYP11B2* encodes aldosterone synthase, which 11-hydroxylates 11-deoxycorticosterone (DOC) to corticosterone and 18-hydroxylates and then 18-oxidizes corticosterone to aldosterone. *CYP11B1* and *CYP11B2* are 40 kilobases apart on chromosome 8q24 and are 95% identical within the coding region. Affected females are virilized because of high DHEA and androstenedione levels. Diagnosis is made by measuring high levels of 11-deoxycortisol. Because DOC has mineralocorticoid activity and also is elevated in 11 $\beta$ -hydroxylase deficiency, affected patients usually maintain normal sodium levels, have suppressed plasma renin activity, and

may be hypertensive or hypokalemic. However, newborns may have mild transient salt loss. Mutations in *CYP11B2* result in deficiencies of 18-hydroxylase or 18-methyl oxidase activity with normal 11-hydroxylase activity. Because aldosterone does not “feed back” to ACTH, affected patients have salt loss and hyperreninemia without virilization or hyperpigmentation. In addition, these newborns are not deficient in cortisol, so hypoglycemia is not a problem (White et al, 1994).

3 $\beta$ -hydroxysteroid dehydrogenase deficiency is rare. Affected females show mild virilization because of the androgenic effects of large amounts of DHEA caused by this enzyme deficiency. Affected males are undervirilized because 3 $\beta$ -hydroxysteroid dehydrogenase is necessary for testosterone production. These patients also tend to have severe mineralocorticoid deficiencies. There are two isoenzymes for 3 $\beta$ -hydroxysteroid dehydrogenase (HSD). The type I enzyme is expressed in the placenta, skin, and adipose tissue; the type II enzyme is expressed in the adrenals and gonads. *HSD3B1* and *HSD3B2* encode active enzymes and are located on chromosome 1p11-13. The classic form of 3 $\beta$ -hydroxysteroid dehydrogenase deficiency is caused by mutations in *HSD3B2*. Because the *HSD3B1* is unaffected, steroid biosynthesis in the placenta is normal (White, 2001).

Other enzymatic defects in the cortisol synthesis pathway also may cause adrenal insufficiency but are exceedingly rare. 17 $\alpha$ -hydroxylase/17,20-lyase deficiency (*P450c17*) has been reported in 120 persons. These patients overproduce deoxycorticosterone and cannot produce testosterone. Therefore, affected patients retain sodium and are hypertensive. Affected male patients have incomplete sexual development, and affected females are phenotypically normal but fail to undergo adrenarche and puberty (Miller, 1991).

Another rare recessive condition that also causes adrenal insufficiency and 46,XY sex reversal is congenital lipoid adrenal hyperplasia (StAR [*steroidogenic acute regulatory*] protein deficiency). The defective gene is on chromosome 8 and encodes the StAR protein, which transports cholesterol from the outer to the inner mitochondrial membrane (Lin et al, 1995).

### **Familial Glucocorticoid Deficiency and Adrenoleukodystrophy**

Familial isolated glucocorticoid deficiency is a rare autosomal recessive disorder. Affected infants demonstrate adrenal unresponsiveness to ACTH and severe glucocorticoid deficiency without mineralocorticoid deficiency. Affected patients may present in the neonatal period with hypoglycemia, hyperpigmentation, muscle weakness, or seizures. Several affected families have defects in the coding region of the ACTH receptor (MC2R) gene. However, many other affected families have no detectable mutation and may have a postreceptor defect. Allgrove or triple A syndrome is a similar disorder that combines alacrima and achalasia with adrenal insufficiency. Some of these families have a defect in the *AAAS* (*alacrima-achalasia-adrenal insufficiency syndrome*) gene, which is postulated to be involved in either cytoplasmic trafficking

or peroxisomal activities (Allolio and Reincke, 1997; Stratakis et al, 1994; Weber and Clark, 1994; Weber et al, 1995; Yamaoka et al, 1992).

Neonatal adrenoleukodystrophy (NALD) is a fatal autosomal recessive disease of impaired peroxisome biogenesis. NALD belongs to a class of disorders involving peroxisomal biogenesis, including Zellweger syndrome and infantile Refsum disease. NALD is the only one of the three diseases that often involves adrenal insufficiency. NALD is a result of a defect in peroxisome biogenesis. Mutations in seven different peroxisome biogenesis factors have been shown to cause NALD (Moser, 1999). Mutations in PEX1 (peroxisome biogenesis factor 1), a member of the AAA ATPase family, are the most common cause of NALD (Tamura et al, 2001). As in X-linked adrenoleukodystrophy, patients with NALD accumulate very long-chain fatty acids and develop degenerative changes of the white matter of the nervous system and adrenal atrophy. Infants with NALD characteristically demonstrate dolichocephaly, prominent and high forehead, esotropia, epicanthic folds, broad nasal bridge, high-arched palate, low-set ears, and anteverted nostrils. Affected patients usually die in early childhood (Moser, 1999; Tamura et al, 2001; Walter et al, 2001). X-linked adrenoleukodystrophy (X-ALD) is a recessively inherited X-linked defect of the adrenoleukodystrophy protein. It is also a peroxisomal defect that usually results in adrenal insufficiency and CNS deterioration. However, X-ALD does not usually manifest before early childhood and often manifests later (Laureti et al, 1996; Moser et al, 1984).

### Other Adrenal Diseases

The clinical picture of adrenal insufficiency and 46,XY gonadal dysgenesis may be caused by a deficiency of 7-dehydrocholesterol C-7 reductase, or Smith-Lemli-Opitz syndrome. The biochemical abnormalities of this syndrome include low cholesterol and high 7-dehydrocholesterol (Bialer et al, 1987; Tint et al, 1995). Other symptoms that may be exhibited include failure to thrive, altered muscle tone, microcephaly, dysmorphic facies, moderate to severe mental retardation, genitourinary anomalies, and limb anomalies. The incidence of Smith-Lemli-Opitz syndrome in persons of Northern and Central European ancestries is 1/20,000 to 1/30,000 (Jones, 1997).

Complete deficiency of lysosomal esterase also may result in adrenal insufficiency in Wolman disease, a rare autosomal recessive disease. Wolman disease usually is fatal in the first year of life. Affected infants exhibit mild mental retardation, hepatosplenomegaly, vomiting, diarrhea, growth failure, and adrenal calcifications. Calcifications that delineate the outline of both adrenals are pathognomonic for this condition (Anderson et al, 1994; Wolman, 1995).

### Acquired Adrenal Insufficiency

The incidence of adrenal hemorrhage in the neonate is reported to be 1.7 cases per 1000 autopsied infants and as high as 3% of infants screened by abdominal ultrasound

examination. The etiology of neonatal adrenal hemorrhage is unknown, but it has been associated with birth trauma related to difficult deliveries, sepsis, coagulopathies, traumatic shock, and ischemic disorders. Infants with minimal hemorrhage may be asymptomatic and discovered incidentally to have adrenal calcifications, indicating an earlier hemorrhage. Major adrenal hemorrhage may manifest as an abdominal mass, anemia from blood loss, or jaundice from reabsorption of the hematoma. Hemorrhage also may lead to adrenal insufficiency, which may manifest as neonatal hypoglycemia, hypotension, hypothermia, apnea, or shock. Because of the location of the right adrenal between the liver and spine, it is the adrenal most often affected by hemorrhage (Velaphi and Perlman, 2001).

*Neisseria meningitidis* is a well-known cause of the Waterhouse-Friderichsen syndrome, or adrenal hemorrhage in association with fulminant septicemia (Enriquez et al, 1990). Other infections in the neonate that have been associated with adrenal hemorrhage and insufficiency include those due to herpesvirus (HSV), *Bacteroides*, herpes simplex virus type 6 (HSV-6), echovirus types 11 and 6 (Bekdash and Slim, 1981; Jain et al, 1996; Morrison et al, 1988; Nakamura et al, 1985; Ohta et al, 1978; Phimney et al, 1982; Schmitt et al, 1996; Ventura et al, 2001).

### Abnormalities of Development: DAX1 and SF-1 Deficiency

Mutations in DAX1 are associated with adrenal hypoplasia congenita (AHC) and have been reported in approximately 70 patients (Achermann et al, 2001). These infants exhibit primary adrenal insufficiency associated with hypogonadotropic hypogonadism. Approximately 60% of boys with DAX1 mutation present with the typical signs and symptoms of adrenal insufficiency, including failure to thrive, poor weight gain, vomiting, prolonged jaundice, hyperpigmentation, and shock. The remaining patients present during childhood and have a more insidious onset of symptoms, including nausea, weight loss, and hyperpigmentation (Achermann, 2001; Habiby et al, 1996). Correlation between specific DAX1 mutations and age at presentation is lacking. Although DAX1 mutations are rare, 70% of boys with adrenal insufficiency and hypogonadotropic hypogonadism have been shown to have a mutation in DAX1 (Achermann, 2001).

Mutations in SF-1 are even rarer, and only two such patients have been reported (Achermann et al, 2001; Achermann et al, 1999; Biason-Lauber and Schoenle, 2000). The first patient had primary adrenal insufficiency and XY sex reversal (Achermann et al, 1999). The second patient had adrenal insufficiency but normal ovarian function at 27 months of age (Biason-Lauber and Schoenle, 2000). Both patients were heterozygotes for different point mutations in SF-1. The first patient described with an SF-1 mutation with adrenal insufficiency and XY sex reversal exhibited signs of adrenal insufficiency within the first 2 weeks of life and presented with vascular collapse at 17 days of life. In the second case, the patient presented at 14 months of age in adrenal crisis 1 week after the onset of otitis media and tonsillitis.

## Secondary and Tertiary Adrenal Insufficiency

Secondary and tertiary forms of adrenal insufficiency result from defects in pituitary corticotroph and hypothalamic function, respectively. Supraphysiologic doses of glucocorticoids often are used for the treatment of hyaline membrane disease. With prolonged (more than 7 to 10 days) use of supraphysiologic doses of glucocorticoids, these neonates are at risk for iatrogenic suppression of corticotroph ACTH release, with secondary adrenocortical atrophy and adrenal insufficiency (Axelrod, 1976). The duration of recovery of corticotroph function from adrenal suppression, once administration of glucocorticoids is discontinued, is quite variable, with evidence of suppression of the HPA axis evident in some patients for more than 1 year (Livanou et al, 1967). In addition to prolonged use of steroids placing these infants at risk for adrenal suppression, there has recently been a concern that dexamethasone use in preterm infants may adversely affect brain development (Tarnow-Mordi and Mitra, 1999; Thebaud et al, 2001).

Secondary or tertiary adrenal insufficiency in the neonate often is a consequence of abnormalities in development of the hypothalamus and pituitary associated with adrenal insufficiency, including de Morsier syndrome (septo-optic dysplasia) (de Morsier, 1956; Willnow et al, 1996), hydran-cephaly or anencephaly, and pituitary hypoplasia or aplasia. If these infants have concomitant diabetes insipidus, they have an increased risk of sudden death during childhood (Brodsky et al, 1997). Patients with developmental abnormalities of the pituitary or hypothalamus often have deficiencies of other hormones. Signs of hypopituitarism in a neonate include hypoglycemia, prolonged jaundice, shock, and microphallus in males. Homozygous inactivating mutations of the pituitary homeobox gene, *HESX1*, have recently been associated with septo-optic dysplasia (Parks et al, 1999; Thomas et al, 2001). Trauma to the hypothalamus, pituitary, or hypophysial portal circulation from significant head injury, cerebrovascular accident, Sheehan syndrome, or hydrocephalus also may be a cause of central adrenal insufficiency. Historic factors associated with increased risk for central adrenal insufficiency include maternal drug use and traumatic delivery.

Least commonly, there have been case reports of families with inherited abnormalities of neuropeptides involved in HPA axis regulation. Adrenal insufficiency, pigmentary abnormalities, and obesity have been described in families with a defect in POMC (Krude et al, 1998; Pernasetti et al, 2000). One kindred has been reported with Arnold-Chiari type I malformation and suspected *CRH* deficiency. The mutation in this kindred is linked to the *CRH* locus; however, a specific mutation in the *CRH* gene has not yet been defined (Kyllo et al, 1996).

## Therapy of Adrenal Insufficiency Disorders

### Primary Adrenal Insufficiency

#### Chronic Replacement

Studies in adults and adolescents have determined that the daily production rate of cortisol is 5.7 to 7 mg/m<sup>2</sup>/day. Because of variable oral absorption, replacement hydro-

cortisone should be initiated at 10 to 15 mg/m<sup>2</sup>/day divided three times per day (Esteban et al, 1991; Kerrigan et al, 1993; Linder et al, 1990). Because the bioavailability of oral steroids varies from person to person, infants need to be monitored closely for signs of either inadequate cortisol replacement or cortisol excess (Heazelwood et al, 1984). Although adults and older children may be able to take hydrocortisone twice daily, most infants should be dosed three times daily to avoid hypoglycemia associated with low cortisol on a twice-daily regimen (DeVile and Stanhope, 1997; Groves et al, 1988). Although other steroids may be used, hydrocortisone is preferred in infants because it has less growth suppressive effects than those associated with use of synthetic steroids (Stempfel et al, 1968; Van Metre et al, 1960). In primary adrenal insufficiency, aldosterone production is usually diminished. Physiologic doses of hydrocortisone do not provide enough mineralocorticoid activity to prevent salt wasting, so these infants often require 0.05 to 0.2 mg/day of fludrocortisone acetate (Florinef). Because after the first month of life aldosterone production does not vary, the dose of fludrocortisone does not change with growth and aging (Doerr et al, 1987; Sippel et al, 1978; Weldon et al, 1967). Infants with mineralocorticoid deficiency require 1 to 4 g of NaCl added to their diet, because formula and breast milk are low in salt (Mullis et al, 1990).

#### Stress Replacement

The normal response to surgery, trauma, or critical illness is to increase plasma ACTH and cortisol levels. The daily secretion rate of cortisol has been found to be proportional to the degree of stress and ranges from 60 to 167 mg/day in adults after surgery (Chernow et al, 1987; Espiner, 1966; Hume et al, 1962; Ichikawa, 1966; Kehlet and Binder, 1973; Wise et al, 1972). Based on data from adults, it is recommended that infants with adrenal insufficiency receive 30 to 100 mg/m<sup>2</sup>/day divided every 6 to 8 hours of hydrocortisone when stressed. Stress doses of hydrocortisone should be given with the onset of fever, gastrointestinal or other significant illness, and continued for 24 hours after the symptoms resolve (Miller, 1991; New, 1995; Nickels and Moore, 1989). If oral steroids are not tolerated, an intramuscular or intravenous dose should be given. For surgery, infants should be given 30 to 100 mg/m<sup>2</sup> of intravenous hydrocortisone on call to the operating room before the administration of anesthesia. Stress dosing for hydrocortisone (30 to 100 mg/m<sup>2</sup>/day divided every 6 to 8 hours) should be continued post-operatively for the next 24 to 48 hours. Electrolytes should be closely monitored, but changes in the dose of fludrocortisone are not needed.

In the event of a suspected adrenal crisis, blood for determination of electrolytes, aldosterone, plasma renin activity, cortisol, and ACTH should be drawn and treatment started before the results are obtained. Fluid resuscitation with normal saline containing 5% dextrose should be given as a bolus to restore cardiovascular stability. Plasma sodium should be monitored closely, as rapid correction of hyponatremia with sodium repletion of more than 0.5 to 1 mEq/L/hour increases the risk of central

pontine myelinolysis. The sodium deficit may be calculated by subtracting the infant's sodium from a "normal" sodium of 140 mEq/L and then multiplying this value by  $0.6 \times$  (weight in kg). The rate of replacement should occur over an initial rate such that the sodium increase does not exceed 0.5 mEq/L/hour. Intravenous hydrocortisone should be given initially at 100 mg/m<sup>2</sup> and then continued at 100 mg/m<sup>2</sup>/day divided, every 6 to 8 hours, until the infant is stable. If the diagnosis of adrenal insufficiency is unclear, then an equivalent dose of dexamethasone (2.5 mg/m<sup>2</sup>/day) should be given in place of the hydrocortisone. Because dexamethasone does not cross-react in standard cortisol assays, it allows a cosyntropin stimulation test to be performed shortly after the initiation of therapy. Long-term dexamethasone therapy is not recommended, as it may be more growth-suppressing than hydrocortisone (Laron and Pertzalan, 1968; Stempfel et al, 1968; Van Metre et al, 1960; White and Speiser, 2000).

### **Special Considerations in Virilizing Forms of Congenital Adrenal Hyperplasia**

Treatment of CAH consists of sufficient cortisol to suppress ACTH production to prevent further virilization and rapid fusion of the growth plates. The dose of cortisol required is usually 10 to 20 mg/m<sup>2</sup>/day divided, three times per day (New, 1995; White, 2001; White and Speiser, 2000). Thrice-daily therapy is preferable, to adequately suppress adrenal androgen production. Although hydrocortisone is the usual form of therapy because it is less growth suppressing than synthetic steroids (Brook et al, 1974; DiMartino-Nardi et al, 1986; Jaaskelainen and Voutilainen, 1997; New et al, 1989; Silva et al, 1997; Urban et al, 1978), a recent study has shown that some children with CAH may have adequate growth with daily dexamethasone therapy (Rivkees and Crawford, 2000). Patients with salt-losing CAH have elevated plasma renin activity and require mineralocorticoid replacement with 0.05 to 0.2 mg per day of fludrocortisone. Angiotensin II, which is increased by elevations in plasma renin, is a mild stimulator of ACTH secretion (Ames et al, 1965; Rayyis and Horton, 1971; Rosler et al, 1977). Therefore, patients without salt loss but with mildly elevated plasma renin activity may require less hydrocortisone for androgen suppression if fludrocortisone is added to their regimen.

Females born with virilizing forms of CAH often are born with ambiguous genitalia. Recent clinical trials have demonstrated that severity of virilization may be reduced by prenatal treatment of the affected female fetus and mother with dexamethasone. Once a child is born with CAH, there is a 1 in 4 chance that the parents will have another affected child and a 1 in 8 chance that it will be an affected female. In subsequent pregnancies, as soon as the mother knows that she is pregnant, dexamethasone therapy is begun. After diagnosis is made by DNA analysis from chorionic villus sampling at 8 to 12 weeks, therapy in unaffected or male patients is discontinued (Carlson et al, 1999; Miller, 1999; New et al, 2001; Speiser, 1999; White and Speiser, 2000). To date, there have been no congenital abnormalities attributed to dexamethasone therapy (New et al, 2001).

For patients with ambiguous genitalia, corrective surgery is usually performed in stages after birth. Most virilized female infants undergo clitoroplasty during the first year of life (Gonzalez and Fernandes, 1990; Newman et al, 1992), although the timing of gender assignment and surgical correction remains controversial (Schober, 1998; Wilson and Reiner, 1998). As management of CAH has improved, many women with CAH have been able to spontaneously conceive and give birth (Premawardhana et al, 1997).

### **Secondary or Tertiary Adrenal Insufficiency**

Cortisol replacement for patients with secondary or tertiary adrenal insufficiency is the same as described for patients with primary adrenal insufficiency. To minimize growth suppression, these children may be treated with doses of hydrocortisone that are slightly less than physiologic replacement doses. Furthermore, because mineralocorticoid production is under the control of the renin-angiotensin system, patients with secondary or tertiary adrenal insufficiency do not require mineralocorticoid replacement. However, these infants do require evaluation for deficiencies of other pituitary hormones.

### **DISORDERS OF ADRENAL EXCESS**

Diseases of adrenal excess are rare in infancy. Adrenocortical tumors are the most common cause of noniatrogenic adrenal excess in infants. The annual incidence of adrenocortical tumors for children below the age of 15 is 0.3 to 0.38 per million children. Presenting signs of an adrenocortical tumor include an abdominal mass, pubic hair, clitoromegaly, hypertrophy of the phallus, hypertension, acne, hirsutism, "moon face," acne, facial hair, weight gain, centripetal fat distribution, accelerated growth velocity, "buffalo hump," and seizures (Mendonca et al, 1995; Sandrini et al, 1997). In one study of 73 children from southern Brazil with adrenocortical tumors, 40% of the children presented with only signs of virilization, 50% presented with signs of virilization and Cushing syndrome, and 3% presented with only signs of Cushing syndrome (Sandrini et al, 1997).

The most important treatment is surgical resection. It is critical to remember that the normal adrenal has been suppressed by dysregulated steroid production by the tumor and that stress doses of hydrocortisone are necessary perioperatively and replacement doses required postoperatively. Chemotherapy has been used on a case-by-case basis but has not been proved as a first-line therapy for adrenocortical tumors in children (Sandrini et al, 1997). Pituitary adenomas or carcinomas are very rare but also may cause Cushing disease or virilization from overproduction of ACTH.

#### **CASE STUDY 1**

A 20-day-old infant with apparently male phenotype presented to the emergency department with lethargy after refusing to eat for the previous 7 hours. The infant was the 3.235-kg, full-term product of an uncomplicated pregnancy. The newborn

examination performed in the nursery identified perineal hypospadias, but the infant was discharged home on day 2 of life. Over the first 2 weeks of life, weight gain was poor, and appetite was markedly decreased over the 1 to 2 days before evaluation in the emergency department. In the emergency department on presentation, the infant was limp and poorly responsive. Initial blood glucose was 30 mg/dL. The infant's mental status was improved after administration of 25% dextrose via an intraosseous line. Resuscitation was continued with dextrose containing normal saline. Initial laboratory values were significant for Na (105 mEq/L), K (8.7 mEq/L), Cl (75 mEq/L), total CO<sub>2</sub> (15.8 mEq/L), BUN (40.5 mg/dL), and creatinine (0.6 mg/dL). After the laboratory results were obtained, the infant was given 100 mg/m<sup>2</sup> of intravenous hydrocortisone. The physical examination was notable for a weight of 3.1 kg and a phallus with a length of 2.5 cm, a midshaft diameter of 1.5 cm with hypospadias near the perineum, a hyperpigmented and rugated shawl scrotum, and no palpable testes. Family history was significant for a male sibling who died at age 1 week. Additional evaluation revealed 46,XX chromosomes and enlarged adrenals and a small uterus on ultrasound examination. The 17-hydroxyprogesterone concentration was 20,700 ng/dL before hydrocortisone administration. These laboratory results all were consistent with classic salt-wasting 21-hydroxylase deficiency. The infant's electrolytes were normalized over several days, and the infant was discharged home on hydrocortisone, fludrocortisone, and salt supplementation.

### Comment

An important point in this case is that the presence of bilateral undescended testes, with or without other evidence of genitourinary anomalies, should be considered ambiguous genitalia and merits further work-up in the immediate perinatal period. Additionally, the institution of state newborn screening for elevated 17-hydroxyprogesterone may allow earlier detection of salt-wasting 21-hydroxylase deficiency, before occurrence of a life-threatening event.

## Ambiguous Genitalia in the Newborn

Gregory Goodwin and Anthony Caldamone

Disorders of sex differentiation can be generally classified as (1) masculinization of the 46,XX female, (2) incomplete masculinization of the 46,XY male, (3) gonadal differentiation and chromosomal disorders, including true hermaphroditism, or (4) syndromes associated with incomplete genital development (Table 91–1). The first two categories comprise the majority of definable cases of ambiguous genitalia.

This chapter presents an overview of the pathophysiology of intersex disorders, including a discussion of the practical aspects of diagnosis and management. An overview of the traditional surgical methods used in the management of infants with intersex disorders, including the risks and benefits of these procedures, is included at the end of the chapter.

### GENERAL CONSIDERATIONS IN THE APPROACH TO THE CHILD WITH AMBIGUOUS GENITALIA

The medical evaluation of ambiguous genitalia is necessarily time consuming. Open and honest discussions with the parents are invaluable in allaying anxiety and establishing a trusting relationship. Full disclosure of available information is essential in this regard.

Care must be taken to avoid premature gender assignment for the infant. Proper evaluation of the infant with ambiguous genitalia requires a multidisciplinary team that should include the primary care physician, neonatologist, pediatric endocrinologist, pediatric urologist, and pediatric geneticist. Psychological assessment and support of the family are essential in the newborn period, along with long-term psychological follow-up evaluation (Slijper et al, 1998). Decisions regarding the gender of rearing should be made collaboratively between the multidisciplinary team and the parents, with the recognition that cultural and psychosocial factors are likely to be influential (Grumbach and Conte, 1998; Kuhnle and Krahl, 2002).

In the past, gender assignment was based largely on phallic size, relative ease of surgical reconstruction, or the potential for fertility. This approach has come under criticism, however, as dissatisfaction with gender assignment based on these criteria has been reported in several case studies (Diamond and Sigmundson, 1997b; Phomphukutul et al, 2000; Reiner, 1996). The importance of prenatal androgen imprinting has been implicated as an important variable in some of these cases (Reiner, 1997). Furthermore, more recent studies in undervirilized 46,XY males indicate that a small phallus can be associated with a satis-

fying adult sex life (Reilly and Woodhouse, 1989). Thus, female gender assignment may not be warranted for intermediately undervirilized 46,XY males.

The degree of genital virilization is still an important determinant of gender assignment in the infant with ambiguous genitalia; however, other, incompletely understood factors appear to be involved. The formation of a healthy gender identity seems to involve a complex interplay between psychobiologic and environmental factors (Meyer-Bahlburg et al, 1996; Money et al, 1972; Slijper et al, 1998).

### THE EMBRYOLOGY OF SEXUAL DIFFERENTIATION

Normal and abnormal sexual differentiation constitute superb examples of how an understanding of embryology is critical to the approach to and management of a group of complex and intriguing clinical disorders.

Sexual differentiation is a sequential process that can be divided into three stages. Jost established the sequence as follows: Chromosomal sex is determined at fertilization and dictates the differentiation of the gonad, which in turn dictates the phenotypic sex, or the differentiation of the internal ductal system and external genitalia (Grumbach and Conte, 1998).

Chromosomal sex is determined at the moment of conception by the sex chromosome complement of the fertilizing sperm. If this sperm carries an X chromosome, a 46,XX (normal female) complement results; if the sex chromosome is Y, a 46,XY (normal male) genotype results. The *SRY* (for “sex-determining region of the Y chromosome”) gene is necessary but not sufficient for testicular differentiation. *SRY* causes the medullary region of the gonad to develop into Sertoli cells and later into testis cords and seminiferous tubules.

In addition to X chromosome genes, autosomal genes also may influence sexual differentiation, insofar as mutations to these genes result in disorders of sexual differentiation. Some of these genes include *WT1* (Wilms tumor gene 1), associated with Denys-Drash syndrome and *WAGR* (Wilms tumor, aniridia, genitourinary abnormalities, mental retardation) syndrome; the sex reversal or adrenal hypoplasia gene (*DAX1*); the steroidogenic factor 1 gene (*SF-1*); and *SOX9*, which has been associated with camptomelic dysplasia (Grumbach and Conte, 1998).

The gonad develops from both somatic and germ cells. The somatic cells are located at the ventral region of the mesonephros and arise from the mesonephric cells and the coelomic epithelium. Somatic cells become the Sertoli cells of the testis and the granulosa cells of the ovary. The germ cells migrate from a more inferior position on the yolk sac to the genital ridge, just medial to the mesonephros on each side (Fig. 91–1, upper left). This occurs between the fourth and sixth weeks of gestation. Once the germ cells reach the gonadal ridge, they become surrounded by the somatic cells, which appear to regulate germ cell differentiation.

Gonadal sex is established by the seventh week of gestation. At this stage, the fetus contains two internal ductal systems—wolffian and müllerian—and undifferentiated external genital primordia. The wolffian or mesonephric duct is a tubular structure that connects the capillary

TABLE 91-1

**Differential Diagnosis of Ambiguous Genitalia****46,XX Virilized Female**

- Congenital adrenal hyperplasia
  - 21-Hydroxylase deficiency
  - 11-Hydroxylase deficiency
  - 3 $\beta$ -Hydroxysteroid dehydrogenase deficiency
  - Aromatase deficiency (fetal and maternal virilization)
- Virilizing maternal conditions
  - Congenital adrenal hyperplasia
  - Adrenal/ovarian tumors/luteoma of pregnancy
  - Maternal ingestion of progestins, androgens

**46,XY Undervirilized Male**

- Androgen insensitivity
  - Partial (PAIS)
  - Complete (CAIS)
- 5 $\alpha$ -Reductase-2 deficiency
- Testosterone biosynthetic defects
  - 17 $\beta$ -Hydroxysteroid hydrogenase 3 deficiency
  - 3 $\beta$ -Hydroxysteroid dehydrogenase deficiency
  - 17 $\alpha$ -Hydroxylase/17,20-lyase deficiency
  - Congenital lipid adrenal hyperplasia
- Leydig cell hypoplasia
- Idiopathic/undetermined
- Drug ingestion: progestins, spironolactone, cimetidine, phenytoin
- Persistent müllerian duct syndrome

**Gonadal Differentiation/Chromosomal Disorders**

- 46,XY gonadal dysgenesis
  - Complete (Swyer syndrome)
  - Partial
  - Mixed (45,X/46,XY)
- True hermaphroditism
  - 46,XX, 46,XY, 46,XX/46,XY

**Syndromes Associated with Ambiguous Genitalia**

- Gonadal dysgenesis
  - 46,XY partial gonadal dysgenesis (Turner syndrome features)
  - Camptomelic dysplasia
- Renal degenerative diseases and gonadal dysgenesis
  - Denys-Drash syndrome
  - Frasier syndrome
  - WAGR (Wilms tumor, aniridia, genitourinary abnormalities, mental retardation) syndrome
- Smith-Lemli-Opitz syndrome (7-dehydrocholesterol reductase deficiency)
- Robinow syndrome

network of the mesonephros to the urogenital sinus. Evagination of the coelomic epithelium leads to formation of a second tubular structure adjacent to the mesonephric duct, the paramesonephric, or müllerian, duct. The distal ends of these two ducts are joined. That portion of the urogenital sinus distal to the termination of these ducts contributes to external genital development, whereas the proximal portion develops into the bladder, trigone, and posterior urethra.

Phenotypic sexual differentiation is predicated on establishment of gonadal sex. If an ovary develops, the wolffian ducts involute due to lack of testosterone, and

only its terminal portion persists as Gartner's duct. The müllerian ducts develop into the proximal vagina, uterus, and fallopian tubes (see Fig. 91-1). The unfused cephalic portions of the müllerian ducts form the fallopian tubes, while the caudal ends fuse to form the ureterovaginal canal (see Fig. 91-1). The union of the fused caudal ends of the müllerian ducts and urogenital sinus forms the vagina. The proximal two thirds of the vagina is of müllerian duct origin, and the distal third is of urogenital sinus origin.

Male phenotypic differentiation is the result of the elaboration of two distinct testicular hormones: testosterone and müllerian-inhibiting factor (MIF). These factors are produced and secreted by the 8-week stage of development, and they are essential for normal male differentiation. Involution of the müllerian ducts is caused by MIF, which is a glycoprotein secreted by the fetal Sertoli cells. The remnants of the müllerian ducts persist caudally as the prostatic utricle and cephalically as the appendix testis. MIF exerts its action unilaterally and locally (exocrine secretion) rather than bilaterally via the systemic circulation.

Immediately after müllerian duct regression, the wolffian ducts develop under the influence of testosterone secreted by the fetal Leydig cells. The Leydig cells, like the Sertoli cells, differentiate from the mesenchymal cells within the gonadal ridges. This occurs at 9 to 10 weeks of gestation. Under the influence of testosterone, the wolffian ducts evolve into the epididymis, vas deferens, and seminal vesicles (see Fig. 91-1). The mesonephric tubules develop into the ductuli efferentes, which will provide continuity between the seminiferous tubules and rete testis to the vas deferens. This process occurs as a direct action of testosterone on the ductal structures.

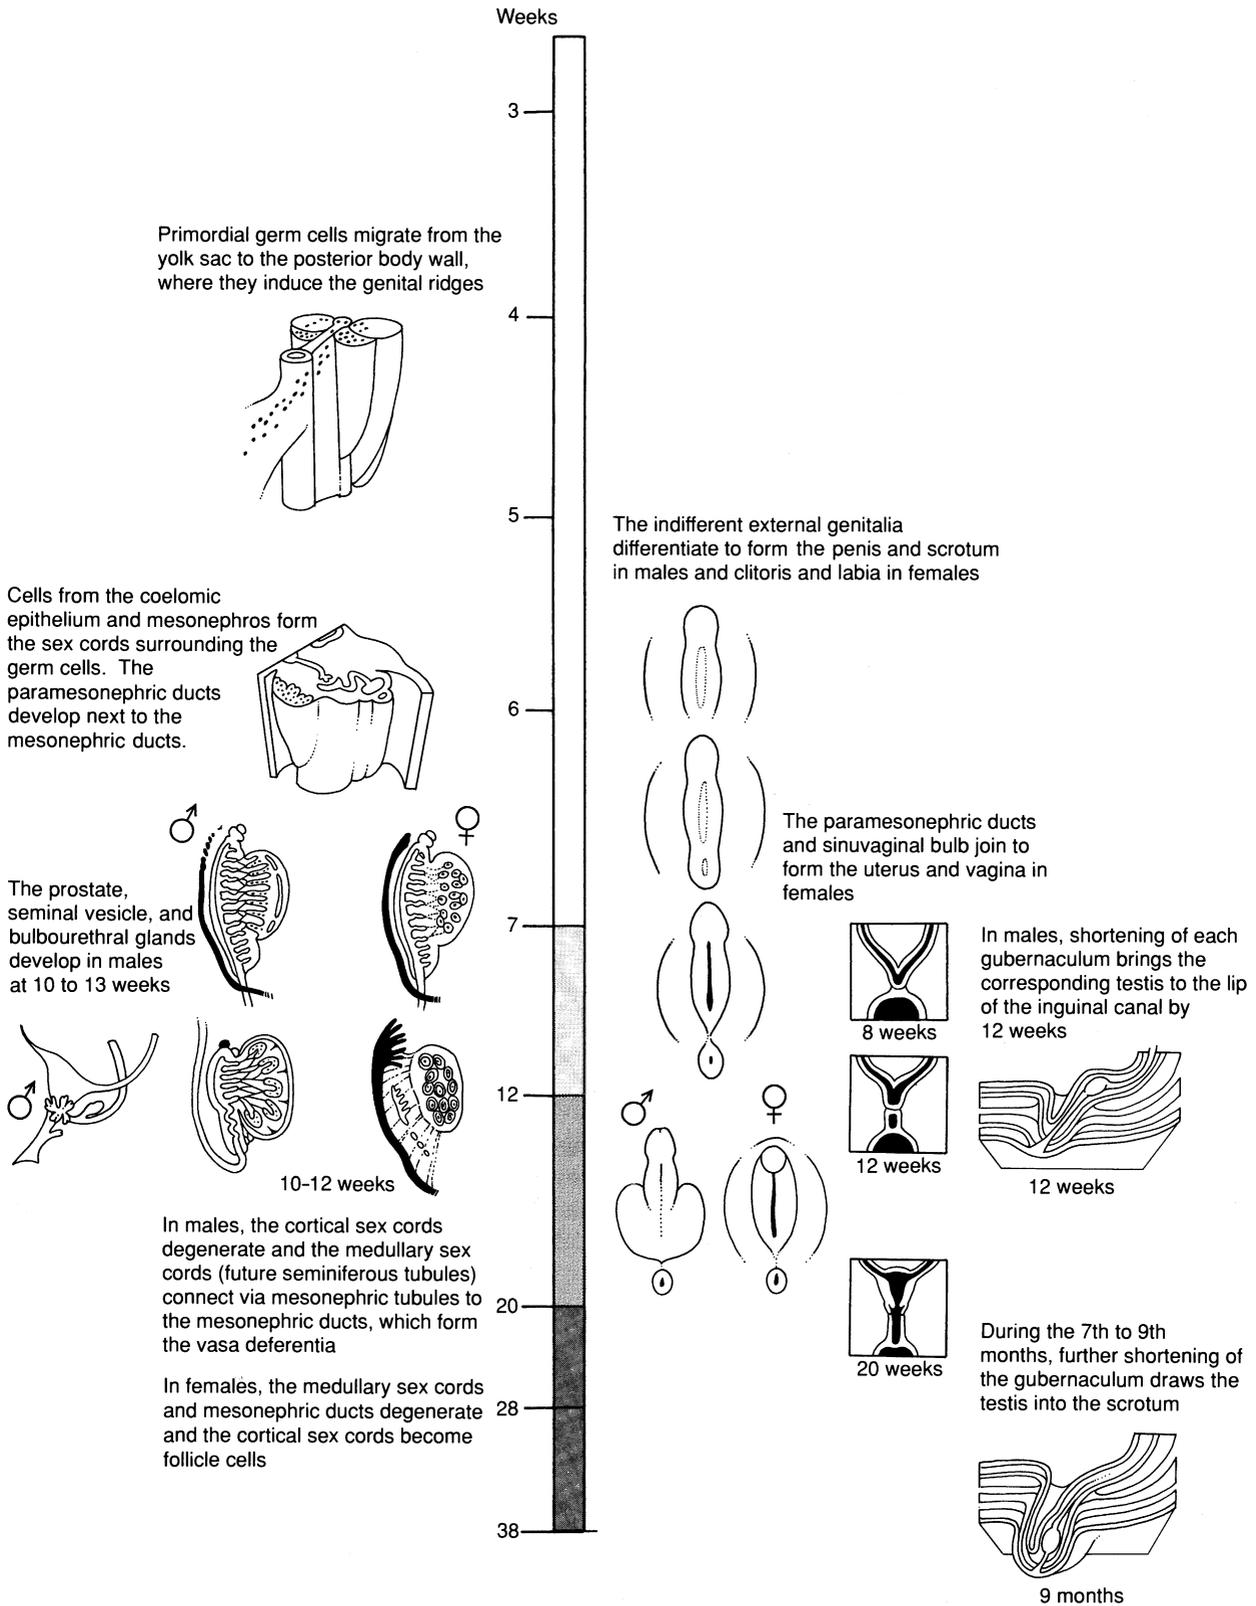

Virilization of the male external genitalia, starting at about 8 weeks of gestation (see Fig. 91-1), relies on the ability of the tissues involved to convert testosterone into a more potent androgen, dihydrotestosterone. The target cells possess the enzyme 5 $\alpha$ -reductase, which is necessary for this conversion. By 12 to 14 weeks of gestation, formation of the male external genitalia is nearly complete. Androgen exposure after this time results in further phallic enlargement.

**CLINICAL ASSESSMENT OF DISORDERS OF SEX DIFFERENTIATION****History**

A detailed *family history* is important in the evaluation of ambiguous genitalia and information on early neonatal deaths, consanguinity, or urogenital anomalies should be obtained. A family history of female infertility or amenorrhea may be suggestive of an intersex disorder. In one study of androgen insensitivity disorders, a positive family history of a sex differentiation disorder was often overlooked (Viner et al, 1997).

The presence of *maternal virilization* may be suggestive of a variety of disorders that may effect fetal masculinization. Features of maternal virilization include hirsutism, severe acne, deepening of the voice, and clitoromegaly on examination.

The ingestion of any recreational drugs, alcohol, or medications by the mother during pregnancy should be noted. Particular attention to medications with androgenic

**FIGURE 91-1.** Embryologic time line for gonadal and internal and external genitalia development. (From Larsen WJ: *Human Embryology*. New York, Churchill Livingstone, 1993, p. 237.)

or progestational activity is indicated. Medications that affect fetal genital development include cimetidine, spironolactone, hydantoin, and progestational agents (Grumbach and Conte, 1998).

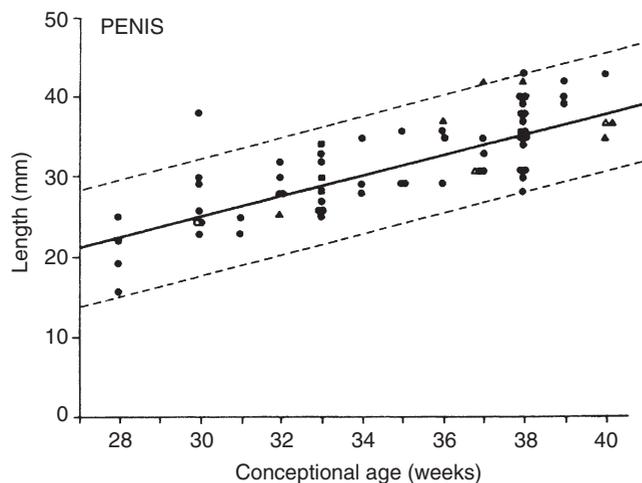

### Physical Examination

There is significant overlap of the genital anatomy among the various sex differentiation disorders. The physical examination, however, may provide the first clues to the underlying pathology. In addition, the physical examination will provide important information about the degree of virilization of the external genitalia and the presence or absence of palpable gonads.

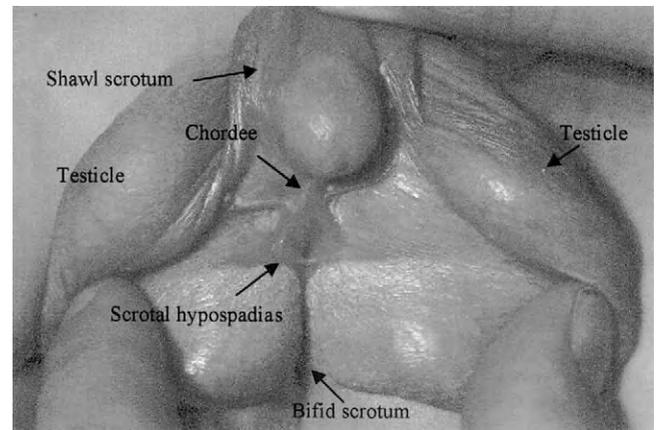

**Clitoris.** Significant clitoral enlargement deserves a careful evaluation. Keep in mind that premature infants have relatively underdeveloped labia majora, so that the clitoris may appear enlarged. A truly enlarged clitoris can be distinguished from a generous clitoral hood by the presence of palpable corporal or erectile tissue.

**Penis/Phallus.** Measurements of the phallic stretch length and mid-shaft diameter are important in determining the degree of virilization. The phallus should be stretched and measured from the pubic ramus to the tip of the glans. Gestational age–corrected phallic stretch lengths are shown in Figure 91–2. The presence of a chordee structure on the ventral surface of the phallus may impair measurement of the true phallic length (Feldman and Smith, 1975) (Fig. 91–3). A chordee is residual urethral tissue that tethers the phallus to the perineum. Measurement of the mid-shaft diameter is particularly useful in this circumstance. For term male infants, a normal mid-shaft diameter is approximately 1 cm (Feldman and Smith, 1975).

A microphallus deserves careful evaluation for the presence of hypopituitarism or growth hormone deficiency, particularly in the presence of hypoglycemia or unexplained

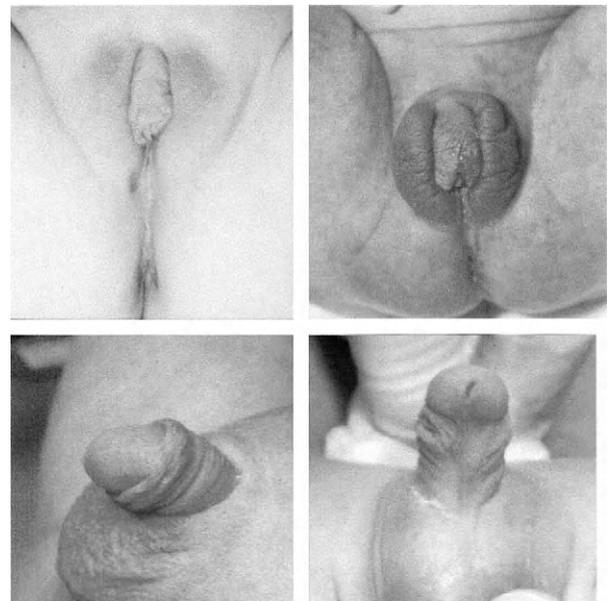

**FIGURE 91–2.** Penis stretch length in 63 normal premature and full-term male infants (●), showing lines of mean  $\pm$  2 SD. Superimposed are data for two small-for-gestational age infants ( $\Delta$ ), seven large-for-gestational age infants ( $\blacktriangle$ ), and twins ( $\blacksquare$ ). (Reproduced with permission from *J Pediatr* 86:395, 1975.)

**FIGURE 91–3.** Undervirilized male demonstrating bifid scrotum, scrotal hypospadias, chordee, and bilateral descended testes.

jaundice. Microphallus and undescended testes may occasionally be the presenting phenotype for an intersex disorder.

**Labioscrotal Folds.** Assessment of the degree of fusion of the labioscrotal folds should be performed. When the infant is exposed to androgens during embryogenesis, fusion of the labioscrotal folds progresses from a posterior to an anterior direction. The spectrum of labial fusion can vary from mild posterior fusion to complete labial fusion (Fig. 91–4). Note whether the folds are rugate or hyperpigmented. Is the phallus positioned in the normal superior position relative to the scrotum or is there a shawl scrotum? (See Fig. 91–3.) Is the scrotum fused normally in the midline or is the scrotum bifid? (See Fig. 91–3.)

**FIGURE 91–4.** Virilization of external genitalia in 46,XX congenital adrenal hypoplasia (21-hydroxylase deficiency). **Upper left panel,** There is a mild to moderate degree of virilization, with primarily clitoral hypertrophy and significant fusion of the labia. **Upper right panel,** Virilization is moderate, with clitoromegaly, labial fusion, and rugation of labial folds. **Lower panels,** Complete masculinization is evident.

**Gonads.** Careful examination for the presence of gonads should be performed in all infants with ambiguous genitalia. The presence of bilateral gonads in the labial folds is highly suggestive of an undermasculinized genetic male (see Fig. 91-3). A unilaterally palpable gonad is often seen in infants with mixed gonad dysgenesis or hermaphroditism (Fig. 91-5), although other disorders such as androgen insensitivity can manifest similarly. When cryptorchidism and hypospadias occur simultaneously, there is a greater than 25% chance of an intersex problem (Albers et al, 1997; Rajfer and Walsh, 1976).

**Hypospadias/Perineum.** The severity of hypospadias can vary, with the condition ranging from mild glandular to penoscrotal, although most disorders of sexual differentiation manifest with severe penoscrotal or scrotal hypospadias (see Figs. 91-3 and 91-5). Examination for the presence of separate urethral and vaginal openings versus a single perineal opening (urogenital sinus) conveys important anatomic information. The vagina may be blind ending or completely formed. A urogenital sinus results from failure of the urologic and genital tracts to completely differentiate. In virilized females, the level at

**FIGURE 91-5.** Asymmetric external genitalia with left unilateral descended testis (left), penoscrotal hypospadias and chordee (right). Asymmetrical external genital development or gonadal descent would be characteristic of mixed gonadal dysgenesis or hermaphroditism.

which the vagina enters the sinus (low- versus high-level vaginal entry) has important implications for determining the ease of subsequent surgical exteriorization of the vagina (Fig. 91-6). Also, when the urethra enters a urogenital sinus, there is potential for urinary stasis and hence urinary tract infections

Excessive pigmentation of the genitals or signs of dehydration should alert the examiner to the possibility of congenital adrenal hyperplasia (CAH).

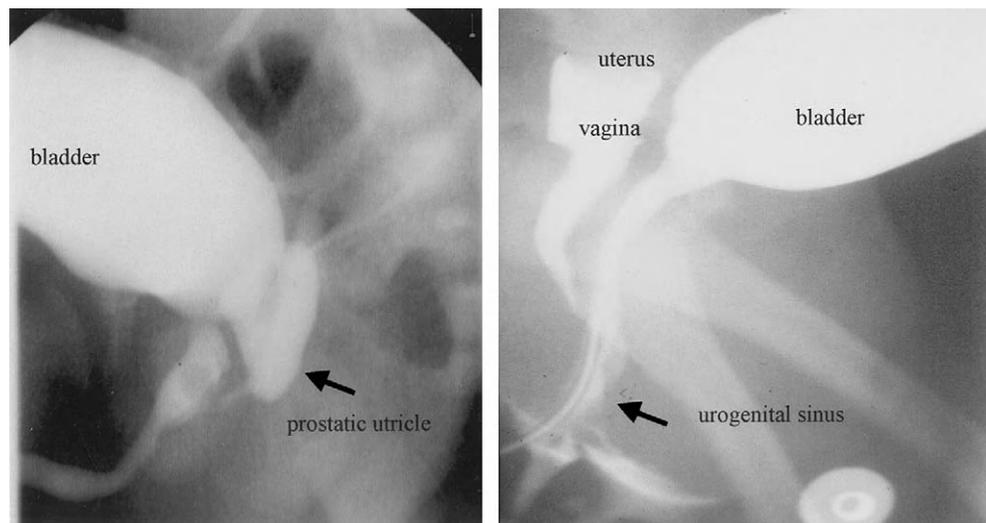

**Dysmorphic features** suggestive of Turner syndrome point to the possibility of gonadal dysgenesis or mixed gonadal dysgenesis. Such abnormalities or multiple congenital anomalies may indicate any of a variety of syndromes associated with ambiguous genitalia (see Table 91-1).

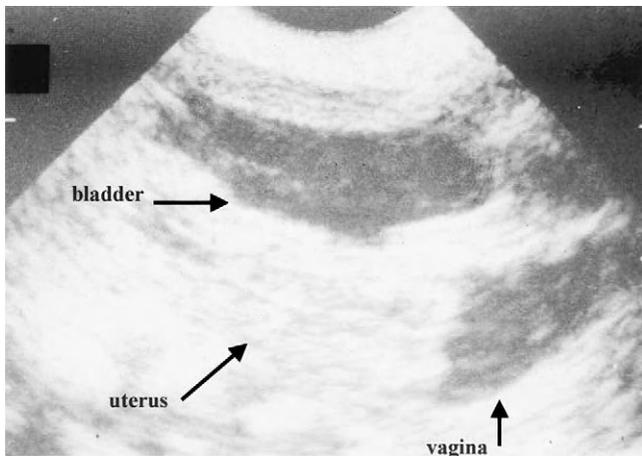

### Radiologic Investigations

**Pelvic Ultrasonography.** Pelvic ultrasonography reveals vital information in the evaluation of intersex disorders. The presence or absence of a uterus is a critically important determinant in the initial evaluation (Figs. 91-7, 91-8, and 91-9). The newborn period is a time when the uterus, ovaries, and adrenals are optimally visualized (Wright et al, 1995). The presence of a well-developed uterus will direct the differential diagnosis toward virilization of the female, true hermaphroditism, or persistent müllerian duct syndrome (PMDS). A rudimentary uterus may be seen in gonadal dysgenesis or hermaphroditism, however. Ultrasonography can locate undescended testes and determine gonadal size or irregularity, such as an oblong ovotestis. In hermaphroditism, loss of the uniform testicular echotexture may suggest the presence of an ovotestis. Ultrasound examination can determine if the adrenal glands appear enlarged, as in CAH. Note that normal adrenal size does not rule out CAH, however.

**Genitourethrogram.** A genitourethrogram is a fluoroscopy-guided genital dye study that can provide important information on the urethra and internal genital ducts (Wright et al, 1995). An experienced radiologist should perform this study. It is important to ensure that all perineal orifices are

**FIGURE 91-6.** Genitourethrograms. Left, Genitogram from a 46,XY infant with microphallus and undescended testes with a clearly delineated prostatic utricle (see Case Study 2). Right, Genitogram from a 46,XX infant with congenital adrenal hyperplasia and severe masculinization of external genitalia. The confluence of the vagina with the urogenital sinus is of intermediate severity.

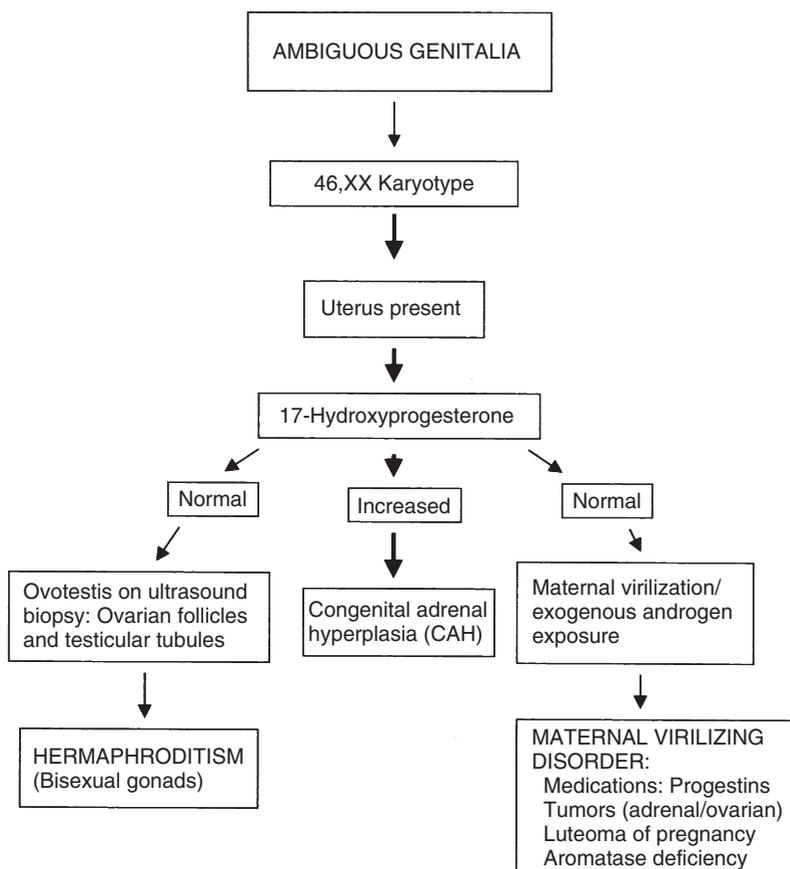

**FIGURE 91-7.** Ultrasound image from a 46,XX infant with ambiguous genitalia. Note the presence of a well-developed uterus with an endometrial stripe.

examined. The main features to be noted are the presence or absence of a vagina (or prostatic utricle) and the relationship between the vagina and the urethra (see Fig. 91-6). Demonstration of the level at which the vagina opens into the urogenital sinus and its relationship to the external sphincter has important surgical implications. Recognition of male or female urethral configurations also may be possible during genitourethrography.

**Magnetic Resonance Imaging.** Magnetic resonance imaging (MRI) has been used to assess the internal genitalia of a limited number of infants and children with genital differentiation disorders. The strength of MRI lies in its ability to image large areas in multiple planes and characterize soft tissues. Detailed information about müllerian and wolffian structures and the position of the gonads may be obtained; however, thin sections (3 to 5 mm) are required for an adequate study. Streak gonads remain difficult to visualize. MRI has the capability to differentiate between an enlarged clitoris and a penis, as the bulbospongiosus muscle and transverse perineal muscle are absent or poorly visualized in the virilized female (Wright et al, 1995). MRI is a promising modality for the evaluation of ambiguous genitalia; however, further studies are needed to demonstrate efficacy over other imaging modalities.

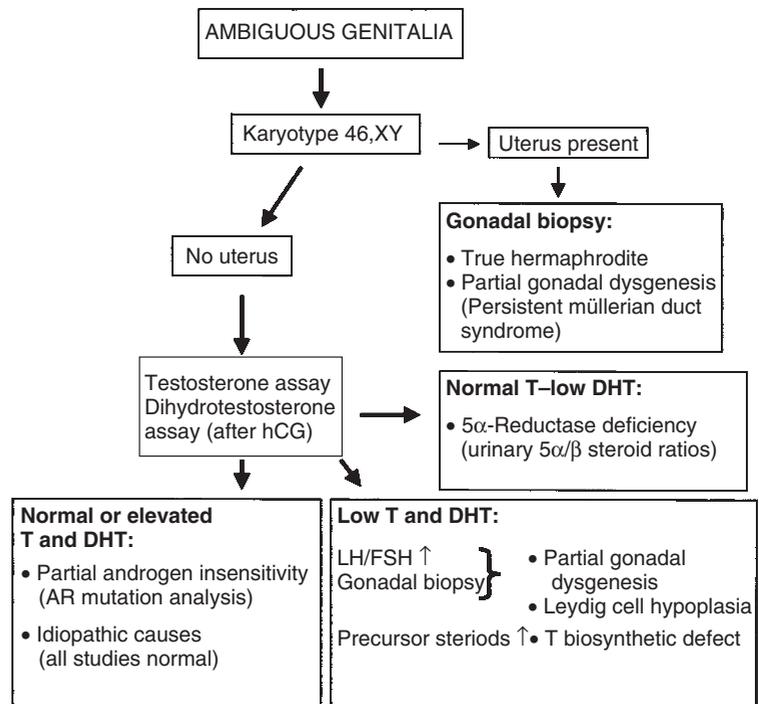

### Laboratory Investigations

Endocrine and genetic laboratory studies are germane in the evaluation of ambiguous genitalia in the newborn. Day 1 of life is an ideal time to obtain serum testosterone and dihydrotestosterone (DHT) levels, as testosterone levels fall rapidly in the first several days of life (Forest et al, 1980). *Chromosomal* studies should optimally be obtained on day 1, as at least 48 to 72 hours are required to complete the study. On day 2 or 3 of life, determinations of serum *17-hydroxyprogesterone*, *17-hydroxypregnenolone*, *11-deoxycortisol*, *dehydroepiandrosterone (DHEA)*, *androstenedione*, and *plasma renin activity* are performed if CAH is suspected.

**FIGURE 91-8.** Algorithm for evaluation of the 46,XX infant with ambiguous genitalia. The presence of a uterus would be determined radiographically by ultrasound examination, genitourethrogram, or magnetic resonance imaging.

**FIGURE 91-9.** Algorithm for evaluation of the infant with ambiguous genitalia and 46,XY karyotype. The presence or absence of a uterus would be determined by radiographic imaging including ultrasound examination, genitourethrogram, or magnetic resonance imaging, as appropriate. Testosterone (T) and dihydrotestosterone (DHT) levels ideally should be obtained after human chorionic gonadotropin (hCG) stimulation. AR, androgen receptor; FSH, follicle-stimulating hormone; LH, luteinizing hormone.

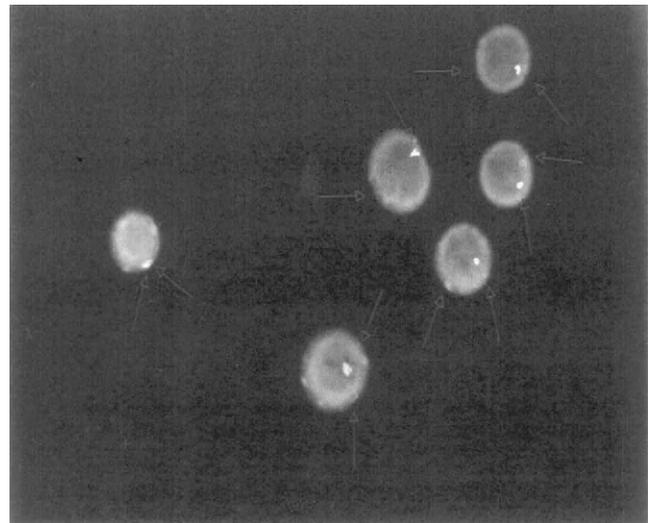

Some clinicians perform an adrenocorticotropic hormone (ACTH) stimulation test at this time to more clearly demonstrate a block in steroid biosynthesis. Results of these studies should be sent immediately to the appropriate reference laboratory for analysis. Alerting the reference laboratory to the urgent nature of the studies performed will facilitate rapid processing. 17-Hydroxyprogesterone levels are physiologically elevated in the first day of life, and screening for congenital adrenal hyperplasia should preferably not be done at this time. Serum gonadotropins are often suppressed in the immediate newborn period, so they should be measured after 1 week of life. Luteinizing hormone (LH) and follicle-stimulating hormone (FSH) levels are helpful in assessing for androgen insensitivity, gonadal dysgenesis, and LH receptor abnormalities. Repeat LH, FSH, testosterone, and DHT should be done between 2 and 8 weeks of life in the evaluation of undervirilized males. This time period coincides with the physiologic testosterone surge seen in normal male infants (Forest et al, 1980). When congenital adrenal hyperplasia is suspected, daily electrolytes are important to determine.

A human chorionic gonadotropin (hCG) test will be useful in the evaluation of suspected incomplete masculinization of the genetic male. Human chorionic gonadotropin binds the LH receptor and stimulates the testes to synthesize sex steroids. An adequate testosterone response rules out a testosterone biosynthetic defect, and a normal testosterone-to-DHT ratio argues against 5 $\alpha$ -reductase-2 deficiency. In addition, the test may result in phallic enlargement. Almaguer and colleagues (1993) reported an increase in phallic length of 0.25 to 0.75 cm in six 46,XY males with idiopathic micropallus within 5 days of beginning injections. A bolus of 1500 IU of hCG was given intramuscularly on 3 consecutive days, with steroids and phallic length measured on the fifth day. Growth of the phallus in response to hCG suggests that the phallus will further virilize at puberty, although no longitudinal study has documented

this assumption. A testosterone level greater than 200 ng/dL with a testosterone-to-DHT ratio of less than 8:1 is considered a normal response to hCG.

Fluorescence in situ hybridization (FISH) can rapidly determine the sex chromosome complement of the newborn by using X chromosome- and Y chromosome-specific centromeric probes (Schwartz et al, 1997) (Fig. 91-10). In addition, this methodology allows for the detection of low levels of chromosomal mosaicism because hundreds of cells can be analyzed rapidly. FISH analysis for determination of sex chromosome constitution has been shown to be

**FIGURE 91-10.** (See also Color Plate 91-10.) Fluorescence in situ hybridization (FISH) technique demonstrating the sex chromosome constitution of peripheral blood leukocytes. Centromeric probes to the X and Y chromosomes are represented by green (X) and orange (Y) markers.

highly reliable, although this methodology has not been used extensively in the evaluation of ambiguous genitalia of the newborn. Therefore, results should be interpreted with some degree of caution until confirmation by karyotypic analysis is available.

In a small percentage of ambiguous genitalia cases, laparoscopy with *gonadal biopsy* is necessary to confirm the diagnosis of true hermaphroditism, gonadal dysgenesis, or Leydig cell aplasia. Obtaining a karyotype from gonadal tissue may be helpful when sex chromosome mosaicism is suspected.

**DISORDERS RESULTING IN AMBIGUOUS GENITALIA**

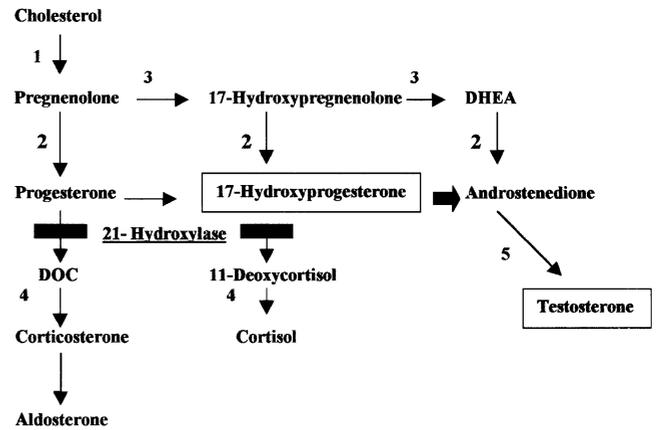

**Virilization of the Female**

Virilization of the female infant is most commonly caused by *congenital adrenal hyperplasia* (CAH), although other virilizing conditions can be involved (see Fig. 91-8). CAH encompasses a group of disorders of adrenal steroid hormone biosynthesis, of which over 95% are due to *21-hydroxylase deficiency* (New, 1992) (Fig. 91-11).

Occasionally, the presence of excess androgens of maternal origin can result in virilization of the female infant. Progestational agents used to prevent miscarriages have caused fetal masculinization (Grumbach and Conte, 1998). A unique cause of both maternal and fetal masculinization is placental aromatase deficiency (Conte et al, 1994).

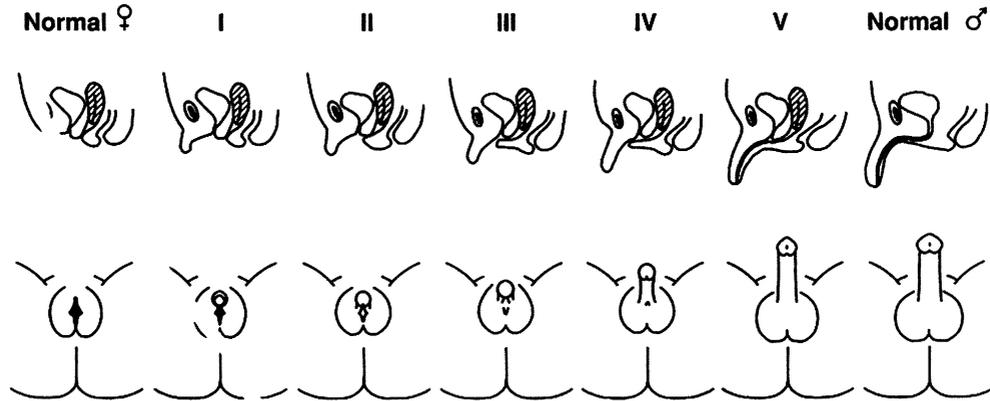

**Congenital Adrenal Hyperplasia**

21-Hydroxylase deficiency is the most common cause of ambiguous genitalia in the newborn female (New, 1992). 21-Hydroxylase deficiency has a population frequency of approximately 1/15,000, and the disorder is inherited in an autosomal recessive fashion. Males and females are equally affected; however, in classic cases, females usually are virilized at birth, resulting in the clinical presentation of ambiguous genitalia.

**FIGURE 91-11.** Steroid biosynthetic pathway demonstrating the defect in 21-hydroxylase deficiency (*solid bars*) and accumulated precursor 17-hydroxyprogesterone. Note increased shunting into androgen-producing pathways. Steroidogenic enzymes are indicated as follows: (1) steroidogenic acute regulatory protein (StAR) and side chain cleavage, (2) 3 $\beta$ -hydroxysteroid dehydrogenase, (3) 17 $\alpha$ -hydroxylase/17,20-lyase, (4) 11 $\beta$ -hydroxylase, and (5) 17 $\beta$ -hydroxysteroid dehydrogenase. DHEA, dehydroxyandrostenedione; DOC, deoxycorticosterone.

Deficiency of the 21-hydroxylase enzyme results in excess accumulation of the substrate 17-hydroxyprogesterone, which is shunted into the androgen synthesizing pathway resulting in excess levels of androstenedione (see Fig. 91-11). Androstenedione is then converted peripherally to testosterone. The excess production of androgens results in masculinization of the external genitalia of the female fetus, while the male infant with 21-hydroxylase deficiency is phenotypically normal. The degree of masculinization in the female is variable, and may range from mild enlargement of the clitoris to complete closure of the urethra at the tip of the phallus (see Fig. 91-4). The degree of virilization can be classified by Prader stages ranging from I to V (Fig. 91-12). Stage I represents mild enlargement of the clitoris only, and stage V, complete masculinization of the external genitalia,

**FIGURE 91-12.** The stages of virilization of the female with congenital adrenal hyperplasia as developed by Prader. Stage I indicates mild clitoromegaly only; stage V indicates complete masculinization. (Reproduced with permission from Migeon CJ, Berkovitz G, Brown T: *Sexual differentiation and ambiguity*. In Kappy MS, Blizzard RM, Migeon CJ [eds]: *Wilkins' The Diagnosis and Treatment of Endocrine Disorders in Childhood and Adolescence*, 4th ed. Springfield, IL, Charles C Thomas, 1994, p 573.)

with intermediate stages designating lesser degrees of involvement. The internal genitalia (ovaries, uterus, fallopian tubes) of virilized females are normal, however, and wolffian duct-derived structures are absent.

The degree of masculinization of the external genitalia of 46,XX fetuses is dependent on the timing and magnitude of androgen exposure of the fetus. Exposure of the female fetus to high androgen levels earlier than 12 weeks of gestation results in fusion of the labial folds with formation of a urogenital sinus. In severely masculinized cases, the external genitalia may appear completely male (see Fig. 91–4, lower panels). High-level androgen exposure after 12 weeks of gestation will result in mainly clitoral hypertrophy (see Fig. 91–4, upper left panel).

21-Hydroxylase deficiency will result in mineralocorticoid deficiency and salt loss in up to 75% of cases (New, 1992; Therrell et al, 1998). However, clinical manifestations of salt loss typically will not become apparent until several days or weeks after birth. Therefore, all infants with suspected salt-losing CAH need to be followed carefully during this time. Note that the male infant with salt-losing CAH will be phenotypically normal, and he is at great risk for salt-losing crisis after discharge from the newborn nursery. Fortunately, many (approximately 18) state newborn screening programs now screen for CAH to prevent males from developing salt-losing crisis, and also to prevent incorrect gender assignment of profoundly virilized female infants (Therrell et al, 1998) (Case Study 1).

### CASE STUDY 1

#### History

- A 3.5-kg term infant born after uncomplicated pregnancy
- Cryptorchidism and hypospadias noted, so infant discharged home as a male with plan for outpatient surgical evaluation
- Infant fed poorly at home, with intake of approximately 4 oz/day, no vomiting
- *Day 5 of life*: notification of abnormal newborn screen for congenital adrenal hyperplasia by health department. Referred to emergency room.

#### Evaluation

- On presentation to emergency department: infant was well appearing, weight 2.9 kg (representing a loss of 0.6 kg)
- Genital examination: 2.3 × 1.1 cm phallus, severe hypospadias, marked labial fusion, no palpable gonads, marked hyperpigmentation of genitalia
- Electrolytes: sodium 140 mEq/L, potassium 5.8 mEq/L, chloride 107 mEq/L, CO<sub>2</sub> 19 mEq/L, BUN 15 mg/dL, Cr 1.0 mg/dL
- Glucose 94 mg/dL
- Ultrasound examination: uterus present, enlarged adrenals, no gonads seen
- Karyotype 46,XX
- 17-Hydroxyprogesterone 20,000 ng/dL (normal: less than 200) (unstimulated)
- Plasma renin activity 201 ng/mL/hour (normal: less than 26)

#### Management and Outcome

- Gender was reassigned female
- Hydrocortisone (Cortef) and fludrocortisone acetate (Florinef) started along with NaCl supplements
- *Day 10 of life*: weight 3.2 kg, feeding 4 oz/4 hours

- *By 4 months of age*: significant reduction in clitoral and labial enlargement as well as resolution of hyperpigmentation.
- *By 3 years of age*: the clitoral size had not normalized and the mother became very concerned about the child showing signs of gender “confusion,” and hence clitoral reduction surgery was performed.

The diagnosis of 21-hydroxylase deficiency should be suspected in all newborns with ambiguous genitalia (or clitoral hypertrophy) and absent gonads in the labial/scrotal folds. A serum 17-hydroxyprogesterone level obtained after the first day of life will often be diagnostic. 17-hydroxyprogesterone levels are usually 50- to 100-fold above the normal range in classic cases, with typical random levels of 10,000 ng/dL or higher (New, 1992). In some cases of 21-hydroxylase deficiency, ACTH stimulation testing may be necessary to establish the diagnosis.

Levels of androstenedione, testosterone, electrolytes, and plasma renin activity should also be determined. Plasma renin activity is a very sensitive indicator of the intravascular volume status of the infant. Impaired sodium-potassium and sodium-hydrogen exchange due to aldosterone deficiency in the distal tubule of the kidney results in hyponatremic dehydration, hyperkalemia, and metabolic acidosis.

Assessment for the less common forms of CAH resulting in ambiguous genitalia—11 $\beta$ -hydroxylase deficiency and 3 $\beta$ -hydroxysteroid dehydrogenase deficiency (3 $\beta$ -HSD)—include measuring 11-deoxycortisol, DOC, and 17-hydroxypregnenolone. (Use of a comprehensive steroid panel from a reliable reference laboratory will limit the amount of required blood to 3 to 5 mL.)

11 $\beta$ -Hydroxylase deficiency accounts for approximately 5% of CAH cases worldwide, and this disorder will result in masculinization of the female fetus (see Fig. 91–11). However, presence of volume overload and hypertension distinguishes this disorder from 21-hydroxylase deficiency (New, 1992). Presumably, the hypertension is due to the excess mineralocorticoid activity of the DOC metabolite. Typically, 11-deoxycortisol (compound S) is elevated and plasma renin activity is suppressed in this disorder.

3 $\beta$ -HSD may result in ambiguous genitalia in the newborn period (see Fig. 91–11). Unlike 21-hydroxylase deficiency, this enzyme is present in the gonads as well as the adrenals, and deficiency of 3 $\beta$ -HSD may result in undermasculinization of the male infant as well as mild masculinization of the female infant. The 3 $\beta$ -HSD enzyme is needed for testosterone biosynthesis; hence the male fetus may be inadequately masculinized. This enzyme deficiency results in excess production of the steroid DHEA, which can be converted to more potent androgens peripherally. The female infant with this disorder can have clitoromegaly, although such children often are phenotypically normal.

A marked increase in the ratios of 17-hydroxyprogesterone to 17-hydroxypregnenolone and of androstenedione to DHEA is diagnostic in mutation-positive forms of this disorder (Sakkal-Alkaddour et al, 1996).

Treatment of CAH in the newborn period consists of glucocorticoid and mineralocorticoid replacement. Hydrocortisone is the most physiologic form of synthetic glucocorticoids and is less likely to result in unwanted side

effects. Hydrocortisone is administered orally at a dose of approximately 25 mg/m<sup>2</sup>/day in the newborn period (divided into three doses). No liquid preparation of hydrocortisone is currently available, so tablets must be crushed and administered carefully with formula or food. Mineralocorticoid replacement (fludrocortisone acetate [Florinef]) at a starting dose of 0.1 mg/day in the newborn is recommended. Sodium chloride supplements (approximately 1-2 g/day) may be a useful adjunctive therapy in salt-losing CAH, as formula and human milk have low salt contents. Once therapy is initiated, careful monitoring of the infant's growth as well as determination of serum 17-hydroxyprogesterone, androstenedione, testosterone, and plasma renin activity is recommended.

Salt-losing crisis and acute adrenal insufficiency should be treated with stress doses of hydrocortisone (100 mg/m<sup>2</sup>/day), which can be given either continuously as a drip or divided into equal doses every 6 hours. Intravenous fluids with ample sodium chloride (normal saline for boluses and one-half normal saline for maintenance fluids) are an essential component of treating salt-losing crisis. Care should be taken not to over- or underhydrate the infant. Hyperkalemia often improves after sodium chloride and hydrocortisone are provided intravenously, although severe cases of hyperkalemia may require additional therapies.

Gender assignment in 46,XX infants with 21-hydroxylase deficiency has traditionally been female (American Academy of Pediatrics Committee, 2000; Forest, 2001; Donahoe, 1991; Migeon et al, 1994; New, 1992). Gender identity of 46,XX adults with CAH typically is female, with varying degrees of masculinized behavior (Money and Ehrhardt, 1972; Reiner, 1997). Cases of gender identity disorder have been reported in treated CAH females, however (Slijper et al, 1998), and cases of gender reassignment from female to male have been reported (Meyer-Bahlburg et al, 1996). Persons with undiagnosed 46,XX CAH who are profoundly virilized have functioned successfully as males (Blizzard, 1999). Diamond and Sigmundson (1997a) have suggested male gender assignment in profoundly virilized 46,XX individuals, although female gender assignment is likely to prevail in current practice until evidence is obtained to indicate otherwise (Lee, 2001).

In addition to medical therapies for CAH, efforts to normalize the appearance of the external genitalia may be pursued. It should be kept in mind that hypertrophy of the clitoris will gradually lessen after medical therapy is instituted; however, complete normalization in the more virilized cases is not likely to occur. In severe cases of clitoral enlargement, clitoral reduction surgery is a treatment option, although suboptimal cosmetic results have been reported in long-term outcome studies. Atrophy or loss of the clitoris or excessive regrowth of clitoral tissue has been described in examinations of adolescent and adult patients who underwent genital surgery in early childhood (Alizai et al, 1999; Creighton et al, 2001). The risk of surgery needs to be balanced against the potential detrimental effects of masculinized genitalia on the development of a poor body image (Meyer-Bahlburg et al, 1996) and of social stigmatization by family or community members (Money et al, 1986).

Surgical correction of the vagina in CAH is performed to exteriorize the vagina and also to enlarge the vaginal opening so that successful intercourse may occur later in life (see later section on surgery). Considerable debate exists about when to perform vaginal exteriorization surgery. A number of studies have demonstrated the development of vaginal stenosis when vaginoplasties are performed in the prepubertal period (Alizai et al, 1999; Creighton et al, 2001; Krege et al, 2000). The investigators advocate delaying vaginoplasty until puberty or later, when manual dilation can be undertaken by the patient and estrogenization of the vaginal mucosa may help prevent stricture formation. Others recommend that vaginoplasties be undertaken early in life, as the procedure is technically easier in the first several years of life and the emotional trauma of a major surgery at adolescence is avoided (Donahoe, 1991; Schnitzer and Donahoe, 2001).

Patient advocate groups such as the Intersex Society of North America (ISNA) and others have called for a general moratorium on all nonessential genital surgery in infancy, until affected persons are old enough to express their wishes and give consent (Diamond and Sigmundson, 1997a). Problems with loss of sexual sensation and pleasure have been reported in adult patients as a consequence of genital surgery in early life. However, in cases of severe discordance between assigned sex and genital appearance, the psychosocial consequences of uncorrected genital anomalies may be damaging (Money and Ehrhardt, 1972; Money et al, 1986). Participation of the parents in the decision to pursue genital surgery after they have been fully informed of the benefits and risks is perhaps the most judicious approach at this time (Daaboul and Frader, 2001; Lee, 2001; Reiner, 1997).

Significant reductions in fertility have been reported in women with salt-losing CAH (Kuhnle et al, 1995; Mulaikal et al, 1987). Suggested explanations for reduced fertility included increased anovulatory cycles, low rates of heterosexual activity, inadequate vaginal introitus, and poor compliance with medical treatment (Mulaikal et al, 1987). Problems with a disturbed body image and feeling less feminine were associated with a lower rate of success among women with CAH in terms of the ability to establish a partnership or marry (Kuhnle et al, 1995). Overall quality of life for female patients with CAH was comparable with that for controls, however, suggesting that affected women may develop coping strategies and cognitive appraisals that enable them to accept their life and view it as satisfying (Kuhnle et al, 1995).

### Increased Maternal Androgens and Progestins

Masculinization of the female fetus has been reported in pregnant mothers taking various *progestational agents* to prevent miscarriage. These agents include norethindrone, ethisterone, and medroxyprogesterone. Danazol, which has been used in the treatment of endometriosis, has been associated with fetal masculinization (Grumbach and Conte, 1998). Masculinization of the female fetus due to *maternal virilizing ovarian or adrenal tumors* or *luteomas* of pregnancy have been reported. In such cases, virilization beyond the time of birth does not

occur, and the prognosis is good (Grumbach and Conte, 1998).

### Placental Aromatase Deficiency

Placental aromatase deficiency has been associated with masculinization of the female fetus. Aromatase is a cytochrome P-450 enzyme that is responsible for the conversion of testosterone to estradiol and of androstenedione to estrone. Autosomal recessive inheritance of aromatase deficiency causes virilization of the female due to failure to metabolize the large amounts of androstenedione and testosterone produced by the placenta. This disorder also will cause significant virilization of the mother. The affected infant will be virilized with normal müllerian structures. Gonadotropins are elevated in infancy, and ovarian cysts may develop. At puberty, females have hypergonadotropic hypogonadism with failure to feminize and progressive virilization. Plasma androstenedione and testosterone are elevated, while estrone and estradiol levels are low. Postpubertal patients have delayed bone maturation, tall stature, and osteopenia (Conte et al, 1994).

### The Incompletely Masculinized Male

Incomplete masculinization refers to absence of or incomplete masculinization of the external and internal genitalia in a person with a 46,XY karyotype and normal testes. Disorders leading to incomplete masculinization of the male include (1) androgen receptor defects, (2) testosterone biosynthetic defects, (3) 5 $\alpha$ -reductase deficiency, (4) Leydig cell hypoplasia, and (5) effects of maternal medications (see Fig. 91–9).

It should be noted that in 25% to 50% of undermasculinized males, a specific etiology cannot be found (Al-Agha et al, 2001; Eil et al, 1984). Other factors such as medications and placental insufficiency may potentially interfere with genital masculinization. Placental insufficiency may be related to genital underdevelopment through the presumed mechanism of inadequate human chorionic gonadotropin (hCG) production. Placental hCG is required for early fetal testosterone production and hence early fetal genital development.

Medications such as cimetidine, spironolactone, phenytoin (Dilantin), phenobarbital, medroxyprogesterone, and cyproterone acetate have been associated with altered androgen action or metabolism. Their use during pregnancy may therefore be detrimental to male genital development (Donahoe, 1991; Grumbach and Conte, 1998). Furthermore, various xenobiotics can bind the androgen receptor, and thus speculations on the role of environmental factors in abnormal sex differentiation have been made (Danzol, 1998).

### Androgen Receptor Defects (Androgen Insensitivity)

Disorders of the androgen receptor are the most common definable cause of incomplete masculinization of the genetic male (Quigley et al, 1995). Disorders of the androgen

receptor can be divided into complete androgen insensitivity (CAIS) and partial androgen insensitivity (PAIS) syndromes. The gene for the androgen receptor (AR) is located on the X chromosome, and over 300 mutations have been found (Griffin et al, 2001). Mutations have been found throughout the AR gene, with most mutations occurring in the DNA or steroid-binding domains. Despite extensive characterization of the molecular genetics of AR mutations, no genotype-phenotype correlation has been found (Quigley et al, 1995).

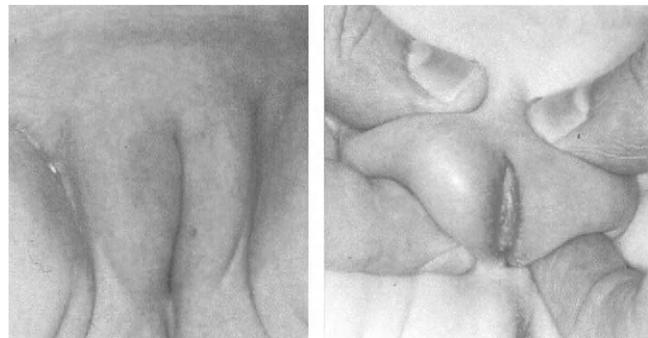

The sex-differentiating actions of testosterone and DHT are mediated by the androgen receptor. Dihydrotestosterone is important in the differentiation of the male external genitalia and prostate, whereas testosterone is important in the differentiation of internal wolffian ducts to epididymis, vas deferens, and seminal vesicles.

### Complete Androgen Insensitivity

Complete androgen insensitivity syndrome (CAIS) in a 46,XY individual is characterized by phenotypically normal female external genitalia (Fig. 91–13). Affected children will present with an inguinal hernia prepubertally or because of primary amenorrhea postpubertally. Robust breast development occurs at puberty that is due to peripheral aromatization of testosterone to estrogen. There is usually scant or absent pubic and axillary hair with some vulvar hair. The vagina is short and blind ending, and müllerian structures (cervix, uterus, fallopian tubes) are absent. There are only vestigial or no wolffian duct-derived internal structures. The testes are located in the abdomen or inguinal canal or in the labia majora. Gender identity and role behaviors are typically female. Removal of the testes is recommended because of risk for development of gonadoblastoma, although there is no consensus on the timing of orchidectomy (Forest, 2001; Migeon et al, 1994).

### Partial Androgen Insensitivity

Partial androgen insensitivity syndrome (PAIS) is characterized by varying degrees of ambiguity of the external genitalia. The term *Reifenstein syndrome* formerly was

**FIGURE 91–13.** Left panel, Appearance of external genitalia of a 46,XY infant with complete androgen insensitivity syndrome (CAIS). Right panel, Note presence of bilateral palpable gonads.

used to describe partial androgen insensitivity with intermediate degrees of masculinization. Affected infants present with a small phallus and a ventral chordee that “tethers” the phallus to the perineum. There is often a penoscrotal hypospadias and a bifid scrotum, which may or may not contain gonads (see Fig. 91–3). Cryptorchidism is not uncommon. Müllerian structures are absent, and the wolffian duct-derived structures are absent or poorly developed. A genitourethrogram may demonstrate a urogenital sinus.

The diagnosis of partial androgen insensitivity is complex. A family history of ambiguous genitalia in male relatives would be suggestive of this diagnosis. However, Viner and colleagues (1997) reported a positive family history in only 25% of patients with PAIS. 5 $\alpha$ -Reductase deficiency and testosterone biosynthetic defects should be ruled out by appropriate steroid analysis. This can be accomplished by measuring intermediates in testosterone biosynthesis as well as measuring the ratio of testosterone to DHT. It should be noted that abnormal testosterone-DHT ratios can be seen in PAIS (Ahmed et al, 1999). This may be due to poor development of tissues, which express 5 $\alpha$ -reductase-2 in PAIS (Griffin et al, 2001).

Androgen levels in normal newborns are highest at birth and then decline rapidly during the first week. A second testosterone surge occurs between 15 and 60 days of life (Forest et al, 1980). Androgen and LH levels should be obtained at these peak production times. Alternatively, an hCG stimulation test may be performed as follows: a dose of 1500 IU of hCG is given intramuscularly (IM) once daily for 3 days; androgen and gonadotropin levels are measured at baseline and then 24 hours after the third dose. Abnormally elevated levels of LH and/or testosterone in the first several months of life are suggestive of androgen insensitivity. However, a recent report of five neonatal cases of PAIS showed testosterone values in the high-normal range on days 2 to 7 of life (mean, 107  $\pm$  27 ng/dL) and on day 30 (mean, 411  $\pm$  154 ng/dL) (Bouvattier et al, 2002). LH levels were elevated in comparison with historic controls (mean LH levels on days 7 to 15 of life were 5.2 IU/L  $\pm$  4.0 ng/dL; on day 30 of life mean levels were 8.7 IU/L  $\pm$  2.5 ng/dL). Testosterone response to hCG and LH response to gonadotropin-releasing hormone (GnRH) were exaggerated (Bouvattier et al, 2002).

Androgen receptor binding assay was considered the gold standard for defining this disorder in the past. However, normal ligand binding does not rule out androgen insensitivity, as there may be mutations in domains of the androgen receptor not involved in ligand binding. Direct sequencing of the androgen receptor for mutation analysis is commercially available (GeneTest) and can detect up to 95% of mutations associated with androgen insensitivity. Androgen receptor mutations, however, are not always found in cases of suspected androgen insensitivity, and it is speculated that defects in androgen receptor-interacting proteins may then be involved.

Determining the gender of rearing in partial androgen insensitivity is a difficult task, and multiple factors must be considered. If there is a significant degree of virilization (Prader stages IV and V) (see Fig. 91–12), then

male sex assignment is made (Reiner, 1997; Diamond and Sigmundson, 1997a). If masculinization is severely limited (Prader stages 1 and 2), then female sex assignment is recommended. In intermediate forms (Prader stage 3), responsiveness to exogenously administered hCG or testosterone may be of help in the decision-making process (Daaboul and Frader, 2001; Grumbach and Conte, 1998). However, adult males with a small phallus have reported satisfactory sex lives (Reilly and Woodhouse, 1989). These cases perhaps de-emphasize the importance of phallic size in male sex assignment. Slijper and colleagues (1998) report the absence of serious gender identity disorder in five undervirilized 46,XY males, although these boys were “more fearful and bothered about the smallness of their penises.” Money and colleagues (1972) caution about the devastating psychosocial effects of male sex assignment when the phallus is only slightly larger than a clitoris and does not respond to testosterone, however.

In a study of 32 undervirilized males assigned female gender of rearing, significant gender transposition (a term meaning gender change as well as homosexual orientation) correlated with the presence of childhood stigmatization and a relatively late age of feminizing surgery (Money et al, 1986). Stigmatization in the home was reflected by treating the child differently from other children, including elaborate efforts at maintaining the privacy of the genital anomaly, keeping the child at home and forbidding play with neighborhood children, and refusal of open communication within the family about the medical condition. Stigmatization in the community was reflected by teasing about the genital anomaly, body habitus, mannerisms, and so on.

Stigmatization by parents or the community also was found to be associated with gender transposition in undervirilized males assigned male gender of rearing; cosmetic inadequacy of the external genitalia was less important (Money and Norman, 1987).

These studies point to the importance of a nurturing, supportive environment to a successful long-term outcome for these children. More comprehensive long-term outcome studies of partial androgen insensitivity are greatly needed, however.

### 5 $\alpha$ -Reductase-2 Deficiency

5 $\alpha$ -Reductase-2 deficiency is an autosomal recessive disorder that results in an inability to convert testosterone to DHT. DHT is required for the development of the male external genitalia.

At birth, these 46,XY infants typically have a very small phallus that appears to be a normal or slightly enlarged clitoris. However, more significant virilization of the phallus may occur, and the affected child will then be identified as a male with hypospadias. There is usually severe penoscrotal hypospadias. The scrotum is bifid, with slight posterior fusion. The testes are usually in the inguinal canals or labial folds. Approximately half of these patients have a penoscrotal urethra with a separate blind-ending vagina; a smaller percentage have a single urogenital sinus opening on the perineum (Griffin et al, 2001).

Müllerian structures are absent, and wolffian duct-derived structures (vas deferens, epididymis, seminal vesicles) are well developed. The prostate is poorly developed.

At the time of puberty, individuals with this disorder will characteristically virilize. The phallus will typically increase to a length of 4 to 8 cm (Migeon et al, 1994). In affected persons who were raised as females, a change to the male gender role after puberty is commonly seen (Griffin et al, 2001; Imperato-McGinley, 1997). Unlike in partial androgen insensitivity, gynecomastia does not occur in the pubertal period.

5 $\alpha$ -Reductase-2 deficiency has been diagnosed in the postpubertal period in most cases, although diagnosis in the newborn period has been reported (Imperato-McGinley et al, 1986; Odame et al, 1992). The disorder is diagnosed by assessing the ratio of testosterone to DHT in blood (Peterson et al, 1977). The normal testosterone-DHT ratio in the newborn period is 4:1, whereas the ratio in infants and children with this disorder is often greater than 14:1. An hCG stimulation test usually is needed to obtain a more definitive diagnosis in the prepubertal period. A positive response to hCG rules out Leydig cell aplasia or a testosterone biosynthetic defect. Measurement of normal androstenedione levels will rule out the testosterone biosynthetic defect: 17 $\beta$ -HSD dehydrogenase deficiency. This enzyme is responsible for the conversion of androstenedione to testosterone, and the clinical presentation in infancy can be similar to that of 5 $\alpha$ -reductase deficiency.

In addition, abnormal ratios of 5 $\beta$ - to 5 $\alpha$ -urinary steroids can establish a definitive diagnosis of 5 $\alpha$ -reductase deficiency-2 (Imperato-McGinley et al, 1986). Distinguishing 5 $\alpha$ -reductase deficiency from partial androgen insensitivity is important, as androgen insensitivity can cause a secondary DHT deficiency due to the incomplete development of tissues that express 5 $\alpha$ -reductase activity (Griffin et al, 2001). Measurement of urinary 5 $\beta$ - to 5 $\alpha$ -glucocorticoids will help make this distinction, as only 5 $\alpha$ -reductase deficiency will also affect glucocorticoid metabolism. Analysis of 5 $\alpha$ -reductase-2 activity in genital fibroblasts also can be determined. Finally, analysis for mutations in *SRD5A2* gene is diagnostic; however, this test is not currently commercially available.

Sex assignment in cases of 5 $\alpha$ -reductase deficiency is a complicated issue, but there is long-term outcome information available. As in androgen insensitivity disorders, sex assignment is often significantly influenced by the degree of masculinization at birth, and because infants with this disorder usually are markedly undervirilized, female sex assignment has been advocated (Grumbach and Conte, 1998; Migeon et al, 1994). However, if the disorder is diagnosed early, topical DHT treatment has been shown to enlarge the phallus (Odame et al, 1992). In addition, the natural history of the disorder is for masculinization of the phallus to occur at puberty. There are frequent reports of reversal from female to male gender behavior after puberty (Wilson, 2001; Wilson et al, 1993). The accumulated evidence would support male sex assignment in this disorder (Imperato-McGinley, 1997), although female sex assignment is likely in the newborn period if the diagnosis is overlooked.

### Testosterone Biosynthetic Defects

Five enzymes are necessary for the synthesis of testosterone. A defect at any step will result in inadequate testosterone synthesis (see Fig. 91–11). Defects in the first three enzymes of the testosterone synthesis pathway will also affect adrenal steroid production, resulting in both an undervirilized male and CAH. Because testosterone production is impaired in these disorders, wolffian duct structures are likely to be underdeveloped, whereas müllerian structures are absent due to normal testicular MIF production. These enzyme deficiencies are quite rare, however, so these disorders are discussed only briefly here.

#### 17 $\beta$ -Hydroxysteroid Dehydrogenase-3 Deficiency (17-Ketosteroid Reductase Deficiency)

The final step in testosterone biosynthesis involves the conversion of androstenedione to testosterone by the enzyme 17 $\beta$ -HSD in the testicle. Mutations that impair the function of 17 $\beta$ -HSD are the cause of this relatively rare autosomal recessive disorder (Wilson, 2001).

The clinical presentation is that of an external female at birth with perhaps a mild degree of clitoral enlargement. The phenotype is female; therefore, these infants typically are raised as females. At puberty, there is progressive masculinization, with enlargement of the phallus to 4 to 6 cm with labial enlargement and rugation. By late puberty, the testes are found at the lower ring of the inguinal canal, and they are of normal size and consistency. Internal wolffian duct-derived structures are found. In addition, a male body habitus develops, and deepening of the voice and male body hair, including mustache and beard are found (Migeon et al, 1994).

Most patients are diagnosed at puberty or as adults. Endocrine studies reveal markedly elevated androstenedione levels, whereas testosterone levels are in the low-normal range (Mendonca et al, 2000). Plasma LH levels are consistently high. In infancy or childhood, the presence of inguinal hernias may bring the child to medical attention. Androstenedione levels in the prepubertal patient may be normal, and the hCG stimulation test is required to elucidate the defect.

Gender of rearing often is influenced by the cultural context. In societies in which a high priority is given to the male gender, gender reassignment at puberty has been successful (Forest, 2001). Mendonca and colleagues (2000) have observed changes in gender role (female to male) in 3 of 10 affected individuals. Despite virilization in some affected persons, however, the female gender role was maintained.

#### Congenital Lipoid Adrenal Hyperplasia

Lipid accumulation in both the adrenals and gonads is characteristic of this disorder pathologically—hence the name *congenital lipoid adrenal hyperplasia*. Because all adrenal and gonadal steroid synthesis is affected by this disorder, infants are likely to present with complete adrenal insufficiency, characterized by vomiting, weight loss, and hypotension. The phenotype is likely to be female, although

there is clinical variability. In the 35 cases reported in the medical literature, only 11 patients have survived beyond infancy (Forest, 2001).

Endocrinologic findings include elevation of ACTH and plasma renin activity but low or unmeasurable levels of all steroid hormones. The main consideration in the differential diagnosis is CAH. The presence of markedly enlarged lipid-laden adrenals on ultrasound, CT, or MRI studies is highly suggestive of the disorder. Successful treatment has occurred and requires replacement of both glucocorticoids and mineralocorticoids. All persons diagnosed with this disorder have been raised as females (Grumbach and Conte, 1998).

In vitro studies performed on either adrenal or testicular tissue demonstrated an inability to convert cholesterol to pregnenolone in these patients. A defect in the first step of adrenal and gonadal steroid biosynthesis mediated by the cytochrome P-450 side chain cleavage (P450<sub>scc</sub>) enzyme was suspected. However, subsequent molecular studies demonstrated mutations in the steroidogenic acute regulatory protein (StAR) (Grumbach and Conte, 1998). StAR acts to promote sterol translocation to the P450<sub>scc</sub> enzyme in mitochondria (see Fig. 91–11).

### **3 $\beta$ -Hydroxysteroid Dehydrogenase Deficiency II**

3 $\beta$ -HSD deficiency was first reported by Bongiovanni (1962). 3 $\beta$ -HSD is an important enzyme required for the conversion of  $\Delta$ -5 to  $\Delta$ -4 steroids in the adrenals and gonads (see Fig. 91–11). There is marked heterogeneity in clinical presentation, and both genders are affected (Forest, 2001). With severe deficiency of 3 $\beta$ -HSD, salt-losing crisis may occur. Male infants may have ambiguous or completely feminine external genitalia, whereas female infants may be mildly virilized. Severely undervirilized males may have normal mineralocorticoid activity; fully masculinized males may display salt loss.

Diagnosis of this disorder in the newborn period may be difficult because of relatively high levels of  $\Delta$ -5 steroids physiologically. The diagnosis is based on the ratio of 17-hydroxyprogesterone to 17-hydroxypregnenolone and of DHEA to androstenedione in the basal and stimulated states (Sakkal-Alkaddour et al, 1996).

### **17 $\alpha$ -Hydroxylase/17,20-Lyase Deficiency**

A single enzyme encoded on the P450<sub>c17</sub> gene mediates the 17-hydroxylation of pregnenolone and progesterone and the conversion of 17-hydroxypregnenolone and 17-hydroxyprogesterone to DHEA and androstenedione. Clinical disorders of this enzyme affect primarily either the hydroxylation or the lyase reaction. Cases of primarily 17-hydroxylase deficiency should be considered in undervirilized males or females with hyporeninemic hypertension and hypokalemic alkalosis. The hypertension is due to elevated levels of DOC and corticosterone (see Fig. 91–11). Most cases are diagnosed in the pubertal period because the 46,XY phenotype is largely female. Of interest, although cortisol synthesis is blocked, the overproduction of DOC and corticosterone is protective against adrenal insufficiency. This disorder is treated with

glucocorticoid, which suppresses ACTH overproduction and subsequently suppresses DOC and corticosterone overproduction (Grumbach and Conte, 1998). Sex steroid replacement is needed at puberty.

17,20-Lyase deficiency results in varying degrees of undermasculinization of the 46,XY infant. The phenotype ranges from complete female external genitalia to ambiguous genitalia to a mildly undervirilized male. 46,XX females will present with failure to enter puberty. Gonadotropins will be elevated, along with impaired formation of DHEA and androstenedione (see Fig. 91–11). DOC and corticosterone are normal in this form of the disorder. Human chorionic gonadotropin and ACTH stimulation tests may be helpful to more fully reveal the steroid biosynthetic block.

### **Leydig Cell Hypoplasia**

Failure of testes to produce testosterone in response to hCG is characteristic of this disorder. Histologic examination of the testes reveals absent or low numbers of Leydig cells, normal-appearing Sertoli cells, and seminiferous tubules with spermatogenic arrest (Grumbach and Conte, 1998). LH receptor mutations have been described in this disorder. Phenotypically, the external genitalia vary from those of a normal female to those of a male with microphallus. Müllerian-derived structures are absent in all patients, whereas wolffian structures may be present. LH and FSH levels are elevated in postpubertal patients and LH levels decrease after testosterone administration. In less severe forms of the disorder, testosterone therapy augments phallic growth. In severe forms of testicular unresponsiveness to hCG/LH, gender assignment has been female. The gonads are removed, and estrogen replacement therapy is instituted at the time of expected puberty (Grumbach and Conte, 1998).

### **Persistent Müllerian Duct Syndrome**

The diagnosis of PMDS often is made in otherwise phenotypically normal 46,XY males at the time of surgery for an inguinal hernia or orchidopexy. In the case of hernia repair, a fallopian tube and uterus are often found along with a partially descended testis. In other cases, testes, uterus, and fallopian tubes are found in the pelvis. PMDS is inherited autosomally recessively, although the female phenotype is completely normal. The disorder has been found to be due to a mutation in the antimüllerian hormone or receptor (Grumbach and Conte, 1998). Therapy involves orchidopexy and partial hysterectomy, with care taken to avoid injuring the vas deferens that is embedded in the uterine wall.

## **Gonadal Differentiation and Chromosomal Disorders**

### **46,XY Complete Gonadal Dysgenesis**

46,XY complete gonadal dysgenesis was first described by Swyer in 1955 (Grumbach and Conte, 1998). The phenotype of the external genitalia was female with normal development of müllerian-derived internal structures. Streak gonads are found that are completely

**FIGURE 91-14.** Left panel, Appearance of external genitalia in complete gonadal dysgenesis in a 46,XY infant with features of Turner syndrome. Upper right panel, Uterus and fallopian tubes were found at surgery, along with a gonadoblastoma, at 1 year of age. Lower right panel, Micrograph of tumor cells.

nonfunctional; therefore, müllerian structures do not regress, and wolffian structures are poorly developed or absent (Fig. 91-14). Most affected persons present in the teenage years with lack of pubertal development. Serum gonadotropin levels are elevated. Mutations in the *SRY* gene account for only a small proportion of these cases (Forest, 2001). Familial cases have been reported. In up to 30% of affected persons, gonadoblastomas will develop in the streak gonad; therefore, removal of the streak gonad is recommended (Migeon et al, 1994) (see Fig. 91-14). Estrogen replacement therapy will provide appropriate feminization.

#### 46,XY Partial Gonadal Dygenesis

Patients with 46,XY partial gonadal dygenesis will typically present in the newborn period for evaluation of ambiguous genitalia (Berkovitz et al, 1991). The extent of masculinization of the external genitalia depends on the extent of testicular differentiation. Gonadal tissue is usually intra-abdominal, but testes can be found in the scrotum. One quarter of these patients will have phenotypic features of Turner syndrome (Migeon et al, 1994). Testosterone response to hCG is variable but usually low. In most cases, there is a mix of müllerian and wolffian structures. The presence of müllerian structures on genitourethrogram or ultrasound increases the index of suspicion for this disorder. The diagnosis is confirmed by gonadal biopsy. Some affected children are found to have one dysgenetic gonad on one side and a streak gonad on the other; others have bilateral dysgenetic gonads. Dysgenetic gonads are histologically defined by poorly formed and disorganized seminiferous tubules surrounded

by wavy ovarian stroma. In many cases, the dysgenetic gonads resemble ovotestes, except that primordial ovarian follicles are lacking (Berkovitz et al, 1991) (Case Study 2).

#### CASE STUDY 2

##### History

- Infant born at 35 weeks of gestation, weight 2.49 kg (50% percentile for gestational age)
- Pregnancy complicated by maternal hypertension treated with propranolol
- Cesarean section performed for breech position, oligohydramnios, and poor growth.

##### Physical Examination and Laboratory Studies

- Genital examination: phallus 1.4 cm in length with poorly formed glans, no palpable testes; no hypospadias
- Ultrasound examination: presence of uterus, no gonads seen
- Genitogram: large prostatic utricle, no uterus (see Fig. 91-6, left panel)
- Karyotype and FISH: 46,XY, no mosaicism
- Endocrine studies

##### Day 3 of life:

17-Hydroxyprogesterone 107 ng/dL (normal: less than 570)  
 Testosterone 4 ng/dL (37 to 198)  
 DHT less than 2.0 ng/dL (10 to 53)  
 Androstenedione 58 ng/dL (80 to 446)

##### Day 11 of life:

Müllerian inhibitory factor 3.0 ng/mL (mean 30)  
 hCG stimulation test (1500 units IM every other day × 3):  
 testosterone increased from 18 to 65 ng/dL (normal response is greater than 150)

- Gonadal biopsies: dysgenetic testes identified and removed.

**Diagnosis**

- 46,XY partial gonadal dysgenesis

**Management and Outcome**

- Testosterone enanthate 25 mg IM given  $\times$  1; phallic growth increased from 1.6 to 2.1 cm
- Male gender assignment made

**Mixed Gonadal Dysgenesis**

Mixed gonadal dysgenesis (MGD) refers to asymmetrical gonadal dysgenesis with ambiguous genitalia (see Fig. 91–5) and a mosaic karyotype with an XY cell line. The most common karyotype is 45,XO/46,XY. There is a wide spectrum of phenotypes, ranging from a female with clitoral enlargement to a male with hypospadias. Asymmetrical external and internal genital development has been classically described in this syndrome (Forest, 2001). Considerable phallic development was described in a majority of patients in one study, and there was often penoscrotal hypospadias (Davidoff and Federman, 1973). The phenotypic features of Turner syndrome are described in a significant percentage of patients, although these features may not be readily apparent in the newborn period. An incompletely formed uterus is found in almost all patients. Fallopian tubes are always found on the side of the streak gonad and often found on the side with the dysgenetic gonad. Wolffian structures may be developed on the side with the dysgenetic gonad.

A genitourethrogram is likely to demonstrate internal müllerian structures which can be confirmed at laparoscopy. Demonstration of abnormal gonadal histopathology will confirm the diagnosis. It should be noted that MGD shares many features with partial gonadal dysgenesis, and some authors view these disorders as representing a continuum of gonadal dysgenesis (Berkovitz et al, 1991). Histologic analysis will also differentiate this disorder from true hermaphroditism.

Although the characteristic karyotype is 45,XO/46,XY, it should be pointed out that this genotype has been associated with normal male differentiation in the majority of cases diagnosed by prenatal amniocentesis (Wheeler et al, 1988).

Some authors advocate female sex assignment in MGD, because surgical repair of the vagina is usually easy and a uterus or hemiuterus is present. In addition, the dysgenetic gonad is at risk for development of a tumor and should be removed, particularly if the gonad cannot be brought down into the scrotum (Forest, 2001). However, sex assignment is likely to be guided by the degree of virilization, with the more virilized cases being assigned as males. The capacity for near normal androgen production in this disorder has been described (Davidoff and Federman, 1973). In all cases, the streak gonads should be removed because of the risk for malignancy.

**Testicular Regression Syndrome**

Testicular regression syndrome refers to the spectrum of disorders affecting persons with 46,XY karyotype who demonstrate evidence of prior testicular function, followed by usually symmetrical gonadal regression. Loss of testicular function between weeks 8 and 10 of gestation would

result in ambiguous genitalia and variable internal genitalia. Loss of testicular function after 12 to 14 weeks of gestation would result in normal male genital differentiation with a small phallus. When the male external and internal ducts are completely normal, the term *vanishing testis syndrome* is used by some authors. Presumably the testes were lost during the second half of pregnancy. Testicular torsion has been invoked as a possible explanation in this syndrome.

FSH levels are elevated in infancy, and an exaggerated response to gonadotropin-releasing hormone (GnRH) in the prepubertal period typically is seen (Grumbach and Conte, 1998). Antimüllerian hormone (AMH) levels in infancy and childhood are very low in anorchia and intermediately low with abnormal testes (Lee et al, 1997).

**True Hermaphroditism**

True hermaphroditism is defined as the presence of both testicular tissue with distinct seminiferous tubules and ovarian tissue containing mature graafian follicles in a single individual. Both testicular and ovarian elements may be found in the same gonad, or one testicle and one ovary may be found in the same individual. In the majority of cases the karyotype is 46,XX; 46,XX/46,XY chimerism and 46,XY karyotypes also can be found. Clinically, the external genitalia are often ambiguous, but predominantly male or female phenotypes have been described (Grumbach and Conte, 1998; Hadjiathanasiou et al, 1994). In ambiguous cases, a relatively marked degree of virilization can be found. Almost all have some degree of hypospadias and incomplete labioscrotal fold fusion. The labioscrotal folds are asymmetrical, with an appearance of a hemiscrotum on one side and labium majora on the other was seen in 10 of 22 cases (Hadjiathanasiou et al, 1994). At least one gonad is usually palpable. A vagina and uterus are present in most patients, and a genitourethrogram may be required for elucidation. Internal duct development is consistent with the associated gonad, although müllerian ducts predominate with an ovotestis. Breast development is common during puberty and menses can occur in up to 50%.

The diagnosis should be suspected in 46,XX/46,XY individuals with ambiguous genitalia. Palpation of a polarized gonad should also lead the clinician to suspect the diagnosis. In one study, 11 of 12 46,XX true hermaphrodites examined before 6 months of age had baseline testosterone levels greater than 40 ng/dL; normal levels for females of this age would be less than 15 ng/dL (Hadjiathanasiou et al, 1994).

Gender assignment depends on the degree of masculinization, capacity of testicular tissue to secrete testosterone, and the presence or absence of a uterus and tubes. In general, a female gender assignment is favored because of the presence of ovarian tissue and external genitalia that can more easily be reconstructed as female. Male gender assignment is more likely if there is significant virilization. Removal of ductal or gonadal structures not consonant with the gender of rearing is recommended. Testes are usually dysgenetic, which carries an increased risk of gonadoblastoma formation; therefore, careful follow-up evaluation is indicated. As in all cases of intersex, gender identity/behavior issues, along with general psychological well-being, should be longitudinally evaluated.

## Syndromes Associated with Ambiguous Genitalia

*Denys-Drash syndrome* is a rare syndrome consisting of the classic triad of congenital nephrotic syndrome leading to end-stage renal failure, XY ambiguous genitalia, and Wilms tumor. The external genitalia of 46,XY individuals are either ambiguous or female. Gonadal development encompasses a spectrum from streak gonads to dysgenetic testes. Nephropathy and proteinuria are noted at an early age, and renal biopsy will demonstrate mesangial sclerosis. Greater than 90% of cases will have a mutation in the *WT1* gene. *WT1* is a gene critical for the development of the normal genital tract. *WT1* also is associated with the WAGR syndrome. Large deletions of chromosome 11p13 that encompass the *WT1* gene are responsible for this disorder. *Frasier syndrome* also involves the *WT1* gene. This syndrome manifests in 46,XY females with gonadal dysgenesis and progressive glomerulopathy.

*Camptomelic dysplasia* is a rare autosomal dominant disorder associated with often lethal skeletal dysplasia, in which 75% of affected 46,XY males have dysgenetic testes associated with undervirilization (Grumbach and Conte, 1998). Manifestations of this disorder include bowing of the femora and tibiae, hypoplastic scapulae, 11 rib pairs, pelvic malformations, bilateral clubfoot, cleft palate, macrocephaly, micrognathia, hypertelorism, and a variety of cardiac and renal defects. The disorder is caused by heterozygous mutations in the *SOX9* gene (Grumbach and Conte, 1998). Most patients die in the neonatal period from respiratory distress.

*Smith-Lemli-Opitz syndrome* is an autosomal recessive disorder with an estimated frequency of 1/20,000 to 1/40,000. The disorder is caused by 7-dehydrocholesterol reductase deficiency (Forest, 2001). This enzyme catalyzes the final step in cholesterol biosynthesis; thus, the combination of low serum cholesterol and a high serum 7-dehydrocholesterol is suggestive of the diagnosis. Growth and developmental delay and multiple congenital anomalies characterize this disorder. Genital anomalies include hypospadias, cryptorchidism, micropenis, and hypoplastic scrotum. Craniofacial abnormalities include microcephaly, narrow bifrontal diameter, broad maxillary ridges, ptosis of the eyelids, micrognathia, and anteverted nostrils (Jones, 1997). Syndactyly of the second or third toes is a common feature. Adrenal insufficiency has been reported in this condition. Treatment with cholesterol improves growth and neurodevelopmental status.

*Robinow syndrome* is an autosomal dominant disorder characterized by a flat facial profile, short forearms, and hypoplastic genitals (Jones, 1997). Sporadic cases have been reported. In males, microphallus may be severe, although normal virilization at the time of puberty has been reported (Jones, 1997). Undescended testes have been reported in 65% of affected boys. Females have characteristic hypoplastic labia and clitoris. Other features include small size at birth, macrocephaly, frontal bossing, hypertelorism, prominent eyes, small upturned nose, micrognathia, and posteriorly rotated ears. Short forearms are seen in 100% of described cases. Other skeletal abnormalities include thoracic hemivertebrae, fusion or absence of ribs, and scoliosis. The abnormal facial features

become less pronounced as the child grows, and cognitive performance has been normal in most affected persons.

## Other Disorders of Genital Differentiation

*Hypospadias* is one of the most common anomalies of male genital development, with an estimated incidence of 4 to 8 cases per 1000 male births (Grumbach and Conte, 1998). Hypospadias can be classified as glandular, penile, penoscrotal, scrotal, and perineal. Typically, the more severe forms of hypospadias have been associated with intersex disorders, although the phenotypic spectrum of intersex disorders is wide. In a study of 33 patients with severe (scrotal or penoscrotal) hypospadias, 12 were found to have an intersex disorder, which included Denys-Drash syndrome (in 3 of the 12), partial androgen insensitivity (in 2), true hermaphroditism (in 2), chromosomal abnormality (in 1), MIF abnormality (in 1), gonadal dysgenesis (in 1), 5 $\alpha$ -reductase deficiency (in 1), and 46,XX male karyotype (in 1, *SRY* positive) (Albers et al, 1997). It should be noted that in 11 of the 12 patients, the testes were undescended. Aarskog (1970) found an approximately 15% prevalence of intersex disorders in association with hypospadias, and a significant role for maternal progesterins was found.

Thus, severe cases of hypospadias require a thorough evaluation including karyotype and hCG stimulation testing, along with examination of the genitourinary tract, particularly if accompanied by undescended testes.

## OVERVIEW OF THE SURGICAL MANAGEMENT OF INTERSEX DISORDERS

Surgery for intersex conditions has recently come under criticism. The criticism has focused not only on the timing of surgery but on whether reconstructive surgery should be done at all. Some authorities have advised that surgery be postponed until the affected person is of an age to make his or her own decision regarding the advisability of surgical correction (Diamond and Sigmundson, 1997a). Others have found that delay in surgery may be associated with problematic outcomes (Meyer-Bahlburg et al, 1996; Money et al, 1986; Reiner, 1997). It is imperative that these divergent viewpoints be discussed with the parents of an infant with an intersex condition.

These issues must be kept in mind in any decision regarding surgery for management of intersex conditions. Current surgical techniques that are available for correction of ambiguous genitalia and intersex conditions are presented next.

### Feminizing Genitoplasty

Feminizing genitoplasty is one of the more common procedures done for correction of ambiguous genitalia. Feminizing genitoplasty is indicated in the genetic female who is externally virilized, most commonly as the result of CAH. The degree of virilization can be quite variable (see Fig. 91-4). The degree of virilization will have a significant influence on the type of procedure done, especially

the vaginoplasty portion of this operation. Reconstruction in this group of patients has three components: (1) clitoral reduction, (2) vaginoplasty, and (3) labial reconstruction. The timing of surgical correction also has undergone some changes over the years. The current thinking is that once a decision is made to proceed with genital reconstruction, performing this type of surgery at a younger age will have distinct advantages, including easier mobilization of the urogenital sinus and a more benign postoperative course.

### **Clitoral Reduction**

Attempts at managing the enlarged clitoris in genetic females with clitoral hypertrophy started with total clitorrectomy. Young (1937) originally advocated this procedure. Later, Lattimer (1961) suggested a recession rather than a resection of the clitoris, and he hoped to be able to preserve the arousal function of the clitoris. This led to cases in which painful clitoral erections occurred later in life; therefore, further modification was needed. In 1973, Spence and Allen (1973) advocated the preservation of the glands with reduction in the size of the clitoris. Since then, several reports have looked at preservation of the neurovascular bundle using a clitoral reduction/recession type of approach. Kogan (1987) and Snyder (1983) and their colleagues separately described a similar approach in which the erectile tissue of the clitoris is removed but preservation of the neurovascular bundle and the glands is afforded to preserve the neurologic and arousal functions of the clitoris. If, however, the gland is unusually large in size, then a reduction of the gland size may be indicated as well.

### **Vaginoplasty**

Reconstruction of the vagina in cases of virilization in females requires an understanding of the anatomy. One may consider the anatomic abnormality an embryologic arrest of maturation with a persistence of an early embryologic stage. The anatomic issue that is important to the surgical management of the common urogenital sinus is the site of the confluence of the genital tract and the urethra. This varies considerably but is somewhat predictable by the appearance of the degree of external virilization. Those children with severe degrees of external virilization are more likely to have a higher confluence of the urethral and vaginal channels, leading to a longer urogenital sinus or a more masculinized urogenital sinus. In the classic article on urogenital sinus abnormalities, Hendron and Crawford (1969) described the variable anatomy that can be seen in these children and noted that the operative procedures needed to be tailored toward the location of the confluence of the urinary and genital tracts. One may describe the confluence anatomically as it relates to the external sphincter, with confluences distal to the external sphincter being considered low and those proximal to the external sphincter referred to as high. One also may describe the variable anatomy according to the length of the urethra from the bladder neck to the point of the confluence. If that length of urethra was long, then one would consider this a low confluence,

whereas if the length of the urethra was short and therefore close to the bladder neck, then a high confluence would be present (see Fig. 91–6, right).

The low-confluence cases can generally be repaired either by a cutback procedure on the fused labial scrotal folds or by a flap vaginoplasty. A cutback procedure would be indicated in cases with a minor degree of fusion of the labioscrotal folds. The mid- to high vaginal confluence, however, generally requires either a pull-through vaginoplasty or a total urogenital mobilization, to bring the vagina down to the perineum.

### **Flap Vaginoplasty**

The flap vaginoplasty should be used for a low confluence of the urogenital sinus. The procedure entails mobilization of a perineum-based flap with its apex at the meatus of the urogenital sinus. Dissection then proceeds along the posterior wall of the urogenital sinus until the vaginal opening is identified. The perineum-based flap is then inserted into the posterior wall of the vagina, therefore, exteriorizing the vagina to the perineum.

### **Total Urethral Mobilization**

Total urogenital mobilization can be used for the high urogenital sinus. This has been advocated by Pena (1997) and subsequently was substantiated by reports from Rink and colleagues (1997). This approach has been shown to have a superior cosmetic result, compared with that obtained with a flap vaginoplasty, for a mid to high confluence. In addition, there has been a reduced incidence of urethral vaginal fistula and vaginal stenosis. The mobilization occurs in a plane both anterior to the urogenital sinus and up to the bladder neck under the pubic symphysis and posteriorly along the urogenital sinus, and then along the posterior wall of the vagina.

### **Pull-Through Vaginoplasty**

The pull-through vaginoplasty is reserved for use in severely masculinized genetic females, whose surgical management continues to present a major challenge. Initially, the approach was a combined perineal and abdominal approach with complete mobilization of the vagina and uterus and separation of the vagina from the urethra at the confluence. The abdominal mobilization will then allow the vagina to be brought down to the perineum. A modification of this approach was described by Passerini-Glazel (1989) in which the more distal urogenital sinus tissue was used to provide an anterior vaginal wall flap, which will then connect to the true vagina. This will allow for a complete perineal approach to the procedure as well.

### **Vaginal Agenesis**

Vaginal replacement has a role in certain intersex conditions or structural abnormalities of the genital urinary tract. The intersex conditions in which vaginal replacement may be indicated are 46,XX vaginal agenesis, 46,XY male

karyotype with severely inadequate virilization or complete androgen insensitivity syndrome, and structural urogenital defects such as cloacal exstrophy or persistent cloaca, or following a pelvic exenteration for malignancy. There are a variety of tissues and techniques used for vaginal reconstruction; skin grafting, progressive perineal indentation, split-thickness or fold thickness tissue grafts with expanders, myocutaneous flaps, and bowel. The critical point in creating a vagina is to maintain an adequate perineal opening, an adequate-length tunnel, and good fixation to pelvic structures. This area is highly controversial in terms of the best management. Overall, the most popular tissue for vaginal plate replacement has been the split-thickness skin graft as described by McIndoe (1950). The major disadvantage of this technique has proved to be the need for long-term dilatation to maintain patency and to avoid vaginal stenosis. The use of bowel segments for vaginal replacement was first described by Baldwin (1904). Due to an extraordinarily high mortality rate associated with this approach, earlier attempts using this technique were abandoned. Since then, this approach has been taken up by many groups and has been shown to be highly successful, with minimal complication rates. A major advantage of a bowel-segment vagina over a skin graft is the minimal risk of "poor take" due to the vascularized pedicle to the segment of bowel that is used. Length and patency of the bowel are not issues for similar reasons, because it maintains its blood supply. No dilatation is needed. Early on, intestinal mucus production can be a problem, but this lessens over time, and mucus may act as a natural lubricant. Minimal perineal scarring is associated with this approach as well, and it can be done at a very young age (Hensle and Dean, 1992).

### Male Pseudohermaphroditism

Inadequate virilization results in hypospadias, with or without cryptorchidism. In more severe cases, such as a complete form of androgen insensitivity, these children may appear as phenotypic normal females and present at the time of puberty with primary amenorrhea. Vaginoplasty is frequently needed after puberty in that population. Those children presenting with varying degrees of hypospadias, with or without cryptorchidism, will usually require a repair following the usual principles of hypospadias and cryptorchidism repair. These are generally done at 6 months of age and are tolerated well as outpatient procedures.

### Gonadectomy

Gonadectomy is required under two circumstances in intersex conditions. Gonadectomy would be recommended when the gonads are inconsistent with the sex of rearing. This is most commonly seen in androgen insensitivity syndrome (46,XY karyotype) in which normal testes are present but a female gender assignment has been made. The timing of the gonadectomy is controversial; however, it is currently thought to be best managed once the diagnosis has been made, because the role of postnatal testosterone imprinting in a child's psychosocial development is uncertain.

The other circumstance in which gonadectomy is recommended is in intersex states in which gonadal malignancy is a significant risk. This is most likely to occur in cases in which dysgenetic gonads and a Y chromosome are present. An example is shown in Figure 91-14, in which a 1-year-old infant with pure XY gonadal dysgenesis was found to have a gonadoblastoma on gonadectomy. Other syndromes in which gonadal malignancy is a concern include mixed gonadal dysgenesis and the presence of a dysplastic testis in a dysgenetic XY male.

### CONCLUSIONS

Significant advances have been made in our understanding of the pathophysiology and molecular genetics of intersex disorders. A systematic diagnostic approach to the infant with ambiguous genitalia should be undertaken to identify the underlying disorder. Establishing the diagnosis will often provide a better understanding of the natural history of the disorder.

The need for surgical intervention in intersex disorders should be assessed on a case-by-case basis. The parents need to be informed about the risks and benefits of surgery. Surgery on the external genitalia should perhaps be reserved for those individuals with significant discord between the sex of rearing and the appearance of the external genitalia.

The infant and the family of a child with an intersex condition often may have to cope with difficult psychosocial challenges throughout life. Physicians caring for these patients should try and ensure the integration of well-trained mental health professionals into the longitudinal care of these complex infants and children.

# Disorders of the Thyroid Gland

Daniel H. Polk and Delbert A. Fisher

## BASIC SCIENCE OF THYROID FUNCTION

### Embryogenesis and Histologic Development of the Thyroid Gland

The human thyroid gland is a derivative of the primitive buccopharyngeal cavity. It develops from contributions of two anlagen: (1) a midline thickening of the pharyngeal floor (median anlage) and (2) paired caudal extensions of the fourth pharyngobranchial pouch (lateral anlagen). All of these structures are discernible by day 16 or 17 of gestation; by day 24, the median anlage has developed a thin flask-like diverticulum extending from the floor of the buccal cavity down to the fourth branchial arch. At 40 days of gestation, the median and lateral anlagen have fused, and by 50 days of gestation, the buccal stalk has ruptured. During this period, the thyroid gland migrates caudally to its definitive location in the anterior neck, helped in part by its relationship with developing cardiac structures.

Developmental abnormalities of the thyroid gland usually represent defects in early morphogenesis resulting from aberrant thyroid tissue migration. The most common anomaly is persistence of the thyroglossal duct. This is not usually associated with altered thyroid status in the newborn but may manifest in later life as an infected fistulous tract. Abnormalities of thyroid embryogenesis (thyroid dysgenesis) include agenesis and presence of ectopic tissue in sublingual, cervical, mediastinal, or even intracardiac locations. Although ectopic thyroid tissue may manifest some function, affected infants usually exhibit some degree of hypothyroidism. In addition, calcitonin deficiency is present in children with congenital hypothyroidism. However, hypoparathyroidism is not associated with thyroid dysgenesis, although the parathyroid glands may be ectopic in these children.

### Thyroid Hormone Synthesis

Circulating plasma iodide enters the thyroid follicular cells and is combined with tyrosine through a series of enzymatically mediated reactions to form the active thyroid hormones 3,5,3'-triiodothyronine ( $T_3$ ) and thyroxine ( $T_4$ ). The steps in the synthesis and release of thyroid hormones include (1) active transport of inorganic iodide from plasma to thyroid cell; (2) synthesis of tyrosine-rich thyroglobulin, which acts as the intermediate iodine acceptor; (3) organification of trapped iodide as iodotyrosines; (4) coupling of monoiodotyrosines (MITs) and

diiodotyrosines (DITs) to form the iodothyronines,  $T_3$  and  $T_4$ , with storage of iodotyrosines and iodothyronines in follicular colloid; (5) endocytosis and proteolysis of colloid thyroglobulin to release MIT, DIT,  $T_3$ , and  $T_4$ ; and, (6) deiodination of released iodotyrosines within the thyroid cell with reutilization of the iodine. These steps and their inhibitors are outlined in Table 92-1. Certain defects in these biochemical processes have been identified, leading in most cases to clinical hypothyroidism. These are discussed later under "Congenital Hypothyroidism."

### Fetal-Placental-Maternal Thyroid Interaction

The relative independence of the maternal and fetal hypothalamic-pituitary-thyroid hormone systems is suggested by several clinical observations. The placenta is impermeable to thyroid-stimulating hormone (TSH) and largely impermeable to the thyroid hormones. These data were reviewed by Roti (1988) and are summarized in Table 92-2. Direct evidence of placental transfer of thyroid hormones is provided by studies using various thyroid hormone analogues and tracers. Human studies have shown limited transfer from mother to fetus. Large doses of  $T_4$  given to women produced only minor changes in cord serum concentrations of hormonal iodine. Supraphysiologic doses of  $T_3$  chronically administered to pregnant women several weeks before delivery significantly increased maternal serum  $T_3$  levels but only minimally lowered fetal  $T_4$  values. Thus, it is clear that under physiologic conditions, placental transfer of thyroid hormones is limited. This limitation is due, at least in part, to the presence in placental tissue of an inner-ring (tyrosyl) iodothyronine deiodinase, which converts  $T_4$  to inactive reverse  $T_3$  ( $rT_3$ ) and converts  $T_3$  to inactive diiodothyronine, or  $T_2$ . Of interest are data suggesting that the maternal compartment may contribute significantly to fetal thyroid hormone levels in the hypothyroid fetus (Vulsma et al, 1989). The physiologic significance of this observation is uncertain.

Maternal immunoglobulins of the IgG subclass are selectively transported across the placenta, particularly late in gestation. Hyperthyroidism or hypothyroidism has been reported in response to maternally derived TSH receptor-stimulating or TSH receptor-blocking antibodies. Usually, these syndromes either are detected by newborn screening or are manifested as neonatal symptoms and signs (Matsurra et al, 1980; Zakarija and McKenzie, 1983). Thyroid scanning in affected infants reveals the presence of a normally situated thyroid gland; the clinical abnormalities wane with degradation of the maternal antibodies. The half-life in newborn blood for the maternally derived IgG antibodies is approximately 20 days.

The placenta is freely permeable to iodide, and the fetal thyroid is particularly sensitive to the inhibitory effects of iodine on thyroid function (Theodoropoulos et al, 1979). Relatively small amounts of maternal iodine exposure have been associated with transient neonatal hypothyroidism. The iodine source may be radiopaque dyes used for radiographic procedures as well as maternal medications, including topically applied iodine washes, which may be absorbed across mucous membrane surfaces.

TABLE 92-1

**Biochemical Steps to Thyroid Hormone Synthesis**

Step	Inhibitor(s)
Iodide transport	$\text{ClO}_4^-$ and $\text{SCN}^-$
Thyroglobulin synthesis	Protein synthesis inhibitors
Organification of iodide	PTU, MMI
MIT, DIT coupling	PTU, MMI
Thyroglobulin endocytosis and proteolysis	$\text{I}^-$ , $\text{Li}^-$ , colchicine, cytochalasin B
Deiodination	Dinitrotyrosine

DIT, diiodotyrosine; MIT, monoiodotyrosine; MMI, methimazole; PTU, propylthiouracil.

This effect is described more fully in the section on congenital hypothyroidism.

The thiourylene antithyroid drugs cross the placenta and may compromise fetal and neonatal thyroid function (Marchant et al, 1977). The placenta also is permeable to selected synthetic thyroid hormone analogues such as 3',5'-dimethyl-5-isopropyl thyronine (DIMIT). There is no current rationale, however, for use of these analogues, because of their low biologic activity. Finally, the placenta is permeable to the hypothalamic peptide thyrotropin-releasing hormone (TRH). Both primate and human fetuses early in the third trimester respond to pharmacologic doses of exogenous TRH with an increase in serum TSH. However, little endogenous TRH is normally detected in adult humans because of the presence of TRH-degrading enzyme systems in the blood. Although the sera of pregnant women contain somewhat lower levels of these enzymes than nonpregnant sera, the nearly unmeasurable levels of TRH in the maternal circulation have little effect on fetal thyroid function.

In addition to producing TRH, the placenta produces thyrotropin-like activity. The alpha subunit of TSH is identical to that of human chorionic gonadotropin (hCG), and the beta subunit of hCG has structural homology with the beta subunit of TSH; thus, hCG has some TSH-like bioactivity. However, the biologic potency of hCG is only

TABLE 92-2

**Placental Permeability for Substances Affecting Thyroid Function**

Substance	Placental Permeability
$\text{I}^-$	++++
TRH	+++
Thiourylenes	+++
IgG antibodies	+++
$\text{T}_3$	0
$\text{T}_4$	+
TSH	0

IgG, immunoglobulin G;  $\text{T}_3$ , triiodothyronine;  $\text{T}_4$ , thyroxine; TRH, thyrotropin-releasing hormone; TSH, thyroid-stimulating hormone.

Data from Roti E: Regulation of thyroid-stimulating hormone (TSH) secretion in the fetus and neonate. *J Endocrinol Invest* 11:145-150, 1988.

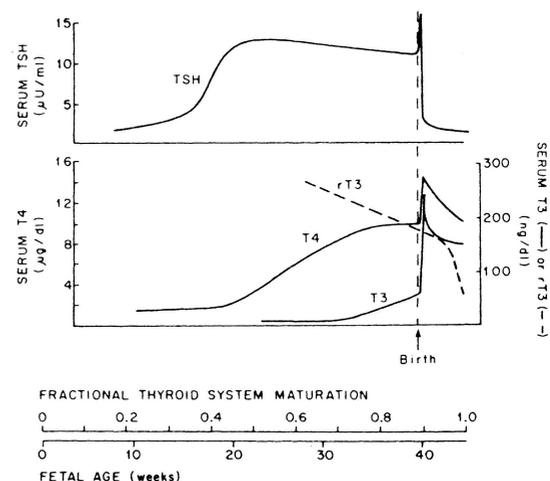

about 0.01% that of TSH, and hCG normally has little influence on fetal thyroid system development or function. Because of the hyperthyroidism sometimes seen in patients with choriocarcinoma, a unique chorionic thyrotropin has been proposed, and a glycoprotein with thyrotropic activity has been isolated from human placenta. A structure has never been characterized, however, and it seems likely that this chorionic thyrotropin represents a variant form of hCG (Harada and Hershman, 1978).

In summary, placental permeability to maternal molecules might be a factor affecting fetal thyroid function as a result of maternal pathophysiologic states (acute iodide administration, autoimmune thyroid disease, or pharmacotherapy of thyrotoxicosis). However, the fetal pituitary-thyroid axis normally develops independently of the maternal thyroid axis influence. The placenta and selected fetal tissues may serve as sources of TRH or TSH, but the extent of this influence on fetal thyroid function is uncertain.

**Control of Thyroid Hormone Production**

The pattern of perinatal thyroid hormone secretion in the human is shown in Figure 92-1. Maturation of thyroid system control can be considered in three phases: hypothalamic, pituitary, and thyroidal. Changes in these systems are complex and superimposed on the increasing production and increasing serum concentration of serum thyroid hormone-binding globulin (TBG) as well as the changing pattern of fetal tissue iodothyronine deiodination during gestation. Maturation of these latter systems is described in the following section.

Although the fetal thyroid gland is able to concentrate iodide and synthesize thyroglobulin at 70 to 80 days of gestation, little thyroid hormone synthesis occurs until about 18 weeks of gestation. At this time, thyroid follicular cell iodine uptake increases, and  $\text{T}_4$  becomes measurable in the serum. Both total and free  $\text{T}_4$  concentrations

**Maturation of Thyroid Hormone Secretion in the Human Fetus**

**FIGURE 92-1.** Patterns of circulating levels of thyroid-stimulating hormone (TSH), reverse triiodothyronine ( $\text{rT}_3$ ), thyroxine ( $\text{T}_4$ ), and  $\text{T}_3$  in the fetus and newborn.

then increase steadily until the final weeks of pregnancy (Fisher, 1985). This pattern differs from the development of serum  $T_3$  levels in the fetus. The fetal serum  $T_3$  concentration is low (less than  $15 \mu\text{g/dL}$ ) until 30 weeks of gestation and then increases slowly in two distinct phases, a prenatal and a postnatal phase. Prenatally, serum  $T_3$  increases slowly after 30 weeks of gestation to reach a level of approximately  $50 \mu\text{g/dL}$  in term cord serum (Fisher and Klein, 1981). Postnatally, both  $T_3$  and  $T_4$  serum concentrations increase fourfold to sixfold within the first few hours of life, peaking at 24 to 36 hours after birth. These levels then gradually decline to adult values over the first 4 to 5 weeks of life. The prenatal increase in serum  $T_3$  seems to be due largely to progressive maturation of hepatic type I (phenolic) outer-ring iodothyronine deiodinase activity and increasing hepatic conversion of  $T_4$  to  $T_3$ , although other tissue sources of deiodinase, such as brown fat and kidney, may be involved.

Fetal serum TSH increases rapidly from a low level at 18 weeks of gestation to a peak value at 24 to 28 weeks and then gradually declines until term. At the time of parturition, partly in response to cold stress, an acute release of TSH occurs, resulting in an elevated level by 30 minutes of life. The level of circulating TSH remains modestly elevated for 2 to 3 days after birth. The increases in thyroid hormone that occur immediately after birth are not totally dependent on TSH and may represent other influences in the thyroid gland at the time of parturition. The high postnatal  $T_3$  levels in the days following birth are due to both TSH stimulation of thyroidal  $T_3$  secretion and further rapid maturation of tissue outer-ring monodeiodinase activity.

Fetal thyroid gland function develops under the influence of a moderately elevated TSH level during the last half of gestation. The increase in serum  $T_4$  that occurs during the last trimester is accompanied by a progressive decrease in serum TSH, suggesting that changes in both thyroid follicular cell sensitivity to TSH and pituitary thyrotroph sensitivity to the negative feedback effect of thyroid hormones occur during this period. The pituitary gland contains a type II outer-ring iodothyronine deiodinase, which converts  $T_4$  to active  $T_3$ , which in turn modulates TSH production. In most circumstances, it is circulating  $T_4$  that is most important in TSH control. Thus, even when the circulating  $T_3$  level is low (as in midgestation), there may be significant negative feedback control (by  $T_4$ ) of pituitary TSH secretion.

The ontogeny of TRH secretion and function in the fetus remains somewhat obscure. TRH immunoactivity is detectable in the hypothalamus by midgestation, increasing markedly in the third trimester after the peak in serum TSH activity is noted. The premature infant (born before 30 to 32 weeks) is characterized by low levels of  $T_4$  and free  $T_4$ , a normal or low level of TSH, and a normal or prolonged TSH response to TRH indicating a state of physiologic TRH deficiency. The full-term human fetus responds to pharmacologic maternal doses of TRH with a somewhat prolonged increase in TSH, suggesting a degree of relative hypothalamic (tertiary) hypothyroidism (Roti et al, 1981). Fetal sources of nonhypothalamic TRH (placenta and pancreas) probably contribute to the elevated circulating levels of fetal and cord blood TRH and

presumably account for the high circulating TSH level characteristic of the midgestation fetus. However, the significance of ectopic TRH to the development of thyroid system control remains to be investigated.

In summary, the control of fetal thyroid hormone secretion can be characterized as a balance among increasing hypothalamic TRH secretion, increasing thyroid follicular cell sensitivity to TSH, and increasing pituitary sensitivity to thyroid hormone inhibition of TSH release. The fetus progresses from a state of both primary (thyroidal) and tertiary (hypothalamic) hypothyroidism in midgestation through a state of mild tertiary hypothyroidism during the final weeks of pregnancy and to fully mature thyroid function in the perinatal period.

### Fetal Thyroid Hormone Metabolism

Although the thyroid gland is the sole source of  $T_4$ , most of the  $T_3$  that circulates in the adult is derived from conversion of  $T_4$  to  $T_3$  via monodeiodination in peripheral tissues. Deiodination of the iodothyronines is the major route of metabolism, and monodeiodination may occur at either the outer (phenolic) ring or the inner (tyrosyl) ring of the iodothyronine molecule. Outer-ring monodeiodination of  $T_4$  produces  $T_3$ , the active form of thyroid hormone with the greatest affinity for the nuclear thyroid hormone receptor. Inner-ring monodeiodination of  $T_4$  produces  $rT_3$ , an inactive metabolite. In mature humans, between 70% and 90% of circulating  $T_3$  is derived from peripheral conversion of  $T_4$ , and 10% to 30%, from direct glandular secretion. Nearly all of the circulating  $rT_3$  derives from peripheral conversion, with only 2% to 3% coming directly from the thyroid gland.  $T_3$  and  $rT_3$  are progressively metabolized to diiodo-, monoiodo-, and noniodinated forms of thyronine, none of which possesses biologic activity.

Two types of outer-ring iodothyronine monodeiodinases (5'-MDIs) have been described. Type I 5'-MDI, expressed predominantly in liver and kidney, is an enzyme inhibited by propylthiouracil, and its activity is stimulated by thyroid hormone. Type II 5'-MDI, located predominantly in brain, pituitary, and brown adipose tissue, is insensitive to propylthiouracil, and its activity is inhibited by thyroid hormone (Refetoff and Larsen, 1989). Type I 5'-MDI activity in the liver, and perhaps the kidney and muscles, probably accounts for most of the peripheral deiodination of  $T_4$ ; type II 5'-MDI acts primarily to increase local intracellular levels of  $T_3$  in the brain and pituitary and is important to brown adipose tissue function during the immediate postnatal period. The outer-ring iodothyronine deiodinase also deiodinates  $rT_3$  to diiodothyronine.

Both type I 5'-MDI and type II 5'-MDI are present in third-trimester fetuses (Polk et al, 1988b). Both deiodinase species are thyroid hormone responsive. However, hepatic type I 5'-MDI activity becomes thyroid hormone responsive (e.g., activity decreases with hypothyroidism) only during the final weeks of gestation. Brain type II activity, in contrast, is responsive (increases with hypothyroidism) throughout the final trimester of gestation. Thus, type II deiodinase probably plays an important role in

providing a source of intracellular  $T_3$  to those tissues (such as pituitary and, in some species, brown fat and brain) dependent on  $T_3$  during fetal life, whereas the ontogeny of the type I enzyme (to provide increased serum  $T_3$  levels) increases only during the final weeks of gestation and during postnatal life.

An inner-ring (tyrosyl) iodothyronine monodeiodinase (type III 5-MDI) has been characterized in most fetal tissues, including the placenta. This enzyme system catalyzes the conversion of  $T_4$  to  $rT_3$  and  $T_3$  to diiodothyronine. Fetal thyroid hormone metabolism is characterized by a predominance of type III enzyme activity, particularly in the liver, kidney, and placenta, and this accounts in part for the increased circulating levels of  $rT_3$  observed in the fetus. Placental type III deiodinase contributes to amniotic fluid  $rT_3$  levels and presumably also contributes to circulating fetal  $rT_3$ . However, the persistence of high circulating  $rT_3$  levels for several weeks in the newborn indicates that type III 5-MDI activities expressed in nonplacental tissues also are important to the maintenance of high circulating  $rT_3$  levels.

Both  $T_3$  and  $T_4$  in blood are associated with various plasma proteins including TBG, thyroxine-binding prealbumin (TBPA), and albumin. TBG serves as the primary transport protein for both  $T_3$  and  $T_4$ ; 70% of the total  $T_4$  and 40% to 60% of total  $T_3$  are bound to TBG. The rest of the thyroid hormones are distributed almost equally between TBPA and albumin. The binding affinities of these proteins are such that adult-free  $T_4$  and  $T_3$  concentrations are about 0.03% and 0.3%, respectively, of the total hormone concentrations. TBG, TBPA, and albumin are produced by the liver, and production of these proteins increases progressively during the final half of gestation. Hepatic TBG production is stimulated by estrogen, and the increasing levels of estrogens during pregnancy account, at least in part, for the total plasma  $T_4$  concentration, which increases progressively from midgestation until 34 to 35 weeks of gestation.

### Thyroid System Effects and Adaptation to Extrauterine Life

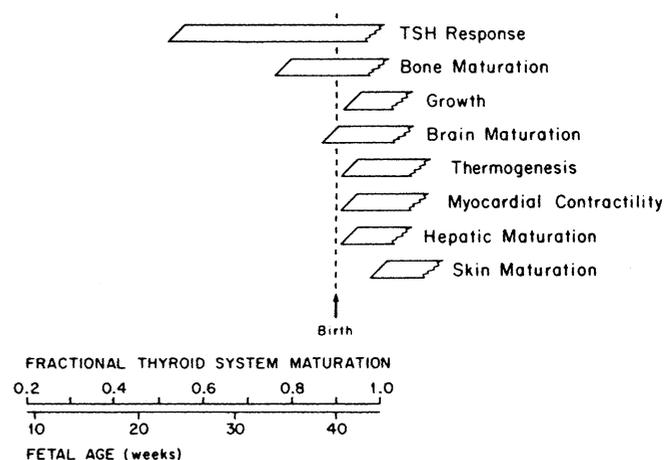

In general, much of the fetal thyroid development is preparatory, providing for the relatively large amounts of thyroid hormones required for normal postnatal development. The production of active thyroid hormones is markedly increased in association with the events of parturition (see Fig. 92-1). During the first hours after birth, there are abrupt threefold to sixfold increases in circulating  $T_4$  and  $T_3$  levels, coincident with an increase in serum TSH concentrations. The initial increases in circulating thyroid hormone levels are due largely to increased hormone secretion from the thyroid gland. Substances other than TSH also may modulate the acute increases in circulating thyroid hormones at birth. A postnatal increase in serum catecholamine concentrations occurs at the time of parturition (Padbury et al, 1985), and the thyroid gland is adrenergically innervated. The cold-stimulated TSH surge is short-lived, and the decrease in TSH that follows during the 72 to 96 hours after birth is due to feedback inhibition by  $T_4$  at either the hypothalamic or the pituitary level (or both). The serum TRH concentration is elevated in

cord blood and declines in the days following birth. A clear increase in the serum TRH value coincident with the increase in TSH after parturition has not been reported, but the parallel increases in both TSH and prolactin levels in the early hours after birth support the view that the TSH surge is mediated by TRH (Roti, 1988). Thyroid hormone levels in the newborn gradually return to adult levels by about 1 month of age. The high level of circulating  $rT_3$  characteristic of the fetus persists following birth, gradually declining to the adult range by 4 to 6 weeks of age.

The metabolic significance of the neonatal thyroid hormone surge is not entirely clear. Physiologic processes known to be modulated by thyroid hormone in adults, such as thermogenesis and cardiovascular responses, clearly are important in the transition from intrauterine to extrauterine life, and it is tempting to link these transitional events with changes in thyroid hormone metabolism. Several studies using animal models have attempted to establish such a link and support the view that the level of thyroid function during the final weeks of gestation is more important than the neonatal increases in  $T_3$  and  $T_4$  for successful neonatal transition (Polk et al, 1988a). The situation in the human newborn may be somewhat different. Newborns with congenital thyroid agenesis have few if any signs or symptoms of thyroid hormone deficiency, and their postnatal environmental adaptation usually is not impaired. The precise timing of maturation of thyroid hormone effects on thermogenesis and cardiovascular function in the human newborn has not been defined.

In humans, thyroid hormone nuclear receptors have been reported in fetal lung, brain, heart, and liver at 13 to 19 weeks of gestation by Gonzales and Ballard (1981) and Bernal and Pekonen (1984). The only thyroid hormone actions that have been characterized in the fetus are the effects of hypothyroidism on serum TSH and bone maturation. Most effects of thyroid hormone on perinatal developmental processes occur postnatally (Fig. 92-2).

In summary, thyroid hormones affect important postnatal processes including growth, thermogenesis, and development. The largely successful transition of athyrotic infants to extrauterine life speaks to the limited impor-

**FIGURE 92-2.** Onset of actions of thyroid hormone in the developing human. The left edge of the bar indicates the initiation of thyroid hormone responsiveness of the indicated parameter.

tance of fetal thyroid hormones in all but the final weeks of gestation. An exception to this may be the fetal brain, a major site of type II iodothyronine monodeiodinase activity in the fetus. The presence of this enzyme system in the brain early in development as well as its demonstrated response to fetal hypothyroidism in the rat and sheep suggests that intracellular conversion of  $T_4$  to  $T_3$  in the brain is important in these species for normal development and differentiation of the central nervous system. The critical period for this effect is not known for the human fetus, but early treatment of congenital hypothyroidism in the newborn prevents mental retardation, suggesting that the period of thyroid dependency of the human brain extends into the postnatal period.

### CONGENITAL HYPOTHYROIDISM

Congenital hypothyroidism has been recognized for centuries and its treatment known for decades, but only recently has a link between early treatment and the prevention of sequelae been proposed. With today's emphasis on early screening, many conditions that lead to the syndrome of congenital hypothyroidism have been recognized (Table 92-3). The importance of adequate neonatal screening in the management of newborn thyroid diseases must be emphasized. Before the advent of screening, less than one third of the infants found ultimately to have congenital hypothyroidism were given the diagnosis before 3 months of age, and only half by 6 months of age; irreversible brain damage developed in most of these infants (Jacobsen and Brandt, 1981).

**TABLE 92-3**

#### Thyroid Disorders and Their Approximate Incidences in the Neonatal Period

Disorder	Incidence
Thyroid dysgenesis	1/4,000
Agenesis	
Hypogenesis	
Ectopia	
Thyroid dyshormonogenesis	1/30,000
TSH receptor defect	
Iodide-trapping defect	
Organification defect	
Iodotyrosine deiodinase deficiency	
Defect in thyroglobulin	
Transient hypothyroidism	1/40,000
Drug-induced	
Maternal antibody-induced	
Idiopathic	
Hypothalamic-pituitary hypothyroidism	1/100,000
Hypothalamic-pituitary anomaly	
Panhypopituitarism	
Isolated TSH deficiency	

TSH, thyroid-stimulating hormone.

Newborn screening programs for congenital hypothyroidism are designed to detect elevated serum TSH levels in blood samples collected on filter paper. Some programs measure TSH directly, and others measure TSH in samples with low or low-normal  $T_4$  concentrations. In most programs in the United States, an initial  $T_4$  measurement is conducted, and TSH is measured in the 10% of samples with the lowest  $T_4$  values. An elevated TSH level (greater than 20  $\mu$ IU/mL) suggests primary hypothyroidism. Most screening programs are just that, and some infants with hypothyroidism are missed in the screening process. Thus, no infant who presents with signs or symptoms suggestive of thyroid dysfunction (Table 92-4) should be excluded from investigation on the basis of previous screening results. A determination of serum  $T_4$  and TSH values is necessary in any infant with suspicious clinical or laboratory findings.

### Causative Disorders

The following are the major pathophysiologic states that may lead to congenital thyroid dysfunction (see Table 92-3).

### Thyroid Dysgenesis

The term *thyroid dysgenesis* describes infants with ectopic or hypoplastic thyroid glands (or both) as well as those with total thyroid agenesis. Thyroid dysgenesis is the etiologic factor in most infants with permanent congenital hypothyroidism detected in newborn screening programs. Some thyroid tissue probably is present in two thirds of these infants, so that the thyroid deficiency in these infants occurs across a spectrum of severity. A normal or near-normal circulating level of  $T_3$  in the face of a low  $T_4$  value suggests the presence of residual thyroid tissue,

**TABLE 92-4**

#### Clinical Signs and Symptoms of Congenital Hypothyroidism in Infancy

Age/Manifestation	Frequency (%)
<b>0 to 7 Days</b>	
Prolonged jaundice >3 days	73
Birth weight >4 kg	40
Poor feeding	40
Transient hypothermia	38
Large posterior fontanel (>5 mm)	32
<b>1 to 4 Weeks</b>	
Failure to gain weight	45
Constipation	35
Hypoactivity	33
<b>1 to 3 Months</b>	
Failure to thrive	90
Umbilical hernia	49
Macroglossia	43
Myxedema	40
Hoarse cry	30

and this can be confirmed by a thyroid scan. A measurable level of serum thyroglobulin also indicates the presence of some thyroid tissue; athyrotic infants have no circulating thyroglobulin (Dammacco et al, 1985).

Thyroid dysgenesis occurs in 1/4000 liveborn infants and is more prevalent in female than in male infants by a ratio of almost 2:1. Studies by Frasier and colleagues (1982) and Brown and coworkers (1981) suggest the disorder may be less common in African-American (1/32,000) than in white infants and may be more frequent (1/2000) in Hispanic infants. Although thyroid dysgenesis usually is sporadic, rare familial cases have been described, and the incidence is increased in infants with Down syndrome (Fort et al, 1984). Seasonal variations in incidence have been observed in Japan, Australia, and Canada. In isolated instances, thyroid dysgenesis has occurred in association with maternal autoimmune thyroiditis. However, this apparent association may be coincidental; there usually is no correlation between thyroid dysgenesis and the presence of maternal autoimmune thyroiditis or circulating thyroid antimicrosomal or antithyroglobulin autoantibodies (Dussault et al, 1980). Immunoglobulins blocking TSH-stimulated thyroid cell growth in tissue culture have been reported in both maternal and newborn blood in about half of the cases of sporadic congenital hypothyroidism, but a role for such growth-blocking immune globulins in the pathogenesis of congenital hypothyroidism *in vivo* has not been established.

As discussed, most newborns with thyroid dysgenesis are asymptomatic, and few infants have signs of hypothyroidism during the early weeks of life. Most affected infants have low serum  $T_4$  and high TSH concentrations in cord blood or in filter-paper blood spots collected at 2 to 5 days of age. Ten percent to 20% of hypothyroid infants have  $T_4$  levels in the low-normal range, with increased TSH values. These infants usually have ectopic functional thyroid tissue on scanning and significant levels of circulating thyroglobulin. Another 5% have a delayed elevation of serum TSH and are missed in the screening process unless a second screening test is done (LaFranchi et al, 1985). Again, thyroid function should be determined in any infant presenting with suspicious clinical signs or symptoms (see Table 92–4). Persons with thyroid dysgenesis also show abnormalities of thyroidal C cells; calcitonin levels and responsiveness are reduced throughout infancy and childhood. Urinary calcium and hydroxyproline levels are increased, and there is a tendency toward osteopenia, but this latter finding seems of limited clinical significance (Kruse et al, 1987).

### Hypothalamic-Pituitary Defects

Congenital hypothyroidism resulting from ineffective TSH stimulation of thyroid hormone secretion can result from a variety of abnormalities in TSH synthesis and metabolism. These include anomalous hypothalamic or pituitary development, isolated or familial deficiencies in TRH or TSH secretion, or TSH deficiency in association with other pituitary hormone deficiencies. Several TSH deficiency syndromes have been described: hypothalamic (tertiary) hypothyroidism with TRH deficiency or pituitary insensitiv-

ity (or both), isolated TSH deficiency, familial panhypopituitarism, congenital absence of the pituitary, and panhypopituitarism with absence of the sella turcica. The combined prevalence of these abnormalities associated with congenital hypothyroidism approximates 1/60,000 to 1/140,000 of live births (Stanbury and Dumont, 1983).

### Inborn Defects of Thyroid Hormone Production

Infants with inborn defects in thyroid metabolism account for nearly 10% of newborns with congenital nonendemic hypothyroidism (see Table 92–3). The defects in such patients include (1) a decreased thyroid response to TSH, (2) decreased thyroid iodide trapping, (3) defective organification of trapped iodide, (4) decreased capacity for deiodinating iodotyrosines, and (5) abnormalities in thyroglobulin synthesis, storage, or release. These disorders usually are transmitted as autosomal recessive traits (Lever et al, 1983). Except for the familial incidence and tendency for goiter to develop in affected persons, the clinical manifestations of congenital hypothyroidism resulting from a biochemical defect are similar to those in infants with thyroid dysgenesis. Thyroid enlargement may be present at birth, but in many patients, development of the goiter is delayed.

### Transient Congenital Hypothyroidism

Congenital hypothyroidism may present as a transient defect persisting for a variable period after birth. Usually, transient neonatal hypothyroidism is caused by maternal ingestion of goitrogenic substances that reach the fetus via placental transfer. One frequently ingested goitrogenic drug is iodide prescribed in expectorants for the treatment of asthma or as treatment for maternal thyrotoxicosis. The mothers of affected infants often have taken large doses of iodide for many years without development of large goiters and have been euthyroid during pregnancy. The fetal thyroid gland is unusually sensitive to iodide-induced hypothyroidism because of immaturity of the mechanisms that decrease thyroid iodide uptake in response to high plasma iodide levels. Urine iodine concentrations in affected infants usually exceed 1 mg/L.

Other substances that have been associated with neonatal goiter include thiourylene (antithyroid) drugs, sulfonamides, and hematinic preparations containing cobalt. Neonatal goiters resulting from antithyroid drug administration are uncommon unless large doses of the drugs are given to the mother (more than 150 mg/day of propylthiouracil or equivalent near term). Amniotic injection of radiographic contrast agents used during amniocentesis also can lead to transient congenital hypothyroidism.

Maternal-to-fetal transfer of TSH receptor–blocking antibodies also can lead to transient perinatal hypothyroidism (Drexhage and Bottazzo, 1985). This condition is rare but has been reported in the newborns of women with either euthyroid or hypothyroid autoimmune thyroid disease. In these infants, TSH receptor autoantibodies are detectable in maternal and cord blood. These antibodies can be measured either as TSH binding–inhibiting immune globulins (TBII) or as TSH (cyclic AMP [cAMP])–blocking

antibodies (TBAs). The duration of the hypothyroid state in these newborns is correlated with the initial titer of blocking antibody and the duration of its presence in newborn blood. Transient congenital hypothyroidism must be differentiated from transient hyperthyrotropinemia (see later section, “Thyroid Dysfunction Syndromes in the Premature Infant”).

## Diagnosis and Management

### Diagnosis

Infants with congenital hypothyroidism are born with little or no clinical evidence of thyroid hormone deficiency. Thus, detection based on signs and symptoms usually is delayed 6 to 12 weeks or longer. Even though the emphasis in the diagnosis of congenital hypothyroidism currently is on newborn screening, not all infants with congenital hypothyroidism are detected by these systems. Early clinical diagnosis must be based on a high index of suspicion regarding nonspecific symptoms and signs. These are outlined in Table 92-4, along with their relative frequency. The diagnosis should be considered in any infant with prolonged jaundice, transient hypothermia, an enlarged (greater than 1 cm) posterior fontanel, failure to feed properly, or respiratory distress with feeding.

The classic signs evolve during the first weeks after birth. There is a rapid reduction in growth rate after birth, with progressively worsening myxedema in the subcutaneous tissues and in the tongue. The thickened tongue becomes protuberant, and increasing difficulty in nursing and handling salivary secretions is noted. The cry is hoarse because of myxedema of the vocal cords. There is marked muscular hypotonia, with an umbilical hernia, constipation, and bradycardia; extremities are cool to the touch and may exhibit pallor and circulatory mottling. The cardiac silhouette may be enlarged; the electrocardiogram shows low voltage and a prolonged conduction time. Some of the signs and symptoms are present by 6 to 12 weeks, especially lethargy, constipation, and the umbilical hernia. The cretinoid facies and growth retardation become increasingly obvious during the first several months of life.

As discussed previously, infants can escape detection by screening because of a delayed elevation in serum TSH or because of errors in sample collection or laboratory routine; it is estimated that 5% to 8% of affected infants may be missed. Infants with TSH deficiency are not detected, because most newborn screening programs report only those infants with elevated TSH levels. Congenital primary hypothyroidism is associated with a low serum  $T_4$  and a high TSH concentration in individual cord blood or neonatal blood samples. A cord serum  $T_4$  of 6.0  $\mu\text{g}/\text{dL}$  or less with a TSH in excess of 80  $\mu\text{IU}/\text{mL}$  suggests hypothyroidism. At 3 to 5 days of age, a serum  $T_4$  of less than 7  $\mu\text{g}/\text{dL}$  with a serum TSH in excess of 20  $\mu\text{IU}/\text{mL}$  suggests hypothyroidism. Up to 10% to 20% of infants with congenital hypothyroidism, however, have  $T_4$  values in the low-normal range (7 to 11  $\mu\text{g}/\text{dL}$ ). During the first 24 to 48 hours of life, serum TSH levels normally are elevated because of the neonatal TSH surge. Obtaining TSH blood samples during this time increases the number of false-positive results, but

infants with congenital hypothyroidism usually are not missed.

The diagnosis of congenital hypothyroidism must be confirmed by measurement of serum  $T_4$  and TSH concentrations in any infant with suspicious screening or neonatal sampling results. After 7 days of age, a serum  $T_4$  of less than 6  $\mu\text{g}/\text{dL}$  with a TSH of more than 50  $\mu\text{IU}/\text{mL}$  indicates primary hypothyroidism. A serum  $T_4$  in the range of 6 to 11  $\mu\text{g}/\text{dL}$  with a TSH level of 20 to 50  $\mu\text{IU}/\text{mL}$  is suggestive, and repeat testing is necessary. Eight percent to 10% of infants with congenital hypothyroidism have screening TSH values of less than 50  $\mu\text{IU}/\text{mL}$ , and 1 in 12 to 24 hypothyroid infants (1/50,000 to 1/100,000 newborns) will have a screening TSH level of less than 20  $\mu\text{IU}/\text{mL}$ , with a delayed postnatal increase to hypothyroid levels.

Hypothalamic-pituitary hypothyroidism is more difficult to diagnose. The disorder is characterized by a low serum  $T_4$  concentration with a normal TSH value. In contrast, a low  $T_4$  and TSH pattern most commonly reflects prematurity or a low TBG concentration. Measurement of a low serum TBG concentration or a normal free  $T_4$  level identifies the patients with low TBG. An infant with a low free  $T_4$  concentration should be carefully examined for evidence of hypothyroidism, and other tests of pituitary function should be conducted. A subnormal TSH response to TRH confirms a diagnosis of pituitary TSH deficiency. The TSH deficiency may be isolated or associated with other pituitary hormone deficiencies. If the peak level of TSH after TRH stimulation is normal or prolonged, hypothalamic TRH deficiency is likely.

### Treatment

The treatment of hypothyroidism relies on replacement with exogenous thyroid hormone. Sodium L-thyroxine ( $\text{Na } T_4$ ) is the drug of choice because of its uniform potency and reliable absorption. Appropriate doses of synthetic  $T_4$  produce normal serum levels of  $T_3$  via peripheral conversion. The best guide to adequacy of therapy is periodic measurement of circulating levels of  $T_4$  and TSH; during the initial stages of treatment, a  $T_3$  determination also may be of value. The history and physical examination are important in the follow-up evaluation, but mild hypothyroidism or hyperthyroidism cannot always be excluded on clinical grounds. The usual starting dose of  $\text{Na } T_4$  for hypothyroid infants is 10 to 15  $\mu\text{g}/\text{kg}/\text{day}$ ; we routinely begin treatment in term infants with a 50- $\mu\text{g } T_4$  tablet daily, crushed and given orally in a small amount of liquid. Using  $\text{Na } T_4$  for treatment, the goal of therapy is to maintain the serum  $T_4$  in the upper normal range (10 to 16  $\mu\text{g}/\text{dL}$ ), which should result in normal serum  $T_3$  levels (70 to 220  $\text{ng}/\text{dL}$ ).

Serum TSH levels may remain elevated in adequately treated patients. The thyroid hormone-pituitary feedback set point seems to be altered in some infants with congenital hypothyroidism, and in such infants the serum TSH concentration remains elevated in the face of a normal or even elevated serum  $T_4$  level (McCrossin et al, 1980).

Infants with presumably transient hypothyroidism resulting from maternal goitrogenic drugs need not be treated unless the low serum  $T_4$  and elevated TSH levels persist beyond 2 weeks. Hyperthyroid mothers on antithyroid drugs may breast-feed their infants, because the

concentration of drug in breast milk is very low. Infants with TSH receptor–blocking antibody–induced hypothyroidism may require treatment for as long as 2 to 5 months.

Adequate dosage of thyroxine in the first year usually ranges between 25 and 50  $\mu\text{g}$  daily. The growth rate should accelerate after initiation of therapy, and any growth deficit is commonly restored within a few months. Bone age is a sensitive index of thyroid deficiency, and delayed bone maturation suggests inadequate treatment even when other signs of hypothyroidism have ameliorated. Overtreatment can induce tachycardia, excessive nervousness, disturbed sleep patterns, and other problems suggesting thyrotoxicosis. Excessive thyroxine administered over a long period can produce premature synostosis of cranial sutures and undue advancement of bone age.

### THYROID DYSFUNCTION SYNDROMES IN THE PREMATURE INFANT

Although the preterm infant is subject to the same pathophysiologic processes affecting the term infant, certain disorders of thyroid function are more common as a result of prematurity and are discussed in the following sections.

#### Transient Hypothyroxinemia

Serum  $\text{T}_4$  concentrations increase progressively with gestational age (see Fig. 92–2). Most term infants have serum  $\text{T}_4$  concentrations above 6.5  $\mu\text{g}/\text{dL}$ ; only 2% to 3% have serum  $\text{T}_4$  levels below this level. In contrast, some 50% of premature infants delivered before 30 weeks of gestation have serum  $\text{T}_4$  values below 6.5  $\mu\text{g}/\text{dL}$  (Hadeed et al, 1981). These preterm infants with hypothyroxinemia also have relatively low levels of free  $\text{T}_4$ . These levels are not as low as those in newborns with congenital hypothyroidism; rather, they are similar to the levels in adults. These relatively low free  $\text{T}_4$  levels in premature infants are associated with normal or even low serum TSH values and normal TSH and  $\text{T}_4$  responses to TRH, indicating responsive pituitary and thyroid glands. The hypothyroxinemia is transient, correcting spontaneously (in 4 to 8 weeks) with progressive maturation.

The physiologic significance of these changes remains controversial. Previous studies have suggested that replacement therapy does not improve postnatal growth or subsequent development (Chowdrey et al, 1984). More recent studies, however, have suggested that low  $\text{T}_4$  values are associated with poorer neurologic outcomes in preterm infants after attempts to adjust for other confounding variables (den Ouden et al, 1996; Reuss et al, 1996). These observations have led to studies examining the influence of thyroxine supplementation on these outcomes. In infants born before 30 weeks of gestation, exogenous thyroxine administration did not improve developmental outcome determined at 2, 5, and 7 years of age (Briet et al, 2001; Van Wassenaeer et al, 1997). Moreover, detrimental effects of  $\text{T}_4$  treatment on cognitive function were noted in preterm infants treated after 29 weeks of gestation. Further studies involving more targeted populations of infants or relying on other dosing strategies are in progress. Currently, it would seem prudent to carefully evaluate preterm

infants presenting with elevated TSH levels in the face of low  $\text{T}_3$  or  $\text{T}_4$  values for hypothyroidism; a course of replacement therapy may be warranted in these infants. However, the routine treatment of preterm infants with supplemental thyroid hormones should take place under the guidance of approved research protocols.

#### Transient Primary Hypothyroidism

Transient hypothyroidism in the newborn, characterized by low serum  $\text{T}_4$  and high TSH concentrations, is more common in Europe than in the United States; its prevalence varies geographically relative to iodine intake. In Belgium, it occurs in 20% of premature infants, with the incidence increasing as gestational age decreases (Delange et al, 1985). Cord blood  $\text{T}_4$  and TSH values in these infants usually are in the normal range for premature infants. Premature infants require higher iodine intake levels than those needed in term infants to maintain a positive iodine balance in the extrauterine environment, however, so in iodine-deficient geographic areas, neonatal iodine deficiency may develop in preterm infants. The primary hypothyroid state develops during the first weeks of extrauterine life and often is superimposed on the transient hypothyroxinemia characteristic of prematurity. Urinary iodine excretion and thyroid iodine content are low. The hypothyroidism is transient but may persist for 2 to 3 months; therefore, treatment is recommended. Iodine treatment also corrects this transient primary hypothyroid state. The average time to recovery of function and discontinuation of treatment in Belgium was 50 days.

Premature infants also are particularly susceptible to transient, iodine-induced hypothyroidism (Delange et al, 1985). The mechanism by which the thyroid cell inhibits iodide transport in response to increased plasma iodide levels matures near term. Thus, either in utero or in the postnatal period, administration of iodine-containing drugs to the mother or amniotic injection of radiographic contrast agents for amniocentesis has induced hypothyroidism. Premature infants are more susceptible, but iodide-induced hypothyroidism also can develop in term infants. The dose of iodine required is approximately 50 to 100  $\mu\text{g}/\text{kg}/\text{day}$ . Urine iodine levels in iodine-induced hypothyroid infants usually exceed 1 mg/L. The hypothyroidism, with or without goiter, is characterized by low serum total  $\text{T}_4$  and free  $\text{T}_4$  concentrations and high levels of TSH and urinary iodide. Treatment is indicated for these infants.

#### Transient Hyperthyrotropinemia

Idiopathic hyperthyrotropinemia is a rare disorder. The serum TSH concentration is increased, often markedly, but other thyroid function parameters are normal, and the infants are euthyroid. In Japan, Miyai and coworkers (1979) have reported an incidence of 1/15,000 to 1/20,000 newborns; the prevalence in Europe and the United States is not precisely known but is much lower. The serum TSH concentration may remain elevated for as long as 9 months before spontaneously normalizing. Affected infants do not require treatment, but prolonged follow-up evaluation is necessary to exclude the possibility of a permanent disorder, such as an ectopic thyroid gland,

an inborn defect in thyroid hormonogenesis, or a thyroid hormone resistance syndrome. Transient hyperthyrotropinemia without hypothyroxinemia in the newborn also may occur in response to intrauterine antithyroid drug exposure, intrauterine iodine excess or deficiency, or a maternal TSH receptor–blocking antibody and has been recorded as a TSH assay artifact. The mechanism of transient idiopathic hyperthyrotropinemia is not clear. Delayed maturation of thyroid responsiveness to TSH or of the iodothyronine feedback control of pituitary TSH secretion has been suggested.

### **Low Triiodothyronine Syndrome in Premature Infants**

In the preterm infant, the changes in thyroid function parameters during neonatal adaptation are qualitatively similar to those in term infants but are quantitatively obtunded (Fisher and Klein, 1981). The neonatal TSH surge and the neonatal T<sub>4</sub> and T<sub>3</sub> peak responses decrease with decreasing gestational age, and the transient low T<sub>3</sub> state that follows probably is related to the state of relative undernutrition in the neonatal period. Premature infants have an increased susceptibility to neonatal morbidity including birth trauma, acidosis, hypoxia, hypoglycemia, hypocalcemia, and infection, all superimposed on feeding disorders and relative malnutrition. All of these factors tend to inhibit peripheral T<sub>4</sub>-to-T<sub>3</sub> conversion, thereby aggravating the extent of the low T<sub>3</sub> state characteristic of prematurity. Serum T<sub>3</sub> values may remain low in these infants for 1 to 2 months.

Features of the low T<sub>3</sub> syndrome in premature infants include a low serum T<sub>3</sub> concentration secondary to a decreased rate of conversion of T<sub>4</sub> to T<sub>3</sub>, variable but usually elevated serum rT<sub>3</sub> levels, and normal or low total serum T<sub>4</sub> concentrations. Free T<sub>4</sub> levels usually are in the range of values for healthy premature infants of matched gestational age and weight. TSH values are low in these infants. Treatment is not warranted (Valero et al, 2004).

## **DISORDERS OF THYROID HORMONE CARRIER PROTEINS**

The wide application of neonatal screening programs for congenital hypothyroidism has resulted in the identification of other causes of low values of T<sub>3</sub> and T<sub>4</sub> in the newborn. Although physiologically these children are euthyroid, a discussion of these syndromes is warranted due to their impact on reported values of T<sub>3</sub> and T<sub>4</sub> in the perinatal period.

The major determinants of the levels of circulating thyroid hormones are the concentrations of thyroid hormone–binding proteins. As discussed, TBG, TBPA, and albumin all participate as thyroid hormone carrier proteins. Abnormalities of serum albumin concentration have been described; the major categories are dysalbuminemia and analbuminemia. However, albumin usually binds only about 10% of the circulating T<sub>4</sub> and 30% to 50% of T<sub>3</sub>, and the concentrations of TBG and TBPA are normal or increased in these disorders. Consequently, the levels of thyroid hormones in these patients usually are in the normal range (Hollander et al, 1985). No confirmed primary

disorder of TBPA resulting in abnormal thyroid hormone levels has been described to date. Thus, the plasma protein disorders associated with abnormal serum T<sub>4</sub> levels include only the variations in TBG and the recently described hyperthyroxinemic state “familial dysalbuminemic hyperthyroxinemia.”

### **Thyroxine-Binding Globulin Deficiency**

The prevalence of TBG deficiency varies from 1/5000 to 1/12,000 newborns and is transmitted as an X-linked trait. Serum TBG levels are very low in affected males and approximately half of normal in carrier females. In about half of the families with this trait, the TBG level shown by radioimmunoassay (RIA) is very low, and in the other half, the defect is partial; serum T<sub>4</sub> levels vary similarly. Affected persons are euthyroid, with normal serum TSH responses to exogenous TRH. Treatment is not indicated.

There are many structural defects of the TBG molecule accounting for defective TBG T<sub>4</sub> binding. Variants have been reported in Australian aborigines and African-Americans as well as in other populations. These inherited defects seem not to be due to large fragment deletions, insertions, or rearrangements of DNA; consequently, polymorphism studies have not been helpful in detection or screening. A single amino acid substitution (asparagine for isoleucine) at position 96 of the TBG molecule accounts for the marked reduction of T<sub>4</sub>-binding capacity of TBG-Gary (Takamatsu et al, 1987). Table 92–5 summarizes the reported properties of several variant TBG molecules investigated. Most patients with partial TBG deficiency demonstrated elevated levels of denatured TBG measured by RIA, and each manifested a defective molecule with reduced stability and decreased binding capacity. Patients with severe TBG deficiency have been postulated to have a defect in hepatic TBG synthesis, but the molecular mechanism remains obscure.

### **Thyroxine-Binding Globulin Excess**

Persons with increased levels of TBG have increased total serum T<sub>4</sub> concentrations with normal TSH levels. Serum T<sub>3</sub> concentrations are modestly increased. In these persons, as in those with low TBG concentrations, TBG production rates and serum levels are correlated, suggesting that the mechanism for the high TBG concentrations is increased production, presumably by the liver. TBG levels are increased fourfold to fivefold in affected persons. Early reports suggested a dominant mode of inheritance, but subsequent studies are compatible with an X-linked mode of inheritance.

### **Familial Dysalbuminemic Hyperthyroxinemia**

Several groups of investigators have described euthyroid persons with increased serum T<sub>4</sub> concentrations but normal free T<sub>4</sub>, total serum T<sub>3</sub>, and TSH levels (Ruiz et al, 1982). Binding of T<sub>4</sub> to albumin is increased, and the albumin in these patients has an affinity for T<sub>4</sub> binding intermediate between TBG and TBPA. T<sub>3</sub> is less avidly bound, accounting for the preferential increase in serum T<sub>4</sub> concentration.

TABLE 92-5

## Properties of Reported Abnormal Thyroxine-Binding Globulin Molecules\*

	TBG Concentration		T <sub>4</sub> Concentration	TBG Affinity
	Normal	Denatured		
Normal TBG	100	100	100	100
TBG-S	88	100	84	100
TBG-A	74	100	58	54
TBG-Quebec	16	260	41	70
TBG-Montreal	14	390	38	<3
TBG-Gary	1	1000	24	<5

\*Values listed as percentage of values in normal subjects. Normal absolute values for the measured parameters are TBG RIA, 1.1 to 2.1 mg/dL; TBG-denatured, <2 to 8 μg/dL; T<sub>4</sub>, 5 to 12 μg/dL; TBG affinity constant for T<sub>4</sub>, 0.7 to 1.35 × 10<sup>-10</sup> M.

RIA, radioimmunoassay; T<sub>4</sub>, thyroxine; TBG, thyroxine-binding globulin.

Data from Takamatsu J, Refetoff S, Charbonneau M, et al: Two new inherited defects of the thyroxine-binding globulin (TBG) molecule presenting as partial TBG deficiency. *J Clin Invest* 79:833-840, 1987.

Patients with the disorder are euthyroid, with normal thyroid hormone production rates. The abnormal albumin seems to be transmitted as an autosomal dominant trait.

Diagnosis in these patients is confirmed by protein electrophoresis of serum containing labeled T<sub>4</sub>. The fraction of T<sub>4</sub> label associated with TBG, TBPA, or albumin is measured, and the albumin-bound T<sub>4</sub> can be calculated and related to normal values. Measurements of TBG and TBPA concentrations also are useful. Antithyroid therapy is not necessary in these patients, but it is important to make the diagnosis to avoid a misdiagnosis of hyperthyroidism.

Finally, although the emphasis of neonatal thyroidology is on early detection and appropriate therapy of the hypothyroid state, hyperthyroid states do occur and are associated with significant morbidity.

### Neonatal Thyrotoxicosis

Neonatal Graves disease is rare, probably because of the low incidence of thyrotoxicosis in pregnancy (1 to 2 cases per 1000 pregnancies) and the fact that the neonatal disease occurs only in about one of 70 cases of thyrotoxic pregnancies (Burrow, 1974). In most cases, the disease is due to transplacental passage of thyroid-stimulating antibody (TSA) from a mother with active or inactive Graves disease or Hashimoto thyroiditis. Thus, prediction of neonatal Graves disease from the maternal clinical status is not always possible. It is possible, however, to predict the occurrence of Graves disease in newborns on the basis of maternal TSA titers. In a report by Zakarija and coworkers (1986), all women with TSA titers exceeding 500% of control values (measured by stimulation of cAMP in human thyroid slices) were delivered of thyrotoxic infants, whereas those with lower titers were delivered of euthyroid infants. In some infants, both TSH receptor-stimulating and TSH receptor-blocking antibodies are acquired from the mother, and the blocking antibodies have been reported to block the effects of the stimulating antibodies for 4 to 6 weeks so that late-onset neonatal

Graves disease develops in a previously undiagnosed infant (McKenzie and Zakarija, 1978).

Graves disease in the newborn is manifested by irritability, flushing, tachycardia, hypertension, poor weight gain, thyroid enlargement, and exophthalmos. Thrombocytopenia, hepatosplenomegaly, jaundice, and hypoprothrombinemia also have been observed. Arrhythmias, cardiac failure, and death may occur if the thyrotoxicity is severe and the treatment is inadequate. The mortality rate approaches 25% in disease severe enough to be diagnosed. In some infants, the onset of symptoms and signs may be delayed as long as 8 or 9 days. This delayed onset is due to the postnatal depletion of transplacentally acquired blocking doses of maternal antithyroid drugs and to the abrupt increase in conversion of T<sub>4</sub> to active T<sub>3</sub> shortly after birth in the newborn. The diagnosis is confirmed by measuring high levels of T<sub>4</sub>, free T<sub>4</sub>, and T<sub>3</sub> in postnatal blood. Cord blood values may be normal or near normal, whereas levels at 2 to 5 days may be markedly increased; the serum TSH is low. Neonatal Graves disease resolves spontaneously as maternal TSA in the newborn is degraded. The usual clinical course of neonatal Graves disease is 3 to 12 weeks.

The treatment of hyperthyroidism in the newborn includes sedatives and digitalis as necessary. Iodide or antithyroid drugs are administered to decrease thyroid hormone secretion. These drugs have additive effects with regard to inhibition of hormone synthesis; in addition, iodide rapidly inhibits hormone release. Lugol solution (5% iodine and 10% potassium iodide, containing 126 mg/mL of iodine) is given in doses of 1 drop (about 8 mg) three times daily. Methimazole, carbimazole, or propylthiouracil is administered in doses of 0.5 to 1 mg/kg/day, 0.5 to 1 mg/kg/day, or 5 to 10 mg/kg/day, respectively, divided, at 8-hour intervals. A therapeutic response should be observed within 24 to 36 hours. If a satisfactory response is not observed, the dose of antithyroid drug and iodide can be increased by 50%. Corticosteroids in anti-inflammatory doses and propranolol (1 to 2 mg/kg/day) also may be helpful. Radiographic contrast agents (ipodate, 200 mg/kg per day) also may be useful in treatment, either alone or in conjunction with antithyroid drug treatment.

## Disorders of Carbohydrate Metabolism

Charles A. Stanley and Eugenia K. Pallotto

At the time of birth, the neonate must abruptly switch from having a continuous supply of glucose from the maternal blood in fetal life to maintaining its own supply of glucose during periods of fasting, and when feedings are interspersed intermittently. Glucose homeostasis requires a complex balance between glucose utilization by various organs and production by the liver. This balance is controlled by insulin and an array of counterregulatory hormones that regulate the key metabolic pathways of fuel production during fasting: glycogenolysis, gluconeogenesis, lipolysis, and ketogenesis. Disturbances of these metabolic and endocrine systems may frequently occur in neonates, because of developmental immaturity. Congenital disorders causing hypoglycemia or genetic disorders that result in impairment in carbohydrate metabolism may also present in the neonatal period. Hypoglycemia in a newborn infant represents an urgent diagnostic and therapeutic challenge that must be answered promptly to avoid the adverse consequences of hypoglycemia—most important, damage to the central nervous system (CNS).

This chapter discusses the mechanisms, etiologic factors, and therapeutic strategies for disorders of glucose homeostasis in newborn infants, with special emphasis on neonatal hypoglycemia and a smaller section devoted to hyperglycemia. Disorders of carbohydrate homeostasis caused by inborn errors of metabolism are addressed in detail in Chapter 22.

### HYPOGLYCEMIA

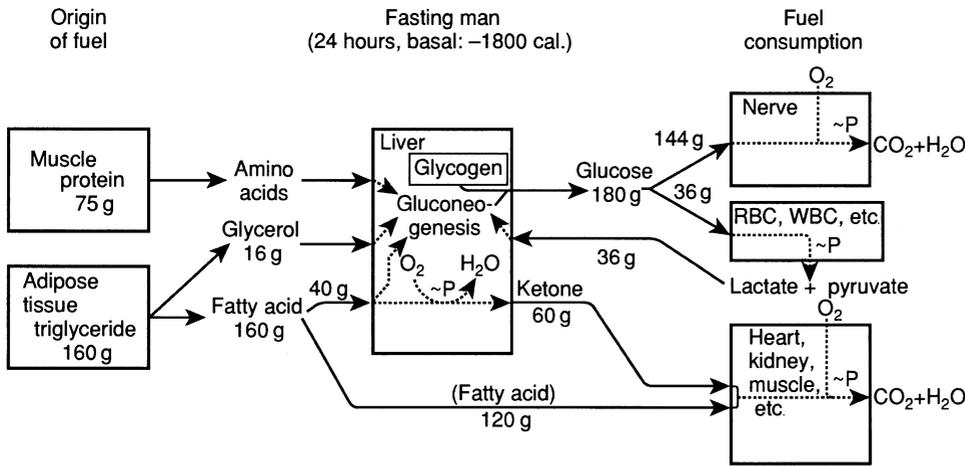

Five systems are involved in maintaining adequate glucose levels for brain metabolism during fasting. Four of these are the major metabolic pathways of fasting adaptation, as shown in Figure 93–1 (Cahill, 1970): (1) hepatic glycogenolysis, (2) hepatic gluconeogenesis, (3) lipolysis, and (4) fatty acid oxidation and ketogenesis. Endocrine control of these four metabolic systems is (5) the important fifth system required for maintaining normal fasting adaptation.

- *Hepatic glycogenolysis*: Once intestinal absorption of a meal is complete and fasting begins, the majority of glucose needed by the body is provided from hepatic glycogen stores. Because the liver contains only 50 to 75 g of glycogen (200 to 300 calories) per kilogram of liver, the supply of glucose from liver stores is sufficient to meet energy requirements for only a few hours.

- *Hepatic gluconeogenesis*: Gluconeogenesis becomes the sole source of glucose as hepatic glycogen stores are depleted. Primary precursors for hepatic gluconeogenesis include amino acids, glycerol from adipose tissue lipolysis and lactate recycled from glycolysis. These precursors are depleted in cases of prolonged demands for glucose. Because there is no reserve of surplus protein in the body and muscle proteolysis is the primary source of amino acids for hepatic gluconeogenesis, the body attempts to limit protein degradation during long-term fasting by switching to fatty acid oxidation.
- *Adipose tissue lipolysis*: Lipolysis releases free fatty acids from adipose tissue stores of triglycerides. Organs such as the heart and kidneys, as well as skeletal muscle, can directly oxidize free fatty acids in place of glucose, thus limiting the need for hepatic gluconeogenesis. Long-chain free fatty acids do not cross the blood-brain barrier; therefore, the brain cannot use them directly. Fatty acids cannot be converted to glucose; however, the glycerol released by lipolysis is used as an important gluconeogenic substrate by liver.
- *Hepatic ketogenesis*: Fatty acids undergo partial oxidation in the liver to produce ketones,  $\beta$ -hydroxybutyrate, and acetoacetate. The brain uses these products of fatty acid oxidation in order to reduce glucose utilization and further reduce the need for protein degradation to support glucose production. Thus, hepatic ketogenesis provides an indirect mechanism for the brain to utilize adipose tissue triglyceride stores during long-term fasting.
- *Hormonal control*: Insulin is the most important hormone involved in the control of fasting adaptation because it acts to inhibit all four of the metabolic fasting systems (Table 93–1). Several counterregulatory hormones oppose the effects of insulin on specific fasting systems (cortisol, growth hormone). Fasting hypoglycemia can result if there is excessive secretion of insulin or a deficiency of one or more counterregulatory hormones.

In infants and children, the pattern of the fasting response is the same as in adults, but the time course is more rapid (Chaussain et al, 1977; Haymond et al, 1982). The accelerated fasting response is due to a greater brain weight relative to body mass. Glucose utilization rates are linearly related to brain size (Zeller and Bougneres, 1992). Therefore, basal glucose consumption in infants is two to three times that in the adult, with preterm infants having higher requirements than those of infants born at term (5 to 8 mg/kg/minute versus 4 to 6 mg/kg/minute, respectively) (Bier et al, 1977; Kalhan and Raghavan, 1998; Ogata, 1986). Infants also have relatively lower muscle mass and less substrate for gluconeogenesis. Thus, fasting hyperketonemia develops within 24 hours in infants and children, compared with 36 to 48 hours in adults.

The fuel and hormonal responses at the time of fasting hypoglycemia provide important information on which of the fasting systems is likely to be involved in the etiology of the hypoglycemia. Specimens of blood and urine obtained at the time of hypoglycemia are termed the “critical” or “Didja” samples (as in “Didja remember to do a glucose [or other] test?”). Plasma samples should be obtained to measure glucose, bicarbonate, lactate, free fatty acids,

**FIGURE 93-1.** General scheme of fuel metabolism in a normal fasted man, showing the two primary sources, muscle and adipose tissue, and the three types of fuel consumers—nerve, pure glycolyzers (such as the red blood cells [RBC] and white blood cells [WBC]), and the remainder of the body (composed of heart, kidney, and skeletal muscle)—that use fatty acids and ketones. ~P represents energy production. (Redrawn from Cahill GF: *Starvation in man*. *N Engl J Med* 282:668-675, 1970.)

$\beta$ -hydroxybutyrate, insulin, cortisol, and growth hormone. Urine should be tested for ketones. Abnormalities in one or more of these levels will direct the clinician toward the mechanism behind the hypoglycemia. Extra plasma and urine specimens should be retained for additional tests that may be required to establish the diagnosis (e.g., acyl-carnitine profile for defects in fatty acid oxidation).

**Etiology of Hypoglycemia in Neonates**

The etiology of hypoglycemia can be identified by the clinical features and the timing of the episode, along with the response of circulating fuels and hormones during the period of fasting hypoglycemia. Table 93-2 classifies the major causes of disorders in fasting adaptation in infants. Table 93-3 lists the risk factors for the development of hypoglycemia in the newborn period and the fasting system involved.

**Development of Fasting Systems**

During fetal life, there is a continuous supply of glucose from the mother through placental transfer. The glucose level of the fetus and that of the mother are highly correlated. Fetal blood glucose is dependent on the maternal-fetal glucose gradient, not on the maternal insulin concentration, as the placenta is impermeable to insulin. Glucose is transported across the placenta by carrier-mediated facilitated diffusion involving non-insulin-dependent glucose transporters. Glut1 and Glut3 both are

expressed in the placenta. Glut3 is a high-affinity transporter that is saturated under normal conditions (Simmons, 1998). Glut1 is abundant in both the basal and apical sides of the syncytiotrophoblast, facilitating entry into the cytoplasm from the maternal blood and exit from the cytoplasm to the pericapillary space of the fetus (Arnott et al, 1994; Reid and Boyd, 1994; Sakata et al, 1995; Takata et al, 1992). Glut1 is the predominant isoform in the fetus; its affinity for glucose is very high. Almost all fetal tissues express Glut1, even tissues that do not express it in the adult (Devaskar and Mueckler, 1991). One of its specialized roles is to shuttle glucose between blood and organs that have limited access to small solutes, including brain and red blood cells, in addition to placenta. This transport is accomplished via passive diffusion (Simmons, 1998). After birth, expression of Glut1 decreases, and other isoforms (e.g., Glut2 in liver, Glut4 in muscle) increase (Wang and Brennan, 1988; Werner et al, 1989). Table 93-4 lists the glucose transporters (Devaskar and Mueckler, 1991; Kahn, 1992). The fetus oxidizes glucose for its energy needs, and the remainder is incorporated in glycogen and used for fat biosynthesis. Glucose provides nearly 100% of the energy needs of the fetus.

After the umbilical cord is cut, the formerly continuous maternal glucose supply to the fetus ceases abruptly. Many of the components of the fasting system the neonate needs to maintain normoglycemia are fully functional, but some remain incompletely developed at delivery. Liver glycogen (system 1) and adipose tissue fat stores (system 3) become filled late in the third trimester but may be limited in preterm and small-for-gestational-age (SGA) infants. Hepatic

Isolated growth hormone deficiency  
Adrenal insufficiency

Acyl CoA, acyl coenzyme A; GSD, glycogen storage disease.

glycogenolysis (system 1) is functional before term, but several enzymes required for gluconeogenesis (system 2) and, especially, ketogenesis (system 4) are not expressed until after birth.

The immaturity of fasting adaptation in the normal newborn is illustrated in Table 93-5 comparing the circulating fuel concentrations immediately after delivery with those in older children during fasting. When the fasting plasma glucose level falls below 50 mg/dL, normal term neonates have higher lactate and lower ketone concentrations, despite adequate free fatty acid concentrations, than those in older infants (Stanley et al, 1979). This indicates that ketogenesis and gluconeogenesis (systems 2 and 5) are not completely mature. The exact timing of complete maturation of these fasting systems is not known, but maturation probably is accomplished before 1 week of age and possibly as early as 24 hours of life in the normal neonate.

This maturation of the fasting systems after delivery is supported by observations in animal models documenting

changes in the enzyme activities involved in ketogenesis and gluconeogenesis after birth. Carnitine palmitoyltransferase-1 (CPT-1) and 3-hydroxy-3-methylglutaryl-coenzyme A synthase (HMG-CoA synthase) are two important enzymes involved in ketogenesis. CPT-1 and HMG-CoA synthase are important rate-limiting steps in the conversion of long-chain fatty acids into ketones (Pegorier et al, 1998). In rat liver, neither of these critical enzymes is expressed until after delivery. Increased expression of the CPT-1 and HMG-CoA synthase genes to levels equal to or greater than those in adult rats occurs by 12 to 24 hours following birth. Long-chain fatty acids provided in colostrum appear to be

Data from Stanley and Baker, 1976; Stanley et al, 1979.

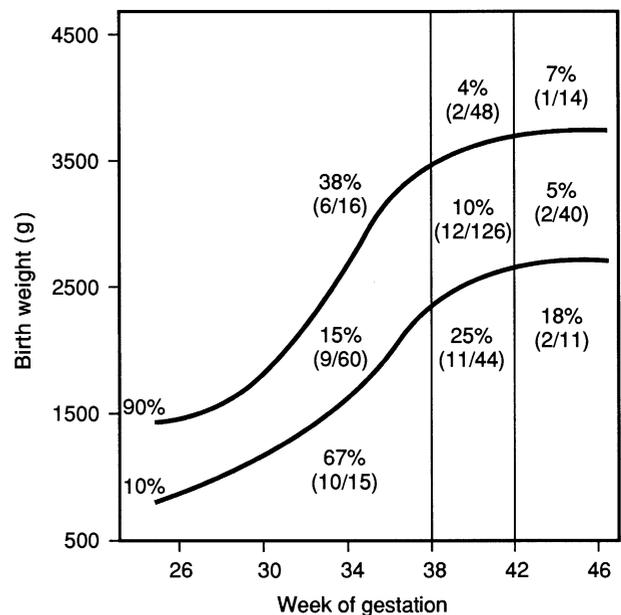

important transcription-activating factors for expression of both genes (Asins et al, 1995; Foster and Bailey, 1976; Pegorier et al, 1998; Serra et al, 1993; Stanley et al, 1983; Thumelin et al, 1993, 1994). Phosphoenolpyruvate carboxykinase (PEP-CK), the rate-limiting step in gluconeogenesis, remains low until after delivery (Kalhan and Raghavan, 1998). Levels of PEP-CK increase in part due to an inhibition of insulin secretion and a surge of glucagon occurring in the time period surrounding delivery (Girard et al, 1973; Granner et al, 1983). Catecholamine release during delivery probably plays a role in the increase in glucagon and decrease in insulin concentrations (Sperling et al, 1984).

Dysregulation of carbohydrate metabolism after birth is evident clinically, as lower glucose measurements have been documented within the first day of life since the first studies in the 1950s. For example, Lubchenko and Bard (1971) reported on a group of infants with glucose measurements prior to the first feed on the first day of life. Ten percent of full-term infants with appropriate growth for gestational age had glucose levels of less than 30 mg/dL prior to the first feeding at 6 to 8 hours of age. In contrast, preprandial glucose levels by days 3 to 4 of life were invariably greater than 50 mg/dL in this group. Srinivansan and colleagues (1986) reported glucose measurements in full-term infants with appropriate-for-gestational age (AGA) birth weights. The range of glucose values at 1 hour of life was 17 to 119 mg/dL, with a mean level of 56 mg/dL. On day 3 of life, the mean fasting glucose had increased to 73 mg/dL, with all glucose values greater than 50 mg/dL. A study by Heck and Erenberg (1987) also demonstrated improved ability to maintain glucose levels after the first day of life. The fifth percentile of glucose values, in a group of infants that included more breast-fed babies than in the study by Srinivansan and colleagues, increased from approximately 35 to 45 mg/dL beyond the first 24 hours of life.

**Causes of Neonatal Hypoglycemia****Self-Limited Disorders****Hypoglycemia during Postnatal Fasting in Normal Neonates**

All neonates are at risk for developing hypoglycemia when exposed to fasting during the first day of life. As shown in Figure 93-2, if the first feeding is withheld until 6 to

8 hours after birth, the frequency of plasma glucose levels falling below 30 mg/dL in term AGA infants is 10%. Thirty percent of these normal neonates were unable to maintain plasma glucose above 50 mg/dL. This marked susceptibility to hypoglycemia disappears rapidly after the first day as the systems of fasting adaptation mature. In a study by Lubchenko and Bard (1971), the frequency of plasma glucose below 50 mg/dL was zero in term AGA infants tested before feedings on the second and third days of life. Similarly, in other groups of infants, including preterm, post-term, large-for-gestational age (LGA), and SGA infants, less than 1% developed a plasma glucose level of less than 50 mg/dL after the first day of life. Hypoglycemia due to immature development of gluconeogenesis and ketogenesis can be avoided easily by feeding earlier than 6 to 8 hours postnatally, preferably within 1 to 2 hours of delivery. Because maturation of these two fasting systems appears to occur during the first 12 to 24 hours

**FIGURE 93-2.** Frequency of hypoglycemia prior to feedings at 6 hours of age in newborn infants grouped by gestational age and birth weight. (Redrawn from Lubchenko LO, Bard H: Incidence of hypoglycemia in newborn infants classified by birth weight and gestational age. *Pediatrics* 47:831-838, 1971.)

of life, the occurrence of hypoglycemia in neonates beyond the first 24 hours of life requires that other possible disorders be considered (Stanley et al, 1979).

### **Postnatal Fasting Hypoglycemia in Preterm or Small-for-Gestational-Age Infants**

Infants who were born prematurely and/or were small for gestational age are at increased risk for hypoglycemia (see Fig. 93–2) (Lubchenko and Bard, 1971). This group of infants with delayed growth in utero has the same impaired gluconeogenesis and ketogenesis as in the AGA infants (Cowett and Schwartz, 1979). These infants have increased glucagon and insulin levels when hypoglycemic. The response to the increased glucagon levels is impaired, suggesting decreased gluconeogenic ability in these infants (Hawdon and Ward Platt, 1993; Hawdon et al, 1993). This hormonal-enzymatic imbalance (high insulin-to-glucagon ratio) probably results in the failure of appropriate gluconeogenesis by delaying PEP-CK induction (the rate-limiting step in gluconeogenesis), because the fall in insulin is one of the main determinants in liver PEP-CK induction, as shown in animal studies (Girard, 1986). Protein, fat, and glycogen stores also may be diminished in these undernourished infants, and they may have an increased glucose utilization rate because of a disproportionately high brain-to-body weight ratio (Hay, 1984; Jones and Roberton, 1984). Management in these high-risk infants includes early institution of oral feedings or intravenous (IV) glucose (Wright et al, 1983). Frequent blood glucose monitoring until oral feedings are tolerated is required to identify those infants who are unable to maintain appropriate fasting blood glucose levels.

### **Neonatal Hypoglycemia Due to Transient Forms of Hyperinsulinism**

#### **Transient Excessive Glucose Utilization (Perinatal Stress-Induced Hyperinsulinism)**

Severe hypoglycemia with excessive glucose utilization is frequently observed in infants with birth asphyxia or other perinatal stresses. This hypoglycemia may last for several days to weeks and may be difficult to manage. A subset of SGA infants probably also fits into this category. Hyperinsulinism has been suggested as the underlying etiology in this group because of several reports documenting high insulin levels as well as good responses to treatment with diazoxide, a drug that acts to suppress beta cell insulin release (Collins and Leonard, 1984, 1990; LeDune, 1972). Glucagon deficiency also has been postulated as playing a role in the etiology of this hypoglycemia (Mehta et al, 1987). Affected infants have excessive glucose requirements, often needing glucose infusion rates greater than 10 to 20 mg/kg/minute. Although very little is known about this form of hyperinsulinism, it may be the most common cause of hypoglycemia beyond the first few days of life. Treatment includes providing adequate dextrose infusions to maintain a plasma glucose level of greater than 60 mg/dL. If high dextrose requirements persist, treatment with oral diazoxide should be considered. Diazoxide treatment may

effectively inhibit insulin secretion until the excessive insulin secretion resolves by a few months of age (Collins and Leonard, 1984, 1990). Glucocorticoids have no role in this disorder, as they are not effective in controlling hyperinsulinism. The use of glucocorticoids as a nonspecific therapy, when the underlying etiology of the hypoglycemia has not been identified, should be avoided. Glucagon infusions may help transiently control the hypoglycemia, by mobilizing glycogen stores, and may be useful in providing further diagnostic information. However, use of glucagon is not a practical long-term therapy.

### **Hyperinsulinism in Infants of Diabetic Mothers**

Infants born to mothers with diabetes mellitus may be chronically exposed to hyperglycemia in utero if maternal glucose control is poor. These infants can develop hyperinsulinism in response to the excess glucose exposure (Adam et al, 1969; Schwartz et al, 1994). Because fetal growth is stimulated by high insulin and other metabolic fuels these infants may be markedly obese with excess stores of glycogen, protein, and fat. Increased fetal growth is evident as increased body fat, muscle mass, and organomegaly without increased brain size. The hyperinsulinism may not immediately resolve at birth and therefore these infants are at increased risk of hypoglycemia. These infants have hypertrophy and hyperplasia of the pancreatic islets, as well as an inappropriate preservation of liver glycogen. This is demonstrated by a rise in blood glucose in response to glucagon given during a hypoglycemic episode. Markers of excess insulin include high glucose demands (greater than 6 to 8 mg/kg/minute) as well as suppression of lipolysis and ketogenesis.

Infants of diabetic mothers are at increased risk of additional medical problems including hypocalcemia, hyperbilirubinemia, polycythemia, respiratory distress syndrome, as well as fetal asphyxia and distress. They are at risk for congenital anomalies when maternal glucose is poorly controlled during the critical period of organogenesis between 4 and 10 weeks of gestation. Anomalies include cardiac defects, vertebral abnormalities, and caudal regression syndrome. Meticulous glucose regulation during and prior to pregnancy is critical for decreasing infant morbidity.

All LGA infants should be suspected of having hyperinsulinism. These infants should be given early feedings and have close monitoring of glucose levels. If hypoglycemia develops, IV glucose should be given according to the individual infant's needs. Keeping plasma glucose values within a range of 60 to 80 mg/dL and avoidance of hyperglycemia to prevent further insulin stimulation and possible rebound hypoglycemia will allow for efficient treatment in these infants. Weaning from glucose infusions should be done gradually. If control of glucose levels cannot be achieved beyond the first few days of life, other disorders should be suspected, specifically congenital hyperinsulinism.

### **Miscellaneous Disorders**

Maternal therapy with beta<sub>2</sub> agonists or use of high-dextrose IV infusions in the period leading up to delivery has been associated with an increase in neonatal hypoglycemia. The

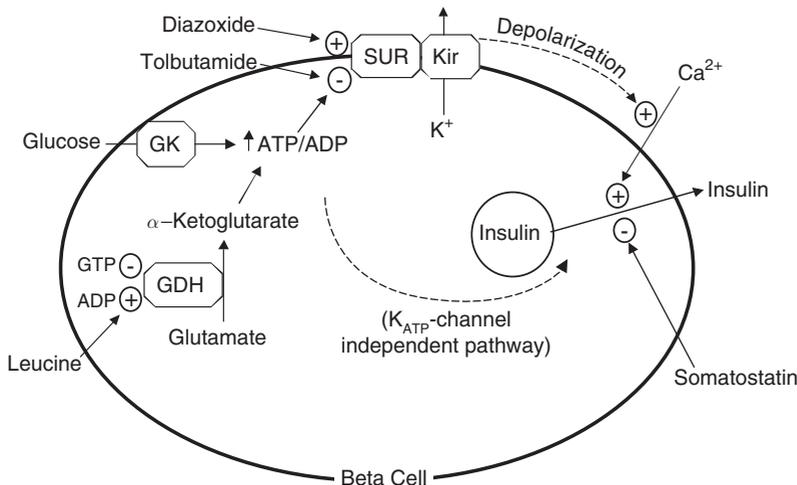

mechanism in both cases probably is related to neonatal hyperinsulinism. The hypoglycemia typically is self-limited and resolves within the first few days of life. Infants with Beckwith-Wiedemann syndrome or erythroblastosis fetalis also may display varying degrees of hyperinsulinism. They will often resemble infants with congenital hyperinsulinism, described in the next section.

### Neonatal Hypoglycemia Due to Persistent (Congenital) Forms of Hyperinsulinism

#### Congenital Hyperinsulinism

Congenital hyperinsulinism is the most common and difficult-to-manage form of persistent hypoglycemia in neonates and infants (Stanley, 1997). Severely affected infants usually present with an abnormally high birth weight but otherwise normal findings on physical examination. In the past, congenital hyperinsulinism had been called “nesidioblastosis,” implying a developmental disorder of pancreatic islet formation. However, it is now known that nesidioblastosis is a normal feature of the newborn pancreas and that hyperinsulinism is due to genetic defects in the regulation of insulin secretion.

The pathways involved in insulin release are shown in Figure 93–3. Glucose-stimulated insulin secretion involves increased glucose metabolism via the Glut2 glucose transporter and glucokinase (GK). This leads to an increased ATP/ADP ratio, resulting in inhibition of a plasma membrane ATP-dependent potassium channel. This  $K_{ATP}$  channel is composed of a sulfonylurea receptor regulatory subunit (SUR1) complexed with its ion pore (Kir6.2). Closure of the  $K_{ATP}$  channel results in membrane depolarization and activation of a voltage-sensitive calcium channel; the resulting increase in cytosolic calcium triggers exocytosis of insulin granules. Insulin secretion also may be stimulated by amino acids through allosteric activation of glutamate dehydrogenase (GDH) by leucine. This results in increased oxidation of glutamate, leading to an increased ATP/ADP ratio, inhibition of the ATP-dependent potassium channel activity, and membrane depolarization.

#### Etiology

Several described defects in the regulation of insulin secretion result in congenital hyperinsulinism. Both recessive and dominant forms of congenital hyperinsulinism have been described and include mutations involving SUR1, Kir6.2, GDH, and GK. Pathologic findings include diffuse involvement of the entire pancreas or focal pancreatic lesions (Delonlay et al, 1997; Glaser et al, 2000; Huopio et al, 2000; Stanley, 1997; Stanley et al, 1998).

#### Recessive (Diffuse) $K_{ATP}$ Channel Hyperinsulinism

The genetic defects in this type of hyperinsulinism are recessive, loss-of-function mutations of the genes encoding the SUR1 and Kir6.2 components of the ATP-sensitive potassium channel complex. These two genes are located adjacent to one another on chromosome 11p (Glaser et al, 2000).

#### Focal $K_{ATP}$ Channel Hyperinsulinism

In the focal form of the disease, a clone of beta cells expresses a paternally derived mutation of SUR1 or Kir6.2 as a result of the loss of heterozygosity for the maternal allele. Infants with mutations of SUR1 or Kir6.2 (either focal or diffuse disease) are the most severely affected and often present with hypoglycemia on the first day of life. Because diazoxide suppression of insulin secretion depends on a functional  $K_{ATP}$  channel (see Fig. 93–3), neonates with diffuse or focal  $K_{ATP}$  hyperinsulinism often cannot be managed medically, necessitating surgical pancreatectomy. Infants with focal and with diffuse disease are indistinguishable clinically; however, infants with focal disease (approximately 40% of cases) are potentially curable by surgery, but those with diffuse disease are not (De Lonlay-Debeney et al, 1999).

#### Dominant $K_{ATP}$ Channel Hyperinsulinism

A recent report describes a family with a dominantly inherited mutation of SUR1 (Huopio et al, 2000). Clinical disease was less severe than with the typical  $K_{ATP}$  channel hyperinsulinism mutation described earlier. Onset of symptoms was

**FIGURE 93–3.** Mechanism of insulin secretion by the beta cell of the pancreas. Glucose is transported into the cell by the insulin-independent glucose transporter (GLUT2). The glucose undergoes phosphorylation by glucokinase (GK). It is then metabolized, with a resultant increase in the ATP/ADP ratio. With this increase in the ATP/ADP ratio, the  $K_{ATP}$  channel closes, initiating a cascade of events including membrane depolarization, calcium influx, and release of insulin from storage granules. Leucine stimulates insulin secretion by activating glutamate dehydrogenase (GDH), which increases the oxidation of glutamate, thereby increasing the ATP/ADP ratio. ADP, adenosine diphosphate; ATP, adenosine triphosphate; GTP, guanosine triphosphate; Kir, potassium channel ion pore; SUR, sulfonylurea receptor regulatory subunit.

later in infancy and responded to diazoxide therapy, indicating that complete loss of channel function did not occur. This report suggests that additional phenotypes of  $K_{ATP}$  hyperinsulinism are likely to be discovered in the future.

### **Dominant Glucokinase Hyperinsulinism**

Dominant GK hyperinsulinism is associated with a regulatory mutation of GK. Presentation in this form occurs beyond the neonatal period (Glaser et al, 1998).

### **Dominant Glutamate Dehydrogenase Hyperinsulinism (Hyperinsulinism/Hyperammonemia Syndrome)**

Dominant GDH hyperinsulinism is the result of a gain-of-function mutation of GDH (Huijmans et al, 2000; MacMullen et al, 2001; Miki et al, 2000; Stanley et al, 1998; Yorifuji et al, 1999). Patients present with symptomatic hypoglycemia along with persistent asymptomatic elevation of plasma ammonia. Infants are of normal size at birth, and episodes of hypoglycemia frequently are not detected until beyond the first year of life. Medical therapy with diazoxide is effective. Most cases are sporadic, but familial autosomal dominant inheritance is reported in approximately 20% of cases. Plasma ammonia levels are constant and do not increase with protein feeding, usually in the range of 60 to 105  $\mu\text{mol/L}$ . Treatment is not needed for elevated ammonia levels.

### **Clinical Presentation**

The infant with congenital hyperinsulinism may present with difficult-to-manage hypoglycemia on the first day of life, requiring glucose infusion rates of greater than 10 to 20 mg/kg/minute (Landau et al, 1982; Stanley and Baker, 1976). Severe forms are associated with  $K_{ATP}$  channel defects and usually manifest in the first hours or days after birth. Less severe forms are associated with GDH or GK mutations. Infants with the less severe forms may have normal birth weights, and episodes of hypoglycemia may not be recognized until beyond the neonatal period. Hyperinsulinism can be devastating to the developing brain. The brain is deprived of glucose as well as alternative fuels, because insulin suppresses lipolysis and ketogenesis by inhibiting adipose tissue lipolysis and preventing transport of free fatty acids into the mitochondria for oxidation and ketogenesis (Stanley and Baker, 1976).

### **Diagnosis**

Using the fasting systems approach, congenital hyperinsulinism can be reliably diagnosed by the pattern of metabolic fuels and hormones at the time of hypoglycemia (glucose less than 50 mg/dL), plasma insulin levels greater than 2 mU/mL, plasma  $\beta$ -hydroxybutyrate less than 2.0 mmol/L, plasma free fatty acids less than 1.5 mmol/L, and a glycemic response to glucagon greater than 30 mg/dL serve to establish the diagnosis (Finegold et al, 1980; Stanley and Baker, 1976). The glycemic response to glucagon demonstrates inappropriate glycogen conservation during the episode of hypoglycemia and is useful in making the presumptive diagnosis of hyperinsulinism. The lack of an elevated insulin level at the time of hypoglycemia alone does not exclude hyperinsulinism. The hypersecretion of insulin may be episodic, or increased portal vein insulin

may not be reflected in peripheral insulin concentrations. Caution must be taken in ruling out pituitary deficiencies if insulin levels are not diagnostically elevated.

### **Treatment**

The first line of treatment for congenital hyperinsulinism is diazoxide, which acts at the  $K_{ATP}$  channel to suppress insulin secretion. If diazoxide fails to control the hypoglycemia, then octreotide, a long-acting somatostatin analogue, may be effective inhibiting insulin secretion (Hirsch et al, 1977). Patients with severe hyperinsulinism often fail to respond to medical management. Surgery may be required to control the hypoglycemia. This may involve resection of a focal lesion, if identified. If a focal lesion is not found, a 95% pancreatectomy is done with the hope that sufficient pancreatic tissue will be removed to control the hypoglycemia. The remaining beta cells still are not normally regulated, so further therapy with diazoxide and/or octreotide or further surgery often is required.

## **Neonatal Hypoglycemia Due to Counterregulatory Hormone Deficiency**

### **Pituitary Deficiency**

Pituitary deficiency is the second most frequent cause of persistent neonatal hypoglycemia. It is often associated with physical features such as midline cleft lip or palate, single central incisor, or optic nerve hypoplasia. Male infants may have micropenis due to gonadotropin deficiency. Caution is advised, because findings on the physical examination also may be normal. Low levels of growth hormone and cortisol, at the time of hypoglycemia, suggest the diagnosis of pituitary deficiency. Provocative testing may be required to confirm the diagnosis. Clinical features in these infants may mimic those of hyperinsulinism, as growth hormone and adrenocorticotropic hormone (ACTH) deficiency permit unopposed insulin action. Thyroid function tests in these infants show low or low-normal levels of thyroxine ( $T_4$ ) and thyroid-stimulating hormone (TSH). Hypoglycemia is correctable with appropriate hormone replacement. A magnetic resonance imaging (MRI) scan should be obtained to identify the presence of other midline defects.

### **Adrenal Insufficiency**

Hypoglycemia is rare in cases of congenital adrenal hyperplasia. It may be present in cases of adrenal hemorrhage, a rare event, or congenital adrenal hypoplasia/aplasia, also rare (Artavia-Loria et al, 1986; Reiner et al, 1983; Toyofuku et al, 1986). Early recognition in these rare cases is crucial, as cortisol deficiency can be life-threatening. Normoglycemia is restored with cortisol replacement.

## **Neonatal Hypoglycemia Due to Defects of Fasting Metabolic Systems**

### **Genetic Metabolic Defects**

Defects in glycogenolysis, gluconeogenesis, and ketogenesis that manifest with hypoglycemia are listed in Table 93–2. They are discussed in greater detail in a separate chapter. Hypoglycemia associated with genetic metabolic

defects often is masked by frequent infant feedings in the newborn period. Thus, such defects often are not recognized until after several months of age. The exception to this rule is in affected neonates who are breast-fed, as the delay in establishing lactation can expose infants to prolonged fasting stress. Growth failure, hepatomegaly, and acidosis are often presenting features.

*Persistent hypoglycorrhachia* (glucose transporter 1 [Glut1] deficiency) has been reported (De Vivo et al, 1991). Affected infants have a genetic defect of the glucose transporter required to transfer glucose across the blood-brain barrier. Patients have low cerebrospinal fluid glucose levels (20 to 30 mg/dL) without evidence of meningitis. Cases have been described in which the presenting manifestations were recurrent seizures, progressive microcephaly, and retardation. A ketogenic diet has been used successfully to provide alternative substrate for the brain, permitting normal brain development in some patients.

## Diagnosis and Treatment of Hypoglycemia

### Plasma Glucose Thresholds

Controversy about appropriate glucose thresholds for neonates has continued over the past decades. The uncertainty in this area derives from the perception from 50 or 60 years ago that glucose levels in newborn infants were often lower than the ranges found in infants, children, and adults. Pediatricians were therefore reluctant to apply the same glucose standards to neonates as those used in older children. This reluctance has recently been compounded by concern about medicolegal implications of neonatal hypoglycemia. The fact that hypoglycemia was not purely benign in neonates was first appreciated in the early 1960s, when Cornblath and colleagues (1959) described symptomatic neonatal hypoglycemia. Dr. Cornblath (Cornblath and Schwartz, 1966) proposed that hypoglycemia could be “defined” in neonates as the presence of glucose levels 2 standard deviations below the mean values found in surveys of glucose levels on the first day of life. They also proposed that a different glucose value be used to define hypoglycemia for low-birth-weight infants, because lower glucose levels were more frequent in this group. The problems with this approach are obvious and include the fact that statistical definitions of hypoglycemia only describe what ranges of glucose levels are common, not what is physiologically normal or optimal for newborns. In addition, it is clear that the distribution of glucose values in neonates reflects feeding practices on the first day of life. This effect of changes in nursery practices is apparent in a comparison of mean glucose levels in term infants from 1961 to 1986. The mean glucose level during the first 3 hours after birth increased from 48 mg/dL to 70 mg/dL (Aynsley-Green, 1991).

Despite the perceptions from over 50 years ago, there is no evidence that newborn infants have a lower requirement for plasma glucose concentrations than those in older infants or adults. Before birth, fetal levels of plasma glucose are nearly identical to maternal values, and the fetus is known to be dependent on glucose as its major source of energy. There is also no evidence that the neonatal brain is specially protected to tolerate hypoglycemia better than the brains of older infants and children.

Pathophysiologic responses to hypoglycemia in neonates, older children, and adults occur at similar thresholds of glucose (Koh et al, 1988; Pryds and Christensen, 1990). In adults, visual evoked potentials were abnormal when blood glucose dropped below 47 mg/dL, and a modest decrease in plasma glucose (below 70 mg/dL) caused early impairment in cognitive function without clinical symptoms (DeFeo et al, 1988; Harrad et al, 1985). A compensatory increase in cerebral blood flow was found in preterm infants during hypoglycemia (Pryds and Christensen, 1990). CNS dysfunction has been reported in neonates with asymptomatic hypoglycemia, as noted by abnormalities in sensory evoked potentials (Koh et al, 1988). Studies of preterm infants associated repetitive decreases in glucose (less than 47 mg/dL), with reduced mental and motor developmental scores and increased neurodevelopmental impairment (Lucas et al, 1988).

Because of the aforementioned concerns, the authors do not recommend using different glucose thresholds for diagnosing and treating hypoglycemia in neonates than in older infants and adults. In the neonate, as in older children and adults, hypoglycemia should be considered the result of a failure in one or more of the metabolic and hormonal systems involved in fasting homeostasis. The physiologically optimal range for plasma glucose levels should be considered to be 70 to 100 mg/dL. The goal of therapy in neonates should be identical to that in older children—that is, to maintain plasma glucose at greater than 60 mg/dL, preferably within the optimal range of 75 to 100 mg/dL. A plasma glucose value of 50 mg/dL is the threshold for terminating provocative tests, such as diagnostic fasting tests. This usually provides an adequate margin of safety to obtain necessary information about fasting adaptation without risking severe symptoms, such as seizures. This threshold level of hypoglycemia is influenced by alternative fuel availability. In some disorders, such as fatty acid oxidation defects, infants can have severe symptoms and be dangerously ill with plasma glucose levels in the range of 45 to 60 mg/dL. In other disorders, such as glucose-6-phosphatase deficiency, CNS symptoms are infrequent when glucose levels fall below 40 mg/dL, because high levels of plasma lactate provide alternative fuel for the brain. Plasma glucose levels above 40 mg/dL are not likely to be responsible for severe symptoms such as seizures, but may be suggestive of an underlying abnormality. It should be emphasized that the need for diagnostic work-up is determined not by the level of plasma glucose but rather by clinical factors such as postnatal age, birth history, feeding intervals, and findings on physical examination. This conservative approach to hypoglycemia emphasizes that glucose values of 40 to 60 mg/dL should be considered suboptimal. In neonates on the first day of life who have no other risk factors, hypoglycemia can be assumed to be due to immaturity of fasting that will not persist. In these otherwise normal infants, appropriate early feeding leads to an appropriate elevation in glucose. If adequate response is not obtained, and especially if difficulties persist beyond the first day of life, the possibility of a disorder in one of the fasting systems should be considered.

Several factors may influence the accuracy of glucose measurements. Glucose meters are useful for rapid bedside screening; however, their range of precision is only

$\pm 10\%$  to  $20\%$  (e.g., at a meter reading of 50 mg/dL, the true value may be as low as 40 mg/dL or as high as 60 mg/dL). Operator technique also may affect results if too much or too little blood is placed on test strips. Corroboration with true laboratory values is required (Perelman et al, 1982). The use of test strips to estimate plasma glucose visually without a meter should be avoided, because this method is grossly inaccurate and outdated. When using whole blood values, one must remember they are 10% to 15% lower than plasma values (Sacks, 1996). When whole blood measurements are performed, falsely low measurements may occur as a result of red cell glycolysis if there is a delay in analyzing specimens or in the presence of polycythemia (hematocrit greater than 70%) (Kaplan et al, 1989). Finally, the site from which the blood was drawn is an important consideration, as arterial glucose values are greater than capillary values, which in turn are greater than venous values (Larsson-Cohn, 1976).

### Clinical Presentation

The classic signs of hypoglycemia relate to adrenergic activation (tachycardia, sweating, jitteriness, etc.) and to CNS impairment (e.g., confusion, lethargy) (Table 93–6). The signs of hypoglycemia in the neonate are more nonspecific, resulting from disturbances in one or more aspects of CNS function. As the signs are often minimal and difficult to appreciate, hypoglycemia should be suspected in any infant who does not appear normal, who has inadequate oral intake, or in any infant known to be at increased risk (see Table 93–3).

### Treatment

Any infant known to be at risk for hypoglycemia should be monitored closely, and either IV glucose or enteral nutrition should be initiated as soon as possible. These include large-for-dates and small-for-dates neonates, neonates with perinatal asphyxia, and infants of diabetic mothers or mothers with toxemia or preeclampsia. In cases of mild or asymptomatic hypoglycemia, enteral feeds should be given if the infant is able to tolerate them. This recommendation applies to otherwise normal infants who have hypoglycemia during the first 24 hours after birth when the problem is believed to be transient and due to a delay in initiation of feedings (e.g., breast-feeding). Beyond the first day, if plasma glucose values below 60 mg/dL continue, further evaluation for the etiology of the hypoglycemia based on the fasting systems approach should be initiated. Breast

milk is beneficial when enteral feeds are initiated in that it may be more ketogenic than formula, but it often is not available within the first 24 hours of life. Standard infant formula should be used if breast milk is not available. Breast milk and formula provide carbohydrates, protein, and fat. They are metabolized more slowly than dextrose in water and provide more energy per milliliter despite having less glucose. Fat intake may be beneficial, as it decreases demand for glucose utilization, stimulates gluconeogenesis, and may play important roles in initiating transcription of enzymes of ketogenesis. If clinically tolerated, enteral feeds should be continued even if IV therapy is required for low glucose values (Hawdon et al, 1992; Lucas et al, 1978).

Severe or symptomatic hypoglycemia should be treated with IV glucose. A bolus of 200 mg/kg of glucose (10% dextrose in water [D<sub>10</sub>W], 2 mL/kg) should be used, along with initiation of or increase in the glucose infusion rate (Lilien et al, 1980). A larger bolus of glucose may be harmful to neurologic function and may be followed by rebound hypoglycemia. Dextrose infusion should be started at 5 to 8 mg/kg/minute to maintain plasma glucose above 60 mg/dL. Rates as high as 20 to 30 mg/kg/minute may be required in disorders such as hyperinsulinism or pituitary deficiency or for infants of diabetic mothers. The infusion rate is calculated as follows:

$$\text{rate (mg/kg/minute)} = (\% \text{ glucose in IV solution} \times \text{IV rate in mL/hr} \times 0.167) \div \text{weight (kg)}$$

Specific therapies such as diazoxide, or somatostatin (octreotide) may be indicated after appropriate diagnostic evaluation to ensure appropriate therapy based on the physiologic mechanism of the hypoglycemia. Glucocorticoids should not be used for nonspecific treatment of hypoglycemia in neonates or older children.

### Diagnosis of Underlying Disorder

In order to appropriately treat infants with evidence of persistent hypoglycemia, the cause of the hypoglycemia must be determined. If the cause of hypoglycemia is clearly a self-limited disorder (such as in the infant of the diabetic mother) then complete diagnostic testing may not be needed. If the etiology is not clear, the history, physical examination, and laboratory findings should be used together to make a diagnosis.

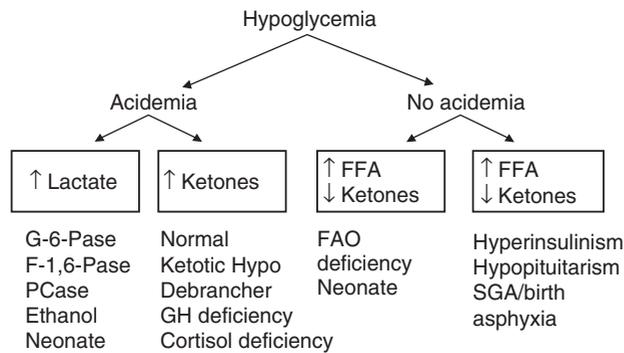

The history should include the duration of fasting prior to the hypoglycemic episode as well as the frequency of episodes. Shorter duration and frequent episodes are consistent with hyperinsulinism. Onset soon after a meal would be consistent with hyperinsulinism or glycogen storage disease. Onset after more prolonged fasting is more consistent with a fatty acid oxidation or gluconeogenic defect. If a mid-line facial malformation, microphthalmia, or microphallus is present, pituitary deficiency should be suspected. In an LGA infant, congenital hyperinsulinism should be suspected. Growth failure with massive hepatomegaly frequently is associated with glucose-6-phosphatase deficiency or debrancher deficiency glycogen storage disease. A fatty acid oxidation defect may be associated with abnormal liver function tests and hyperammonemia.

An important part of the laboratory evaluation includes the hormonal and fuel responses at the time of fasting

**TABLE 93–6**

### Signs of Neonatal Hypoglycemia

Tremors	Lethargy
Irritability	Diaphoresis
Poor feeding	Abnormal cry
Apnea	Cyanosis
Seizures	Limpness
Jitteriness	Twitching
Hypothermia	Tachycardia
Tachypnea	

**FIGURE 93-4.** Algorithm for the diagnosis of hypoglycemia based on results of “critical” blood tests at the time of hypoglycemia. FAO, fatty acid oxidation; FFA, free fatty acids; F-1,6-Pase, fructose-1,6-diphosphatase; GH, growth hormone; G-6-Pase, glucose-6-phosphatase; hypo, hypoglycemia; PCase, pyruvate carboxylase; SGA, small for gestational age.

hypoglycemia. Plasma should be obtained for the “critical” blood measurements at the time of hypoglycemia including levels of lactate, free fatty acids, ketones, insulin, cortisol, and growth hormone (2 to 3 mL). Obtaining an adequate urine sample for the measurement of urinary organic acids is needed (5 to 10 mL). The algorithm presented in Figure 93-4 outlines the differential diagnosis of hypoglycemia based on results of these blood tests. A glucagon stimulation test also provides useful diagnostic information. At the time of hypoglycemia, 0.5 to 1 mg of IV glucagon is given. A rise in glucose greater than 30 mg/dL suggests inappropriate preservation of liver glycogen stores. This may be seen in hyperinsulinism as well as in neonatal panhypopituitarism. Additional tests of pituitary function should be included if pituitary deficiency is suspected.

## HYPERGLYCEMIA

Neonatal hyperglycemia may be seen in the neonatal intensive care unit. It is most commonly a problem encountered in sick neonates, particularly very low-birth-weight (VLBW) infants. This is most commonly seen within 24 hours after birth in the VLBW infant in association with increased glucose infusion rates (greater than 6 mg/kg/minute) but also may be noted at lower glucose infusion rates (Dweck and Cassady, 1974; Zarif et al, 1976). The risk for hyperglycemia is 18 times greater in infants weighing less than 1000 g than in those weighing more than 2000 g (Louik et al, 1985). This risk also is increased in those infants with serious illnesses or stresses such as anesthesia or surgery (Lilien et al, 1979; Ward Platt et al, 1990). Hyperglycemia beyond the initial few days of life in the VLBW infant has been associated with bacterial and fungal infections as well as drugs such as postnatal dexamethasone and methylxanthines (Fanaroff et al, 1998; Farrag and Cowett, 2000; Rowen et al, 1995; Vermont Oxford Network Steroid Study Group, 2001).

Studies of the mechanism of hyperglycemia in the VLBW infant suggest that the neonate has a decreased insulin response to a glucose load, representing a lag in the beta cell response to the hyperglycemia. Other studies suggest that newborns with hyperglycemia have a relative insulin

resistance, resulting in decreased suppression of hepatic glucose production throughout a wide range of glucose and insulin infusions and concentrations (Cowett and colleagues, 1983; Hay, 1998). Elevated levels of circulating cortisol, glucagon and catecholamines are implicated when the hyperglycemia is present in association with “stress” conditions such as postsurgery and sepsis (Farrag and Cowett, 2000).

Plasma glucose levels greater than 150 mg/dL generally are considered to indicate hyperglycemia. This level of hyperglycemia is based on statistical studies and does not take into account the underlying events and biologic variations that may be altering the infant’s response to exogenous glucose. The long-term effects of mild elevations in glucose are not well studied. In clinical practice, VLBW infants demonstrating glucose intolerance frequently have glucose levels exceeding 200 mg/dL. Physiologic concerns with high glucose levels include osmotic diuresis, dehydration, and weight loss. In severe hyperglycemia (glucose levels greater than 500 mg/dL), cerebral hemorrhage may result from the increased serum osmolarity, causing water to shift from the intracellular to the extracellular compartment (Miranda and Dweck, 1977). Some clinical studies suggest increased mortality, intraventricular hemorrhage, and major handicaps in infants with hyperglycemia (Dweck and Cassady, 1974; Zarif et al, 1976), although it has been difficult to fully evaluate hyperglycemia as an independent risk without other confounding factors. Adult animal and human studies have linked hyperglycemia with increased brain damage when associated with hypoxic brain injury (Binder et al, 1989; Myers and Yamaguchi, 1977; Pulsinelli et al, 1982, 1983).

Therapy for hyperglycemia in the neonate is linked to the severity of glucose elevation. If hyperglycemia is mild and brief (duration less than 24 to 48 hours), a decrease in the glucose infusion rate is frequently successful in treating the hyperglycemia. Use of hypotonic IV solutions should be avoided. In prolonged cases of hyperglycemia, the nutritional needs of the infant may be significantly compromised. Low-dose insulin therapy may be useful in increasing the availability of calories needed for growth from parenteral nutrition when the glucose concentration is consistently greater than 200 to 250 mg/dL (Binder et al, 1989; Collins et al, 1991). Continuous insulin infusions starting at 0.01 unit/kg/hour and increasing gradually up to 0.05 to 0.1 unit/kg/hour will control the hyperglycemia. Caution is indicated regarding use of continuous insulin infusions, as the insulin frequently adsorbs to glass and plastic surfaces and can be degraded by light.

Neonatal onset of diabetes mellitus is rare, with an incidence estimated at about 1/500,000 (Von Muhlenhah and Herkenhoff, 1995). Affected infants are usually born small for gestational age. They present within the first 1 to 3 months of life with elevated blood glucose levels and glycosuria. Ketosis may be present but is frequently mild. Infants invariably present with dehydration. They have low insulin levels during the hyperglycemia and decreased insulin response to secretagogues. Insulin therapy usually is required, but the prognosis is excellent, with frequent spontaneous resolution. Three forms have been reported: transient, permanent, and transient with later recurrence (Von Muhlenhah and Herkenhoff, 1995). The clinical features of the transient and the permanent forms are similar,

but the underlying genetics are different. Paternal uniparental isodisomy of chromosome 6 has been reported in cases of the transient disease form, with linkage to 6q23-q24 (Hermann et al, 2000; Temple et al, 2000). The permanent form of the disease is less understood. It has been associated with abnormalities in pancreatic development including aplasia and hypoplasia (Lemons et al, 1979; Winter et al, 1986). A mutation in the insulin promoter factor-1 (*IPF1*) gene has been identified in a patient with pancreatic agenesis (Stoffers et al, 1977). The *IPF1* locus has been mapped to 13q12.1 (Stoffel et al, 1995). Cases of permanent diabetes mellitus due to complete deficiency of the glycolytic enzyme glucokinase also have been reported (Njolstad et al, 2001).

# ORTHOPEDIC CONDITIONS

Editor: H. WILLIAM TAEUSCH

## CHAPTER 94

### Common Neonatal Orthopedic Ailments

Brian E. Grottkau and Michael J. Goldberg

Although orthopedic afflictions of the newborn generally are not life-threatening, they do have the potential to significantly impair functional performance, even when diagnosed and treated early. A few are also the basis for a disproportionate number of medicolegal proceedings. This chapter discusses the most commonly encountered of these orthopedic problems.

#### DEVELOPMENTAL DYSPLASIA OF THE HIP

The term *developmental dysplasia of the hip* (DDH) encompasses a spectrum of pathology from “located” hips that are unstable (femoral head can be moved within or outside the confines of the acetabulum) to frankly dislocated hips in which there is a complete loss of contact between the femoral head and acetabulum. DDH occurs in 11.5 in 1000 infants, with frank dislocations occurring in 1-2/1000 (American Academy of Pediatrics [AAP], 2000; Guille et al, 2000). Risk factors for a positive newborn screening examination include female gender (19/1000 risk), positive family history (boys, 9.4/1000; girls, 44/1000) and breech presentation (boys, 26/1000; girls, 120/1000) (AAP, 2000). The left hip alone is affected in 60%, the right hip in 20%, and both hips in 20% of infants (Guille et al, 2000).

Dislocations can be divided into two groups: teratologic and typical. *Teratologic* dislocations are most frequently associated with neuromuscular conditions such as myelodysplasia and arthrogryposis or with dysmorphic syndromes such as Larsen syndrome. These abnormalities probably occur in either week 12 or 18 of gestation (AAP, 2000). *Typical* dislocations occur in otherwise healthy infants in the prenatal or postnatal period.

Congruent reduction and stability of the femoral head are necessary for normal growth and development of the hip joint. The natural history of untreated DDH is controversial, as newborn instability may resolve or progress to subluxation

or dislocation. In cases that progress, infants have significantly increased risk of developing precocious arthritis with moderate to severe hip pain as young adults (Cooperman et al, 1983; Wedge and Wasylenko, 1979). This pain can be debilitating. Early detection and treatment of DDH are therefore important in avoiding the devastating sequelae of a late diagnosis.

There are no pathognomonic signs of a dislocated hip. The physical examination requires patience on the part of the examiner and may be facilitated by having the baby feed from a bottle. Evaluation for asymmetry is perhaps the most important key to the evaluation for DDH, although asymmetry may not be evident in bilateral dislocations. Presence of asymmetrical thigh and/or buttock folds is suggestive of a dislocation, as is a Galeazzi sign. The Galeazzi sign is elicited with the baby placed supine on an examining table so that the pelvis is level, with the hips and knees flexed to 90 degrees. With the baby’s hips in neutral abduction, the examiner determines if the knees are at the same height. If one femur appears shorter, the hip may be dislocated posteriorly (Fig. 94–1). Limitations in hip abduction can also herald a dislocated hip. In babies older than 12 weeks, it is the most reliable examination finding suggestive of DDH. Adduction of 30 degrees and abduction of 75 degrees should be possible in most newborns. Variations side to side should be noted. Each of these signs, individually or in combination, may serve to increase the index of suspicion of the examiner and lower the threshold for further diagnostic studies or referral to an orthopedist.

There are two common ways of assessing hip stability in the newborn. The Ortolani test is performed with the calm newborn supine on the examining table. The index and middle fingers of the examiner are placed along the greater trochanter, while the thumb is placed on the medial aspect of the thigh over the lesser trochanter. The pelvis is stabilized by placing the thumb and ring or long finger of the opposite hand on top of both anterior iliac crests simultaneously. Alternatively, the opposite thigh may be held in the same manner as the examined side while the hip is held in abduction. The hip is flexed to 90 degrees and gently abducted while the leg is lifted with the hip in neutral external/internal rotation. A palpable “clunk” is felt as the dislocated femoral head reduces into the acetabulum. This finding is reported as the Ortolani sign (positive result on the Ortolani test). The Barlow test is an attempt to dislocate or subluxate a reduced but unstable hip. The thigh is held and the pelvis stabilized in the same manner as for the Ortolani test. With the hip in neutral external/internal rotation and at 90 degrees of flexion, the leg is then gently adducted with a mild posteriorly

**FIGURE 94-1.** Presence of Galeazzi sign.

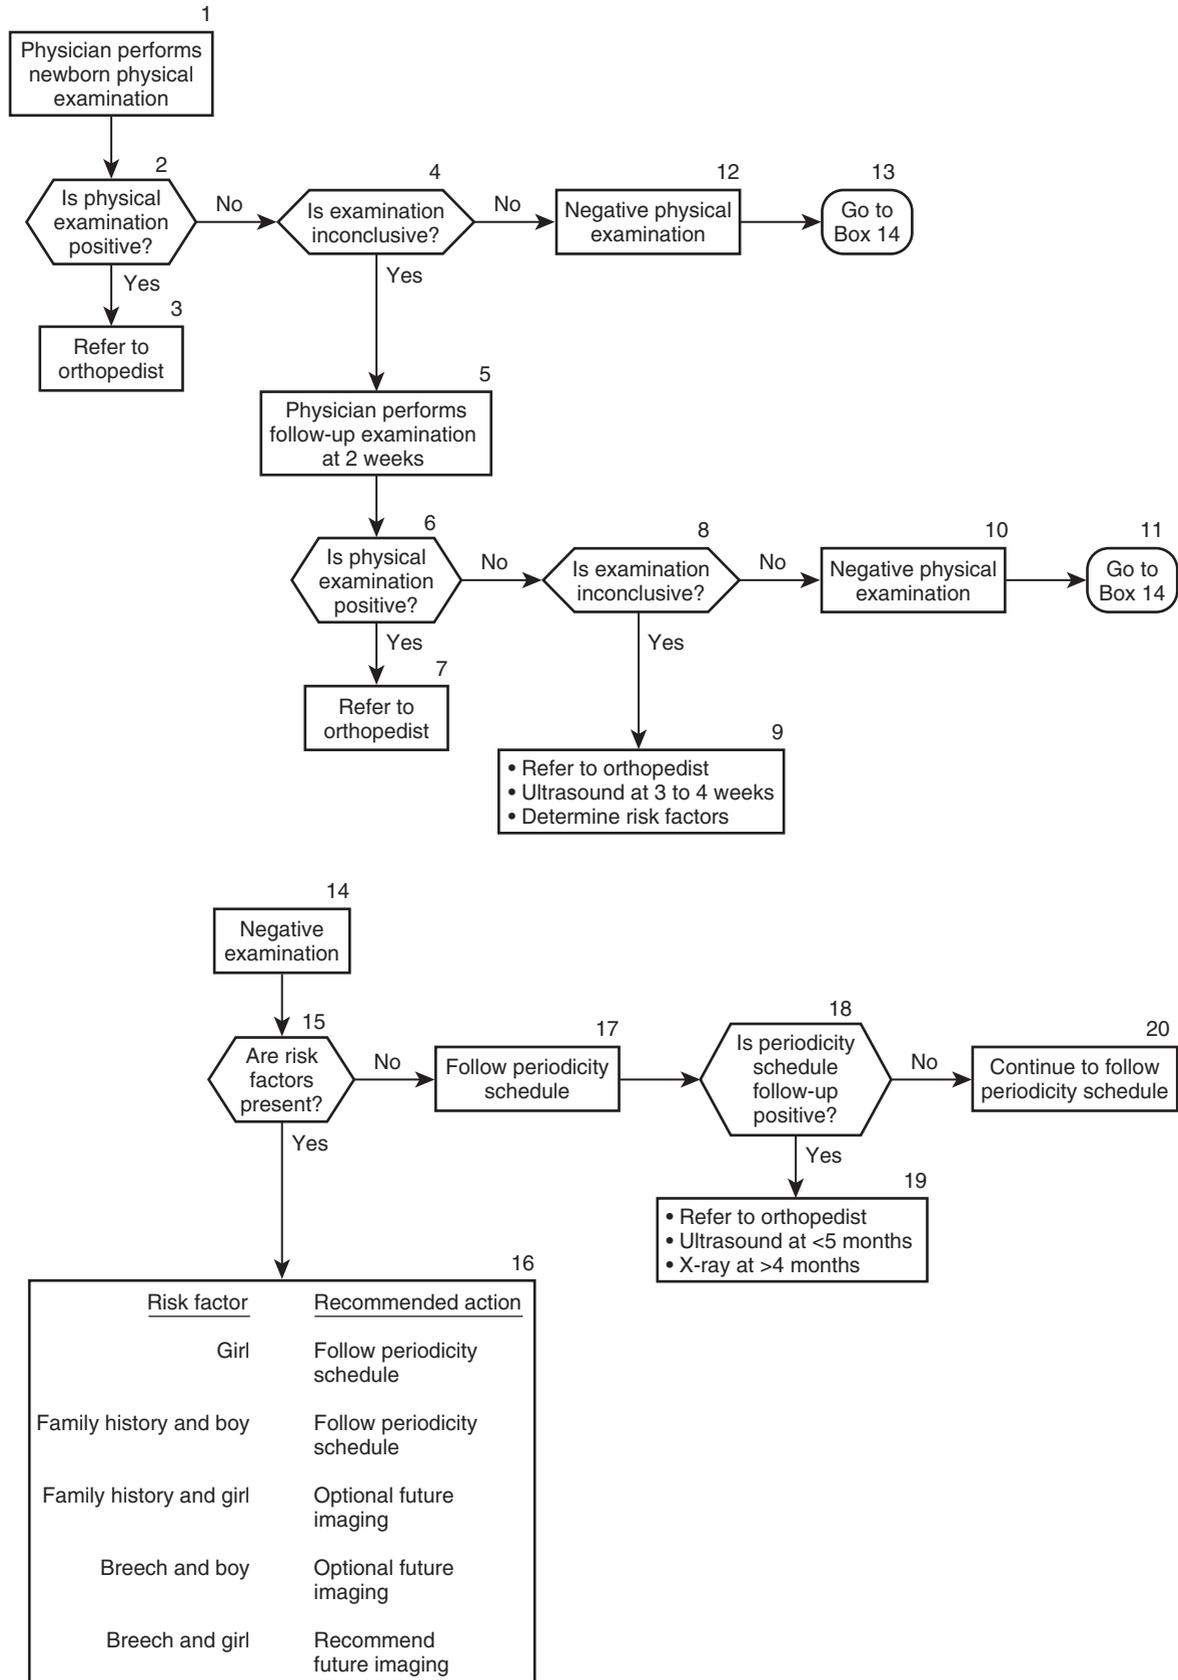

directed pressure applied to the knee. A palpable “clunk” or sensation of posterior movement constitutes a positive result (i.e., the Barlow sign). Each hip should be examined separately. High-pitched “clicks” are frequently elicited with hip range of motion. These sounds are most frequently attributed to snapping of the iliotibial band over the greater trochanter and are not associated with dysplasia (Bond et al, 1997). With progressive soft tissue contractures, both the Ortolani and Barlow tests become unreliable after 3 months of age.

Radiologic imaging of the immature hip can be a valuable adjunct to the physical examination. An anteroposterior (AP) roentgenogram of the pelvis is difficult to interpret before age 4 to 5 months. The femoral head is composed entirely of cartilage until the secondary center of ossification appears. Before the appearance of the secondary center, ultrasound examination is the method of choice for visualizing the cartilaginous femoral head and acetabulum. Static ultrasound images allow visualization of acetabular and femoral head anatomy, while the complementary dynamic images give information on the stability of the hip joint (Clarke et al, 1985; Graf, 1984). The primary limitation of hip ultrasonography is that results are dependent on the experience and skill of the operator, especially when performed within the first 3 weeks of life (Marks et al, 1994). For these reasons ultrasonography is recommended as an adjunct to clinical evaluation rather than as a screening tool (AAP, 2000). Studies conducted before 4 weeks of life too often reveal minor degrees of dysplasia that resolve spontaneously. It is the technique of choice for assessing infants at high risk for DDH after 4 to 6 weeks of age and is useful in following the results of intervention. Beginning at 4 to 6 months, the gold standard remains the AP pelvic radiograph.

Recently, the American Academy of Pediatrics published clinical practice guidelines to aid in the early diagnosis and initiation of appropriate intervention of DDH (AAP, 2000). The proposed clinical algorithm is presented in Figure 94-2 and summarized here: All newborns should be examined for DDH by a properly trained health care

provider. If an Ortolani or a Barlow sign is noted, the newborn should be referred to an orthopedist. Neither an ultrasound study nor a radiograph is recommended, as treatment decisions will be based on physical examination findings. If findings on the newborn examination are equivocal, a follow-up examination in 2 weeks by the health care provider is recommended. Triple diapering is not recommended, but communication between providers is encouraged if the practitioner examining the newborn in the hospital is different from the 2-week follow-up examiner. If the follow-up examination yields an Ortolani or a Barlow sign or other convincing evidence of DDH, a referral to an orthopedist is necessary. If findings on examination are again equivocal, consideration should be given to referring the baby to an orthopedist for evaluation or obtaining an ultrasound study at age 3 to 4 weeks. If the 2-week follow-up assessment yields normal findings, a follow-up examination is recommended at the next scheduled well-baby visit. Periodically, the hip examination should be repeated in all babies at each of the well-baby visits scheduled throughout the first year of life. At any time during this period, if DDH is suspected, referral to an orthopedist or evaluation by ultrasound examination for an infant younger than 5 months of age or by radiograph if the infant is older than 4 months should be considered. Risk factors for DDH need to be considered in newborns with negative and equivocal examinations. As noted previously, females, infants with a positive family history of DDH, and babies who were born breech are at increased risk for DDH. Newborn girls should be reexamined at 2 weeks in the event of a normal newborn examination and at scheduled well-baby visits subsequently. If examination findings are positive, referral is in order. In infant boys with a positive family history, management should follow the same protocol outlined for girls. Because newborn girls with a positive family history have a 44/1000 risk for DDH, an ultrasound examination at 6 weeks of age or a radiograph of the pelvis at 4 months of age is recommended despite normal findings on the physical examination. Because the risk of DDH is so high in girls (120/1000) born breech, imaging with ultrasound at 4 weeks and/or radiograph at 4 to 6 months of age is recommended in the face of normal findings on the physical examination. Despite newborn screening programs, 1 in 5000 will have a dislocated hip detected at 18 months of age or older (Dezateux and Godward, 1995). It is important to appreciate that not all dislocated hips are present at birth, and not all hips dislocated at birth are detectable in the newborn period.

Treatment of DDH is dependent on the age at presentation. For children 0 to 6 months of age, a reducible hip is treated in a Pavlik harness. The Pavlik is a dynamic splint that allows the infant to actively move the hips through a sphere of motion that encourages deepening and stabilization of the acetabulum (Fig. 94-3). The harness is applied as soon as possible after the diagnosis of DDH is made. The length of treatment is dependent on age at presentation. Progress is judged by serial physical examinations and static and dynamic ultrasonography. If no improvement is noted within 2 to 3 weeks of splint application, this treatment is abandoned, and a closed reduction, usually with arthrographic evaluation and subsequent spica casting, is

**FIGURE 94-2.** American Academy of Pediatrics clinical algorithm: Screening for developmental hip dysplasia. employed. For an irreducible dislocation, which is unusual in the 0- to 6-month age group, open operative reduction of the hip with subsequent spica casting is undertaken. Pavlik harness treatment is successful more than 90% of the time, however (Guille et al, 1999).

### TORTICOLLIS

Congenital muscular torticollis (CMT) manifests at birth or soon thereafter and is the most frequent cause of “wryneck.” However, other conditions, some more serious, may cause torticollis. These include congenital anomalies of the vertebra and skull (Klippel-Feil syndrome, hemivertebrae, basilar invagination, craniosynostosis) (Dubousset, 1986; Hensinger et al, 1974; Raco et al, 1999); abnormalities of the central nervous system (CNS) (syringomyelia, tumors) (Kiwak et al, 1983); Chiari malformations (Dure et al, 1989); ocular abnormalities (Bixenman, 1981); pharyngeal abscess; and gastroesophageal reflux (Sandifer syndrome) (Ramenofsky et al, 1978). Patients with CMT can be divided into those who demonstrate a sternocleidomastoid muscle (SCM) “pseudotumor,” those with tightness or fibrosis of the SCM without pseudotumor (termed *muscular torticollis*), and those with all of the characteristic features of congenital torticollis without evidence of contracture or fibrosis of muscle (termed *postural torticollis*) (Cheng et al, 2001). CMT has been estimated to occur in 3/1000 to 20/100,000 live births (Cheng et al, 2001). It is usually discovered between 6 and 8 weeks of life. The infant presents with a “cock robin” appearance, with the head tilted toward and chin

rotated away from the affected SCM. Twenty percent to 30% of patients will have a palpable pseudotumor present in the middle to inferior aspect of the affected SCM, which spontaneously regresses with time, leaving a fibrous band (Herring, 2002). More than half will have facial asymmetry. The left and right SCMs are affected in equal proportions. CMT probably results from ischemia within the SCM, leading to fibrosis (Davids et al, 1993). The cause of the ischemia is unknown, but intrauterine crowding may play a role, as there appears to be a 10% to 20% association with DDH and an increased association with metatarsus adductus (Morrison and MacEwen, 1982; Tien et al, 2001).

Excellent results with a manual stretching program can be attained in children first seen before 1 year of age (Morrison and MacEwen, 1982). Initially, the parents are instructed in the technique of stretching the contracted SCM by rotating the infant’s chin toward the affected SCM while simultaneously tilting the head away from it. This is completed 10 times each session and held for a count of 10 at least 10 times per day. Unfortunately, compliance may be an issue. If the child fails to improve substantially within 3 to 4 weeks, a physical therapist is enlisted to see the child 2 or 3 times weekly to supervise the program and reinforce the home therapy. Additionally, the parents are instructed to configure the infant’s crib and toys in such a manner as to encourage active rotation toward the involved side. There is no justification to undertake surgery in any child less than 1 year of age or in any child who has not completed a minimum of 6 months of therapy (Cheng et al, 2001; Morrison and MacEwen, 1982). In a recent prospective study of 821 children with muscular torticollis, only 8% of patients with the history of a pseudotumor and 3% of those without required surgical intervention following a well-structured stretching program (Cheng et al, 2001). No patients with postural torticollis required surgery. Risk factors for surgery included late initial presentation, presence of a pseudotumor, and rotation deficit of greater than 15 degrees.

The timing of surgical intervention remains controversial. In patients with significant plagiocephaly and facial asymmetry, surgery should be considered just before 2 years of age in order to maximize the chance for complete remodeling. For those with either no or mild facial asymmetry, good to excellent results can be expected with surgery up to 6 years of age (Ling, 1976). Beyond 6 years of age, acceptable results are reported, but the ability to remodel facial asymmetry appears diminished. Surgery entails either release or lengthening of the SCM through cosmetically pleasing incisions.

A less frequent cause of congenital torticollis is osseous fusion between bones in the cervical spine. These fusions may be between the skull and C1 and/or C2 or in the lower cervical spine. They result from failure of the bones to properly segment during embryogenesis. These abnormalities, in combination with a low posterior hairline and a short webbed neck with limited range of motion and head tilt, constitute the triad referred to as *Klippel-Feil syndrome* (Copley and Dormans, 1998). These congenital bone fusions can range from involvement of two segments to involvement of the entire cervical spine. Colloquially, Klippel-Feil syndrome has come to refer to any failure of

segmentation in the cervical spine with or without other elements of the triad. In infants and young children, the neck may remain quite flexible despite the bone abnormalities. In a newborn with torticollis who does not improve with passive stretching exercises, radiologic evaluation is mandatory. Cervical spine films are not recommended in all patients initially presenting with neonatal torticollis, as these films are quite difficult to interpret in this age group due to the predominance of cartilage in the bones of the neck. Furthermore, many neonates would be subjected to unnecessary ionizing radiation.

The natural history of Klippel-Feil in most cases is quite favorable, requiring nothing more than periodic observation. In patients with severe involvement, however, the consequences of this disorder can include early spondylosis with the development of pain or stenosis, the development of progressive torticollis and scoliosis, and the occurrence of neurologic compromise and sudden death secondary to even minimal trauma (Herring, 2002). Despite these potentially devastating sequelae, the greatest advantage to early detection of Klippel-Feil syndrome is in being alerted to commonly associated disorders including congenital heart disease (14% to 29%), renal anomalies (25% to 35%), scoliosis (60%), audiologic anomalies (80%), deafness (15% to 35%), synkinesis (15% to 20%), and, less commonly, posterior fossa desmoid tumors (Herring, 2002; Muzumdar and Goel, 2001). The recognition of a Klippel-Feil anomaly should prompt a thorough evaluation for these associations. Treatment for Klippel-Feil most often involves a therapy program of neck flexibility and intermittent observation with activity modification. In the face of progression of deformity or severe deformity, spinal fusion may be warranted.

Sandifer syndrome (gastroesophageal reflux) also can cause a torticollis. With this syndrome, the torticollis is intermittent and may alternate directions, and there is no tightness of the SCM, with normal findings on radiographs (Ramenofsky et al, 1978).

Hemiatlas, or the failure of formation of a portion of the first cervical vertebra, is also a rare cause of torticollis (Dubousset, 1986). In the infant, the neck may be quite flexible and the torticollis passively correctable. An open-mouth (odontoid view) cervical spine radiograph reveals this deformity. If the torticollis is progressive or severe, gradual correction of the deformity with a halo vest followed by posterior occiput-to-cervical spine fusion is necessary. Other potential causes of torticollis in the neonate include CNS tumors and syringomyelia. If radiographs appear normal, a thorough neurologic examination and referral to a neurologist are recommended.

## FOOT DEFORMITIES

Congenital deformities of the foot are relatively common but frequently overlooked in newborns. Consequently, the true incidence of the milder, self-limited deformities is unknown. For identification purposes, congenital foot abnormalities can be divided into those that result in the toes pointing upward (calcaneovalgus) and those that result in the toes pointing inward (metatarsus adductus, clubfoot).

*Calcaneovalgus* is thought to be a postural deformity secondary to intrauterine positioning in which the dorsum of the foot is, or can be, directly apposed to the anterior aspect of the leg. The estimated incidence of calcaneovalgus is 0.4/1000 to 1/1000 live births (Nunes and Dutra, 1986; Wynne-Davies, 1964). It appears to be more common in girls and following breech deliveries (Nunes and Dutra, 1986). There may be an increased association with hip dysplasia, so a thorough hip examination is warranted, as outlined in the previous section on DDH. Calcaneovalgus may be seen in conjunction with external rotation of the tibia, so that the toes appear to be rotated upward and outward. Additionally, a common association occurs with posteromedial bowing of the tibia, a unilateral deformity. This is likely to slowly resolve but eventually leads to a leg length inequality necessitating limb equalization surgery. Early referral to an orthopedist is suggested. Calcaneovalgus needs to be differentiated from congenital vertical talus, a rare condition that frequently is associated with neuromuscular conditions and syndromes. Congenital vertical talus can be differentiated from calcaneovalgus by viewing the hindfoot. If the hindfoot is fixed in equinus (plantar flexion), the foot demonstrates a “rocker bottom” appearance characteristic of congenital vertical talus. This finding mandates referral to an orthopedist. In the calcaneovalgus foot, the hindfoot is in the dorsiflexed position (calcaneus position) so that the plantar aspect of the forefoot is collinear with it. Plantar flexion of the foot is often limited from contracture of the anterior ankle soft tissues. The prognosis for complete resolution with gentle stretching exercises conducted by the parents with diaper changes is excellent in the vast majority of cases. Complete resolution generally occurs by 3 to 6 months of age. Occasionally, in the most severe cases, serial casting is employed to facilitate correction.

The two common neonatal foot deformities resulting in medial deviation of the toes are metatarsus adductus and talipes equinovarus (clubfoot). *Metatarsus adductus* is present at birth but frequently diagnosed later during the first year of life. It has been estimated to occur in 1 in 100 births (Widhe et al, 1988). The pathogenesis is unproved, but the condition is thought to result from intrauterine crowding. Characteristic features include a concave medial border of the foot with a curved lateral border, a “bean-shaped” sole of the foot, a higher-than-normal-appearing arch, fixed adductus of the forefoot when the hindfoot is held in neutral position, separation of the first and second toes, and spontaneous medial deviation of the foot with active movement by the infant (Kite, 1967) (Fig. 94–4). *Metatarsus adductus* can be classified into cases that passively correct and those that do not. Feet in which passive correction is possible are best left alone and will improve spontaneously. Feet in which passive correction cannot be obtained should be treated with manipulation and serial casting. The corrections can then be maintained with straight-last shoes if necessary or with nighttime bivalved casts. Operative treatment should be considered only in children older than 3 years of age who have a rigid deformity and have failed to respond to a manipulation and serial casting program (Weinstein, 2000). Farsetti and colleagues (1994) reported on 45 feet demonstrating metatarsus adductus, with an average follow-up period of

**FIGURE 94-4.** The appearance of the foot with metatarsus adductus.

33 years. The 16 feet in which the deformities were passively correctible, and in which no intervention was undertaken, were all rated as good, demonstrating spontaneous resolution of the metatarsus adductus. The 29 feet with deformities initially deemed partially correctible or rigid were treated with manipulation and casting. At follow-up examination, 26 feet (90%) were reported as good. None required surgery. The difficulty in treating metatarsus adductus is in convincing the parents and grandparents of the affected infant that the condition will resolve without intervention. Frequently, reverse-last and straight-last shoes are prescribed for benefit of the parent rather than the child.

The term *clubfoot* describes a foot demonstrating hindfoot equinus (plantar flexion) with adduction and supination of the forefoot (Fig. 94-5). Clubfoot represents a spectrum of congenital deformity that ranges from the mild “postural” clubfoot to the severe arthrogryptic clubfoot. It occurs in 1/1000 to 2/1000 live births (Herring, 2002). Three prominent theories for the etiology of clubfoot have emerged. An arrest in embryonic development in the 6- to 8-week fetus (Bohm, 1929) secondary to connective tissue abnormalities, a primary germ plasm defect, (Brockman, 1930), and a neuromuscular defect (Handelsman and Badalamente, 1982) each have been proposed. A recently documented risk factor for clubfoot is early amniocentesis (11- to 13-weeks of gestation), which is hypothesized to cause decreased fetal movement during a critical phase of foot development (Tredwell et al, 2001). Although the etiology of clubfoot remains unproved, there appears to be dysplasia of all osseous, muscular, tendinous, cartilaginous, skin, and neurovascular tissues distal to the knee in the affected limb. On the mild end of the spectrum, postural clubfoot appears to represent a packaging problem due to intrauterine positioning. Postural clubfoot is passively correctible, lacks deep medial creasing, demonstrates minimal or no calf atrophy, and responds quickly

**FIGURE 94-5.** The appearance of an untreated newborn clubfoot.

to a stretching and casting regimen. At the opposite end of the spectrum is the arthrogryptic or neuromuscular clubfoot that demonstrates severe rigidity; absence of skin creases, suggesting early in utero affliction; and failure to respond to nonoperative therapies. Between these two extremes lies the classic clubfoot deformity. The anatomic deformities in clubfoot are numerous, complex, and somewhat controversial. Although the specific anatomic abnormalities are well beyond the scope of this chapter, the most notable abnormalities include a small, contracted heel cord complex; medial subluxation of the navicular bone on the talar head so that it abuts or nearly abuts the medial malleolus; and parallelism between the calcaneus and talus bones when these are viewed radiographically from the lateral aspect and from an anterior-to-posterior perspective. Clinically, the foot demonstrates a medial crease, with the toes pointed toward the midline, the sole of the foot angulated medially, the hindfoot plantar flexed, and a smaller foot and calf than on the contralateral side (see Fig. 94-5).

All clubfoot deformities should be referred to an orthopedist for treatment. Initial treatment for all cases of congenital clubfoot is nonoperative. The earlier treatment is commenced, the more successful nonoperative treatment is likely to be, owing to improved pliability of the tissues and resilience to immobilization, which can be prolonged over the course of therapy. We prefer to initiate treatment in the newborn nursery within the first 48 hours of delivery. Initial treatment usually consists of a manipulation and serial casting or taping program. Manipulation of the foot is carried out, and the correction is maintained with a long-leg cast. The casts are removed at weekly intervals, with repeated manipulation and casting over 3 to 4 months. By that time, the treating surgeon usually will be able to determine if surgery is warranted as a result of failure or plateauing of the correction. Surgery, if necessary, is generally undertaken at between 9 and 12 months of age,

to allow treatment to be completed by the time the child is starting to walk. Attempts at early surgical correction have yielded poor results and high recurrence, and this approach has been abandoned. Despite adept surgical correction, approximately 15% of cases of clubfoot will demonstrate recurrence necessitating further surgical intervention. Some surgeons have advocated a completely nonoperative approach to clubfoot correction (Kite, 1964; Ponsetti, 1996; Seringe and Atia, 1990) based on observations that in operated cases of clubfoot, the feet often appear stiff and gradually develop scarring, which diminishes the result. These programs vary in the specifics of treatment but share a labor-intensive approach. One method necessitates daily manipulations by a trained physical therapist for 8 weeks, with the addition of continuous passive motion during the first 4 weeks. This is followed by strapping and continued bracing. The method has been successfully duplicated at one U.S. hospital (Herring, 2002), with good short-term results. Even these “nonoperative” methods frequently employ heel cord-lengthening surgery or tendon transfers to attain the desired result. Unfortunately, with the economics of the U.S. health care system, this approach is presently impractical for most physicians and hospitals. Untreated clubfoot has a poor natural history, with development of early degenerative changes in the foot joints. With treatment, good results can be expected with both the standard and nonoperative methods in 85% of cases (Weinstein, 2000).

### **TORSIONAL DEFORMITIES OF THE LOWER EXTREMITIES**

Torsional and angular deformities of the legs constitute the most frequent nontraumatic reason for referral to a children’s orthopedist. Torsional deformities of the lower extremities rarely come to the attention of the physician before the child reaches walking age. Occasionally a neonate demonstrates bowing of the legs, or *genu varum*, of a sufficient degree to concern parents or grandparents. The true incidence of genu varum is unknown, but based on our experience, it is extremely common. The overwhelming majority of cases of genu varum resolve spontaneously, with a small minority of affected children manifesting a pathologic condition.

The legs of most neonates are bowed. This results from a combination of an external rotation contracture of the hips and internal tibial torsion. The apex anterior bowing of the femora in conjunction with the external rotation contractures of both hips allow the femoral bowing to be seen tangentially when the baby is viewed from the front. These contractures may not resolve until after walking age. Internal tibial torsion is nearly universal in neonates and spontaneously resolves between 2 and 3 years of age. Internal tibial torsion imparts an appearance of bowing to the tibia. When tibial bowing is viewed in combination with the apparent femoral bowing, a striking amount of leg bowing may be present. This is often concerning to both parent and physician.

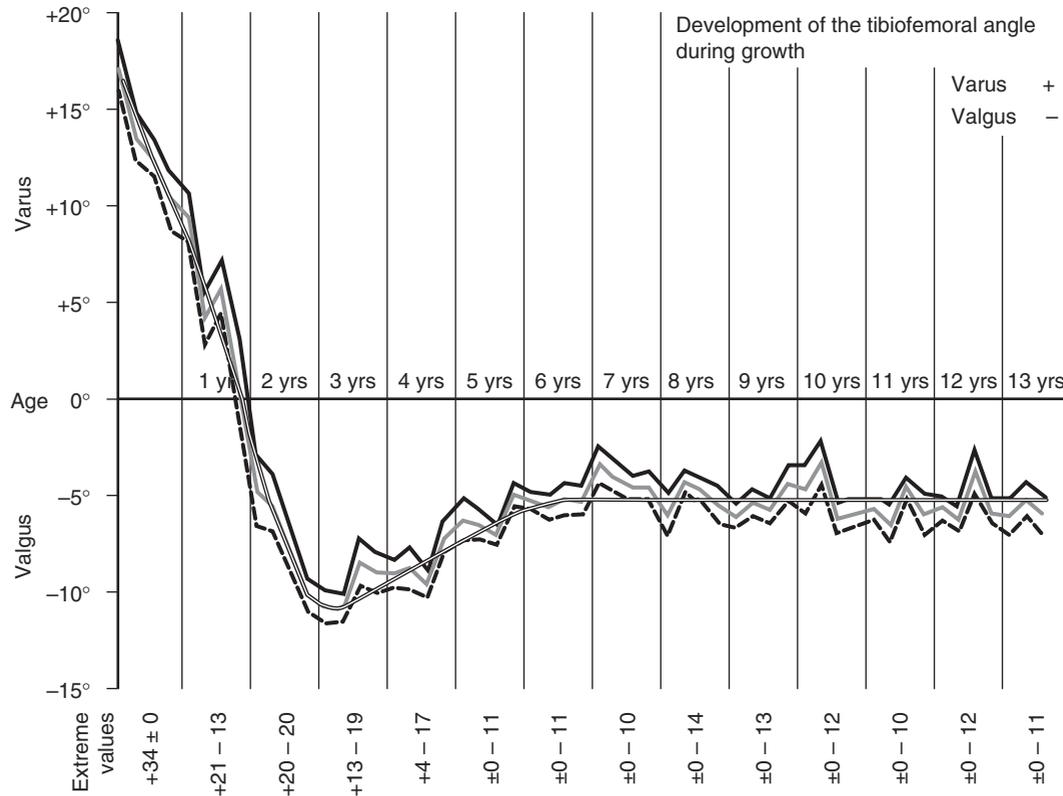

Genu varum is physiologic up to the age of 2 years. Salenius and Vankka (1975) documented the tibiofemoral angles both clinically and roentgenographically in 979

children on the basis of 1408 examinations between birth and 16 years of age. They noted that newborns demonstrate a mean varus alignment of 15 degrees, which increases and becomes maximal at 6 months of age and then decreases to neutral at approximately 18 months. The maximum valgus of 12 degrees is then achieved by 3 to 4 years. By age 7, normal adult valgus alignment is achieved (Fig. 94–6). Natural history studies have demonstrated that physiologic genu varum is a self-limited process. Genu varum with angulation greater than 30 degrees has been shown to correct spontaneously with growth (Heath and Staheli, 1993).

Physical examination should include evaluation of the torsional profile (Staheli, 1977), which includes measurements of internal and external rotation of the hips and the thigh-foot angle. Measurement of the thigh-foot angle is performed with the child in the prone position and is an indicator of tibial torsion. The examiner should look for evidence of rhizomelic shortening, which may herald a diagnosis of achondroplasia. Although genu varum progressively worsens with growth in achondroplasia, rather than ameliorating, newborns generally do not demonstrate this disorder. Finally, note is made of whether onset of the varus of the lower extremities is gradual or abrupt. If it was abrupt, can the deformity be localized to the distal femur, the proximal tibia, or the midportion of the tibia? Considerations in the differential diagnosis of genu varum include focal fibrocartilage dysplasia, achondroplasia, osteogenesis imperfecta, vitamin D-resistant rickets, renal osteodystrophy, and tibia vara, or Blount disease. Blount disease does not occur before walking age, and most clinicians agree that this diagnosis cannot be made before 2 years of age.

Radiographs are indicated only with asymmetrical deformities, with short stature, or in infants with progressive deformities. Photographs are the preferred method of follow-up evaluation for progression. Management of physiologic genu varum and tibial torsion consists of serial observation, reassurance, and parental education. Treatment with orthotics such as the Denis Browne splint is not indicated and in fact may be harmful to the ligaments of the knee.

Focal fibrocartilaginous dysplasia (FFD) involving the medial aspect of the proximal tibial metaphysis is a relatively rare cause of tibia vara in the newborn and infant. It was first reported in 1985 (Bell et al, 1985) and continues to be recognized in scattered case reports. The pathophysiologic basis for the disease may be abnormal development of fibrocartilage at the insertion of the pes anserinus (sartorius, gracilis, and semitendinosus tendons). Children with FFD present before 1 year of age with unilateral bowing of the tibia that has prompted radiologic evaluation. The radiographs demonstrate a lytic defect in the proximal medial metaphysis of the tibia with surrounding sclerosis. The natural history of the deformity is that of progression until 2 years of age, with subsequent resolution by 4 years of age. During the progression, the deformity can become quite pronounced and unsettling. Up to 1 cm of tibial length discrepancy is likely. Use of orthotics is not indicated. Surgery is indicated only in patients older than 4 years without evidence of spontaneous resolution (Zayer, 1980).

**FIGURE 94-6.** Development of the tibiofemoral angle during growth. (Data from Salenius P, Vankka GK: *The development of the tibiofemoral angle in children.* *J Bone Joint Surg Am* 57:259-261, 1975.)

Tibial bowing can be the cause of angular deformities in the shaft of the tibia. Two major types of bowing can be identified according to the direction of the apex of the bow. Posteromedial bowing has been previously described in conjunction with calcaneovalgus foot position in the neonate. Its etiology is unknown, but numerous hypotheses have been proffered, including intrauterine fracture with malunion and in utero malpositioning with subsequent growth retardation and soft tissue contractures (Thompson, 2001).

The deformity is unilateral and evident at birth. There is an associated calcaneovalgus foot deformity. Other features include shortening of the tibia and a smaller calf circumference and a smaller foot relative to the contralateral side. Frequently there is a dimple at the apex of the deformity. Radiographic examination of the entire extremity from hip to ankle should be performed. Radiographs demonstrate the degree of bowing well. Other radiographic findings include a normal proximal tibia with thickening and sclerosis of the diaphyseal cortices on the compression side of the deformity with obliteration of the intramedullary canal. There is no increased fracture risk associated with the deformity. Posteromedial bowing tends to resolve with growth, so that much of the deformity resolves by 2 years of age, with continued gradual correction beyond that. The shortening of the tibia and fibula persists, however, and progressively worsens during growth. Leg length inequality at skeletal maturity averages 4.1 cm (Hofmann and Wenger, 1981). Early referral to and serial follow-up assessments by an orthopedist are

necessary to appropriately time epiphysiodesis surgery of the normal leg to allow for equal leg lengths at skeletal maturity. The foot deformity generally resolves by 9 to 12 months with stretching.

The second and most serious type of tibial bowing is anterolateral. It is usually identified at the newborn examination. It most frequently is associated with congenital pseudoarthrosis of the tibia but also can be associated with congenital longitudinal deficiency of the tibia or the fibula. Although its etiology is unknown, congenital pseudoarthrosis of the tibia is associated with neurofibromatosis (NF) in 40% to 80% of the cases (Masserman et al, 1974; Paterson, 1989; Thompson, 2001). It is arguably the most challenging congenital malformation to treat in orthopedics. It is estimated to occur in 1 in 140,000 live births (Crawford and Schorry, 1999). "Congenital pseudoarthrosis" implies that there is a nonunited fracture, which usually is not the case, so the term *congenital tibial dysplasia* (CTD) has been suggested (Crawford and Schorry, 1999). The newborn examination is notable for anterolateral bowing, which is unilateral. Other, cutaneous signs of NF may be evident. If they are not, NF should be considered, and the child serially followed expectantly. If fracture has occurred, motion at the pseudoarthrosis site will be apparent. The foot may be normal or slightly small. The ankle may be in slight valgus to compensate for the bowing.

The natural history of congenital pseudoarthrosis of the tibia is that of fracture with nonunion and repeated surgical attempts at obtaining union. Most of these

attempts fail; if one such procedure succeeds, however, repeat fracture is likely, and the cycle begins again. Frequently, amputation is the end result. Because of this possibility, efforts are best directed at prevention of initial fracture. Orthopedic consultation is imperative. In the preambulatory child, a total-contact ankle-foot orthosis should be fabricated and worn at all times except for bathing, to diminish the chance of fracture. When the child begins to walk, the orthosis should be extended above the knee with a drop-lock hinge to allow sitting. Bracing is continued until skeletal maturity is attained. Although no definite proof that long-term bracing affects the natural history of this condition exists, most orthopedists consider that it is warranted. Under no circumstances should an osteotomy be undertaken in a nonfractured tibia to correct the bowing, as pseudoarthrosis is likely to result.

Many treatment options exist once a documented pseudoarthrosis occurs. Long-term immobilization, external fixation, internal fixation, bone transport, bone grafting, microvascular bone transfer, and electrical stimulation each have been attempted, all with less than stellar results (Crawford and Schorry, 1999). When union is achieved, there is concern over its quality and longevity. Amputation has been advocated as a salvage procedure after failed attempts at union and as primary treatment for the initial pseudoarthrosis (Jacobsen et al, 1983). Herring and colleagues (1986) reported that children who underwent Symes amputation (none of whom had CTD as the surgical indication, however) had better psychological and orthopedic functioning than that described in children who underwent numerous corrective surgical procedures. Similar results were reported by other authors (Davidson and Bohne, 1975).

## OBSTETRIC TRAUMA

Birth trauma can be divided into two categories: fractures and neurologic injuries. *Birth fractures* most commonly involve the clavicle, with clavicular fractures occurring in 2/1000 to 35/1000 vaginal births (Cohen and Otto, 1980; Farkas and Levine, 1950; Kaplan et al, 1998; Sanford, 1931). Birth fractures also occur in the proximal humerus (Broker and Burbach, 1990; Fisher et al, 1995), the femur (0.13/1000 births) (Morris et al, 2002), and even the thoracic spine. It is important to note that clavicular fracture can be seen in combination with a proximal humeral physeal separation or in combination with a brachial plexus injury. Risk factors for upper extremity birth fractures in one study included large size of the baby, limited experience of the obstetrician, and a midforceps delivery (Cohen and Otto, 1980). Risk factors for femoral fracture included twin gestation, breech presentation, prematurity, and osteoporosis (Morris et al, 2002). The natural history of isolated birth fractures to the extremities is that of uneventful rapid healing without untoward sequelae. Clavicle fractures may be difficult to diagnose, as the neonate may be asymptomatic. In a study of 300 newborns, radiographs revealed five unsuspected clavicle fractures (Farkas and Levine, 1950). Newborns with either a clavicle fracture or a proximal humeral physeal separation often present with

pseudoparalysis of the upper extremity. Considerations in the differential diagnosis include an obstetric brachial plexus palsy and hematogenous metaphyseal osteomyelitis of the humerus with septic glenohumeral arthritis. Pain with direct palpation of the clavicle may be present with obvious deformity. Pain with motion of the shoulder joint and with palpation of the proximal humerus may be caused by either fracture or infection. Eliciting neonatal reflexes such as the Moro reflex and asymmetrical tonic neck reflex (ATNR) may be helpful in evaluating active upper extremity muscle function (Sanford, 1931). Radiographs should be obtained. Ultrasound evaluation of the proximal humerus may be helpful because the proximal humeral epiphysis is entirely cartilaginous at birth and is radiolucent. Ultrasound examination can detect proximal physeal separation, metaphyseal osteomyelitis, and septic shoulder arthritis (Broker and Burbach, 1990; Fisher et al, 1995).

Asymptomatic birth fractures of the clavicle and humerus in neonates can be observed. The fracture will unite in short order, with remodeling of bone with growth. Symptomatic fractures in which the child exhibits pseudoparalysis of the upper extremity should be treated with 2 weeks of immobilization in a soft dressing until symptoms subside. Femoral birth fractures can be treated with a Pavlik harness with good results (Morris et al, 2002). This device provides a simple means of immobilization that is accepted well by new parents. Excellent outcomes with no residual deformities or limb length inequalities can be expected.

*Brachial plexus injuries* represent the second category of birth trauma afflicting newborns. The brachial plexus receives contributions from the anterior spinal nerve roots of C5 through T1. The various nerve roots combine to form trunks, which combine in turn to form divisions, which combine to form cords, which combine and divide to form the peripheral nerves that supply the motor innervation to the upper extremity. The mechanism of injury to the plexus is a forceful separation of the head from the shoulder by lateral bending of the neck with simultaneous shoulder depression during vaginal delivery. These injuries occur in 1/1000 to 4/1000 live births (Greenwald et al, 1984; Hardy, 1981). Obstetric brachial plexus palsies are most common in vertex deliveries with shoulder dystocia, in large-birth-weight babies (in whom the increased size usually is secondary to maternal diabetes), and in multiparous pregnancies (Waters, 1997). It is rarely seen in cesarean section deliveries. Not all cases can be reliably predicted prepartum, nor prevented. Three major injuries are encountered. The most frequent injury is to the upper trunk that involves the C5 and C6 nerve roots primarily and is termed *Erb's palsy*. Affected infants lack external rotation and abduction of the shoulder. Hand function is preserved. The next most frequently occurring injury is a *global plexus palsy* involving the C5 through T1 nerve roots. This results in flaccid paralysis of the involved upper extremity including the hand. Finally, an isolated lower plexus injury involving the C8 and T1 nerve roots is termed *Klumpke's palsy*. This injury is the least common and may be a manifestation of a recovered global plexus injury (Waters, 1997).

The physical examination has proved to be the most reliable method of assessing the level and severity of the

neural injury and thereby predicting the potential for spontaneous recovery (Noetzel et al, 2001; Waters, 1997). Myelography, computed tomographic myelography, magnetic resonance imaging, and electrodiagnostic studies have not proved useful in predicting recovery (Waters, 1997). Active shoulder, elbow, wrist, and finger motion need to be assessed. Frequently, such assessment can be facilitated by eliciting some primitive reflexes that are transiently present in normal newborns. The *hand grasp reflex* is normal in all newborns and disappears between 2 and 4 months. The examiner's little finger is placed on the ulnar aspect of the infant's palm, and the infant's fingers reflexively flex and grasp the examiner's finger. The *Moro reflex* begins to fade at 3 months of age. It is elicited by holding the newborn's hands while raising the baby off the table and then suddenly releasing them. In response, the newborn extends the spine, abducts and extends all four limbs and digits, and then subsequently adducts and flexes the limbs and digits. Last, the *ATNR*, or *fencing reflex*, can be elicited in a normal newborn until the age of 4 months. With the infant lying supine on an examining table, the head is rotated to one side by the examiner. The infant should respond by extending the elbow on the side toward which the face is looking and by flexing the opposite elbow. In newborns with a brachial plexus injury, some of these reflexes will be abnormal due to lack of motor control. For instance, the newborn with an Erb's palsy will, most notably, not be able to actively flex at the elbow during the ATNR or the Moro. The presence or absence of Horner syndrome also must be noted. The infant needs repeat serial examinations until 6 months of age.

Return of biceps function by 3 months is the most important indicator of brachial plexus recovery (Michelow et al, 1994). When biceps recovery is combined with the return of shoulder abduction, wrist extension, and finger extension, there is a 95% chance of normal function (Michelow et al, 1994). When biceps function recovers later than 3 months, it is rare for the child to have complete recovery of normal function (Waters, 1999). A total plexus palsy or the presence of Horner syndrome also heralds a poor prognosis (Michelow et al, 1994; Waters, 1997). In one study of 142 patients with obstetric brachial plexus palsies, 50% demonstrated biceps recovery by 6 weeks, with the remainder demonstrating recovery at varying intervals beyond 6 weeks. At final follow-up evaluation, 67% had excellent shoulder function, 12% good, 5% fair, and 10% poor (Benson et al, 1996). In a similar prospective study, Waters (1999) found that 22 patients out of 66 studied had return of biceps function by 3 months. Each of these went on to have normal function. Infants in whom recovery was delayed until the fourth to the sixth month had significantly worse function.

The initial treatment for obstetric brachial plexus injury is aimed at avoiding contractures of the shoulder, elbow, forearm, and hand during the observation-for-recovery phase. Secondary treatment involves the restoration of neurologic function that will not recover. Finally, augmenting weak muscles, improving functional ranges of motion, and improving the appearance of residual deformities should be undertaken in children without full neurologic recovery.

Each neonate with an obstetric brachial plexus birth palsy must be referred to an orthopedist for early evaluation. Referral to a qualified therapist for passive range of motion exercises also is suggested. Monthly examinations by the orthopedist are undertaken. Brachial plexus exploration with subsequent reconstruction is indicated for infants with total plexus involvement, Horner syndrome, and no return of biceps function at 3 months, and for infants with a C5 to C6 (Erb's) plexopathy and no return of biceps function at 3 to 6 months (Waters, 1997). Surgery is undertaken between 3 and 6 months of age. Utilizing this algorithm prospectively, Waters (1999) operated on 6 infants at 6 months and found that their results were better than those for the 15 patients with biceps recovery at 5 months but worse than those for the 11 patients with biceps recovery at 4 months. Despite treatment as outlined, some children will have residual deficits. Secondary reconstruction for chronic brachial plexopathy resulting in a dysfunctional shoulder can be achieved with a tendon transfer of the latissimus dorsi and teres major to the rotator cuff or by derotational osteotomy of the humerus. These procedures and others designed to correct limitations in hand and forearm function are undertaken after the true scope of the disability has been assessed.

### NEONATAL OSTEOMYELITIS AND SEPTIC ARTHRITIS

*Osteomyelitis* refers to a bacterial infection of bone, and *septic arthritis* is a pyogenic infection of a diarthrodial joint. Incidence rates of 0.12 per 1000 live births and 0.67 per 1000 neonatal intensive care unit (NICU) admissions (Ho et al, 1989) have been reported for septic arthritis. The mortality rate is reported to be 7.3% (Caksen et al, 2000). The hip, knee, and shoulder joints are involved most frequently. Neonates are particularly susceptible to osteomyelitis and septic arthritis, due to an immature immune response resulting in vulnerability to organisms that are not ordinarily virulent in infants and children and a delay in expressing the classic physical findings associated with these conditions (Morrissy, 2001). Two subgroups of neonates are affected: premature neonates requiring prolonged hospitalization and otherwise healthy newborns who present within 2 to 4 weeks of discharge (Morrissy, 2001).

Most cases of neonatal osteomyelitis and septic arthritis result from hematogenous spread, but some occur from direct inoculation during femoral arterial blood sampling. Acute hematogenous osteomyelitis (AHO) and septic arthritis in hospitalized neonates usually occur in premature infants undergoing blood drawing, invasive monitoring, intravenous feedings, and intravenous drug administration, especially in those with indwelling umbilical vessel catheters (Lim et al, 1977). These infections are frequently caused by *S. aureus* or gram-negative organisms (10% to 15%). Up to 40% of these patients may demonstrate multiple areas of involvement characterized by swelling and tenderness and are systemically ill (Bergdahl et al, 1985; Fox and Sprunt, 1978). This contrasts with the typical out-of-hospital newborn with AHO and septic arthritis, who presents in weeks 2 to 4 of life with swelling,

pseudoparalysis, and tenderness of the extremity and who feeds well and is not systemically ill (Morrissy, 2001). *S. aureus* and group B streptococci are the most common organisms encountered in this population.

Due to the immature immune response, neonates with AHO and septic arthritis frequently do not necessarily demonstrate fever, leukocytosis, or elevation in their erythrocyte sedimentation rates (Scott et al, 1990). However, C-reactive protein appears to be a reasonable indicator of AHO and septic arthritis (Pulliam et al, 2001; Unkila-Kallio et al, 1994). Blood cultures are positive in only 50% of patients; cultures of synovial aspirates identify an organism in only 30% (Lyon and Evanich, 1999). Plain radiographs demonstrate soft tissue swelling by 3 days, but bone changes are not present for a week after the onset of symptoms (Dormans and Drummond, 1994; Jackson and Nelson, 1982). Bone scan is positive in only 32% of foci of osteomyelitis in neonates due to the usual location of infection near the growth plate (Ash and Gilday, 1980). Ultrasound examination has been advocated as a useful method for the diagnosis and assessment of osteomyelitis (Mah et al, 1994) and is our preferred radiologic method for evaluating the neonate with suspected AHO and/or septic arthritis.

AHO and septic arthritis coexist in up to 76% of neonates as a result of the unique blood supply of the chondroepiphysis (Bergdahl et al, 1985; Fox and Sprunt, 1978), which changes with growth. Infection begins in the metaphyseal veins. Vascular canals traverse the growth plate in the neonate, allowing for rapid spreading of the infection to the cartilaginous chondroepiphysis with subsequent abscess formation. These abscesses frequently rupture into the joint (Ogden, 1979). The growth plate becomes a barrier to the spread of infection in the older child. Additionally, the hip and shoulder, two of the more common sites of neonatal septic arthritis, have intraarticular metaphyses, allowing for a subperiosteal route of decompression for pus into the joint. Due to this unique ability to spread from the metaphysis through the growth plate into the joint, early detection and treatment are necessary to avoid permanent damage to each of these structures. The proteolytic enzymes released by the host response to infection can result in destruction of the growth cartilage and articular cartilage in short order, resulting in growth disturbances and precocious arthritis. When an area of involvement is suspected, aspiration should be undertaken (Morrissy, 2001). This may confirm the diagnosis and provide fluid for Gram stain and culture in order to better direct treatment. If pus is discovered in the neonate, surgical débridement in the operating room is required.

## Congenital Malignant Disorders

Mignon L. Loh and Katherine K. Matthay

Neonatal malignancies differ in incidence, clinical behavior, and heritable features from the cancers seen in older children. Syndromes associated with an inherited predisposition to develop malignancies can manifest in the newborn period. Exposure to potential carcinogens or teratogens during the prenatal period also may be related etiologically. Special consideration must be given to treatment problems unique to the newborn age group, including differences in drug metabolism from older children and the possible intolerance of rapidly growing and developing normal tissues to the inhibitory effects of antineoplastic chemotherapeutic agents and radiation. In addition, special consideration also must be given to the postsurgical management of infants with respect to fluid management, pain control, and nutrition. Late effects on reproductive capacity and intellectual development and the potential for induction of secondary malignancy also are of heightened concerns in the treatment of malignant disorders in the newborn. The epidemiology, etiology, and the diagnosis of neonatal malignancy are reviewed here, followed by discussion of the most commonly encountered malignancies in the newborn.

### EPIDEMIOLOGY, ETIOLOGY, AND DIAGNOSIS OF NEONATAL MALIGNANCY

#### Epidemiology: Incidence and Mortality

A study of U.S. population-based data from the Surveillance, Epidemiology, and End Results (SEER) program gathered between 1976 and 1984 and between 1984 and 1996 reveals an average yearly incidence of malignancy in children in the first year of life of 233/1,000,000 (Ries et al, 1999). Most striking, the peak cancer incidence among all children was during the first year of life, and 13% of these cases were diagnosed in the first month (Ries et al, 1999). Although trend analyses indicate that the incidence of malignancy in the infant population appears to be increas-

ing, these data should be interpreted with caution, due to potential changes in population characteristics, screening fetal ultrasound practices, case ascertainment, and other factors (Gurney et al, 1997; Ries et al, 1999).

The most common malignancy in neonates is neuroblastoma, followed by leukemia and germ cell tumors. In fact, a majority of germ cell tumors occurring in infancy were diagnosed in the first 2 months of life (Ries et al, 1999). In the seventh month of life there is an additional peak of diagnosed cases of leukemia, exceeding that in the first month of life. Female and male infants have similar cancer incidence rates, but white infants have significantly higher rates than those reported in African-American infants for all histologic types. The distribution of the major types of cancers in newborns, infants, and children is depicted in Table 95-1.

The mortality rates for infants with cancer exceed those for older children, even among similar histologic groups (Ries et al, 1999). Despite cure rates exceeding 75% for children older than 1 year diagnosed with acute lymphoblastic leukemia (ALL), infants with ALL continue to experience cure rates of only 40% to 50%. These lower rates probably are due to biologic differences in the leukemias afflicting infants versus older children, as it is well established that infants with leukemia often harbor rearrangements of the *MLL* ("mixed lineage leukemia") gene, whereas older children do not. The poorer survival patterns for infants also are seen in rhabdomyosarcoma and central nervous system (CNS) tumors including primitive neuroectodermal tumor (PNET) and ependymomas, but the reasons for this association are less clear (Ries et al, 1999). Two exceptions are neuroblastoma, for which the incidence in newborns is more than 10 times higher than the mortality rate, and infantile fibrosarcoma, for which cure rates often exceed those achieved in older children or adults (Table 95-2). A study of mortality rates differs markedly from one of incidence, because certain malignancies are rapidly fatal, others lead to death beyond the neonatal period, and a large number are cured or undergo spontaneous regression. The relative frequencies of most types of malignancy in infants are unchanged from those reported earlier (Table 95-3).

#### Etiology

##### *Genetic Predisposition Syndromes and Congenital Defects*

Certain host factors can predispose a person to the development of neoplastic disease. Some of the genes responsible for such predispositions are known, whereas others are not. For instance, an increased incidence of leukemia

TABLE 95-1

**Percent Distribution of the Major Types of Cancer in Children, Newborns, and Infants**

Histologic Type	Children <15 yr (%)	Newborns <30 d (%)	Infants <1 yr (%)

has been noted in persons with trisomy 21, Fanconi anemia, and Bloom syndrome. In addition, children born with immunodeficiency disorders such as ataxia-telangiectasia, Wiskott-Aldrich syndrome, and severe combined immunodeficiency are at higher risk of developing lymphoma later in life.

A small number of well-defined hereditary conditions are associated with an increased incidence of specific neoplasms and are listed in Table 95-4. Except for retinoblastoma, hepatoblastoma, and Wilms tumor, the neoplasms associated with these syndromes seldom manifest in the neonatal period, but the associated abnormalities may be

recognized early. The early recognition, in combination with the family history, alerts the clinician to the need for screening. The lack of family history, however, should not dissuade the clinician from investigating these syndromes, as both spontaneous germline mutations and parental mosaicism occur. In many of these neoplasms, the genetic defect has been identified. For example, the *NF1* gene is located at 17q11.2 and encodes a protein, neurofibromin, that normally acts as a guanosine tri-phosphatase activating protein that down regulates the *ras* pathway. Dysregulation of cell growth results when a mutation is present because there is no functional "off" switch, accounting for the increase in malignancies in patients with neurofibromatosis. In Li-Fraumeni syndrome, germline mutations in the tumor suppressor gene *TP53* have been demonstrated in some of the families in which members had sarcomas, breast cancer, brain tumors, and leukemia (Malkin et al, 1990).

An unexpectedly large number of childhood tumors occurs in association with certain congenital defects. For instance, children with congenital aniridia have an increased incidence of Wilms tumors. Aniridia is a rare anomaly found in only 1 of 75,000 persons. It is about 1000 times more likely to occur in children with Wilms tumor (1 in 75). The association with a deletion in the *WT1* gene on chromosome 11p13 has been described in at least 20 patients (Yunis and Ramsay, 1980). Most of these patients also have genitourinary abnormalities and mental retardation; other problems that can be associated with aniridia and Wilms tumor include cardiac septal defects. Collectively, the associated abnormalities are known as the WAGR (Wilms tumor, aniridia, genitourinary abnormalities, mental retardation) syndrome. From a clinical perspective, if an infant has

## Hereditary Conditions with Associated Tumors

Syndrome	Gene	Locus	Inheritance Pattern	Most Common Tumors
Ataxia-telangiectasia	<i>ATM</i>	11q22-q23	Recessive	Leukemias Lymphomas
Beckwith-Wiedemann syndrome	<i>IGF2</i>	11p15	Some auto dominant imprinting	Wilms tumor Hepatoblastoma Rhabdomyosarcoma
Bloom syndrome	<i>BLM</i>	15q26	Auto recessive	Leukemias
Denys-Drash syndrome	<i>WT1</i>	11p13	Auto dominant	Familial Wilms tumor
Down syndrome		Trisomy 21	Sporadic	—
Fanconi anemia		Many	Auto recessive	Leukemias
Gonadal dysgenesis		45X/46XY	?X-linked	Gonadoblastoma Germinoma
Gorlins syndrome	<i>PTCH2</i>	1p33	Auto dominant	Medulloblastoma Basal cell carcinoma
Klinefelter syndrome	?	XXY	Sporadic	Teratoma Leukemia Breast cancers
Li-Fraumeni syndrome	<i>TP53</i>		Auto dominant	Sarcoma, CNS, Breast tumors
Neurofibromatosis	<i>NF1</i>	17q11.2	Auto dominant	Glioma Leukemia (JMML) Sarcoma
Retinoblastoma	<i>RB</i>	13q14	Auto dominant	Retinoblastoma Osteosarcoma Rhabdomyosarcoma Wilms tumor
Trisomy 18	?	Trisomy 18	Sporadic	—
Turner syndrome		XO	Sporadic	—
Von Hippel-Lindau syndrome	<i>VHL</i>	3p26	Auto dominant	Hemangioblastoma
WAGR syndrome	<i>WT1</i>	11p13		Wilms tumor
Wiskott Aldrich syndrome	<i>WAS</i>	Xp11.23	X-linked	Non-Hodgkin lymphoma
X-linked lymphoproliferative disorders	<i>SAP</i>	Xq25	X-linked	EBV lymphomas

Auto, autosomal; CNS, Central nervous system; EBV, Epstein-Barr virus; JMML, juvenile myelomonocytic leukemia; WAGR, Wilms tumors, aniridia, genitourinary abnormalities, mental retardation.

aniridia, chromosome analysis should be undertaken. If a deletion of chromosome 11p13 is found, the child should be monitored for the development of Wilms tumor with serial ultrasonographic studies of the kidneys. Wilms tumor develops in approximately half of these patients.

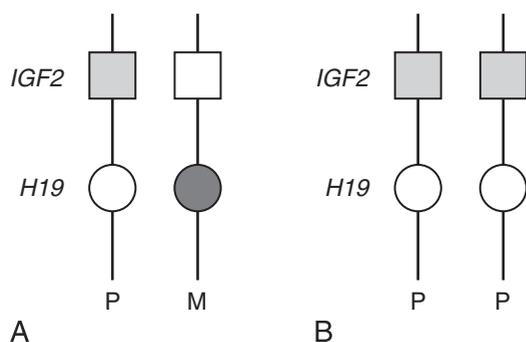

Wilms tumor and several other childhood neoplasms also are associated with the Beckwith-Wiedemann syndrome (BWS) and/or hemihypertrophy syndromes, typified by macroglossia, gigantism, and abdominal wall defects, but also including visceromegaly, flame nevus, neonatal hypoglycemia, microcephaly, and retardation (Sotelo-Avila et al, 1980a, 1980b). The associated neoplasms are seen in approximately 8% of infants with either the complete or partial syndrome and include Wilms tumor, adrenal cortical carcinoma, and hepatoblastoma—tumors of the same organs in which visceromegaly develops. Also reported are rhabdomyosarcoma, neuroblastoma, ganglioneuroma, and adenomas and hamartomas.

BWS is linked with abnormalities of 11p15, where the insulin-like growth factor II gene (*IGF2*) and tumor suppressor gene *H19* are located (Kubota et al, 1994). These two genes are examples of genes that are normally im-

printed, or expressed from one parent. The paternal copy of the *IGF2* gene is normally expressed, while the maternal copy is silenced. The maternal copy of *H19* is normally expressed, while the paternal copy is silenced. However, in BWS, uniparental disomy (in which two copies of a chromosomal region come from one parent and none from the other) of the paternal *IGF2* and *H19* locus occurs, which causes a loss of the maternal genes balanced by a gain of the paternal genes (Fig. 95-1). The result is biallelic expression of paternal *IGF2* and no expression of *H19*, leading to the multiorgan hyperplasia (due to increased *IGF2*) and a predisposition to development of neoplasia (due to lack of *H19*).

#### Transplacental Tumor Passage

Malignancies diagnosed during pregnancy are estimated to occur in 1 out of every 1000 pregnancies (Greenlund et al, 2001; Pavlidis, 2002). The choice to terminate a pregnancy is a painful and individual decision best made in consultation with the family, obstetrician, oncologist, and spiritual counsel (Eisinger and Noizet, 2002; Mathieu et al, 2002;

**FIGURE 95-1.** A schematic of uniparental disomy causing Beckwith-Wiedemann syndrome. **A**, In the normal pattern of inheritance, there is expression of paternally inherited *IGF-2* and no expression of *H19*. Conversely, there is expression of *H19* from the maternal allele but no expression of *IGF-2*. **B**, Two copies of the paternal allele have been inherited, leading to over-expression of *IGF-2* and no expression of *H19*. M, maternal; P, paternal.

Pautier et al, 2002). Some important factors to consider include the gestational age of the fetus at the time of maternal diagnosis, the stage of the disease and the risks of waiting to treat, and the treatment required. Unfortunately, the most common malignancy among women of childbearing age is leukemia, a disease that is generally fatal if not promptly treated. Most chemotherapy agents are known to be teratogenic in animal models, and some—in particular, all-*trans*-retinoic acid—are known to be potent teratogens in humans. However, there is a dearth of information regarding the pharmacokinetics and transplacental concentrations of many of the chemotherapy agents used. That being said, in numerous case reports in the literature, healthy infants have been born to women diagnosed and treated during pregnancy for leukemia, lymphoma, and breast cancer, among others (Aviles and Neri, 2001; Breccia et al, 2002; Fadilah et al, 2002; Ikeda et al, 2002; McNally et al, 2002; Safdar et al, 2002; Ward and Bristow, 2002).

The transmission of cancer across the placenta is an uncommon but recognized phenomenon. The development of choriocarcinoma in an infant as a complication of placental choriocarcinoma is one example of this rare disease. In addition, both mother and infant have been reported to be affected in some instances (Kishkurno et al, 1997). Chemotherapy has been used successfully in both the mother and infant (McNally et al, 2002). This represents tumor transmission from the fetus to the mother, because the trophoblast, the site of origin, is composed of fetal rather than maternal tissue. In most of the recorded cases, there was either a recognized placental choriocarcinoma or absence of a primary site in the infants with disseminated malignancy. The characteristic presentation is one of hematemesis or hemoptysis, anemia, hepatomegaly, and pulmonary metastases in the infant. The diagnosis is established by the demonstration of an elevated urinary or plasma  $\beta$ -human chorionic gonadotropin (hCG) in the infant (Belchis et al, 1993). The mother is screened for the disease by pathologic examination of the placenta, obtaining a chest radiograph, and following serial hCG levels. The half-life of hCG is on the order of hours,

and an assay showing appropriate decay of this marker effectively rules out disease in the mother.

Transmission of maternal leukemia to the infant, either at or shortly after birth, has not been documented (Dildy et al, 1989). A few cases of malignant melanoma of the mother with spread to the fetus have been reported and reviewed (Anderson et al, 1989). Factors suggestive of an unfavorable fetal or infant outcome are maternal age of less than 30 years, primiparity, primary lesion on the leg, onset of disease more than 3 years before pregnancy, metastatic status before pregnancy, birth at greater than 36 weeks of gestation, and male gender. Maternal virilizing tumors have resulted in in utero virilization of the infant as the result of transplacental passage of androgens secreted by the neoplasm, but the tumors have not spread to the fetus (Haymond and Weldon, 1973). Multiple myeloma has been reported in a small number of pregnant women (Lergier et al, 1974). In two instances, no abnormal myeloma protein was found in the infants, but a transient abnormal protein believed to have been passively transferred from the mother was demonstrated in two others. None of the infants had evidence of disease. Recently, transplacental transmission of small cell lung cancer has been reported after the mother presented with advanced-stage disease at the time of delivery (Tolar et al, 2002).

#### *Twin-to-Twin Transmission*

Although the risk of development of leukemia is increased slightly in a dizygotic twin or other sibling of a child who has the disease, the chance of developing leukemia is greatest in a monozygotic twin. If one monozygotic twin has leukemia, the co-twin has an approximately 25% chance of developing leukemia, usually within weeks or months of the diagnosis of the sibling. Growing evidence suggests that this increased incidence is likely due to twin-to-twin transmission of a preleukemic clone rather than to the simultaneous development of a shared germline mutation facilitating the later development of leukemia (Ford et al, 1993, 1998).

#### *Environmental Factors*

One of the most compelling connections between the environment and an increased risk of developing cancer was demonstrated in 1971 by studies linking maternal exposure to diethylstilbestrol (DES) with clear cell adenocarcinoma of the vagina and cervix in daughters born from those pregnancies (Herbst et al, 1971). According to the calculations of Herbst and colleagues (1977), the risk of development of such tumors is 0.14 to 1.4 per 1000 DES-exposed females up until the age of 24 years. Melnick and coworkers (1987) reported the risk up to age 34 as 1 case per 1000. The tumors are rare in females younger than 14 years of age, but the frequency increases rapidly to a peak at age 17 to 22 years, after which there is a precipitous drop. In addition to neoplastic changes, several nonmalignant epithelial and structural alterations of the lower genital tract have been noted, as have deformities of the endometrial cavity (Cunha et al, 1987; Hatch et al, 2001). Other authors have reported an increased risk of unfavorable outcome of pregnancy in daughters exposed in utero to DES. Detailed studies of males exposed in utero to DES

show increased frequencies of testicular hypoplasia, cryptorchidism, epididymal cysts, microphallus, increased abnormal spermatozoal forms, and lowered sperm counts but no increased risk of cancer (Strohsnitter et al, 2001). An estimated 30% of the males studied are probably infertile (Bibbo et al, 1977; Gill et al, 1977).

Other causal relationships between the environment and an increased risk of developing cancer are known. In particular, exposure to ionizing radiation during pregnancy is known to increase the risk of acute leukemias in exposed offspring. Stewart and Draper (1968) examined the risk for development of cancer in children exposed prenatally to diagnostic x-rays when radiography was used routinely to screen mothers for cephalopelvic disproportion and found it to be in excess of what was expected. Since then, other investigators have validated this association (Monson, 1997). A report by Yoshimoto and colleagues (1991) involving longer follow-up suggests that the relative risk of cancer in adult life after intrauterine exposure to radiation from the Hiroshima and Nagasaki atomic bombs was significantly increased.

A comprehensive review summarizes data on the studies of preconceptional and postconceptional parental exposures to chemicals, solvents, radiation, and electromagnetic field exposure as they relate to cancer incidence in offspring (Gold and Sever, 1994). Although many moderately significant correlations have been reported for prenatal exposures and various childhood cancers, the findings are often contradictory. Many possible mechanisms and factors must be considered in studies of the relationship of environmental factors to cancer pathogenesis in children. For example, preconception exposures could lead to genetic alterations transmitted to offspring by either parent. Also, a link to a particular exposure might really be a surrogate for another; thus, occupations in the lumber and paper industries might reflect hydrocarbon exposure as well as wood dust.

The use of fertility drugs may increase the risk of developing cancer in the exposed offspring, but this association is controversial. A case-control study in patients with neuroblastoma showed no association with contraceptive exposure but did suggest a modest increase in risk for children of women exposed to fertility drugs (Olshan et al, 1999). However, in a recent study published by Bruinsma and colleagues (2000), there does not appear to be an increased incidence of cancer among 5249 children born after the use of preconception fertility drugs and in vitro fertilization.

A number of other agents known to be teratogenic also may be carcinogenic to offspring. In utero exposure to phenytoin or other antiepileptic drugs is associated with a well-recognized syndrome in the newborn that includes hypoplasia of the midface, tapering of the fingers and toes, and hypoplasia or aplasia of the nails. At least five children with this syndrome were reported to have neuroblastomas (Ehrenbard and Chaganti, 1981), and one child was found to have an extrarenal Wilms tumor (Taylor et al, 1980). One young adult with a history of exposure in utero to phenytoin had a malignant mesenchymoma (Blattner et al, 1977). Excessive maternal alcohol consumption does appear to be strongly linked with an increased risk of developing cancer in the newborn period, particularly acute myeloid leukemia (Severson et al, 1993; Shu et al, 1996). The fetal alcohol syndrome, a disorder occurring in the children of mothers who consume excessive amounts of alcohol, is

characterized by developmental delay, growth deficiency, and multiple minor anomalies. One child with this syndrome has been reported with neuroblastoma (Kinney et al, 1980), a second with hepatoblastoma, and a third with adrenocortical carcinoma, but these are case reports in the literature.

The association of neoplasms with other environmental factors, such as maternal use of tobacco, has not been conclusively proven (Shu et al, 1996). Jick and associates (1981) noted an increase in pregnancies ending in spontaneous abortions and an increased incidence of congenital anomalies in live infants born to women presumed to have used vaginal spermicides near the time of conception. Two of the children were found to have neoplasms shortly after birth. A case-control study from the Children's Cancer Group and the Pediatric Oncology Group of 504 newly diagnosed cases of neuroblastoma reinforced some prior evidence of increased risks in parental electrical, farming and gardening, and painting occupations but failed to confirm other previously reported associations (Olshan et al, 1999).

### Diagnosis and Evaluation

The diagnostic evaluation of a newborn infant suspected to have cancer is obviously guided by the signs and symptoms of the disease. Table 95-5 lists some of the most common signs and symptoms associated with the more common malignancies found in the neonatal period. Prenatal ultrasonography can detect some tumors; however, not all women undergo screening at 18 to 20 weeks. In addition, not all tumors are large enough to be detected at 18 weeks, as the fetus experiences most in utero growth after this point in gestation. However, certain conditions may be associated with malignancies, such as polyhydramnios, hydrops fetalis, or intrauterine growth restriction/retardation.

The laboratory and pathologic evaluations should be directed at making the diagnosis most efficiently, to spare the newborn unnecessary procedures that may lead to significant acute and chronic morbidity. Consultation with a pediatric oncologist should be obtained for help in making the initial diagnosis, as the eventual recommendations for therapy may help to spare the infant the sequelae of major surgery. In particular, surgeons and pathologists should be encouraged to submit any diagnostic tissue for routine histologic examination and immunoperoxidase staining as well as cytogenetic analysis. In addition, samples for tumor banking should be set aside for cryopreservation in compliance with parental consent and adherence to the local institution's guidelines for handling of these rare but potentially precious and informative tumors.

## SPECIFIC NEOPLASMS

### Neuroblastoma

Neuroblastoma is the most common malignant tumor in infants, with approximately 20% of all cases occurring before age 6 months (Huddart et al, 1993). The small round blue cell neoplasm originates from neural crest cells that normally gives rise to the adrenal medulla and sympathetic ganglia (Fig. 95-2). In infants, the first clinical manifestations in more than half the cases usually result from the presence of metastatic disease rather than the primary

TABLE 95-5

**Differential Diagnosis of Malignant and Nonmalignant Conditions in Infancy**

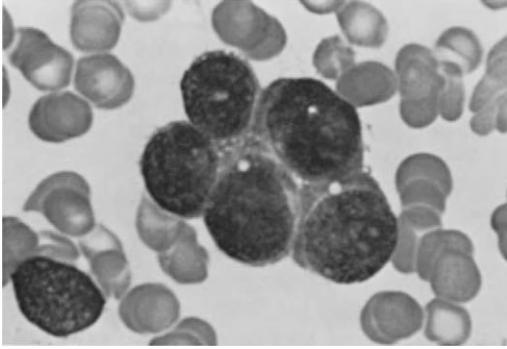

Feature	Malignancy	Nonmalignant Condition
Skin nodules	Neuroblastoma Acute leukemia Reticuloendothelioses	Congenital viral infections Vasculitis Fibromatosis Neurofibromatosis Xanthoma
Head and neck masses	Rhabdomyosarcoma Orbital tumors Cervical tumors Nasopharyngeal Neuroblastoma Lymphoma	Brachial cleft cyst Thyroglossal duct cyst Cystic hygroma Fibromatosis Hemangioma Abscess Cellulitis Reactive hyperplasia of cervical nodes Granulomatous lesions (e.g., atypical tuberculosis)
Abdominal or pelvic masses	Neuroblastoma Wilms tumor Sarcoma Malignant teratoma Lymphoma Germ cell tumor	Polycystic kidneys Hydronephrosis Benign teratoma Urinary retention Gastrointestinal duplication Intussusception Chordoma Meningomyelocele Horseshoe kidney Splenomegaly Hepatomegaly
Hepatomegaly	Neuroblastoma Acute leukemia Hepatoblastoma	Congenital viral infections Storage diseases Cavernous hemangioma Hemangioendothelioma
Signs/symptoms of increased intracranial pressure	Brain tumors Acute leukemia Retinoblastoma	Intracranial hemorrhage Communicating hydrocephalus Dandy-Walker malformation Vascular malformations
Anemia	Acute leukemia Neuroblastoma	Acute or chronic blood loss Hypoproliferative anemia (nutritional, congenital) Dyserythropoietic anemias Transient erythroblastopenia
Pancytopenia	Acute leukemia Neuroblastoma Retinoblastoma (disseminated)	Congenital viral infections Immune-mediated neutropenia and thrombocytopenia Congenital and acquired aplastic anemias

tumor. Yet despite the occurrence of widespread disease, the tumors seen in newborn infants are almost always biologically favorable, and carry a remarkably good prognosis.

### Clinical Manifestations

Neuroblastoma may manifest as a tumor mass anywhere sympathetic neural tissue normally occurs. In more than half of affected children, the primary tumor is located within the abdomen, arising in the adrenal medulla or a

sympathetic ganglion. The tumor also may arise in the posterior mediastinum with resultant bronchial obstruction. Increasing dyspnea, cough, wheezing, or pulmonary infection may be the presenting sign or symptom. The neoplasm also may arise in the neck or pelvis. Involvement of the stellate ganglion may result in Horner syndrome, which includes sinking in of the eyeball, ptosis of the upper eyelid, slight elevation of the lower lid, miosis, narrowing of the palpebral fissure, and anhidrosis (Fig. 95-3). The neoplasm arising from a paravertebral sympathetic

**FIGURE 95-2.** Clump of neuroblastoma cells found in bone marrow aspirate.

**FIGURE 95-3.** Horner syndrome in an infant with neuroblastoma arising from the left cervical sympathetic ganglion.

ganglion has a tendency to grow into the intervertebral foramina, causing spinal cord compression and resultant paralysis. Careful periodic neurologic evaluation should be performed on the child with a neuroblastoma arising in this location, because the onset of cord compression may necessitate emergency intervention with chemotherapy, surgery, or irradiation.

Metastatic lesions, especially of the skin and liver, are common presenting features during the neonatal period. Often the primary site cannot be discovered. The skin nodu-

les may first become erythematous for 2 or 3 minutes after palpation and then blanch, presumably due to vasoconstriction from release of catecholamines from the tumor cells. This may be a diagnostic sign of subcutaneous neuroblastoma (Fig. 95-4).

The liver often bears the brunt of metastatic dissemination, becoming studded with innumerable foci of tumor growth. The infant has a distended abdomen and respiratory distress (Fig. 95-5) from the rapidly growing hepatic neoplasm. Rarely, stippled calcifications occur in the liver

A

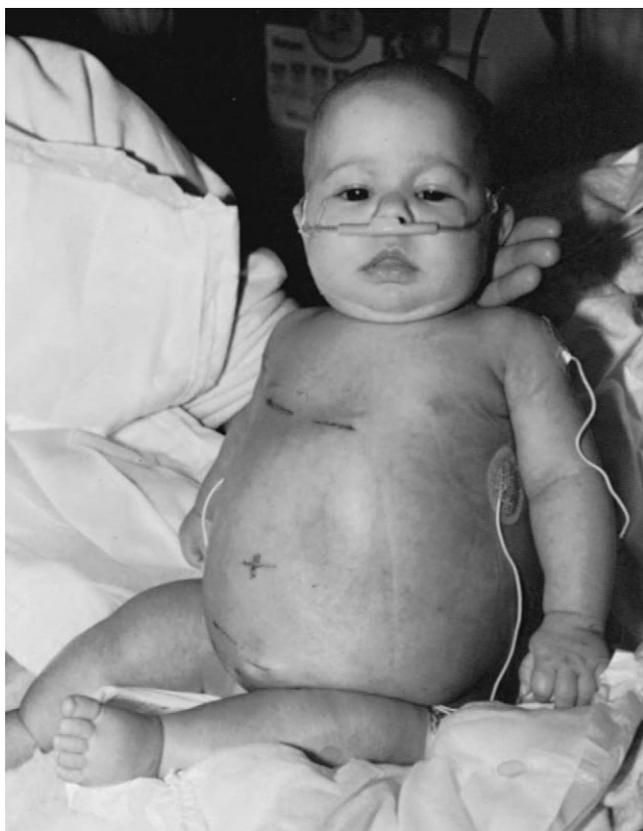

B

C

**FIGURE 95-4.** A newborn with stage 4S neuroblastoma in whom progression was followed by spontaneous maturation and regression.

**FIGURE 95-5.** Stage 4S neuroblastoma causing abdominal distention and respiratory distress secondary to hepatic infiltration.

metastases. The liver may be large enough at the time of birth to cause dystocia. The massive liver involvement common in newborns with disseminated neuroblastoma causing respiratory distress and coagulopathy is responsible for the higher mortality rate in newborns than in older infants (Nickerson et al, 2000).

### Unusual Presentations

Several children with neuroblastoma have been reported whose sole presenting manifestation was persistent, intractable diarrhea. The children had been believed to have either cystic fibrosis or celiac syndrome before roentgenographic discoveries of calcified masses were made. Their symptoms dramatically abated following surgical removal of the tumors. It is thought that such symptoms are due to excessive excretion by the tumor of a vasoactive intestinal peptide (Swift et al, 1975).

The association of opsoclonus and myoclonus (“dancing eyes, dancing feet”) and neuroblastoma has been described by numerous authors. The usual findings are rapid multidirectional eye movements (opsoclonus), myoclonus, and truncal ataxia (OMA) in the absence of increased intracranial pressure. The condition may be due to an autoimmune reaction, as the presence of antineuronal antibodies has been shown to be significantly more common in children with neuroblastoma and OMA than in case-control neuroblastoma patients (Antunes et al, 2000). This presentation of neuroblastoma is very rarely seen in the new-

born, as most patients do not come to medical attention until they are 1 to 3 years of age (Rudnick et al, 2001). Removal of the tumor usually results in a decrease in neurologic signs and symptoms, but the use of steroids is frequently required for complete resolution of the acute condition. In general, the prognosis for survival of children with opsomyoclonus is excellent, although long-term neurologic deficits and learning delays are common and can be quite debilitating. A report from the Netherlands suggests that signs and symptoms may develop in mothers whose fetuses have neuroblastoma. Six women had sweating, pallor, headaches, palpitations, hypertension, and tingling in the feet and hands during the eighth and ninth months of pregnancy (Voute et al, 1970). All of the children delivered were given the diagnosis of neuroblastoma shortly after birth or during the first few months of life. Because the mothers’ symptoms disappeared post partum, the authors propose that they were caused by fetal catecholamines entering the maternal circulation.

Neuroblastomas arising from sympathetic ganglia lower in the abdomen give rise to a clinical picture consistent with their location. Thus, presacral neuroblastomas, which arise from the organ of Zuckerkandl, may mimic presacral teratomas and be distinguished from them only by biopsy.

Occasionally, a newborn with congenital neuroblastoma may be thought to have erythroblastosis. Severe jaundice with hepatosplenomegaly and an increase in nucleated red blood cells has been noted. Two newborns with congenital neuroblastoma that metastasized to the liver and placenta initially were thought to have hydrops fetalis (Anders et al, 1970). In one of these infants, the diagnosis was established by histologic examination of the placenta.

Although neuroblastoma usually occurs sporadically, 1% to 2% of patients have a family history of the disease. This frequency is similar to that reported for the other embryonal cancers of childhood in which a familial predisposition is observed. Familial neuroblastoma is inherited in an autosomal dominant mendelian fashion with incomplete penetrance. Affected children from these families differ from those with sporadic disease in that they are often diagnosed at an earlier age (usually infancy) and/or they have multiple primary tumors. These clinical characteristics are hallmarks of the “two-hit” cancer predisposition model first proposed for retinoblastoma. It therefore seems likely that familial neuroblastoma occurs as a result of a germline mutation in one allele of a tumor suppressor gene. In addition, Knudson and Strong proposed that a new germinal mutation in a predisposition gene may account for the initiation of tumorigenesis in up to 22% of cases of nonfamilial neuroblastomas as well. Some recent reports suggest that such cases may involve a constitutional deletion of chromosome 1p36, the same site showing deletion or loss of heterozygosity in many neuroblastoma tumors (Biegel et al, 1993; Fong et al, 1989). At least 14 other cases of constitutional chromosomal rearrangements in neuroblastoma patients have been identified, but the lack of a consistent pattern indicates that many of these rearrangements may be coincidental rather than causal (Maris and Matthay, 1999; Maris et al, 1996). Neuroblastoma also has been reported in families in conjunction with other neurocristopathies, such as Hirschsprung disease and central hypoventilation (“Ondine’s curse”). There is remarkable

heterogeneity among patients with familial neuroblastoma. Within individual families, the disease can range in severity from an asymptomatic and spontaneously regressing neuroblastoma to a rapidly progressive and fatal disease. The clinical heterogeneity of familial neuroblastoma may partially explain its rarity, because some tumors remain occult or regress and are never detected, whereas others result in death before reproductive age.

### Biochemical Features

Due to the derivation of these cells from neural crest, a hallmark of neuroblastoma cells is the ability to store and secrete catecholamines. Patients with neuroblastoma usually have elevated urinary levels of norepinephrine as well as its biochemical precursors and their metabolites, including dopa, dopamine, normetanephrine, homovanillic acid (HVA), and vanillylmandelic acid (VMA). Ninety percent to 95% of patients have an elevated urinary excretion of VMA or HVA or both. Currently, accurate VMA and HVA determinations can be made on random urine samples when values are normalized for creatinine concentration. In occasional cases, however, there is no elevation of catecholamines, necessitating a 24-hour urine collection. It is therefore important to measure urinary catecholamines in a child before surgical removal of a neuroblastoma or initiation of therapy, to determine whether it is a catecholamine-producing tumor. This unique property of the neoplasm can be used not only as a diagnostic aid but also as a means of assessing the response to therapy or detecting the recurrence of tumor.

### Newborn Screening

Urinary catecholamine screening for neuroblastoma was initially proposed by Woods and Tuchman. The incidence of 8.7 per 1 million children per year is comparable with or higher than that for other congenital diseases for which screening is already in place, such as hypothyroidism, galactosemia, and phenylketonuria (Woods and Tuchman, 1987). The poor prognosis for advanced neuroblastoma in children older than 12 months of age at diagnosis, compared with the favorable outcome for those diagnosed in infancy, raised the expectation that diagnosis at an earlier age might improve overall outcome. Rapid quantitative screening methods have been developed that have high degrees of sensitivity and specificity. However, the cumulative data from 30 years of screening in Japan, the Quebec Neuroblastoma Screening (QNS) Project, and screening projects in Europe have shown that screening infants at 6 months of age or earlier results in a significant apparent increase in the overall incidence of neuroblastoma but fails to reduce the frequency of cases with poor prognosis from advanced-stage disease (Suita et al, 1996; Woods et al, 1996, 2002; Yamamoto et al, 1995). Neuroblastomas detected by screening have almost exclusively favorable biologic features (*MYCN* nonamplified, triploid, favorable Shimada histologic features) (Nakagawara et al, 1991; Takeuchi et al, 1995). Thus, screening practices result in the overdiagnosis of tumors that would otherwise have spontaneously regressed. A recent publication from the Quebec project conclusively showed that screening at 3 weeks and then 6 months in a cohort of 476,654 infants born over a 5-year

period did not have any impact on overall mortality rate for the screened cohort compared with multiple control populations from Minnesota, the Delaware Valley, Florida, and the rest of Canada, verifying the earlier studies (Woods et al, 2002). Nor did a second study done to screen children at 1 year of age reveal a favorable impact on outcome (Schilling et al, 2002). Urine screening was done in 1-year-olds in 6 of 16 German states from 1995 to 2000. Children in the remaining states served as controls. A total of 1,475,773 children (61.2% of those who were born between July 1, 1994, and October 31, 1999) underwent screening. In this group, neuroblastoma was detected by screening in 149 children, of whom 3 died. Fifty-five children who had negative results on screening tests were subsequently given a diagnosis of neuroblastoma; 14 of these children died. The screened group and children in the control area had a similar incidence of stage 4 neuroblastoma (3.7 cases per 100,000 screened children and 3.8 per 100,000 controls) and a similar rate of death among children with neuroblastoma (1.3 deaths per 100,000 screened children and 1.2 per 100,000 controls). Comparison of the screened group with the children in the control area revealed substantial overdiagnosis in the former group (an estimated rate of 7 cases per 100,000 children; 95% confidence interval, 4.6 to 9.2); the overdiagnosis rate represents children who had neuroblastoma that was diagnosed by screening but who would not benefit from earlier diagnosis and treatment (Schilling et al, 2002).

### Diagnosis

Neuroblastoma of the newborn most commonly manifests by enlargement of the liver alone, seen in 65% of the cases, followed by subcutaneous metastases, seen in 32%. These percentages differ strikingly from those for older infants and children (Table 95–6). Metastases to lungs, bones, skull, and orbit are rare in the newborn, although clumps of tumor cells often are found if bone marrow aspiration specimens are carefully examined (see Fig. 95–2). Otherwise, a localized primary tumor may be palpable or cause symptoms from spinal cord compression or Horner syndrome. Metastatic evaluation should include computed tomography (CT) or magnetic resonance imaging (MRI) of the primary lesion, MRI of the spine for paraspinal and posterior mediastinal lesions, bone scan, bone marrow aspiration and biopsy, and an [<sup>123</sup>I]- or [<sup>131</sup>I]metaiodobenzylguanidine (MIBG) scan. MIBG is a norepinephrine analogue specifically taken up by neuroblastoma in both bone and soft tissue; thus, MIBG scanning is a sensitive modality for disease localization (Feine et al, 1987; Geatti et al, 1985). Immunocytologic staining of bone marrow with monoclonal antibodies such as neuron-specific enolase (NSE) can increase sensitivity of the detection of bone marrow disease (Moss et al, 1985). The current staging system utilizes the International Neuroblastoma Staging System (INSS) summarized in Table 95–7 (Shimada et al, 1999a; Brodeur et al, 1993).

### Pathologic Classification

The histopathologic appearance of neuroblastoma ranges from undifferentiated neuroblasts, to more mature ganglioneuroblastoma, to fully differentiated and benign ganglioneuroma. The most widely used morphologic classification

**TABLE 95-6**

**Sites of Metastatic Disease at Diagnosis for the 81 Patients with Stage IVS, the 133 Patients with Stage IV <1 Year, and the 434 Patients with Stage IV ≥1 Year.**

	Stage IVS	Stage IV <1 year	Stage IV ≥1 year	Total (%)
<b>Sites of Metastases:</b>				
Bone marrow <sup>°, **</sup>	28 (34.6)	76 (57.1)	353 (81.3)	70.5
Bone <sup>**</sup>	0 (0.0)	65 (48.9)	296 (68.2)	55.7
Lymph node	7 (8.6)	38 (28.6)	155 (35.7)	30.9
Liver <sup>°, **</sup>	65 (80.2)	71 (53.4)	56 (12.9)	29.6
Intracranial/Orbit	0 (0.0)	34 (25.6)	84 (19.6)	18.2

system is based on the system proposed by Shimada and now recommended by the International Neuroblastoma Pathology Committee (INPC) (Brodeur et al, 1993; Shimada et al, 1999a, 1999b). The INPC classification is dependent

on age, the degree of differentiation of the neuroblasts, the cellular turnover index, and the presence or absence of Schwannian stromal development. Table 95-8 summarizes the INPC classifications.

**TABLE 95-7**

**International Staging System for Neuroblastoma**

Stage	Definition
Stage 1	Localized tumor confined to the area of origin; complete gross excision, with or without microscopic residual disease; identifiable ipsilateral and contralateral lymph nodes negative microscopically (adherent nodes may be positive)
Stage 2A	Localized tumor with incomplete gross excision; identifiable ipsilateral and contralateral lymph nodes negative microscopically
Stage 2B	Localized tumor with complete or incomplete gross excision, with positive ipsilateral non-adherent regional lymph nodes; identifiable contralateral lymph nodes negative microscopically
Stage 3	Unresectable tumor initiating across the midline with or without regional lymph node involvement; or unilateral tumor with contralateral regional lymph node involvement; or, midline tumor with bilateral regional lymph node involvement; bilateral extension by infiltration
Stage 4	Dissemination of tumor to distant lymph nodes, bone, bone marrow, and liver and/or other organs (except as defined in stage 4S)
Stage 4S	Localized primary tumor as defined for stage 1 or 2 with dissemination limited to liver, skin, and bone marrow in infant <1 year of age

**Genetic Prognostic Factors**

The outcome for patients with neuroblastoma has long been known to depend on the age at diagnosis and the stage of disease. However, these two variables alone do not define

**TABLE 95-8**

**International Neuroblastoma Pathology Classifications**

Age	Neuroblast Differentiation	MKI
<i>Favorable</i>		
<1.5 years	Poor or differentiating	Low or intermediate
1.5-5 years	Differentiating	Low
<i>Unfavorable</i>		
<1.5 years	Undifferentiated	High
1.5-5 years	Undifferentiated or poorly differentiated	Intermediate or high
>5 years	Any	Any
1. Ganglioneuroblastoma		
Composite of schwannian stroma-rich and stroma-poor, or schwannian stroma-rich		
2. Ganglioneuroma		
Schwannian stroma-dominant		
3. Neuroblastoma		
Schwannian stroma-poor		

a homogeneous group with respect to outcome. Additional molecular characteristics that have been correlated with unfavorable prognosis include *N-myc* oncogene amplification (Seeger et al, 1985); diploid cellular DNA content (Bowman et al, 1997); chromosomal 1p deletions, 11q deletions, and 17q gains (Bown et al, 1999); and low expression of the nerve growth factor receptor TrkA (Nakagawara et al, 1993; Suzuki et al, 1993). Patients with stage 1 and stage 2 neuroblastomas have a 96% to 100% survival rate with surgery alone (Perez et al, 2000). Infants with stage 3 and stage 4 disease have a poorer survival, even with aggressive chemotherapy, although the outcome, with better than 70% surviving overall, is far better than the 10% to 20% reported for older children (Schmidt et al, 2000).

Stage 4S comprises a unique group of patients with disseminated disease but a good prognosis, a combination that occurs exclusively in infants younger than 1 year of age. In this special group of children, typical findings include a small primary tumor that does not cross the midline and remote spread involving the liver, skin, or bone marrow (with less than 15% of marrow replacement with tumor), without roentgenographic evidence of skeletal metastases. The primary tumor may be unidentifiable. Eighteen of 20 infants younger than 1 year of age with stage 4S disease, in the original observation by D'Angio and associates (1971), were cured of their disease. The 5-year survival rate of all those with stage 4S disease is 92% (Nickerson et al, 2000), compared with 30% of all children with stage 4 disease or 70% of infants younger than 1 year with stage 4 disease (D'Angio et al, 1971; Matthay et al, 1999; Schmidt et al, 2000). Haas and colleagues (1988) reviewed outcomes in 212 infants with stage 4S neuroblastoma and found that only 13% died of disease progression, whereas 12% died of therapy-related causes. Biologic differences have been demonstrated between stage 4S and stage 4 neuroblastoma, with lack of elevated serum ferritin levels in stage 4S disease compared with stage 4 disease (Hann et al, 1981). There is usually lack of *N-myc* oncogene amplification in stage 4S tumors, in contrast to stage 4 tumors (Seeger et al, 1985). In general, infants with stage 4S disease can be observed without chemotherapy unless they experience symptoms secondary to local disease progression, such as respiratory distress from increasing hepatomegaly.

Amplification of the *N-myc* oncogene in primary neuroblastoma also has been shown to correlate with advanced-stage disease and with rapid tumor progression regardless of stage (Brodeur et al, 1984; Seeger et al, 1985). Estimated progression-free survival rates were 68%, 30%, and 0%, respectively, for patients whose tumors had 1, 3 to 10, or more than 10 copies of the *N-myc* oncogene. Patients with stage 1, 2, or 4S disease demonstrate *N-myc* amplification only rarely; when present, it has been associated with rapid disease progression in these usually favorable stages (Bourhis et al, 1991; Perez et al, 2000). Approximately 10% of patients with stage 2 disease exhibit amplification; a majority of such patients to date has development of rapid disease progression and death within 2 years of diagnosis. Thus, *N-myc* amplification is a significant prognostic factor that is independent of stage. It is most helpful in identifying newborns with high-risk disease. In the most recent Children's Cancer Group study of stage 4 neuroblastoma in infants, the progression-free survival rate after 3 years

was less than 10% in children with tumors that demonstrate *N-myc* amplification, compared with 93% for those with single-copy tumors (Schmidt et al, 2000).

Total cellular DNA content also may predict response to therapy in infants with neuroblastoma (Bowman et al, 1997; Look et al, 1991). Infants with hyperdiploid tumors had a significantly better response to therapy than was noted in those with diploid tumors. Furthermore, hyperdiploidy correlated with stage 4S. Diploidy often correlates with tumor *N-myc* amplification, although in rare cases of hyperdiploidy with *N-myc* amplification, the *N-myc* amplification portends an unfavorable outcome. Other researchers confirmed the poor prognosis of patients with diploid (euploid) tumors and correlated tumor DNA with histologic grading and clinical stage (Gansler et al, 1986; Hayashi et al, 1989).

Tumor karyotype also may influence outcome in neuroblastoma: Abnormalities of the short arm of chromosome 1 are more common in patients with metastatic disease but are rare in patients with stage 1, 2, and 4S disease (Christiansen and Lampert, 1988; Fong et al, 1989). Both allelic losses on chromosome 1 and gains on chromosome 17q are unfavorable prognostic factors in neuroblastoma (Bown et al, 1999; Caron, 1995). It has been shown by multiple groups of investigators that expression of high-affinity nerve growth factor receptors (e.g., glycoprotein [gp] 140<sup>trk-A</sup>) is a favorable prognostic factor, highly predictive of a good outcome regardless of age. Infants whose tumor has high gp 140<sup>trk-A</sup> expression have an 87% survival rate, compared with those with low expression, who have a 26% survival rate (Nakagawara et al, 1993; Suzuki et al, 1993).

## Treatment

A number of children—most commonly, infants with stage 4S disease—have experienced spontaneous tumor regression despite the presence of metastases. In other instances, malignant neuroblastomas have apparently undergone maturation into benign ganglioneuromas. The case shown in Figure 95-4 is an example of spontaneous maturation and regression (Haas et al, 1988). The diagnosis of neuroblastoma was made before the age of 6 months in 21 of 29 collected case reports in which spontaneous regression occurred (Everson, 1967). The remainder of the cases were diagnosed in patients between 6 and 24 months of age.

The relationship of spontaneous regression to age also has been noted (Evans et al, 1971). In one study, a majority of patients who experienced tumor regression were younger than 6 months of age and were usually those with stage 2 or stage 4S disease (Evans et al, 1971). Some patients with spontaneous regression of stage 4 disease have been reported (Sitarz et al, 1975). The mechanism of the spontaneous regression is uncertain, although in at least three cases, pathologic differentiation and maturation to ganglioneuroma have been documented. Regression has now also been documented in patients with neuroblastomas that are localized and detected either on prenatal ultrasound examination or by urine screening. Such patients have sometimes been observed rather than undergoing surgical resection, with documented regression in 11 patients (Yamamoto et al, 1998).

The unpredictable course of neuroblastoma, with its occasional spontaneous maturation or regression, not only makes the tumor unusual but also causes difficulty in planning therapy. The type and intensity of treatment can be based on the ability to define infants with relatively good, intermediate, and poor prognoses based on stage, Shimada histology, ploidy, and *N-myc* amplification. Patients who have localized disease (stage 1 or 2) without amplification of *N-myc* have a 90% to 100% survival with surgery alone, even if the tumor is not completely resected. Such patients should undergo surgical resection or partial resection, but they probably will not derive any additional benefits from postoperative radiation therapy or chemotherapy. An exception to this rule is in the case of spinal cord compression, in which prompt decompression either with chemotherapy, local irradiation, or laminoplasty may be used to preserve function. There is an increasing trend to use chemotherapy first, given the exquisite sensitivity of the tumor to chemotherapeutic agents, but a rapid deterioration in neurologic function should prompt alternative interventions. A neurosurgeon should always be consulted early in the diagnosis (De Bernardi et al, 2001; Katzenstein et al, 2001). The combination of extensive laminectomy with postoperative irradiation should be avoided, because later spinal deformity is almost inevitable. If a recurrence develops after local therapy for stage 2 neuroblastoma, the patient almost always has a good response and outcome with further treatment (Matthay et al, 1989; Perez et al, 2000).

Patients with stage 4S disease have a highly favorable prognosis and may require minimal therapy. Because many patients undergo spontaneous regression without chemotherapy and the overall disease-free survival rate is 85% to 90%, therapy should be directed toward supportive care, with use of chemotherapy and surgery restricted to relieving symptoms. The main cause of death is massive hepatic involvement resulting in respiratory insufficiency or compromise of renal or gastrointestinal function. In a review of 212 cases in the literature (Haas, 1988), 21 patients died of local disease progression, 20 died of therapy-related causes, and only 7 died of progression to a stage 4 tumor. The hepatic tumor often regresses with low-dose radiation therapy at a dose of 450 cGy given in three fractions through across-table, opposed ports angled to avoid the kidneys, spine, and ovaries. Concomitant low-dose cyclophosphamide often hastens tumor regression. No benefit has been shown to result from resection of the primary tumor, despite anecdotal case reports. Nutritional and blood product support also may be necessary until the lesions begin to resolve. Only in the rare 3% of cases in which progression to a stage 4 lesion occurs is intensive antineoplastic treatment required.

Infants with stage 3 and stage 4 disease usually are treated with combination chemotherapy and local surgery, with radiation therapy given only as necessary to eradicate residual disease. Current Children's Oncology Group protocols assign infants with stage 3 or 4 disease to the intermediate-risk group if the tumors lack *N-myc* amplification. Active drugs that are most commonly used in treatment programs for neuroblastoma include cisplatin, etoposide, doxorubicin, cyclophosphamide, vincristine, and ifosfamide. A small group of infants with a very unfavorable prognosis is comprised of patients with stage 4 disease with amplifi-

cation of the *N-myc* oncogene; it is possible that for such patients, as in older children with neuroblastoma, standard chemotherapy regimens will be insufficient for cure. In these high-risk patients, intensive chemotherapy with higher doses of the aforementioned agents, in combination with myeloablative therapy followed by bone marrow infusion, may offer additional benefit (Matthay et al, 1999; Valteau-Couanet et al, 2000). In addition, the use of the differentiation agent *cis*-retinoic acid has been shown to improve survival in patients with advanced-stage, high-risk neuroblastoma (Matthay et al, 1999).

## Congenital Leukemia

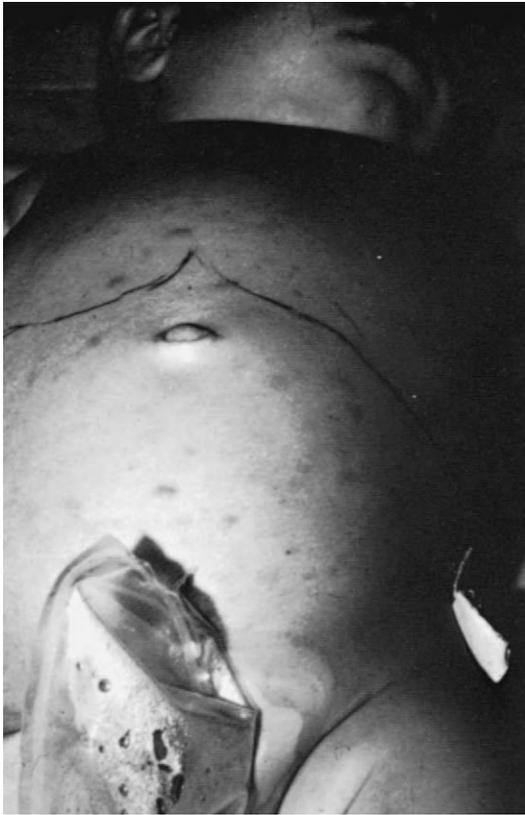

### Epidemiology

Despite the fact that leukemia is the second most common malignancy diagnosed in infants before the age of 1 year, this disease rarely occurs during the first month of life. Most of the neonatal cases of congenital leukemia are reported to arise from the myeloid lineage, in contrast with the predominance of acute lymphoblastic leukemia (ALL) found in later childhood. In particular, constitutional chromosomal disorders such as trisomy 21 are associated with acute myelogenous leukemia (AML) in the newborn period and, perhaps more intriguingly, with transient myeloproliferative disorder (TMD). However, despite the relative infrequency of congenital leukemia in the newborn period, both myeloid and lymphoid diseases are associated with a high mortality rate secondary to the aggressive biology of the diseases and the complications of the required treatment.

The etiology of infant leukemia is unclear; however genetic epidemiologic studies indicate that many cases, if not all, are initiated in utero. Several studies have demonstrated the presence of leukemia-associated gene rearrangements in the newborn Guthrie "blood spots" of children who subsequently developed leukemia (Ford et al, 1993, 1998).

### Clinical Manifestations

The clinical signs of leukemia may be evident at birth: hepatosplenomegaly, petechiae, and ecchymoses. In addition, myeloid leukemic cell infiltration into the skin (leukemia cutis) results in nodular fibroma-like masses. These tumors are freely movable over the subcutaneous tissue, with a greenish-blue discoloration of the overlying skin (Fig. 95-6). These solid masses of myeloid leukemia are called *chloromas* because of the abundance of myeloperoxidase causing the greenish discoloration. Such cutaneous lesions are commonly found when the disease appears at birth and have been noted in stillborn premature infants with leukemia. They may be the first clinical sign of the disease. If chloromas are present on the head or neck of young infants, further imaging of the head and neck area should be done to assess for the presence of intracranial or skull involvement. At birth, many of the infants have respiratory distress from leukemic infiltration in the lungs. Severe respiratory difficulty may develop soon after birth from pulmonary hemorrhage secondary to thrombocytopenia. In addition, some infants may appear somnolent or have periodic apnea as a result of CNS leukostasis, caused by sludging of the increased white blood cells in the vessels.

**FIGURE 95-6.** Leukemia cutis in a newborn infant.

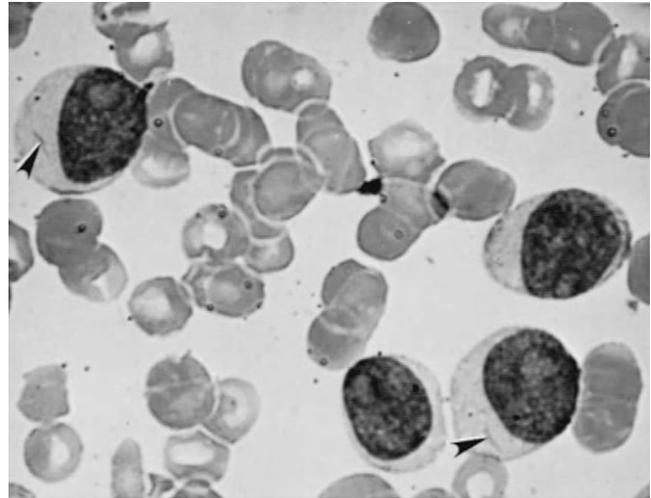

In those infants in whom signs of the disease develop within the first month but in whom no detectable signs of leukemia were noted at birth, the symptoms often are ill defined, with lethargy, diarrhea, hepatomegaly, and poor feeding with failure to gain weight. In addition, affected infants can present with fever due to bacterial infections. Hemorrhagic manifestations also can be the first signs of the disease, and leukemia cutis is less common.

#### Laboratory Manifestations

Hemoglobin levels often appear normal at first, but they soon decline to low levels as the normal decrease in red cell production after birth is combined with the expansion of the leukemia. Total white blood cell counts may be within normal limits or diminished, but leukocytosis is more often present. White blood cell counts of 150,000 to 250,000/mm<sup>3</sup> or more are common, and counts as high as 1.3 million/mm<sup>3</sup> have been recorded. There is usually a predominance of blast cells and immature granulocytes. Auer rods, pathognomonic of AML, may be present in the blast cells (Fig. 95-7). These intracellular inclusions are composed of lysosomes.

#### Differential Diagnosis

A number of newborns described in the earlier literature who were originally believed to have leukemia were later found to have other diseases. Confusion with infections such as congenital syphilis, cytomegalovirus (CMV) infection, toxoplasmosis, and bacterial infections may occur

**FIGURE 95-7.** Malignant blast cells with Auer rods (*arrowheads*) present in cytoplasm. This finding is diagnostic of acute myelogenous leukemia.

because of the leukocytosis, organomegaly, and thrombocytopenia that can accompany these diseases. The low platelet counts and leukemoid reactions reported in infants with congenital amegakaryocytic thrombocytopenia may also lead to an incorrect diagnosis of leukemia, but the absence of radii commonly seen in these children is a major clue to the correct diagnosis. In addition, infants with trisomy 21 are at higher risk for TMDs and leukemia. These topics are discussed in a section on Down syndrome.

Severe erythroblastosis fetalis can mimic leukemia. Affected infants usually have hepatosplenomegaly, large numbers of nucleated erythroblasts in the peripheral blood, and occasionally, thrombocytopenia. Small infiltrates of extramedullary erythropoiesis may appear in the skin, superficially resembling leukemia cutis. Infants with neonatal neuroblastoma often have hepatomegaly and may also have discolored tumor nodules in the subcutaneous tissue (see Figs. 95-4 and Fig. 95-5). Their blood cell counts are usually normal without circulating blasts, and specimens of bone marrow, if involved, reveal small clusters of neuroblastoma cells (see Fig. 95-2). Although these cells may resemble leukemia blast cells, their tendency to occur in clumps in an otherwise normal bone marrow distinguishes them from leukemic blasts, which usually completely replace the normal bone marrow. In rare cases of complete bone marrow replacement, increased excretion of catecholamine metabolites and the presence of an abdominal mass or other primary lesion are clues to the diagnosis of neuroblastoma. In addition, histochemical stains also can differentiate neuroblastoma from leukemia.

Congenital human immunodeficiency virus (HIV) infection also may rarely be confused with leukemia. Clonal B-cell expansions in such patients may cause lymphadenopathy. One newborn infected with HIV reported by Voelkerding presented with thrombocytopenia and had lymphocyte clusters in the bone marrow that were of B-cell lineage, clonal as defined by immune globulin gene arrangement, and positive for the common acute lymphoblastic leukemia antigen (CD10) (Voelkerding et al, 1988).

However, the patient was well and without evidence of lymphoproliferative disease one year later.

A marked but transient leukemoid reaction may occur in the newborn following in utero exposure to betamethasone (Barak et al, 1992; Calhoun et al, 1996). Lack of the usual clinical and laboratory findings of leukemia and of the appropriate clinical history usually excludes the diagnosis of leukemia.

### Cellular Morphology and Immunophenotype

The bone marrow of a normal newborn is normally hypercellular, so a bone marrow aspirate from an afflicted newborn with leukemia shows extreme hypercellularity in combination with a marked predominance of the immature cells of the cell series affected, either myeloid or lymphoid. ALL and AML are differentiated on the basis of typical morphologic characteristics, such as the presence of granules or Auer rods (in AML) and nuclear and cytoplasmic morphology, cytochemical stains, immunophenotyping, and chromosome analysis. Periodic acid-Schiff stain shows large aggregates of pink glycogen in the cytoplasm of the blast cells in ALL, whereas the pattern in AML is finely granular and diffuse. Most ALL cells stain positively for terminal deoxynucleotidyl transferase, a DNA polymerase that catalyzes the polymerization of deoxynucleotides in thymocytes. This enzyme is present in 90% of cases of ALL but in less than 5% of cases of AML. In addition, the blasts in AML are generally positive for myeloperoxidase, whereas lymphoblasts are not. Both types of leukemia are subclassified according to an international French-American-British (FAB) classification based on morphology and histochemistry (Pui et al, 1995) (see Table 95–8). The most common FAB morphology in infantile and neonatal AML is monocytic (FAB M5) or myelomonocytic (FAB M4) (Odom and Gordon, 1984; van Wering and Kamps, 1986), whereas the most common subtype in ALL is the FAB L1 variety (Sande et al, 1999).

The immunophenotype of the leukemia is determined using a panel of fluorescently labeled monoclonal antibodies against a variety of cluster of differentiation (CD) antigens and is critical for differentiating lymphoid from myeloid leukemias (Pui et al, 1993). The myeloid leukemias react with antibodies to the CD13/CD33 antigens, present on cells of myeloid and monocytic lineage. The only exception is the FAB M7 category, also known as acute megakaryoblastic leukemia, which expresses the CD41/CD42 platelet glycoprotein and CD61. Acute megakaryoblastic leukemia is most commonly seen in patients with trisomy 21. Most of the neonatal and infant acute lymphoblastic leukemia cells exhibit an early precursor B-cell phenotype and often are CD1a, CD19, CD24, and CD15 positive and CD10 negative (Crist et al, 1986; Katz et al, 1988; Pui et al, 1987, 1995). In addition, coexpression of myeloid antigens is frequently present. The frequent rearrangements of the immune globulin heavy-chain gene and occasionally the light-chain gene, but almost never the T-cell receptor gene, also may be helpful in the subclassification and elucidation of the biology of neonatal ALL (Felix et al, 1987; Ludwig et al, 1989). The acute leukemia surface antigen expression is summarized in Table 95–8.

### Genetics and Prognosis

The discovery of chromosomal abnormalities in leukemic cells has contributed greatly to the classification and understanding of the biology of acute leukemias. In addition, certain translocations have prognostic significance for both ALL and AML. The most common chromosome locus involved in infantile ALL and AML is found on 11q23. Abnormalities of 11q23 are found in at least 50% of infant leukemias and in a predominance of neonatal cases (Kaneko et al, 1988). The gene that is disrupted by 11q23 translocations, designated *MLL*, *HRX*, *ALL-1*, or *HTRX-1*, is the human homologue of the trithorax gene in *Drosophila melanogaster* (Ziemin-van der Poel et al, 1991). The trithorax gene is critical for the exoskeletal development of the fly. In mice and in humans, the *MLL* protein positively regulates *HOX* genes, which are critical for hematopoietic development (Armstrong et al, 2002).

Rearrangements involving 11q23 are the most common clonal chromosomal abnormalities found in infant leukemias (Pui and Evans, 1999; Pui et al, 2000). In older children and adults, this gene is frequently disrupted in secondary (therapy-related) AML induced by epipodophyllotoxin therapy. Epipodophyllotoxins (e.g., etoposide) act by inhibiting topoisomerase 2, a DNA repair enzyme. Accordingly, intrauterine exposure to topoisomerase 2 inhibitors may be responsible for some cases of leukemia in infants (Pui and Evans, 1999; Ross, 2000; Ross et al, 1996). In addition, it has been shown that the nucleotides involved in the breakpoint of the 11q23 locus may be more susceptible to topoisomerase 2–induced breaks (Strick et al, 2000). The Children's Cancer Group has reported a higher incidence of acute myeloid, but not lymphoid, leukemia in the infants of mothers who consumed larger amounts of naturally occurring topoisomerase 2 inhibitors, such as those in foods high in flavonoids and phytates (Ross, 2000; Ross et al, 1996).

The t(4;11)(q21;q23) gene rearrangement is detected in up to 40% of infants with acute lymphoblastic leukemia by molecular analysis. It generally is associated with a poor prognosis when it is accompanied by coexpression of myeloid antigens in infants younger than 6 months of age (Chen et al, 1993; Heerema et al, 1994; Rubnitz et al, 1994). Additional rearrangements can be detected in the remainder of the infant population with other fusion partners, raising the incidence of 11q23 abnormalities up to 80%. The t(4;11)(q21;q23) is the best characterized of the rearrangements involving the *MLL* gene. It generally is associated with hyperleukocytosis, CNS leukemia, and a precursor B-cell immunophenotype with CD19<sup>+</sup>, CD15<sup>+</sup>, CD10<sup>-</sup>. Curiously, older children harboring this same rearrangement do not have the same dismal prognosis as that identified for infants younger than 1 year; reasons for this are still unclear. Recent work in gene expression analysis demonstrates unique genetic signatures that separate infant ALL with *MLL* rearrangements from ALL and AML in older children (Armstrong et al, 2002). These studies may provide the basis for novel drug discovery focusing on genes overexpressed in *MLL*-rearranged leukemias, given the poor prognosis of many of these infants with current therapies.

The t(9;11)(p22;q23), t(1;22)(p13;q13), and t(11;19)(p21;q23) are three of the more frequent cytogenetic

abnormalities found in infants with acute myeloid leukemia and 11q23 rearrangements (Sande et al, 1999). Hyperleukocytosis and extramedullary involvement are common in infants with AML. In case reports of leukemia cutis and even leukemia occurring in infants without bone marrow involvement, spontaneous resolution has occurred without chemotherapy (Mora et al, 2000). In general, these leukemias lack 11q23 rearrangements. When 11q23 rearrangements are present, they generally progress to systemic disease; therefore, systemic therapy is advised for those patients with cutaneous disease only who harbor such rearrangements.

### Treatment

The course of congenital leukemia usually has been one of rapid deterioration and death from hemorrhage or infection. Although the length of survival has been significantly prolonged in children with leukemia, success has been limited in newborns. The infant with leukemia frequently presents with hyperleukocytosis (blast cell count in excess of 100,000/mm<sup>3</sup>). Hyperleukocytosis may result in sludging of blast cells in capillaries with resultant intracranial hemorrhage, respiratory distress, or problems from tumor lysis with hyperkalemia, hyperphosphatemia, hypocalcemia, hyperuricemia, and renal failure. These metabolic problems should be corrected before initiation of chemotherapy. In the infant, exchange transfusion is the easiest way to accomplish this and simultaneously lower the white blood cell count, which further decreases tumor lysis problems once chemotherapy is begun.

Disseminated intravascular coagulation is another common complication seen in hyperleukocytosis and infantile leukemia, especially when monocytic subtypes are suspected. The monoblasts release procoagulants, causing a consumptive coagulopathy, which initially may be exacerbated with further cell lysis from chemotherapy, necessitating support with transfusion of platelets and fresh frozen plasma. In addition, CNS involvement is common in infants with ALL and AML. Evaluation of cerebrospinal fluid and intrathecal prophylactic chemotherapy is a routine part of treatment. Radiation therapy, which is indicated in older children with CNS leukemia, is deferred in most instances until 1 year after diagnosis, to limit potential late effects in neonates.

The current improved success of remission induction with treatment of AML in infants younger than 1 year is similar to that obtained in older children using intensive combination chemotherapy regimens (Bresters et al, 2002; Chessells et al, 2002). The chemotherapy regimens used in infants with myeloid leukemia are identical to those used in older children. The experience with newborns is limited, but between 1984 and 1989, 5 of 12 newborns with AML sustained complete remissions with chemotherapy; all were in the myelomonocytic or monocytic category (Kaneko et al, 1988; Odom and Gordon, 1984).

Up until recently, the treatment outcome in ALL was significantly poorer in infants younger than 1 year at diagnosis (20% to 50% disease-free survival, compared with 80% for older children). Several studies of infant leukemia reported only 10% to 20% survival for infants younger than 6 months of age at diagnosis, compared with 40% for

those older than 6 months (Chessells et al, 1994; Heerema et al, 1994). Less than 15% of newborns with acute lymphoblastic leukemia had remissions lasting more than a few months with use of protocols similar to those used in older children. However, recent outcomes for infants have improved slightly with the addition of high-dose cytarabine and high-dose methotrexate. The addition of these two agents has improved the 4-year event-free survival (EFS) rate in some small series to approximately 50% (Silverman et al, 1997). The use of cytarabine, which generally is used in the treatment of AML, may address the more primitive nature of the *MLL*-rearranged ALL cell, with its frequent coexpression of myeloid antigens and lack of CD10 positivity. An international protocol, Interfant 99, currently being used to treat infants in the United States and Europe incorporates these agents; data from this trial are expected to verify their importance in a larger population. In general, the use of bone marrow transplantation has not been shown to be of benefit (Pui et al, 2002). The use of bone marrow transplantation is restricted in the Interfant 99 protocol to those patients who have had poor responses to systemic steroids. These patients tend to relapse within the first year of diagnosis, so that lack of disease beyond the first year is an important landmark in caring for them.

### **Transient Myeloproliferative Disorders and Leukemia in Patients with Down Syndrome**

An increased incidence of acute leukemia in children with Down syndrome (10- to 30-fold increased risk) is well recognized (Fong and Brodeur, 1987). A review of the world literature by Rosner and Lee (1972) revealed 227 children with both disorders; 31% had acute myelogenous leukemia, and 69% had ALL. Among the 47 infants with leukemia, 58% had myeloblastic leukemia and 42% had lymphoblastic leukemia. In infants younger than 3 years of age with Down syndrome and leukemia, the rare megakaryoblastic subtype (M7) predominates and carries a favorable prognosis (Pui, 1995). In addition, neonates with Down syndrome can present with a TMD that usually resolves without treatment. Approximately 30% of these affected children are at risk for developing leukemia later in life. A comprehensive review on the hematopoietic disorders affecting children with Down syndrome summarizes their management (Lange, 2000).

### **Transient Myeloproliferative Disorder**

Patients with Down syndrome can manifest a myeloproliferative disorder in the newborn period indistinguishable from leukemia. Various terms (in addition to "transient myeloproliferative disorder") have been used to describe this phenomenon, including transient leukemia and transient congenital leukemia. TMD also may be seen in trisomy 21 mosaicism (Seibel et al, 1984) and has been reported in two normal infants in whom the trisomy was detected only in the leukemic cells (Ridgway et al, 1990). Some infants with the TMD without Down syndrome also have been described, and true leukemia has subsequently recurred (Brissette et al, 1994). Patients with Down syndrome and

TMD have a 30% chance of developing leukemia later in life, either by developing a recurrence of TMD that progresses to leukemia or by developing a new leukemia unrelated to the TMD.

TMD is a clonal disorder typically manifested by hepatomegaly, splenomegaly, and circulating myeloblasts. There may or may not be associated anemia and thrombocytopenia. The morphology of the blasts often appears to be megakaryoblastic. In general, the blast count of the peripheral blood exceeds that of the marrow. Cytogenetic analysis may or may not reveal abnormalities, but findings often are normal, with the exception of the trisomy 21. Eighteen Down syndrome infants who had a TMD initially indistinguishable from AML experienced complete clinical and hematologic recovery without systemic therapy. Recently, somatic mutations in the *GATA1* transcription factor have been detected in 100% of patients with trisomy 21 and TMD (Mundschau et al, 2003).

In a majority of infants, the blast count slowly decreases over 2 to 3 weeks, and the hemoglobin and platelet counts normalize. However, less commonly, spontaneous resolution does not occur, and the neonate may experience clinical deterioration manifested by progressive hepatosplenomegaly and hepatic dysfunction, formation of pleural or pericardial effusions, and marrow failure. In these cases, treatment with low-dose cytarabine can be life-saving. In some instances, these complications can occur in utero, and varying degrees of hydrops fetalis can result. CNS involvement is rare in these neonates with clinically symptomatic TMD. In addition, 25% of infants with resolved TMD have later experienced recurrence of their disease with progression to AML (Isaacs, 1997). These patients, as well as other patients with Down syndrome and de novo AML, are treated with a less intensive regimen of chemotherapy, with excellent outcomes (Lange et al, 1998).

### **Leukemia and Down Syndrome**

As stated earlier, patients with Down syndrome are at a higher risk of developing leukemia, but the reasons for this increased risk remain unclear. The most popular hypothesis is that there is a leukemia predisposition gene on chromosome 21 which is over-expressed as a result of the constitutional trisomy 21. Acute megakaryoblastic leukemia (AMKL) predominates in infants, while the incidence of ALL increases with age. Similar to what has been described in TMD, mutations in *GATA1* have been reported in all cases of AMKL-DS analyzed to date. Specifically, mutations in *GATA1* have not been detected in non-DS-AMKL (Wechsler et al, 2002).

Patients with Down syndrome and AML have excellent outcomes compared with persons without Down syndrome and AML. In particular, megakaryoblastic AML in normal hosts often carries a dire prognosis, while the same disease in patients with Down syndrome is usually curable (Lange et al, 1998). Reasons for this are unclear but it is well known that patients with Down syndrome also experience greater toxicity from all of the chemotherapy agents used. Some investigators have hypothesized three possible mechanisms to explain simultaneous enhanced efficacy and host

toxicity in this population: reduced folate pools, increased free radical generation, and increased generation of the active daunorubicin metabolite (Taub et al, 1996, 1997). Thus, patients with Down syndrome and AML receive treatment protocols involving less intensive chemotherapy regimens, with excellent outcomes. Current treatment protocols sponsored by the Children's Oncology Group are enrolling patients with Down syndrome and TMD or AML in order to capture data on the natural history of TMD, the progression to AML, and secondary biologic factors that may affect the disease.

Older patients with Down syndrome also develop ALL at a higher frequency. Outcomes are similar to those for non-Down syndrome patients and do not appear to be related to tolerance of therapy (Dordelmann et al, 1998). Delays in therapy secondary to excess toxicity, however, can pose unique challenges in the treatment for these patients (Levitt et al, 1990).

### **Germ Cell Tumors**

Germ cell tumors are neoplasms that contain derivatives of more than one of the three primary germ layers of the embryo. Although these tumors most often are benign in the newborn, one or more of the germ layer derivatives may develop malignant characteristics. A mature teratoma, a term used for a benign germ cell tumor, may arise in a wide variety of locations of the body but usually occurs along the axial midline during early childhood, such as the pineal gland, neck, mediastinum, retroperitoneum, and sacrococcygeal region. In the neonatal period, a majority of teratomas occurs in the sacrococcygeal region, followed next by tumors in the neck. After puberty, teratomas most frequently occur in the gonads, particularly the ovary.

### **Staging**

Appropriate imaging of the primary tumor using MRI or CT is indicated to best visualize the extent of the disease. In particular, sacrococcygeal tumors should be visualized by MRI to exclude involvement of the spinal cord (Gobel et al, 1998, 2001). In addition, the remainder of the abdomen should be visualized to assess for the extent of local invasion—in particular, involvement of the rectal wall. All patients with germ cell tumors and elevated age-adjusted hormonal markers, such as alpha-fetoprotein (AFP) or hCG, also should have a diagnostic chest CT scan to rule out metastasis. Baseline levels of AFP and hCG are elevated in healthy neonates. The half-life of AFP is 5 to 7 days; that of hCG is 24 to 36 hours. The normal range of serum AFP is discussed in Chapter 18.

### **Pathology**

Teratomas are composed of tissues arising from all three layers of the embryonic disk. Ectodermal components, including glial tissue, are a major component of teratomas presenting at birth, in particular, sacrococcygeal tumors (Isaacs, 1997). There are often skin, hair, and teeth elements as well. Mesodermal components, including fat, bone, and muscle, also are present. Less commonly seen are endodermal components such as digestive tract tissue.

Occasionally, less mature elements coexist within the teratoma and are typified by higher grade histologic features including nuclear atypia, mitotic activity, and hypercellularity. Hormonal markers, including serum AFP and hCG, often are elevated in the presence of malignant tissue within the teratoma and are useful to follow as therapy progresses. Elevated serum AFP indicates the presence of immature endodermal sinus tissue or yolk sac elements, while elevated hCG indicates the presence of embryonal carcinoma. Choriocarcinoma also manifests with an elevated hCG and clinical bleeding but is rarely found in teratomas of the newborn (Isaacs, 1997). More often, it represents a placental disease or, rarely, a primary intracranial, liver, or kidney tumor.

### Sacrococcygeal Teratomas

The sacrococcygeal teratoma is the most common solid tumor in the newborn, although it is rarely malignant. The estimated incidence is 1/20,000 to 1/40,000 births (Isaacs, 1997). Females are affected two to four times more frequently than males. The earliest detection of a teratoma may occur prenatally or at birth. Polyhydramnios, nonimmune fetal hydrops, and dystocia all have been described in association with germ cell tumors. Congenital anomalies are often present in association with sacrococcygeal teratomas, including genitourinary, hindgut, and lower vertebral malformations. In most cases, the tumor manifests as a mass protruding between the coccyx and rectum; the mass may be quite large (Fig. 95–8). About 10% of these tumors are found by rectal examination. Nearly all arise at the tip or inner surface of the coccyx and can be diagnosed early in life by the pediatrician who makes the rectal examination a routine part of the physical examination. An estimated 30 children per year are diagnosed in North America with sacrococcygeal teratomas before the age of 2 to 3 months.

### Differential Diagnosis

Sacrococcygeal teratomas may be confused with meningo-myeloceles, rectal abscesses, pelvic neuroblastomas, pilonidal cysts, and a variety of very rare neoplasms that may occur in that region. Most benign teratomas in this area produce no functional difficulties, even when marked intrapelvic

**FIGURE 95–8.** Large sacrococcygeal teratoma in a newborn girl.

extension is present. Thus, bowel or bladder dysfunction, painful defecation, and vascular or lymphatic obstruction suggest that the lesion is malignant.

### Treatment

Treatment of sacrococcygeal tumors is primarily surgical if age-adjusted AFP and hCG levels are normal (Gobel et al, 1998). They should be radically excised as soon as possible because small, undifferentiated foci may proliferate and become aggressive. They are attached to the coccyx; therefore, removal of the entire coccyx is an absolutely necessary part of the surgical procedure. Failure to remove the coccyx carries a 30% to 40% risk of local recurrence, and such recurrences may be accompanied by malignant elements. Fetal surgery has been used successfully with long-term survival in at least one report, but the co-morbidities that accompany this high risk procedure preclude its routine use (Graf et al, 2000). Sixty percent to 70% of sacrococcygeal teratomas in newborns are unequivocally benign, as determined by the presence of mature tissues. In general, the risk for malignancy is present only in the sacrococcygeal tumors, whereas those in the nasopharynx, neck, mediastinum, or retroperitoneum do not usually contain malignant germ cell elements. Local recurrence or metastasis of teratoma is rare but may occur when immature elements are present or when surgical resection is incomplete. In the series of 398 cases reported by Altman and associates (1974), 60% of the patients with malignant tumors died within 10 months of surgery, 21% were alive with residual disease, 11% were alive without apparent disease, and 9% were lost to follow-up. These findings contrast markedly with the mortality rate reported for children with benign lesions, which was approximately 5%.

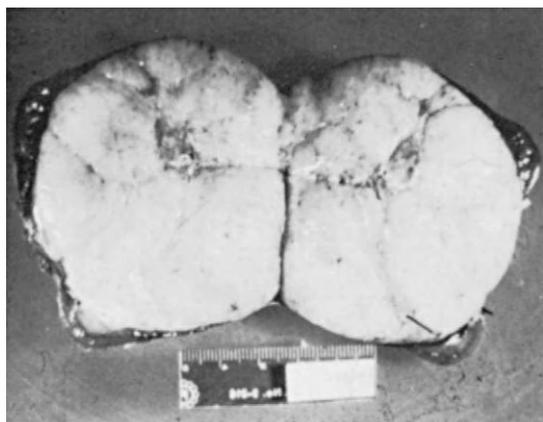

Chemotherapy regimens including cisplatin and/or bleomycin have markedly improved the survival of patients with malignant germ cell tumors. In a nonrandomized trial between 1983 and 1995, 71 patients with malignant sacrococcygeal tumors received a combination of surgery and chemotherapy (Gobel et al, 2001). Treatment decisions were made on the basis of the diagnostic scan and the surgical resection. The 5-year EFS rate was 76%, and the overall survival rate was 81%. Current recommendations for patients presenting with elevated age-adjusted AFP and sacrococcygeal tumors are for complete surgical resection only if the primary tumor is small and focal. Patients who have tumors containing immature elements are followed with serial AFP measurements. They are treated with chemotherapy if the serum AFP remains elevated or begins to increase. In all other cases, chemotherapy regimens containing cisplatin for four cycles is recommended, followed by surgical resection. This approach maximizes the possibility of achieving a complete resection, a goal worth attaining in these tumors. The addition of regimens containing cisplatin, carboplatin, etoposide, and bleomycin to the therapy for disseminated germ cell tumors has improved the disease-free survival rate to more than 50% (Ablin et al, 1991; Marina et al, 1992; Nair et al, 1994). Some infants have died of the complications of the intensive therapy (Raney et al, 1981), and it is important to make appropriate dose modifications.

## Renal Neoplasms

Approximately two thirds of intra-abdominal masses in the neonatal period arise from the kidney. The vast majority of these neoplasms are nonmalignant and are generally due to congenital defects such as polycystic or dysplastic kidneys or other conditions causing hydronephrosis. The most common intrarenal neoplasm manifesting at birth is congenital mesoblastic nephroma, followed by Wilms tumor. In addition, it may be difficult to differentiate an intra-abdominal neuroblastoma from an intrarenal tumor, although this distinction is more easily made with current imaging modalities, such as CT or MRI. Wilms tumor distorts the kidney, whereas neuroblastoma displaces it; this preoperative distinction may be difficult to make when neuroblastoma arises within kidney substance. Less common intrarenal neoplasms also seen in the newborn period are rhabdoid tumor, nephroblastomatosis, cystic renal tumors, renal cell carcinoma, rhabdomyosarcoma, heman-gioepicytoma, and lymphoma.

### Congenital Mesoblastic Nephroma

The congenital mesoblastic nephroma (CMN), or fetal mesenchymal hamartoma, is clearly distinguishable from Wilms tumor by its benign nature. It is the most common intrarenal neoplasm in the neonate. The involved kidney is usually greatly enlarged and distorted by the tumor, but, contrary to the findings with Wilms tumor, there is usually no lobulation, necrosis, hemorrhage, or discrete capsule between the neoplasm and compressed kidney (Fig. 95–9). Although in most cases the tumor manifests as an asymptomatic abdominal mass, the large size may cause problems. Polyhydramnios and premature labor occur with increased frequency in women whose infants have mesoblastic nephroma. Polyhydramnios occurs in approximately 71% of pregnancies complicated by CMN. The tumor may be diagnosed prenatally with ultrasonography, which helps to differentiate it from Wilms tumor because of its typical sonographic appearance of concentric echogenic ring–echo-poor ring pattern (Chan et al, 1987). Prenatal diagnosis may allow earlier treatment in symptomatic cases; in one such case, compression of the aorta caused severe

**FIGURE 95–9.** Congenital mesoblastic nephroma compressing and nearly totally replacing the kidney.

congestive heart failure in the fetus, necessitating emergency surgery (Matsumura et al, 1993).

Two histologic subtypes of CMN have been identified: the “classic” histologic subtype and the “cellular” variant. The classic histologic subtype has a preponderance of interlacing bundles of spindle-shaped cells, within which dysplastic tubules and glomeruli are irregularly scattered. Extrarenal infiltration is common, especially into the perihilar connective tissues. Since the initial description, a cellular or atypical variant of congenital mesoblastic nephroma with increased cellularity, focal hemorrhage, necrosis, hypercellularity, and a high mitotic index was described. The cellular variants usually manifest at an older age (mean 5.3 months later) than the classic type (mean age at presentation 16 days) (Pettinato et al, 1989). Cytogenetic analysis of the more cellular tumors often reveals trisomy of chromosomes 8, 11, 17, and 20 (Schofield et al, 1993). Recently, a genetic link between CMN and another infantile tumor, congenital infantile fibrosarcoma, has been established, in part due to the characteristic polysomic and histologic features that these tumors share. Both the cellular variant of CMN and infantile fibrosarcoma harbor a cryptic translocation, the t(12;15) (p13q25), which fuses the *TEL* gene on chromosome 12 with the *TRKC* gene on chromosome 15 (Knezevich et al, 1998; Rubin et al, 1998). Of interest, because the classic form of CMN has not been shown to harbor this rearrangement, some investigators speculate that the classic and cellular forms of CMN are genetically distinct (Knezevich et al, 1998). However, mixed lesions also have been observed, and these generally express the t(12;15) rearrangement. Investigations into the biologic events responsible for neoplasia are ongoing (Wai et al, 2000).

Most patients with CMN have been cured by nephrectomy alone, even in the presence of localized extrarenal extension (Pettinato et al, 1989). Radical nephrectomy with complete excision of the tumor is the treatment of choice; however, in rare instances the tumor is unusually aggressive (Isaacs, 1997). In such instances, metastases have been reported to occur in the lungs and the brain. In cases of advanced disease or surgically unresectable disease, chemotherapy has been used with success (Isaacs, 1997; Loeb et al, 2002).

### Wilms Tumor

Wilms tumor, or nephroblastoma, is the most common intra-abdominal tumor of childhood but is relatively rare in the neonatal period; it affects 1 in 8000 children. In subsets of children with aniridia, the incidence is much higher. With optimal treatment, cure rates for this neoplasm have increased dramatically, and the overall favorable prognosis for Wilms tumor represents one of the dramatic success stories in the field of cancer therapy. The National Wilms Tumor Study (NWTs), established in 1969, has helped in the rapid accumulation of information regarding the prognosis and treatment of this tumor.

#### Clinical Manifestations

Most children with Wilms tumor have either an abdominal or flank mass or an increase in abdominal size noted as

the first clinical evidence of disease. This is often first discovered by a parent and brought to the attention of the physician. The tumor lies deep in the flank, is attached to the kidney or is part of it, and usually is firm and smooth. It seldom extends beyond the midline, even though it may grow downward beyond the iliac crest. In 5% to 10% of all cases, tumors involve both kidneys. Gross hematuria is a rare presenting symptom, but microscopic hematuria is found in approximately one fourth of cases. Hematuria in Wilms tumor is not a poor prognostic sign. Hypertension, occasionally noted in older infants and children, has not been observed in the newborn. The tumor may sometimes manifest with abdominal pain and be discovered at laparotomy, and occasionally acute hemorrhage into the tumor may result in a rapidly enlarging mass, usually associated with anemia and fever.

Wilms tumor is seldom diagnosed at birth or during the neonatal period, although several renal tumors have been so large as to have caused dystocia during delivery. Characteristics associated with an earlier presentation include bilaterality and associated aniridia or hypospadias (Pastore et al, 1988) and a positive family history. Rare cases of Wilms tumor associated with polycythemia have been reported; this finding is secondary to an increased production of erythropoietin by the neoplasm. The demonstration of elevated plasma erythropoietin levels in nonpolycythemic children with Wilms tumor studied preoperatively led to the suggestion that this test may be useful in the diagnosis and evaluation of response to therapy.

#### Hereditary Associations and Congenital Anomalies

The association among Wilms tumor, hemihypertrophy, cardiac anomalies, congenital aniridia, hamartomas, and genitourinary defects and associated chromosomal changes is discussed earlier in this chapter (under "Genetic Predisposition Syndromes and Congenital Defects"). The finding of hemihypertrophy should alert the physician to observe the child for the possible development of Wilms tumor, adrenal cortical tumor, or hepatoma. Some affected patients may have incomplete forms of BWS (Sotelo-Avila et al, 1980a, 1980b). Occasionally, certain members of a family may have the congenital anomaly and others may have the neoplasm. Meadows and coworkers (1974) described one family in which the mother had congenital hemihypertrophy, three of the children had Wilms tumor, and a fourth had a urinary tract anomaly (Meadows et al, 1974).

The Wilms tumor-aniridia syndrome, a combination of mental retardation, microcephaly, bilateral aniridia, anomalies of the pinna, Wilms tumor, and ambiguous genitalia, is associated with a small deletion of chromosome 11 (11p13-14.1). In some tumor tissues, the same section of DNA deleted from one chromosome may be duplicated on another. Although usually sporadic, this syndrome may occasionally be familial (Yunis and Ramsay, 1980). Rarely, affected persons may demonstrate all of the listed features except the Wilms tumor (Riccardi et al, 1978). In two reports of aniridia in monozygous twins, Wilms tumor developed in only one member of each pair (Maurer et al, 1979). Other congenital conditions that may predispose the patient to Wilms tumor include Turner syndrome and trisomy 18. A variant mutation at 11p13 results in Denys-

Drash syndrome: Wilms tumor, genital anomalies, and nephropathy (Coppes and Clericuzio, 1994). Some familial and sporadic cases of Wilms tumor also have been shown to involve loss of heterozygosity at 16q (Newsham et al, 1995) and, in rare cases, changes in chromosome 7 (Wilmore et al, 1994). Bloom syndrome, a rare autosomal recessive disease already known to be associated with a high risk of cancer, has been reported to predispose patients to Wilms tumor (Cairney et al, 1987). Pedigrees showing a predisposition to Wilms tumor are rare, with only 1% of patients having affected siblings or parents; however, such cases tend to occur earlier in infancy. The specific germline abnormality has not yet been successfully localized, although a number of such cases has been examined for the candidate loci on 11p and 16q (Baird et al, 1994). However, the heritability of the unilateral sporadic form of Wilms tumor was examined in 96 long-term survivors (Li, 1988). No Wilms tumor developed in 179 offspring of these patients, confirming the low likelihood of heritability in the sporadic form.

#### Prognostic Factors

Several factors seem to influence the response to therapy and ultimate prognosis of the child with Wilms tumor: the histologic pattern, the age of the patient at the time of diagnosis, and the extent of disease. Tumors with better differentiation, showing glomeruloid and tubular formation, indicate a better chance for survival than do those with anaplastic and sarcomatous patterns. Patients younger than 2 years of age at diagnosis have fewer relapses, especially to distant sites, than are seen in older children. Age, however, seems to be of little prognostic significance regarding mortality rate. Specimens weighing more than 250 grams and positive regional lymph nodes, however, are often important predictors of both relapse and death.

#### Staging

The most common staging system in use is that devised by the NWTS (Table 95-9). The clinical staging is an important factor in predicting survival; tumors with more extensive spread carry a poorer prognosis. Therefore, adequate evaluation of the extent of tumor involvement is essential and should include CT scans of the abdomen and chest to fully evaluate both kidneys, the inferior vena cava for tumor thrombus, and the liver and lungs, which are the most commonly involved areas of hematogenous spread (Fig. 95-10). Other commonly involved sites of metastatic spread are the retroperitoneum, peritoneum, mediastinum, and pleurae. If histologic studies show a clear cell sarcoma, bone metastases may occur, so a bone scan should be included in the evaluation; rhabdoid tumors, which frequently metastasize to brain, necessitate CT or MRI of the brain.

#### Treatment

Before 1950, the two major modalities of therapy for Wilms tumor, surgical removal and radiation therapy, resulted in cure rates approaching 50%. The advantage of treatment with the chemotherapeutic agent dactinomycin was demonstrated in 1966 by Farber, who reported an 89% survival rate in children who had no evidence of metastatic disease at the time of diagnosis and who were followed up

TABLE 95-9

## Morphologic and Immunophenotypic Classification of Childhood Acute Leukemia

FAB	Morphology	Antigen Expression*
ALL <sup>†</sup>		
L <sub>1</sub>	Small cells, homogeneous Regular nuclei, scant cytoplasm Inconspicuous nucleoli	Pre=B: HLA-DR, CD10, CD19, CD20, CD24
OR		OR
L <sub>2</sub>	Large cells, heterogeneous, irregular or cleft nuclei May be multiple large nucleoli Moderate cytoplasm	T: CD2, CD5, CD7
L <sub>3</sub>	Large cells, homogeneous Regular nuclear shape Prominent nucleoli Moderately abundant, deeply basophilic cytoplasm with vacuolation	B: HLA-DR, CD10, CD19, CD20, CD24, Slg <sup>°</sup>
ANLL		
M0	Minimal myeloid differentiation (MPO <sup>-</sup> )	CD13, CD33, CD34
M1	Poorly differentiated myeloblasts (MPO <sup>+</sup> )	CD13, CD33, CD34
M2	Myeloblastic with differentiation (MPO <sup>+</sup> )	CD13, CD33, CD34
M3	Promyelocytic (MPO <sup>+</sup> )	CD11b, CD13, CD33, CD34
M4	Myelomonoblastic (MPO <sup>+</sup> , NSE <sup>+</sup> )	CD11b, CD13, CD14, CD15, CD33, CD34
M5	Monoblastic (NSE <sup>+</sup> )	CD11b, CD13, CD14, CD15, CD33, CD34
M6	Erythroleukemic (MPO <sup>+</sup> , PAS <sup>+</sup> )	Glycophorin CD34
M7	Megakaryoblastic (PPO <sup>+</sup> )	CD41, CD42, CD34, CD61

L<sub>1</sub> or L<sub>2</sub> may show either pre-B or T antigens.

\*The indicated FAB type may express some or all of the indicated antigens.

<sup>†</sup>ALL, acute lymphocytic leukemia; ANLL, acute nonlymphocytic leukemia; FAB, French-American-British; MPO, myeloperoxidase; NSE, nonspecific esterase; PPO, platelet peroxidase; Slg, surface immune globulin.

for at least 2 years, and a 53% survival rate in patients presenting with evidence of metastatic disease. The drug therapy appeared to prevent clinical hematogenous metastases following surgical removal and radiation to the tumor bed, presumably by destroying nondetectable, microscopic tumor foci, especially in the lungs. Vincristine also has striking activity against Wilms tumor and appears to be at least as effective as dactinomycin. Other single agents shown to have activity against this tumor include doxorubicin, cyclophosphamide, ifosfamide, and bleomycin.

Infants younger than 12 months of age have experienced undue toxicities to the liver, hematopoietic system, and lungs from the prescribed doses of dactinomycin, vincristine, and

FIGURE 95-10. Pulmonary metastases from Wilms tumor.

doxorubicin. In the earlier NWTS trials, 47% of infants had severe hematologic toxicity, and toxicity-related deaths occurred in 6%. Dosages were subsequently reduced to 50% of the usual per kilogram dose given to older children, with a decrease in rate of hematologic toxicity to 13% and elimination of toxic deaths. Of importance, dosage reduction did not compromise therapeutic effect as judged by the 2-year relapse-free survival figures (Morgan et al, 1988).

Results of the first two NWTS trials showed that treatment with vincristine plus dactinomycin is superior to treatment with either drug alone. Postoperative radiation therapy adds little benefit to children with completely excised tumors, and 6 months of therapy with two drugs appears to be as effective as 15 months of therapy in these patients. Patients with more advanced disease fared better following treatment with three drugs (dactinomycin, vincristine, doxorubicin) than with two (dactinomycin, vincristine). Patients with tumors of unfavorable histologic subtype had a significantly poorer prognosis than that for patients whose tumors had favorable histologic features; prognosis also was poorer in those patients with positive nodes (D'Angio et al, 1981). Treatment results from the NTWTS 3 are shown in Table 95-10 (D'Angio et al, 1989). NTWTS 4 demonstrated that children could receive pulse-intensive chemotherapy safely at less cost without sacrificing efficacy (Green et al, 1998). Thus, Wilms tumor, a neoplasm that is fatal if untreated, presently has an overall cure rate approaching 90%.

TABLE 95-10

**Treatment Results of the Third National Wilms Tumor Study According to Stage and Histology**

Stage	Histology	No.	% Relapse-Free		% Alive
			2 yr	4 Yr	4 Yr
I	Favorable	607	91.6	90.4	96.5

**Persistent Renal Blastema and Nephroblastomatosis**

Accumulations of immature renal tissue are not normally found beyond 36 weeks of gestation, the time at which nephrogenesis normally ceases. Nodular renal blastema is characterized by microscopic nests of primitive cells in the subcapsular renal cortex resembling the blastemal cells of Wilms tumor but lacking mitoses. Although benign, these nodules are believed to have the potential for neoplastic transformation. They are found in 1 of every 200 to 400 postmortem examinations of infants dying from other causes prior to 4 months of age. When nodular renal blastema becomes massive and confluent and replaces the cortex, it is referred to as *nephroblastomatosis* (Bove and McAdams, 1976). Kumar and associates (1978) reported the nodular renal blastema–nephroblastomatosis complex in 8 of 118 patients (6.8%) with Wilms tumor. Five of these eight patients had bilateral tumors. Children with this disorder also may have the congenital anomalies associated with Wilms tumor (Fig. 95-11). The fact that nodular renal blastema is rarely found in older children suggests that a majority of these lesions regresses, a situation analogous to the course of neuroblastoma in situ. It is believed that those that persist give rise to Wilms tumor, whereas a small number progresses to diffuse nephroblastomatosis. Complete progression of nodular renal blastema to nephroblastomatosis to Wilms tumor has been documented (Kulkarni et al, 2002). Children with massive bilateral involvement often respond to therapies used for Wilms tumor. Although persistent renal blastema is not a true malignancy, it probably has been confused with Wilms tumor in the past, and it appears in many instances to be a precursor of this malignancy.

**Cystic Partially Differentiated Nephroblastoma**

One renal neoplasm in infants is known by a variety of names: polycystic nephroblastoma, benign multilocular cystic nephroma, well-differentiated polycystic Wilms tumor, and cystic partially differentiated nephroblastoma. It is a cystic encapsulated tumor occurring before 2 years of age.

**FIGURE 95-11.** Congenital epidermal nevus in association with hemihypertrophy and nephroblastomatosis.

The cysts are lined by epithelium and show a mixture of partially differentiated and undifferentiated metanephrogenic blastemas, a finding that differentiates this lesion from multilocular cysts of the kidney. The tumor appears to have a benign course, and nephrectomy is the treatment of choice (Joshi et al, 1977). These neoplasms probably represent a differentiated form of nephroblastoma. A number of neonatal renal tumors have been confused with the typical Wilms tumor in the past. Because these neoplasms have been recognized as separate entities, they are more commonly diagnosed during the neonatal period than is the classic nephroblastoma, which rarely occurs during the first month of life.

**Rhabdoid Tumor of Kidney**

Rhabdoid tumor of the kidney is an uncommon renal tumor of children that is one of the most lethal neoplasms of early neonatal life, with a mortality rate exceeding 80%. It has a predilection for males, with a male-to-female ratio of 1.5:1, and for infants, with median age at diagnosis of 11 months. Overall, rhabdoid tumors comprised 1.8% of all malignant childhood renal tumors entered in the NWTs. Rhabdoid tumors frequently manifest simultaneously with embryonal primary tumors of the CNS, such as medul-

loblastoma (Bonnin et al, 1984). Originally believed to represent a “rhabdomyosarcomatoid” pattern of Wilms tumor, this lesion subsequently was shown to lack any evidence of myoblastic differentiation or any morphologic or clinical linkage to Wilms tumor. Review of 111 cases by Weeks and coworkers and the NWTs showed several findings suggesting that rhabdoid tumors may arise from cells involved in formation of the renal medulla but that they have no histogenetic relationship to Wilms tumor (Weeks et al, 1989). The prognosis is extremely poor, particularly for infants with evidence of dissemination. The only patients who survived were those with completely resected disease and negative lymph nodes (50%), whereas all those with metastases died. A consistently detected cytogenetic abnormality is the deletion of 22q11-12, which has been mapped to the *IN11* or *hSNF5* gene (Versteeg et al, 1988). This deletion also is detected in the rhabdoid tumors of the CNS. *IN11* is essential for normal development and has been reported to act as a tumor suppressor gene (Roberts et al, 2000). Mice that are *IN11* heterozygotes develop rhabdoid tumors as early as 5 weeks of age (Roberts et al, 2000).

### Retinoblastoma

Retinoblastoma is a malignant ocular tumor that arises in embryonic retinal cells. The incidence of retinoblastoma in the United States is approximately 1/18,000 live births. Bilateral involvement is observed in 20% to 35% of retinoblastomas; the tumor is detected in only one eye in as many as one fourth of these patients.

#### Genetics

The gene for retinoblastoma, located on chromosome 13q14, has been cloned and belongs to a class of tumor suppressor genes whose function is to control cellular growth. When the retinoblastoma gene (*RB*) is inactivated, by either a mutation or a deletion, the block to cellular proliferation is removed, leading to tumor formation. Mutations at the *RB* locus can be inherited in an autosomal dominant pattern or arise spontaneously. The Knudson “two-hit” hypothesis postulates that the first genetic mutation can occur in a germ cell (inherited cases) or in a retinoblast (in sporadic cases); only with the second mutation in a somatic target cell (retinoblast) already carrying a first “hit” will that cell be transformed.

All patients with bilateral retinoblastoma have either a new *RB* germline mutation or an inherited one. Approximately 80% of unilateral retinoblastomas occur as a result of a somatic nonheritable mutation (Cowell and Pritchard, 1987). The germline trait responsible for retinoblastoma is a dominant one with 80% to 96% penetrance. There is also a small number of patients (5% of retinoblastoma) born with a constitutional deletion of chromosome 13, 13q-, who have the associated anomalies of microencephaly, macroglossia, malformed ears and thumbs, hypertelorism, microphthalmia, ptosis, protruding upper incisors, short stature, cleft palate, developmental delay, and psychomotor retardation (Knudson et al, 1976). Children with the bilateral and hereditary form often are diagnosed at an earlier age, in part because the family history alerts the pediatrician to the need for early screening and in part

because the chromosomal abnormality is present at birth, providing a greater susceptibility to tumorigenesis. In rare instances, family history of the disorder may be lacking; hereditary bilateral retinoblastoma may be the result of germline mosaicism in the parent. It is possible using DNA restriction fragment length polymorphisms to predict susceptibility to retinoblastoma (Cavenee et al, 1986; Wiggs et al, 1988).

#### Clinical Manifestations

Patients with retinoblastoma commonly present either with leukocoria or “cat’s eye” on ocular examination or with strabismus caused by loss of vision in the affected eye. Multifocal retinal involvement is common, occurring in 84% of the cases. Intraocular spread may fill the vitreous body by extension or seeding, whereas exophytic tumors arise from the outer retinal layer and cause retinal detachment. Extraocular spread is seen in less than 15% of patients, usually occurring by direct invasion of the optic nerve and eventually leading to subarachnoid involvement and intracranial spread. In such cases the cerebrospinal fluid may contain tumor cells. Rarely, tumors may spread by invasion of the orbit or by hematogenous dissemination to bones and bone marrow. Children with bilateral retinoblastoma are at risk for dissemination to the pineal gland and should undergo periodic brain MRI for evaluation; this syndrome is known as *trilateral retinoblastoma*.

The diagnosis is made by ophthalmoscopic examination performed with the patient under general anesthesia. CT or MRI of the eye is useful to determine tumor extent and optic nerve involvement. A lumbar puncture for cerebrospinal fluid cytology should be performed if there is optic nerve invasion; bone scan and bone marrow biopsy detect hematogenous spread. In general, repeated metastatic evaluations are not indicated for follow-up study of this tumor because of the extreme rarity of extraocular dissemination. Only cases with extraocular involvement initially or with clinical findings compatible with spread require such evaluations. Tumors are then staged according to the Reese-Ellsworth classification on the basis of the number and size of the lesions and whether they extend anterior to the ora serrata. In addition, any extraocular extension must be characterized.

#### Treatment

Because extraocular spread and death from dissemination are rare, the main goal of treatment is local control and preservation of vision. Surgical enucleation is used only when there is no chance for useful vision, if glaucoma is present, or if conservative measures fail to control the tumor. External beam radiation therapy, administered by experienced clinicians using careful positioning and general anesthesia, is known to cure the disease. Doses range from 3500 to 5000 cGy given in three fractions per week. However, patients with hereditary retinoblastoma are at increased risk for radiation-induced sarcomas. Thus, current therapies are focused on avoiding external beam irradiation when possible. If local extension has occurred, the field must be enlarged to include the orbit or a craniospinal field for meningeal or brain involvement (Donaldson and Smith, 1989). In addition, systemic chemotherapy may be

used, as there have been some reports of success with this modality (Schouten-van Meeteren et al, 2002).

Small tumors confined to the retina often can be controlled with cryotherapy and photocoagulation. Because of the late effects of radiation on bone growth and the potential for second tumor induction, aggressive cryotherapy and laser therapy are preferable when possible. Use of chemotherapeutic regimens including agents such as vincristine, doxorubicin, cyclophosphamide, cisplatin, and etoposide have achieved responses and may be indicated in patients with advanced local disease before enucleation or disseminated disease. Thus far, no advantage has been demonstrated for the use of chemotherapy as adjuvant treatment given in addition to radiation therapy or enucleation.

### Prognosis

The prognosis for children with unilateral retinoblastoma is excellent, with cure rates of 85% to 90% obtained using conservative local treatment. However, patients with bilateral disease have a much lower long-term survival rate, not because of the retinoblastoma but because of a high predisposition to second malignancy, which may occur at any point in the lifespan. Although patients with hereditary disease are most susceptible to sarcomas in the radiation field, they are at increased risk of sarcomas in other regions. Local extension also confers a poor prognosis, with survival rates of less than 10% with orbital extension or distant dissemination.

## Central Nervous System Tumors

### Incidence and Epidemiology

CNS malignancies are rare in newborns and comprise approximately 13% of infant cancers overall (Gurney et al, 1997). Most of the brain tumors that occur in infants are supratentorial. Half of the CNS malignancies are gliomas, including astrocytomas, which occur at an incidence rate of 15 cases per 1 million infants. Primitive neuroectodermal tumors (PNETs) and medulloblastomas occur at an incidence rate of 9 cases per 1 million infants, followed by ependymomas, which occur at a rate of 5/1 million. In general, infants with CNS malignancies tend to do more poorly than older children. Infants with PNET or ependymoma have particularly poor prognoses. Atypical teratoid or rhabdoid tumor of the CNS occurs rarely but is associated with a high mortality rate (Packer et al, 2002). Although reasons for the poorer outcome are not completely clear, it probably is due to a combination of tumor biology and treatment delivered. Infants are much more susceptible to the side effects of radiation therapy, and the lower radiation doses used to avoid devastating late effects may result in inferior cure rates.

### Clinical Manifestations

Infants who have CNS malignancies often present with signs and symptoms of increased intracranial pressure (ICP) not apparent in older children or adults, such as a bulging fontanelle, split sutures, or rapidly enlarging head size. Poor feeding, vomiting, lethargy, and irritability also can be symptoms of increased ICP. Funduscopic examination may or may not show papilledema. Loss of developmental milestones also can be seen. Specific neurologic abnormalities

include Parinaud syndrome (in infants, manifested by impaired upward gaze secondary to increased pressure in the dorsal midbrain), abnormalities related to cranial nerve palsies (i.e., esotropia/exotropia, cranial nerve VI palsy resulting in the inability to abduct the affected eye, or a cranial nerve IV palsy resulting in deviation of the affected eye upward and laterally), and nystagmus. Another common manifestation of CNS malignancies is head tilting secondary to cervical root irritation from posterior cerebellar masses. The *diencephalic syndrome*, which consists of the clinical triad of emesis, emaciation, and euphoria, describes the rare presentation of a hypothalamic lesion that can be seen in older infants. Such infants often present with chronic vomiting and failure to thrive but on clinical examination appear curiously well muscled despite the lack of subcutaneous fat and are extraordinarily good-natured.

### Treatment

The optimal therapy continues to be surgical resection of the tumor, when possible. However, several factors must be taken into consideration in the approach to an infant with a CNS lesion. First, these tumors tend to be highly malignant and invasive, leading to difficulties with resection. Second, these tumors also tend to be highly vascular, making it challenging to remove the tissue with minimal morbidity. Finally, infants tend to present with large tumors, which can also interfere with the resection.

Radiation therapy is a backbone of the treatment given to older children with malignant brain tumors. Infants are highly susceptible to the late effects of radiation therapy, however. They can sustain severe cognitive deficits in addition to growth impairment as a result of craniospinal irradiation. Recent treatment protocols have focused on minimizing the early exposure to high doses of radiation therapy by maximizing effective chemotherapy, when possible. Developments in the subspecialty of radiation oncology have made it possible to deliver more focused radiation, which may help minimize the morbidity that infants may experience. Taken together, all of these factors should alert the clinician to the need for referral of such patients to a center specializing in pediatric care, including a team composed of a pediatric radiation oncologist, a neuro-oncologist, and a pediatric neurosurgeon.

## Sarcomas

Soft tissue sarcomas are rarely seen in newborns; only 13 of 3217 infants and children diagnosed with rhabdomyosarcoma (RMS) were younger than 30 days of age at diagnosis (Lobe et al, 1994). The most commonly diagnosed soft tissue sarcoma in the neonatal age group is infantile or congenital fibrosarcoma, which is diagnosed in all infants between 1 and 12 months at a rate of 5/1 million (Ries et al, 1999). In general, the standard of care for treating infantile fibrosarcoma is complete surgical excision, although neoadjuvant chemotherapy with a variety of agents has been successfully used for tumor shrinkage, with subsequent reduction in the morbidity related to radical surgical procedures. The cure rates for infantile fibrosarcoma, with surgery alone or with chemotherapy and surgery, approach 100% (Kurkchubasche et al, 2000; Loh et al, 2002; Singh et al, 1995).

The initial evaluation of a patient with a congenital fibrosarcoma includes imaging of the primary tumor with either an MRI or a CT study and a chest CT scan. Chemotherapy regimens used successfully for treatment of this tumor include vincristine, actinomycin D, and lower dose cyclophosphamide, as well as etoposide (VP-16) and ifosfamide (Kurkchubasche et al, 2000; Kynaston et al, 1993; Loh et al, 2002; Ninane et al, 1991; Sheng et al, 2001). Doxorubicin, while efficacious, is generally avoided because of the late cardiotoxicity risk. Duration of therapy depends on the size, location, and response of the tumor, but the general goal is to reduce the tumor size to maximize chances of surgical local control. Radiation therapy has been traditionally avoided to spare the infant the associated late effects of poor growth and secondary cancers.

### Histiocytosis

*Histiocytosis* refers to any of a diverse group of poorly understood disorders of abnormal histiocytes in which the cells are derived from the monophagocytic pathway. They occur rarely in neonates. They have been categorized by the Histiocyte Society, an international group, into three classes (Table 95–11). Class I disorders include Langerhans cell histiocytosis (LCH) (formerly known variously as histiocytosis X, Letterer-Siwe disease, Hand-Schüller-Christian disease, and eosinophilic granuloma), and pure cutaneous histiocytosis. The class II disorders include familial erythrophagocytic lymphohistiocytosis and infection-associated hemophagocytic syndrome. The class III disorders are truly malignant disorders of mononuclear phagocytes, including acute monocytic leukemia, malignant histiocytosis, and histiocytic lymphoma. In addition to these three classes, other rare, noncategorized histiocytoses can occur in newborns, in particular, juvenile xanthogranuloma and Omenn disease.

It is postulated that an immunologic stimulus to a normal antigen-processing cell, the Langerhans cell, results in uncontrolled proliferation in class I disorders. The lesions are granulomatous in nature, with infiltration of Langerhans cells with cleaved nuclei and eosinophils. Birbeck granules are seen by electron microscopy, and cell surface antigens include S-100 and CD1a. Multinucleate giant cells are sometimes seen. Class II disorders are believed to represent a secondary histiocytic reaction to an unknown antigenic stimulation or infectious agent, with erythrophagocytosis possibly reflecting foreign antigens adsorbed on erythrocytes or activation of macrophages by excess lymphokine production because of abnormal immunoregulation. The class II lesions are characterized by morphologically normal reactive macrophages without Birbeck granules and with prominent erythrophagocytes, and the process involves the entire reticuloendothelial system. The infiltrates are mixed lymphohistiocytic, unlike in class I disease, in which either mixed histiocytic-eosinophilic or pure histiocytic infiltrates are seen.

#### Class I Disorders

The class I disorders are often classified by the site and/or number of organs involved. In particular, LCH confined to bone is called *eosinophilic granuloma*. This lesion often

can be completely ablated with surgical curettage alone or with low-dose radiation (Titgemeyer et al, 2001). However, mono-ostotic LCH in young infants frequently is associated with the appearance of subsequent bone lesions that require chemotherapy with vinblastine and prednisone (Ladisch and Gardner, 1994). Polyostotic LCH can become a chronic disease requiring years of low-dose therapy until it “burns” itself out. In particular, LCH manifesting with diabetes insipidus secondary to pituitary involvement, bone lesions, and exophthalmos (retro-orbital granulomas) formerly was called *Hand-Schüller-Christian disease*.

Disseminated LCH involving skin, hepatosplenomegaly, and lymphadenopathy formerly was called *Letterer-Siwe disease*. The peak incidence is at 6 months of life (Isaacs, 1997), and additional organs, including the bone marrow, lung, and gastrointestinal tract, may be involved. Prognosis is poor for infants who present with disseminated disease (Gardner et al, 1994). The skin involvement of infants with histiocytosis can be mistaken for common conditions such as seborrhea or eczema, particularly in the groin, on the scalp, or over posterior auricles. In addition, chronically draining ears and/or swollen gums with overlying whitish nodules can indicate disease. CNS involvement, while rare, also can occur, either in the sella turcica, causing diabetes insipidus, or in the cerebellar vermis, causing ataxia.

Although LCH appears to respond to low-dose radiation and to many chemotherapeutic agents including vincristine, vinblastine, prednisone, 6-mercaptopurine, chlorambucil, methotrexate, and cyclophosphamide, investigators have been unable to show any definitive improvement in cure rates using these modalities. Other agents reported to show efficacy include cladribine and cyclosporine. To optimize therapy, the Histiocyte Society has conducted international randomized trials of therapies for LCH since 1994 (Henter et al, 1997). However, novel approaches are still needed to improve the outcomes in the very young infants with widely disseminated disease.

#### Class II Disorders

The class II disorders are non-Langerhans cell histiocytoses in which the histiocytic proliferation is stimulated by different pathogenetic mechanisms. Familial erythrophagocytic lymphohistiocytosis (FHL) is a rare and almost always fatal disease of infants and young children. Definitive diagnosis may be preceded by a positive family history, but the inheritance pattern is autosomal recessive, making this an unreliable marker. Patients present with fever, wasting, hepatosplenomegaly, and progressive pancytopenia (Table 95–12). CNS symptoms with seizures, disorientation, and coma with elevated cerebrospinal fluid protein levels and pleocytosis are common. Biopsy specimens of lesions found in the liver, spleen, lymph nodes, lungs, or bone marrow can show erythrophagocytosis and a lymphohistiocytic infiltrate. The disease usually has a fulminant downhill course, but the advent of bone marrow transplantation in recent years has resulted in an estimated 5-year survival rate of 66%, compared with 10% with chemotherapy alone (Arico et al, 1996). Thirty percent of patients with FHL have been reported to harbor mutations in the perforin gene, which encodes an essential protein for cellular immune activation (Stepp et al, 1999).

**TABLE 95-11**

**Classification of Childhood Histiocytoses**

<b>Feature</b>	<b>Class I</b>	<b>Class II</b>	<b>Class III</b>
Diseases included	Langerhans cell histiocytosis	IAHS; FEL; grouped together as the hemophagocytic lymphohistiocytoses (HLHs)	Malignant histiocytosis; acute monocytic leukemia; true histiocytic lymphoma
Cellular characteristics	Langerhans cells with cleaved nuclei and Birbeck granules seen by electron microscopy; cell surface antigens include S100 and CD1a; cells mixed with varying proportions of eosinophils; multinucleated giant cells sometimes seen	Morphologically normal, reactive macrophages with prominent erythrophagocytosis; process involves entire reticuloendothelial system	Neoplastic cellular proliferation of cells exhibiting characteristics of macrophages or dendritic cells or their precursors; localized or systemic
Proposed pathophysiologic mechanisms	Immunologic stimulation of a normal antigen-presenting cell—the Langerhans cell—in an uncontrolled manner	Histiocytic reaction secondary to an unknown antigenic stimulation (FEL) or to an infectious agent (IAHS), with erythrophagocytosis possibly reflecting foreign antigens absorbed on erythrocytes or activation of macrophages by excess lymphokine production due to abnormal immunoregulation	Neoplasm; clonal autonomous uncontrolled proliferative process

FEL, familial erythrophagocytic lymphohistiocytosis; IAHS, infection-associated hemophagocytic syndrome.

Note: Previously known as histiocytosis X and its related syndromes of eosinophilic granuloma, Hand-Schüller-Christian disease, and Letterer-Siwe disease.

TABLE 95-12

**Clinical and Laboratory Findings in the Hemophagocytic Lymphohistiocytoses**

Required for Diagnosis*	Consistent with Diagnosis
<b>Clinical</b> Fever Splenomegaly  <b>Laboratory</b> Cytopenias (affecting $\geq 2$ of 3 lineages in the peripheral blood and not caused by a hypocellular or dysplastic bone marrow): Hemoglobin ( $< 9.0$ g/dL) Neutrophils ( $< 1.0 \times 10^9/L$ ) Hypertriglyceridemia or hypofibrinogenemia (fasting triglycerides $\geq 2.0$ mmol/L or $\geq 3SD$ of the normal value for age, fibrinogen $\leq 1.5$ g/L or $\leq 3SD$ ) Histopathologic criteria: Hemophagocytosis in bone marrow or spleen or lymph nodes; no evidence of malignancy	<b>Clinical</b> Jaundice Edema Lymphadenopathy  <b>Laboratory</b> ↑ Circulating soluble interleukin-2 receptors  Hepatic enzyme abnormalities ↑ Very-low-density lipoprotein ↓ High-density lipoprotein ↓ Natural killer cell activity

\*All are required for the diagnosis of hemophagocytic lymphohistiocytosis [infection-associated hemophagocytic syndrome or familial erthrophagocytic lymphohistiocytosis (FEL)]; in addition, the diagnosis of FEL is justified by a positive family history, and parental consanguinity is suggestive.

Data from Henter J-I, Elinder G, Ost A: Diagnostic guidelines for hemophagocytic lymphohistiocytosis. *Semin Oncol* 18:29, 1991.

Patients with infection-associated hemophagocytic syndrome (IAHS) can present with clinical features similar to those of FHL. Involvement of the bone marrow is typical, with marked erythrophagocytosis involving normal-appearing histiocytes engulfing red blood cells and platelets. The condition usually is activated in the setting of an immunodeficiency, whether it is secondary to an infection (viral, bacterial, fungal, and parasitic infections all have been reported), malignancy, or immunosuppressive medications. In general, treatment centers on reducing the immunosuppression, through either stopping immunosuppressive drugs or treating the inciting infection. Low-dose etoposide has been used with some success, but many investigators advocate watchful waiting and supportive care.

### Class III Disorders

True malignant histiocytosis has been reported occasionally in newborns (Ishii et al, 1998). Acute monocytic leukemia has been classified as a class III histiocytosis but is discussed elsewhere in this chapter. True malignant histiocytosis is characterized clinically by symptoms similar to those of FEL, with fever, hepatosplenomegaly, lymphadenopathy, and pancytopenia. However, the family history is negative, and pathologic examination shows malignant cells with large nuclei and prominent nucleoli that have histochemical features of histiocytes. Erythrophagocytosis may be present but less prominent than in FEL. The disease is more responsive to chemotherapy regimens containing cyclophosphamide, prednisone, doxorubicin, vincristine, etoposide, and cytarabine.

### Hepatoblastoma

Primary malignant tumors of the liver are uncommon in infants and children. The most common malignant neoplasm involving the liver in infancy is metastatic neuroblastoma. Although rare, the most common benign hepatic neoplasms in the neonate are mesenchymal hamartomas and hemangiomas. The two major histologic types of primary malignant hepatic tumors are hepatoblastoma and hepatocellular carcinoma. Hepatoblastomas usually occur in infants and are rarely seen after 3 years of age. In an older series of 129 infants and children with hepatoblastoma, only 11 were younger than 6 weeks of age (Exelby et al, 1975). Hepatocellular carcinomas appear to have a bimodal age distribution, occurring either in children younger than 4 years or in patients between the ages of 12 and 15 years. Both types of tumors occur more commonly in males. Hepatoblastoma occurs in association with BWS and its variants. Hemihypertrophy occurs in 2% of hepatoblastoma patients. In addition, there is a strong association between prematurity and the development of hepatoblastoma (Ross and Gurney, 1998). Recent analysis of data for 105 children with hepatoblastoma reveals a 15-fold increase in the expected rate for the development of this tumor in patients with birth weights of less than 1000 g (Feusner and Plaschkes, 2002).

Chromosome abnormalities in tumor tissue include loss of heterozygosity at 11p15.5, the Beckwith-Wiedemann locus, and, in non-BWS patients, 1(8q) and trisomy 20. There is also an increased risk of hepatoblastoma in familial adenomatous polyposis coli; the genetic abnormality in this disorder maps to chromosome 5q (Phillips et al, 1989).

The most common presenting manifestations of hepatic tumors are an upper abdominal mass and an enlarging abdomen. Anorexia, weight loss, and pain also are frequent findings. Laboratory studies of liver function are rarely helpful in establishing the diagnosis, and results of such tests usually are normal. AFP often is present in the serum of children with hepatic malignancy.

Hepatic calcification is demonstrated in 10% of cases on plain abdominal roentgenogram. Ultrasonography is useful to distinguish cystic and solid masses from a diffusely enlarged liver. CT shows the extent of tumor involvement, anatomic landmarks, and operability, whereas MRI most accurately shows adenopathy, tumor margins, and vessel involvement. The goal of therapy is to surgically resect the tumor. If one lobe is free of malignancy and there is no evidence of distant metastases, a lobectomy of the involved portion of the liver should be performed. Even though 60% of children with stage I, fully resected tumors are cured of their disease with surgery alone, chemotherapy after complete resection has resulted in an increase in long-term survival rates (96%) in one series (Fuchs et al, 2002). For those children who present with unresectable but nonmetastatic tumors, initial chemotherapy is used to shrink the tumor for resection. Orthotopic liver transplant is curative in those patients with unresectable, nonmetastatic hepatoblastomas.

## TREATMENT CONSIDERATIONS IN INFANTS

### Chemotherapy Dosing

Age-related differences in body composition, drug bioavailability, and drug metabolism have been identified for neonates, infants, children, and adults. Total body water content is higher in neonates (75%) than in adults (55%) (Friis-Hansen, 1971). Extracellular water decreases from 45% in the newborn to 20% in the adult. In addition, many drugs bind less well to circulating serum proteins in the neonate, leading to potentially greater amounts of active drug (Stewart and Hampton, 1987). Also, there is decreased activity of drug-metabolizing enzymes in the newborn period, particularly of the P-450 enzymes (Pelkonen et al, 1973). Finally, kidney function in newborns is less efficient. Taken together, it is plausible that standard doses of chemotherapy tolerated by older children and adults would be toxic to young infants. Unfortunately, available pharmacokinetic data are very limited for educated dosing in infants. Various formulas for dosing infants have been used; most commonly, in infants with body surface areas of less than 0.6 m<sup>2</sup>, doses per kg are used. However, no one dosing rule is universally applicable in view of the aforementioned variations, juxtaposed against the background of rapid growth and development in this age group (McLeod et al, 1992).

Infants have been shown to experience excessive neurotoxicity from vincristine, with the development of hypotonia, a poor cry, inability to feed, and flaccid paralysis (Reaman et al, 1985). As discussed earlier, infants who received standard doses of actinomycin D, vincristine, and cyclophosphamide (Cytoxan) in early clinical trials for Wilms tumor had a higher rate of hepatotoxicity until the doses were lowered, with no decrease in efficacy observed (Morgan et al, 1988). However, an interesting observation made by Bleyer and colleagues (1977) was that the volume of the

CNS in relation to body surface area is much greater in young children than in adults. In fact, current dosing of intrathecal chemotherapy is based on age rather than size, in order to avoid the underdosage of young children with ALL or AML.

### Radiation Effects

The use of radiation therapy in newborn infants is reserved for acute life-threatening situations in which the potential for adverse late effects of radiation, including growth impairment, cognitive impairment, and risk of secondary malignancies, is clearly outweighed by the benefits. The general principle is to use as little radiation as possible to spare the infant potentially morbid side effects.

### Supportive Care

Appropriate supportive care for infants with cancer is paramount. The most important principle in the treatment of cancer in infants is to anticipate problems, so as to prevent rather than treat complications.

### Pain Management

Recent literature demonstrates that infants can experience pain and should be treated appropriately with adequate pain medication (Rouzan, 2001). Signs of pain in the neonate can be subtle and include crying, grimacing, tachycardia, high blood pressure, and poor feeding. Nonsteroidal anti-inflammatory medications are traditionally avoided in patients with cancer because of the risks of interfering with platelet function. In addition, acetaminophen (Tylenol) must be used judiciously in immunocompromised patients to prevent masking a fever that could signify an infection, particularly if a central line is in place or if the white blood cell count is low. Narcotics should be used as needed, with appreciation of the possibility of oversedation or respiratory depression. Parents may express apprehension at the use of narcotics for fear of later addiction, but they should be reassured that addiction is a psychological dependence and unlikely to occur. Patients receiving narcotics for more than 1 week are known to become physically dependent on these drugs, which should be tapered slowly to avoid symptoms of withdrawal.

### Nutrition

Adequate nutrition should be provided to patients, either with oral feedings or via parenteral nutrition by intravenous line. It is easy to lose track of the time during which the infant is without adequate nutrition in the diagnostic workup for the cancer, given the tests, scans, and procedures that must be done with anesthesia. Breast-feeding generally provides optimal nutrition; however, cases of CMV infection have been transmitted from CMV-positive mothers through breast milk to preterm infants and should be recommended for infants with cancer on an individual basis (Hamprecht et al, 2001).

### **Intravenous Access**

In most cases, it is prudent to place a central venous catheter in a young infant who will need frequent chemotherapy, blood or platelet transfusions, or parenteral nutrition. Some of the chemotherapy drugs used are vesicants and can cause severe burns if infiltrated underneath the skin. Central lines can have single or double lumens, although the size of the baby may affect the type of line placed. In general, it is best to discuss placing a central line with the oncologist, who can better predict the course of therapy. For older infants with more subcutaneous chest wall fat, implantable devices can be placed, which will minimize daily care.

### **Transfusions**

Any infant suspected of having a malignancy that may require chemotherapy should receive only CMV-negative and irradiated blood products. In addition, the use of leukocyte-depleted products is recommended to minimize future febrile or allergic reactions. A primary CMV infection in an immunocompromised host can be life-threatening. Most blood banks have a policy of transfusing all neonates with CMV-negative blood. Irradiation is also critical to inactivate the donor white blood cells, which, if given unirradiated, could result in an overwhelming graft-versus-host reaction. Donor-designated blood generally is discouraged in infants with congenital leukemia, given the possibility of future bone marrow transplantation.

### **Immunizations**

Immunizations generally are avoided until the patient has been off chemotherapy for at least 6 months. In addition, all close contacts of the patient should receive the inactivated polio vaccine rather than the live oral polio vaccine. There is no contraindication to immunizing first-degree relatives with the varicella vaccine. However, any person in whom a rash develops after the vaccination should be sequestered from the patient.

### **Psychosocial Considerations**

Adequate social services and psychological support are critical for families with a sick neonate. In particular, special services are available for families of children with cancer and should be made available as soon as a diagnosis is made. Management of an infant with cancer is best achieved through the efforts of a multidisciplinary team composed of special nurses and social workers in addition to the pediatric oncologist.

### **Late Effects**

Infants who receive treatment for cancer during the first year of life are at risk for many late effects directly related to chemotherapy, surgery, and radiation therapy, in addition to the psychosocial late effects stemming from their diagnosis. These infants require follow-up evaluations at

routine intervals by a pediatric oncologist, who can help identify appropriate screening tests.

# DERMATOLOGIC CONDITIONS

Editor: CHRISTINE A. GLEASON

## CHAPTER 96

### Newborn Skin: Development and Basic Concepts\*

Bernard A. Cohen and Elaine C. Siegfried

#### SKIN DEVELOPMENT

Skin is the interface between an organism and its environment. It plays an important role in fluid balance and temperature regulation and provides a barrier against invading microbes and systemic absorption of topically applied agents. This chapter provides an overview of skin development. Emphasis has been placed on factors that influence the clinical management of premature infants and the prenatal diagnosis of heritable skin diseases.

The study of skin ontogenesis has been organized primarily on the basis of the development of individual components: epidermis, basement membrane zone, dermis, immigrant cells, and appendageal structures. However, the initiation, differentiation, and growth of all of its components are intimately related. Prenatal skin biopsy for early diagnosis of severe genodermatoses is a useful procedure that depends on precise knowledge of the details of skin development. Disorders of keratinization, basement membrane integrity, melanocytes, and epidermal appendages have been detected as early as 16 weeks of gestation using this technique. In turn, fetal skin biopsy has helped to further clarify the details of epidermal development (Holbrook, 1991; Holbrook et al, 1993). Recent discoveries of genetic markers for a number of genodermatoses have also allowed for rapid precise prenatal and neonatal diagnoses and added to the understanding of molecular mechanisms of disease.

#### Epidermis

The epidermis consists of ectodermally derived, stratified squamous cells with localized proliferations that form the

appendages: hair follicles, sebaceous glands, eccrine sweat glands, apocrine glands, and the nail matrix. Melanocytes immigrate into the epidermis from the neural crest, and Langerhans cells immigrate from mesoderm. The epidermis forms initially as a single layer of “indifferent ectoderm” and then differentiates into two layers of epidermal cells by 6 weeks. The outermost layer, called periderm, covers the basal layer stem cells. During the next 2 weeks, the basal cells give rise to an intermediate layer beneath the periderm. By 8 weeks, epithelial cells are capable of expressing keratins, the major cytoskeletal proteins of the epidermis. K5 and K14 are the high-molecular-weight keratins expressed primarily by basal-layer cells, whereas intermediate-layer cells express K1 and K10 (Smack et al, 1994). Genetic abnormalities of these cytoskeletal components give rise to a spectrum of inherited scaling skin diseases that can now be diagnosed by detection of specific genetic mutations and characteristic features on histologic examination and electron microscopy of skin specimens obtained by fetal skin biopsy, amniocentesis, and chorionic villus biopsy. The third month of gestation is an important period in skin development. Differentiation of the epidermis begins as two or three more layers of “intermediate cells” are added between the basal cells and periderm, while coordinated maturation progresses within other strata of the skin. By 22 to 24 weeks, granular cells have formed beneath the periderm. Granular cells are named for their prominent organelles, the keratohyalin granules. These granules contain a high-molecular-weight protein called profillagrin, which plays a crucial role in terminal differentiation of keratinocytes in the stratum corneum. Cornified cells first appear within the pilosebaceous follicle as early as 15 weeks. Interfollicular keratinization follows at 24 to 26 weeks of gestation. At 28 weeks the stratum corneum consists of two or three cell layers. By 32 weeks there are more than 15 layers of corneocytes, equivalent to those in adult skin (Holbrook, 1991).

#### Basement Membrane Zone

Components of the basement membrane zone appear with the first epidermal cells at 35 days of gestation. Important components of the dermoepidermal junction, such as hemidesmosomes, anchoring filaments, and anchoring fibrils, are completely formed by 8 to 10 weeks. The epidermis and basement membrane generally are flat during fetal development. The undulating rete ridges that expand the surface area of the dermoepidermal junction do not appear until the third trimester and are not fully

\*This chapter includes material from the previous edition, to which Nancy B. Esterly, MD, contributed.

developed until 6 months after birth, coincident with accumulation of dermal matrix (Holbrook, 1991).

### Dermis

A network of stellate mesodermal cells is present beneath the epidermis of a 1- to 2-month embryo. The primary matrix secreted by these cells is composed of glycosaminoglycans (GAGs). Hyaluronic acid is the predominant GAG during the first trimester. Matrix proteins also are synthesized in the first trimester, including immature fibers resembling elastin and collagen types I, III, V, and VI. Type III and type V collagen are increased in quantity compared with adult dermis. In the third month, the dermis is transformed from a cellular to a fibrous tissue, coincident with epidermal differentiation. During months 3 to 5, the size and quantity of the matrix proteins increase, and the composition of GAGs changes. Immigrant cells, including Schwann cells, Merkel cells, melanoblasts, pericytes, and mast cells, are found in the dermis by the fifth month. The dermis continues to mature for approximately 6 months postnatally (Holbrook, 1991).

Human fetal skin wounds reportedly heal without scarring. This clinical observation, first made by surgeons pioneering antenatal diagnosis and treatment, has been followed by an explosion of experimental data elucidating the unique aspects of fetal wound healing (Dostal and Gamelli, 1993; Longaker and Adzick, 1991; Mast et al, 1992). Wound healing in the fetus differs from that in the adult in several ways, including nature of tissue environment, inflammatory response, and components of the dermal extracellular matrix (Table 96-1). Wounds can cause scars in some human infants (Cartledge et al, 1990; Den Ouden et al, 1986), but prospective examination of sternotomy scars (Lista and Thompson, 1988) and bacille Calmette-Guérin (BCG) vaccination sites (Sivarajah et al, 1990) in

children found a direct correlation between increasing age and more prominent scarring.

### Immigrant Cells

Melanocytes from the neural crest and mesenchymally derived Langerhans cells migrate to the epidermis by week 8 but do not develop their characteristic organelles until after 65 days of estimated gestational age (EGA). Melanin production and transfer to adjacent keratinocytes occur during the fourth to the fifth month, but melanin production is relatively low, even at birth. The antigen-presenting function of Langerhans cells has not been documented in utero (Holbrook, 1991).

### Epidermal Appendages

Primordia of hair follicles, apocrine glands, eccrine sweat glands, and nails first appear at 10 to 12 weeks of estimated gestational age (EGA). The pilosebaceous unit is formed, hair is keratinized, and sebum is synthesized as early as 16 to 18 weeks. Sebum production and secretion are greatly increased in the third trimester under the influence of fetal and maternal androgens. The number of lipid-filled sebocytes in amniotic fluid has been used to assess fetal maturity. Sebaceous lipids, squalane, and wax esters constitute most of the vernix caseosa, especially in male infants. The vernix of female infants has a slightly higher proportion of cholesterol and cholesterol esters, lipids derived from keratinocytes (Holbrook, 1991; Nazzaro-Porro et al, 1979). Apocrine gland formation follows that of the sebaceous glands by 8 weeks. Apocrine secretion has been detected during the third trimester but not in the neonatal period. The palmoplantar eccrine sweat ducts are the first portion of the apparatus to develop. By 22 weeks of EGA, they open to the skin surface and join the differentiated secretory cells of the eccrine sweat gland. Maturation of the eccrine apparatus elsewhere on the body follows at 24 to 26 weeks. Neither the morphology of the glandular coil cells nor eccrine gland function is fully developed in the premature infant, but the full complement of the sweat glands and hair follicles is completely formed in utero, making them more densely distributed in infant than in adult skin. However, even in the full-term infant, thermal stress-induced sweating requires a greater stimulus than is needed to induce sweating in older children and adults. This functional response to heat improves with postnatal age (Green and Behrendt, 1973; Harpin and Rutter, 1982). Nail primordia begin to form at 8 to 10 weeks. Nail plate formation is initiated at 17 weeks and is complete by the fifth month (Holbrook, 1991).

**TABLE 96-1**

#### Comparison of Fetal and Adult Wound Repair

Variable	Fetus (<24 wk)	Adult
Tissue environment	Amniotic fluid rich in growth factors and hyaluronic acid	Air
Inflammatory infiltrate	Relative hypoxemia Sterile Limited neutrophils and lymphocytes predominate	Macrophages predominate
Extracellular matrix	Nonexcessive deposition of Types III and V collagen organized into a reticular pattern Increased amount of hyaluronic acid	Abundant Type I collagen deposited into disorganized bundles

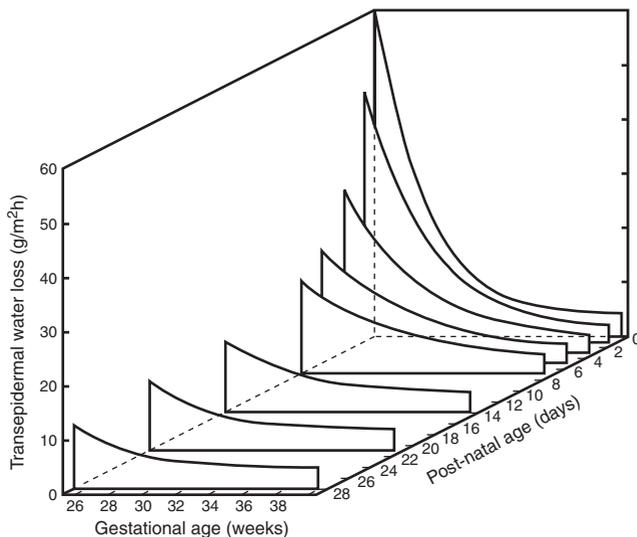

### NEWBORN SKIN

The most clinically significant difference between the skin of premature and term infants is in the structure of the stratum corneum. Infants born before 32 weeks of gestation have a very thin stratum corneum, which gives rise to a variety of problems (Rutter, 1988). The primary functions of the stratum corneum are conservation of body

water and barrier protection. A premature stratum corneum does not effectively prevent transepidermal water loss, percutaneous absorption of exogenously applied compounds, or invasion of microbes. In the dry postnatal environment, the premature infant experiences excessive losses of body fluid and heat (Baumgart, 1982; Rutter and Hull, 1979). A variety of seemingly benign clinical interventions can dramatically increase these losses. Desiccated skin is even more easily injured, providing a portal of entry for invading microbes and increasing the risk of disseminated infection (Baumgart, 1982; Gunnar et al, 1985; Harper and Rutter, 1983; Rosen et al, 1995; Rutter, 1988). A premature infant's increased ratio of body surface area to body weight, diminished metabolic capacity, and decreased immune responses compound these problems.

Rates of transepidermal water loss (TEWL) are objective measures of stratum corneum integrity. TEWL has been well studied in premature infants, using the evaporimeter, a device that provides direct measurements (Gunnar et al, 1985). During the first 4 weeks after birth, there is an exponential relationship between TEWL and gestational age in appropriate-for-gestational-age (AGA) infants. TEWL is up to 15 times higher in 1-day-old infants born at 25 weeks of gestation than in term neonates. In very low-birth-weight (VLBW) infants, this can translate into a fluid loss of up to 30% of total body weight in 24 hours. As the stratum corneum develops, TEWL gradually decreases, but at 4 weeks postgestation, TEWL from an infant born at 26 weeks is still twice that of a term infant (Fig. 96-1).

Loss of body water is accompanied by evaporative heat loss at a rate of  $2.4 \times 10^3$  J/g (or 576 calories of body heat for every milliliter of water) (Hammarlund and Sedin, 1982; Smack et al, 1994). Evaporative losses are greatest in younger, more premature infants. Routine clinical interventions can exacerbate TEWL. Maintenance on an open

**FIGURE 96-1.** Transepidermal water loss in relation to gestational age at different postnatal ages in appropriate-for-gestational-age infants. (From Hammarlund K, Sedin G, Stromberg B: *Transepidermal water loss in newborn infants: VIII. Relation to gestational age and postnatal age in appropriate and small for gestational age infants. Acta Paediatr Scand* 72:721, 1983.)

radiant warmer bed in a nursery with low ambient humidity results in high evaporative loss of body water and heat (LeBlanc, 1991). Higher ambient temperatures are required to maintain normal body temperature under these conditions (Hammarlund and Sedin, 1982).

Traditional efforts to minimize these losses have centered on intravascular fluid replacement and modification of the infant's hospital bed. These approaches have inherent problems. Evaporative losses originate as free water from the extracellular compartment. Replacement has been conventionally determined by calculation based on standardized maintenance fluid requirements and measured changes of body weight and extracellular electrolytes, which have a typical lag time of several hours. Replacement fluids given in the form of isotonic intravenous solutions may result in sodium and glucose overload. Enclosed isolettes with high ambient humidity carry a risk of colonization with pathogenic bacteria, although an increased incidence of infection has not been documented (LeBlanc, 1991). Shielding devices used on open radiant warmer beds limit access to infants. Furthermore, some materials used for shielding (glass, Plexiglas, Lucite, Perspex) absorb infrared energy, blocking overhead transmission of heat to the infant (Baumgart, 1990; LeBlanc, 1991). Pure polyethylene plastic wraps (e.g., Glad Wrap) are transparent to infrared heat, but plastic wrap made of more complex polymers may retain heat and have the potential to burn contacted skin (LeBlanc, 1991). More recent data have focused on limiting skin injury and developing methods to improve the cutaneous barrier.

Clinically occult skin injury accompanies routine care. Skin stripping by removal of adhesive-backed products causes acute injury as well as the potential for secondary infection and significant scarring (Carlidge et al, 1990). Removal of a piece of tape or an adhesive-backed electrode will markedly compromise the stratum corneum (Carlidge and Rutter, 1987; Harper and Rutter, 1983), an observation that has been used in a positive way to facilitate transcutaneous monitoring of serum glucose in newborns (De Boer et al, 1994). We have observed several cases of full-thickness skin injuries from presumed innocuous local application of pressure or thermal heat (Fig. 96-2). The precise causes of this type of wound are often difficult

**FIGURE 96-2.** The cause of this full-thickness skin injury in a 26-week-old infant was innocuous enough to elude identification.

to identify and remain unreported. Ultraviolet light burns have occurred in association with white light phototherapy for jaundice, from relatively limited inadvertent exposure to near-ultraviolet A (UVA) light, which is 1000 times less erythemogenic than ultraviolet B (UVB) light (Siegfried et al, 1992). A Plexiglas safety shield, placed in front of daylight fluorescent bulbs, will filter out the UVA. However, white light phototherapy also is a source of infrared heat, and heat stress will exacerbate TEWL. In contrast, phototherapy delivered with blue light alone does not increase TEWL (Kjartansson et al, 1992).

Increased percutaneous absorption of topically applied compounds through an immature stratum corneum has been both advantageous and hazardous to neonates. A finding described in 1971 as “raccoon facies” is a visible periorbital ring of pallor from cutaneous vasoconstriction after the application of phenylephrine eyedrops (Rutter, 1987). This effect can be quantified and is directly proportional to measurements of TEWL. Both methods have been established as useful markers of stratum corneum integrity in infants (Plantin et al, 1992; Rutter, 1987). Transdermal delivery may be the optimal route of administration for theophylline (Cartwright et al, 1990; Rutter, 1987) and diamorphine (Barrett et al, 1993) in premature infants. Lidocaine applied topically to premature skin probably is much more effective than after application to mature skin

(Barrett and Rutter, 1994). Even supplemental oxygen has been administered percutaneously to very small preterm infants with poor pulmonary function (Cartledge and Rutter, 1988a, 1988b).

In contradistinction, numerous reports have described percutaneous toxicity in infants caused by absorption of topically applied agents (Lane, 1987; Rutter, 1987). Published accounts serve to document the most severe cases of toxicity, often manifested as nursery epidemics of obvious clinical signs or deaths (Table 96–2). The potential for subclinical toxicities must be considered by everyone caring for small newborns (Table 96–3). When several topical therapeutic options are available, the one with the least potential for toxicity should be used. *Poisindex* is an extensive, frequently updated, computer-based reference source for the identification of potentially toxic compounds (Micromedex, 2002). The information from this database and current published literature indicates a lower risk of percutaneous or systemic toxicity from chlorhexidine skin antiseptics than from povidone-iodine.

The important role of nutrition in skin maturation and wound healing can be overlooked in small, sick infants, who are maintained on varying amounts of complex parenteral fluids. Acquired deficiencies as well as those resulting from inborn errors of metabolism (Table 96–4) are associated with classic cutaneous findings. Deficiencies of

TABLE 96–2

## Reported Hazards of Percutaneous Absorption in the Newborn

Compound	Reference	Product	Toxicity
Aniline	Rutter, 1987	Dye used as a laundry marker	Methemoglobinemia,° death
Mercury	Dinehart et al, 1988	Diaper rinses; teething powders	Rash, hypotonia
Phenolic compounds: Pentachlorophenol	West et al, 1981	Laundry disinfectant	Tachycardia, sweating, hepatomegaly, metabolic acidosis, death
Hexachlorophene		Topical antiseptic (pHisoHex)	Vacuolar encephalopathy, death
Resorcinol	West et al, 1981	Topical antiseptic	Methemoglobinemia°
Boric acid	Goldbloom and Goldbloom, 1953	Baby powder	Vomiting, diarrhea, erythroderma, seizures, death
Lindane	Rutter, 1987; West et al, 1981	Scabicide	Neurotoxicity
Salicylic acid	Abidel-Magid and El Awad Ahmed, 1994; West et al, 1981	Keratolytic emollient	Metabolic acidosis, salicylism
Isopropyl alcohol (under occlusion)	Rutter, 1987	Topical antiseptic	Cutaneous hemorrhagic necrosis
Silver sulfadiazine	Payne et al, 1992	Topical antibiotic (Silvadene)	Kernicterus (sulfa component), argyria (silver component)
Urea	Anonymous, 1987	Keratolytic emollient (Carmol)	Uremia
Povidine-iodine	Rutter, 1987; West et al, 1981	Topical antiseptic (Betadine)	Hypothyroidism, goiter
Neomycin	Rutter, 1987	Topical antibiotic	Neural deafness
Corticosteroids	Rutter, 1987; West et al, 1981	Topical anti-inflammatory (Lotrisone)	Skin atrophy, adrenal suppression
Benzocaine	Gelman et al, 1996	Mucosal anesthetic (teething products)	Methemoglobinemia°
Prilocaine	Frayling et al, 1990; Reynolds, 1996	Epidermal anesthetic (Emla)	Methemoglobinemia°

°Heritable glucose-6-phosphate deficiencies are associated with an increased susceptibility to methemoglobinemia, as is coadministration of several drugs, including sulfonamides, acetaminophen, nitroprusside, phenobarbital, and phenytoin.

TABLE 96-3

**Topically Applied Products that Should Be Used with Caution in the Newborn**

Compound	Product	Concern
Triclosan	Lever 2000, liquid deodorant soaps	Risk of toxicities seen with other phenolic compounds
Propylene glycol (MacDonald et al, 1987)	Emollients, cleansing agents (Cetaphil lotion)	Excessive enteral and parenteral administration has caused hyperosmolality and seizures in infants
Benzethonium chloride	Skin cleansers	Poisoning by ingestion, carcinogenesis
Glycerin	Emollients, cleansing agents (Aquanil lotion)	Hyperosmolality, seizures
Ammonium lactate	Keratolytic emollient (Lac-Hydrin)	Possible lactic acidosis
Coal tar (van Shooten et al, 1994)	Shampoos, topical anti-inflammatory ointments	Excessive use of polycyclic aromatic hydrocarbons is associated with an increased risk of cancer

TABLE 96-4

**Metabolic and Nutritional Disorders Presenting with Dermatitis**

Disorder	Reference
Acrodermatitis enteropathica	Goskowics and Eichenfield, 1993
Biotin-dependent multiple carboxylase deficiency	Wolf and Heard, 1991
Prolidase deficiency	Bissonnette et al, 1993
Methylmalonic acidemia	Bodemer et al, 1994; de Raeve et al, 1994
Maple syrup urine disease	Giacoa and Berry, 1994
Propionic acidemia	Bodemar et al, 1994; de Raeve et al, 1994
Citrullinemia	Goldblum et al, 1986
Cystic fibrosis	Darmstadt et al, 1992
Gaucher's disease	Sherer et al 1993; Sidransky et al, 1992
Kwashiorkor	Goskowics and Eichenfield, 1993

protein, essential fatty acids, zinc, biotin, vitamins A and C, and several B vitamins are possible. Daily requirements for most of these nutrients are higher in premature than in term infants (Table 96-5).

Attention to skin integrity will help control translocation of water through the skin of premature neonates. Appropriate hydration of keratinocytes is essential for normal skin maturation (Rawlings et al, 1994), an optimized barrier against exogenous assault, and maintenance of thermal, fluid, and electrolyte balance. A successful basic skin care regimen should also allow easy access to and handling of infants. Therapeutic goals include minimizing postnatal trauma and providing an artificial barrier until the stratum corneum matures. Currently, there is no uniformly defined or accepted standard of care for the skin of premature infants. Formal clinical investigation has been limited. A few studies have verified the safety and efficacy of semiocclusive, adhesive-backed polyurethane

membrane barriers in preventing fluid losses (Barak et al, 1989; Knauth et al, 1989; Mancini et al, 1994; Vernon et al, 1990). However, these dressings are not widely used because they are difficult to apply and thought to limit available area for surface monitors. Neonatal intensive care unit (NICU) staff members often provide topical emollient therapy to infants in a random way. The risks and benefits of the use of commercially available topical emollients have not been well defined. Concerns include the risk of systemic absorption and resulting toxicity, overgrowth of microbes, and secondary heat accumulation that could increase surface and core temperature.

There have been many studies of the mechanism of action and benefits of emollients on injured and diseased skin in adults. Petroleum wax-based ointment emollients (e.g., Vaseline petroleum jelly) act primarily by decreasing TEWL and accelerating barrier recovery (Ghadially and Elias, 1992). Some oils, such as safflower oil, contain essential fatty acids, which greatly influence cutaneous structure and function (Schurer et al, 1991; Ziboh and Chapkin, 1987). However, topical application of safflower oil does not prevent essential fatty acid deficiencies in preterm infants (Lee et al, 1993). Oils, oil- and water-based creams, and lotion emollients have greater tactile acceptance than has been identified for greasy ointments. However, these preparations provide a less effective moisture barrier than is conferred by ointment emollients (Lane and Drost, 1993). In addition, formulation of a cream or lotion emulsion requires the addition of several potentially irritating or toxic ingredients. Eucerin Creme is an emollient that has been studied for use in the nursery (Lane and Drost, 1993). It contains water, petrolatum, mineral oil, ceresin, lanolin alcohol, and methylchloroisothiazolinone/methylisothiazolinone (CMI/MI). Although susceptibility of premature infants to allergic contact sensitization is unknown, CMI/MI has been associated with allergic contact sensitization in up to 10% of exposed adults (Frosch et al, 1994). Aquaphor ointment contains essentially two ingredients: petrolatum in ointment—liquid (mineral oil) and solid (mineral wax) phases—and wool wax alcohol. A recent study documented that application of Aquaphor every 12 hours reduced TEWL, improved skin integrity, did not alter skin flora, and was associated with a significant reduction of

TABLE 96-5

**Nutritional Requirements and Cutaneous Signs of Deficiency**

Nutrient	Infant's Daily Requirement		Cutaneous Signs
	Premature	Term	
Protein (g/kg/day)	2.7-3.0	2.5-2.7	"Flaky paint" scaling, hypopigmentation, peripheral edema
Linoleic acid (g/kg/day)	1.2	0.3-0.8	Alopecia, erythema with coarse scaling, erosive intertriginous dermatitis, poor wound healing
Zinc (μg/kg/day)	400	100	Alopecia, acral and periorificial erosive, pustular dermatitis, poor wound healing
Biotin (μg/kg/day)	6.0	5.0 (not >20)	Alopecia, intertriginous and periorificial dermatitis, generalized scaling
Vitamin C (mg/kg/day)	25	20 (not >80)	Perifollicular hemorrhages, poor wound healing, friable gums
Vitamin A (μg/kg/day)	500	175 (not >700)	Generalized scaling
Riboflavin (mg/kg/day)	0.15	0.35° (not >1.4)	Intertriginous and periorificial dermatitis, mucositis
Pyridoxine (mg/kg/day)	0.18	0.25° (not >1.0)	Intertriginous and periorificial dermatitis, mucositis
Niacin (mg/kg/day)	6.8	4.25° (not >17)	Mucositis, symmetrical hyperpigmented plaques at sun-exposed sites

\*For full-term infants, the recommended doses of some water-soluble vitamins are probably high because toxicity has not been reported.

Adapted from Greene HL, Hambridge KM, Schanler R, Tsang RC: Guidelines for the use of vitamins, trace elements, calcium, magnesium, and phosphorus in infants and children receiving total parenteral nutrition: Report of the Subcommittee on Pediatric Parenteral Nutrient Requirements from the Committee on Clinical Practice Issues of the American Society for Clinical Nutrition 1-3. *Am J Clin Nutr* 48:1324, 1988; © Am J Clin Nutr American Society for Clinical Nutrition; and (2) Miler SJ: Nutritional deficiency and the skin. *J Am Acad Dermatol* 21:1, 1989. Used with permission.

the incidence of sepsis. No adverse effects were reported (Nopper et al, 1994). Skin surface temperature was stable, and there was no evidence of hyperthermia or burns after application of the petroleum-based emollient used under infrared warmers, even in infants receiving concomitant white light phototherapy, confirming the results of a previous pilot study (Schwayder and Hetzel, 1989). These findings were also corroborated by Pabst and colleagues (1999) in their study of 19 infants between 26 and 30 weeks of gestational age.

Increased understanding of the mechanisms contributing to skin development may one day provide therapy to accelerate barrier maturation in very premature infants. Until that time, therapy should be directed toward providing a safe, temporary barrier and minimizing additional skin injury. Proposed recommendations for the care of premature skin are outlined in Table 96-6. A summary of dressing materials is outlined in Table 96-7.

### DIFFERENTIAL DIAGNOSIS BY CUTANEOUS MORPHOLOGY

Diagnosis of skin disease is based on recognition of definitive morphology of the cutaneous examination. Dermatologists are trained to interpret the important features, including color, shape, texture, and distribution, while ignoring unimportant or misleading features. Skin disease is often categorized into morphologic groups based on the most prominent primary lesion. Use of this classification scheme helps in formulating a differential diagnosis

and in directing further investigation. Important morphologic groups in neonatal dermatology are vesicles and pustules, erythroderma, collodion baby, nonblanching violaceous papules and plaques, vascular defects, pigmented lesions, and midline anomalies. Subsequent chapters in this section present more detailed information on specific disorders.

### Vesicles and Pustules

Many conditions cause blisters and pustules in the newborn. Vesicles are, by definition, small intra- or subepidermal pockets of clear fluid. If the lesions are large (greater than 1 cm in diameter), they are referred to as bullae. Pustules are filled with purulent fluid. Diseases in this category range from the totally innocuous and self-limited to the severe and life-threatening.

A directed history, including family history of blistering diseases, and physical examination, including examination of the placenta, can focus the differential diagnosis. Small lesions in an otherwise healthy infant usually suggest a purely cutaneous process. Bullae and widespread involvement should prompt a more aggressive workup.

The initial diagnostic workup should include the following:

- Fluid aspirate taken from an intact pustule for Gram stain, Wright stain, and fungal, viral, and bacterial cultures
- Potassium hydroxide (KOH) preparation (or calcofluor white immunofluorescence), of the blister roof

TABLE 96-6

**Proposed Guidelines for Basic Skin Care of the Newborn**

1. *Use adhesives sparingly.*  
Place protective dressing (e.g., DuoDerm or Tegaderm) at sites of frequent taping (endotracheal tube and nasogastric tube placement).  
Use nonadhesive electrodes, and change them only when they become nonfunctional (Carlidge and Rutter, 1987).
2. *Limit bathing.*  
Defer initial cleansing until body temperature has stabilized.  
Avoid cleansing agents for the first 2 weeks.  
Use warm water and moistened cotton pledgets in a humid environment.  
Surface cleansing is required no more than twice a week.  
If antimicrobial skin preparation is required, use short-contact chlorhexidine (except on the face).
3. *Be aware of the composition and quantity of all topically applied agents.*  
This includes antimicrobial cleansers, diaper wipes, adhesive removers, and perineal products.  
Dispense from single-use containers, if possible.
4. *Ensure adequate intake of protein, essential fatty acids, zinc, biotin, and vitamins A, D, and Bs.*  
Erosive periorificial dermatitis is a sign of nutritional deficiency.
5. *Apply a simple cream or ointment emollient every 8 hours* (Nopper et al, 1994).
6. *Guard against excessive thermal and ultraviolet exposure.*  
Use thermally controlled water for bathing.  
Avoid surface monitors with metal contacts.  
Use Plexiglas shielding over daylight fluorescent phototherapy.
7. *Protect sites of cutaneous injury with the appropriate occlusive dressing.*  
Use a film dressing on nonexudative sites (Barak et al, 1989; Knauth et al, 1989; Vernon et al, 1990).  
Use a hydrogel dressing on exudative wounds.  
Maintain appropriate hydration at the skin-dressing interface.  
Remove necrotic debris with each dressing change.

- Scraping from the base of the blister for Tzanck smear
- Scraping from a carefully selected intact lesion, mounted in mineral oil, for scabies preparation
- Skin biopsy as indicated, depending on the morphology and extent of the lesions, and results of other evaluations

TABLE 96-7

**Occlusive Dressing Materials**

Class	Examples	Indications
<b>Films</b>		
Polyurethane ± adhesive backing	Tegaderm, Op-Site, Bioclusive, Omniderm	Superficial, nonexudative wounds, sites of friction
Microporous Teflon/silicone	Silon	
<b>Hydrocolloids</b>		
Hydrophilic colloidal particles in polyurethane foam	DuoDerm, Cutinova hydro, Restore	Exudative wounds, sites of friction
<b>Hydrogels</b>		
Cross-linked polyvinyl or other polymer; 80%-99% water	Vigilon, Cutinova gel, Biofilm	Exudative wounds, fragile skin, sites of friction

Reprinted from *Dermatologic Surgery*, Kannon GA, Garrett AB: Moist wound healing with occlusive dressings, p 583. Copyright 1995, with permission from Elsevier Science, Inc.

**Differential Diagnosis****Infections Localized to Skin**

- Candidiasis: KOH (or calcofluor white) preparation of the blister roof reveals pseudohyphae.
- Bullous impetigo: Wright stain reveals polymorphonuclear neutrophil leukocytes (PMNs); Gram stain shows gram-positive cocci.
- Gram-positive folliculitis: Wright stain reveals PMNs; Gram stain shows gram-positive cocci.
- Pityrosporum folliculitis: KOH preparation reveals short hyphae and spores.
- Neonatal herpes: Tzanck smear reveals viral cytopathic changes; polymerase chain reaction and immunohistochemical marker assays are highly sensitive studies and can be performed using a smear on glass slides submitted to the laboratory.
- Scabies: Mineral oil preparation reveals mites, ova, and feces.

**Transient Noninfectious Causes**

- Erythema toxicum neonatorum: Wright stain shows eosinophils.
- Neonatal pustular melanosis: Wright stain shows keratinous debris with PMNs; the Gram stain is negative.
- Neonatal acne: Close inspection reveals comedones.
- Milia: Wright stain shows keratinocytes only.
- Miliaria crystallina: These tiny, superficial noninflammatory vesicles represent obstruction of the sweat duct.
- Infantile acropustulosis: This pruritic condition mimics infantile scabies.
- Eosinophilic pustular folliculitis

### **Bullae and Extensive Blistering**

The bullous diseases may be life-threatening and may be impossible to distinguish from one another without skin biopsy. Appropriate therapy depends on correct diagnosis.

Staphylococcal scalded skin syndrome: Skin biopsy reveals a split in the superficial epidermis. Culture of blister contents is negative; the locus of infection is nasopharyngeal, perianal, focus of impetigo, or abscess; mucous membranes may be red but not blistered or eroded.

Congenital herpes simplex infection: Skin, eye, or mouth lesions are presenting signs in one third of infants.

Toxic epidermal necrolysis: Skin biopsy reveals a split at the dermoepidermal junction; mucous membranes are diffusely eroded.

Bullous mastocytosis: Stroking will produce a wheal and flare (Darier sign), and a Tzanck smear may show mast cells.

Genetic disorders: These disorders vary in severity and probability of long-term sequelae. Early diagnosis and genetic counseling are important aspects of management.

Epidermolysis bullosa: Blisters are most prominent at sites of friction. Familial forms are classified as simplex, junctional, and dystrophic, based on the skin cleavage plane. Electron microscopic analysis or immunofluorescence mapping or both are required for precise diagnosis.

Epidermolytic hyperkeratosis: Widespread erythema and blistering may be present at birth, causing confusion with epidermolysis bullosa and other blistering dermatoses. Thick, greasy, foul-smelling scale accentuated in skin creases may not become apparent until later in the first year of life.

Incontinentia pigmenti: Vesicular skin lesions have a characteristic distribution along the lines of Blaschko. This striking pattern is seen with a variety of cutaneous abnormalities as a result of genetic mosaicism. Tzanck smear may show eosinophils but no multinucleate giant cells.

### **Erythroderma**

Generalized redness and scaling in infancy have an alarming appearance and are often clinically and histologically nonspecific. An infant's general state of well-being is an important clue to the extent of the disease. Definitive diagnosis may be possible only after a period of observation. The erythrodermic newborn will have increased insensible heat and water loss requiring careful monitoring of weight, fluid and electrolytes, and temperature. A neutrothermal and humidified environment may be necessary for the first few days of life.

Careful history, family history, physical examination, and directed laboratory evaluation may help clarify the cause. The spectrum of disease includes common conditions limited to skin, infections, nutritional deficiencies, and immunologic disorders.

Infectious causes of erythroderma should always be considered first. The infant's skin should be carefully examined for more specific primary skin lesions. Laboratory

evaluation should include complete blood count, KOH preparation (or calcofluor white immunofluorescence technique), Tzanck smear, and surveillance cultures of the nasopharynx, rectum, umbilicus, conjunctivae, urine, and blood. Consider syphilis serologic studies and human immunodeficiency virus (HIV) assay in epidemiologically relevant locales. Begin empiric therapy, as needed.

The diagnostic evaluation should be more aggressive in any infant who is not thriving, to search for metabolic or immunologic abnormalities. Components of the investigation should include dietary history, electrolytes, protein, albumin, alkaline phosphatase, microscopic examination of hair, and a sweat test. The results of these screening tests can suggest the need for further laboratory evaluation.

More directed laboratory evaluation includes blood smear to look for leukocyte vacuoles, HIV screen, plasma zinc determination, measurement of serum linoleic and arachidonic acids, amino acid profile, specific assays for biotinidase activity, antinuclear antibody (SS-A and SS-B) titers, quantitative immunoglobulins, tests of cell-mediated immunity, skeletal survey, hair examination, and skin biopsy.

### **Differential Diagnosis**

#### ***Systemic Infections Associated with Erythroderma***

Candidiasis

Staphylococcal scalded skin syndrome

Syphilis

Acquired immunodeficiency syndrome (AIDS)

#### ***Primary Cutaneous Conditions***

Atopic dermatitis: Pruritus and involvement of the face and extensor extremities with marked sparing of the diaper area are helpful diagnostic clues.

Seborrheic dermatitis: The diaper area and skinfolds are often prominently involved.

Psoriasis: Skin lesions are often sharply circumscribed, but scale may not be prominent.

### **Genodermatoses**

Skin biopsy helps to distinguish among the ichthyosis-associated abnormalities disorders: lamellar ichthyosis, congenital nonbullous ichthyosiform erythroderma, epidermolytic hyperkeratosis, X-linked ichthyosis, multiple sulfatase deficiency, neutral lipid storage disease, Sjögren-Larsson syndrome, trichothiodystrophy, Netherton syndrome, and X-linked dominant chondrodysplasia punctata. The Foundation for Ichthyosis and Related Skin Types ([info@scalyskin.org](mailto:info@scalyskin.org)) is a useful source of information and will assist in the genetic evaluation of patients.

### **Ectodermal Dysplasias**

Ectodermal dysplasias are a group of disorders involving abnormalities of the skin and its appendages. Excessive desquamation resembling that seen with postmaturity is a characteristic finding. The most well-recognized form is

X-linked recessive hypohidrotic ectodermal dysplasia. Infants with this disorder have a decreased ability to sweat and a tendency toward hyperthermia.

### **Immunologic Disorders Associated with Erythroderma**

A clinical syndrome of erythroderma, diarrhea, and failure to thrive in infancy was first described in 1908 by Leiner, in association with unsupplemented breast-feeding. Subsequently, similar signs have been reported in infants with increased susceptibility to infection. A defect in yeast opsonization was found in two infants with “Leiner’s disease” in 1972. However, this defect, present in 5% of the general population, does not define the disease. Other patients experienced dramatic clinical improvement after infusion of fresh plasma or a purified preparation containing the fifth component of complement, C5. Consequently, “Leiner’s disease” has been associated with C5 dysfunction. More recently, a variety of immunologic abnormalities has been reported in infants with similar clinical presentation; this condition has been called *syndrome of erythroderma, failure to thrive, and diarrhea in infancy* to avoid confusion (Glover et al, 1988). Other defined disorders in this category include the following:

Primary immunodeficiencies (severe combined immunodeficiency [SCID], Wiskott-Aldrich syndrome, hyperimmunoglobulin E syndrome, Omenn syndrome)  
 Secondary immunodeficiencies (AIDS, graft-versus-host disease)  
 Langerhans cell histiocytosis  
 Neonatal lupus  
 Diffuse cutaneous mastocytosis

### **Metabolic and Nutritional Disorders Associated with Erythroderma**

Patients with metabolic and nutritional disorders associated with erythroderma often present with erosive, periorificial dermatitis (see Table 96–5).

### **Other Disorders**

Boric acid poisoning: This condition was reported with the use of boric acid baby powders. It can be clinically indistinguishable from staphylococcal scalded skin syndrome (Goldbloom and Goldbloom, 1953).

### **Collodion Baby**

Collodion baby represents a distinct subset of neonatal erythroderma that can be a clinical marker of a variety of underlying abnormalities. The phenotype includes parchment-like hyperkeratosis, pseudocontractures, ectropion, eclabium, absence of eyebrows, and sparse hair. These infants have defective cutaneous barrier function, with resultant losses of free water and thermal energy. They are extremely susceptible to hypothermia, hypernatremic dehydration, and percutaneous infection.

### **Nonblanching Violaceous Papules and Plaques**

Nonblanching violaceous papules and plaques may be localized or disseminated. Infants with widespread lesions have been described as “blueberry muffin babies.” The diseases in this category represent a variety of processes; most require aggressive evaluation and treatment.

Initial evaluation of a blueberry muffin infant should include complete blood count with white blood cell differential; platelet count; reticulocyte count; liver function tests; maternal and neonatal TORCH (toxoplasmosis, other infections, rubella, cytomegalovirus infection, and herpes simplex) infectious agent titers; rapid plasma reagin (RPR) assay; blood cultures for bacteria; urine, nasopharyngeal swab, and rectal swab samples for viral cultures; and ophthalmologic examination.

Skin biopsy is necessary to distinguish between simple hemorrhage into the dermis (purpura) and other infiltrative conditions (e.g., dermal hematopoiesis, tumor) manifesting in the neonatal period.

### **Differential Diagnosis**

#### **Purpura**

Ecchymoses: These lesions constitute traumatic purpura, usually secondary to labor and delivery.

Bland thrombosis: Conditions in this category that can occur in the neonatal period include the following:

Embolization of foreign material: This has been reported in infants receiving extracorporeal membrane oxygenation (ECMO).

Purpura fulminans: Neonatal purpura fulminans is most often associated with homozygous protein C or protein S deficiency (Marlar et al, 1989).

Cryoglobulinemia

Infectious vasculitis: Purpuric lesions represent infectious, inflammatory microemboli, most commonly associated with the following:

Gram-negative bacterial sepsis, including that due to *E. coli* or meningococci, and ecthyma gangrenosum (*Pseudomonas*)

Listeriosis

Aspergillosis

Thrombocytopenia, usually manifesting with widely scattered petechiae

Isoimmune thrombocytopenic purpura (ITP)

Maternal ITP

Disseminated intravascular coagulopathy

#### **Dermal Hematopoiesis**

Dermal hematopoiesis is the histologic basis for the blueberry muffin skin lesions. Before 34 weeks of gestation, the skin serves as a hematopoietic center. It has yet to be shown whether blueberry muffin lesions are due to persistence or recurrence of the fetal potential.

Rubella

Cytomegalovirus infection

Syphilis

Other viral infections (e.g., coxsackievirus B2 infection)  
Twin-to-twin transfusion syndrome  
Rh hemolytic disease of the newborn

### **Malignancy**

Congenital leukemia  
Langerhans cell histiocytosis  
Neuroblastoma

### **Vascular Defects**

It can be difficult to distinguish among the different forms of cutaneous vascular lesions manifesting in the neonatal period. Nonvascular look-alikes also fall into this category but can be differentiated by skin biopsy.

### **Differential Diagnosis**

#### **Hemangioma**

The most common tumor of infancy, hemangioma usually becomes apparent during the first 2 to 4 weeks after birth and exhibits a characteristic rapid growth phase, peaking at 4 to 6 months in most infants, with stabilization between 6 and 12 months followed by slow involution over the next 5 to 10 years. Although these lesions usually are not associated with extracutaneous findings, hemangiomas in special locations require further evaluation:

Lumbosacral and anogenital: Exclude lumbosacral spine anomalies.  
Large facial, scalp, neck, thoracic (PHACES syndrome): Exclude cardiac and posterior fossa anomalies.  
“Beard” distribution: Monitor airway.  
Large segmental: Evaluate for vascular and soft tissue anomalies of the involved area.

### **Vascular Malformations**

Vascular malformations are a group of lesions, usually apparent at birth, that do not generally grow or involute. Some vascular malformations are associated with characteristic extracutaneous abnormalities:

Salmon patch  
Nevus flammeus (port-wine stain)  
Klippel-Trénaunay syndrome  
Cobb syndrome  
Arterial, lymph, venous, or mixed malformations  
Cutis marmorata telangiectatica congenita

### **Lesions that Mimic Vascular Birthmarks**

Pilomatrixoma  
Giant juvenile xanthogranuloma  
Langerhans cell histiocytosis  
Congenital myofibromatosis

### **Pigmented Lesions**

It can be difficult to distinguish among the lesions in the pigmented lesion category without histopathologic examination. The majority of congenital pigmented lesions are isolated and benign, but it is important to recognize those that are syndrome-associated or potentially life-threatening. Both melanocytic and nonmelanocytic lesions are included in this category.

In general, skin biopsy of a congenital pigmented lesion can be postponed until after the neonatal period. The one exception is a nodular lesion suggestive of melanoma. (See Chapter 100 for additional details.)

### **Differential Diagnosis**

Congenital nevocellular nevus  
Café au lait macule  
Nevus spilus (speckled lentiginous nevus)  
Mongolian spot  
Smooth muscle hamartoma  
Plexiform neurofibroma  
Nevus of Ota  
Epidermal nevus  
Urticaria pigmentosa, solitary mastocytoma  
Lentigines

### **Midline Facial Lesions**

See Chapter 100 for a more detailed discussion of midline facial lesions. The main types are as follows:

Dermoid  
Nasal glioma  
Encephalocele

## Congenital and Hereditary Disorders of the Skin\*

Timothy P. Monahan, Bernard A. Cohen,  
and Elaine C. Siegfried

The heritable disorders of skin—the genodermatoses—feature diverse aberrations of color, texture, and structural integrity of the epidermis, epidermal appendages, and connective tissue. Some of these diseases are cutaneous only; others are associated with anomalies of multiple organ systems. Many genodermatoses can be diagnosed prenatally, by skin biopsy (Holbrook et al, 1993) (Table 97-1). This technique is being replaced, however, by molecular diagnostic methods, as the genetic nature of most of these disorders is identified. Enormous progress has been made in the last few years in elucidating the molecular genetics responsible for many of the dermatoses in this chapter. With these exciting new discoveries comes the hope for novel and more efficacious therapies.

### GENODERMATOSES AND MOSAICISM

A *genetic mosaic* is an organism composed of two or more genetically different populations of cells that originate from one zygote. When the skin is involved, unique patterning is seen, reflecting the cellular heterogeneity. Variations of this striking pattern were clinically described and mapped in 1901 by Alfred Blaschko. The distribution is known as *Blaschko's lines*. Blaschko's lines are distinct from dermatomes, skin tension lines, and lines of lymphatic drainage. The pattern is linear and whorled and may be bilaterally symmetrical, with a midline demarcation (Fig. 97-1). An anatomic equivalent has been described in the eyes and teeth (Bolognia et al, 1994).

Several diseases are expressed in this fashion. The first to be recognized were X-linked disorders. Affected females are obligate heterozygotes, due to the Lyon effect of X-inactivation. Examples include female carriers of the X-linked recessive disorder hypohidrotic ectodermal dysplasia and females with the X-linked dominant disorders, incontinentia pigmenti, chondrodysplasia punctata, CHILD syndrome (see later), and focal dermal hypoplasia. These conditions are seen almost exclusively in females, presumably because they are lethal in males. Autosomal mosaicism is not heritable unless the germ cells are affected (Happle, 1993).

\*This chapter includes material from a chapter in the previous edition, to which Elaine C. Siegfried, MD, and Nancy B. Esterly, MD, contributed.

## SPECIFIC GENODERMATOSES

### The Ichthyoses

The *ichthyoses* are a diverse group of heritable and acquired skin disorders that share the primary problem of widespread scaly, dry skin. Several distinct types of ichthyosis have been described on the basis of their clinical and histologic features and by their patterns of genetic transmission (Williams, 1983, 1986); however, nosology is constantly evolving. Several types of ichthyoses are primary disorders of cornification, with manifestations confined to the skin. Ichthyosiform syndromes have characteristic extracutaneous manifestations. More precise diagnostic criteria and better treatments are being recognized through collaborative research efforts, including genetic analysis. The National Registry for Ichthyosis and Related Disorders was created in 1995 to aid in this effort and can be contacted by telephone at (800) 595-1265. The Foundation for Ichthyosis and Related Skin Types (FIRST) is a privately funded national organization providing information and support for families with these disorders (for contact information, see Resources section at the end of the chapter).

### Ichthyoses That Manifest in the Neonatal Period

Three ichthyosiform conditions have alarming presentations at birth. Two of these, the collodion baby and harlequin ichthyosis, have been historically described as distinct entities based on the associated striking and unique clinical appearance. Long-term survival of affected infants and more refined diagnostic studies have permitted identification of these conditions as phenotypically distinct but genotypically heterogeneous. A third condition, epidermolytic hyperkeratosis (autosomal dominant bullous congenital ichthyosiform erythroderma), has an equally striking neonatal appearance. Another severe category of infantile ichthyosis, congenital nonbullous ichthyosiform erythrodermal/lamellar ichthyosis, presents a difficult diagnostic and management problem. Recognition of these conditions and appropriate management are vital to the survival of these infants.

### Collodion Baby

Neonates affected with the uncommon condition termed *collodion baby* have a pathognomonic appearance. With time, they usually manifest more specific features of one of the ichthyoses.

### Clinical Findings

Collodion babies are often premature and small for gestational age. Their skin is parchment-like, shiny, and thickened at birth, distorting their facial features with ectropion and eclabium, flattening the ears, and resulting in pseudocontractures of the digits (Fig. 97-2). Histologic examination of the skin at this stage has been nonspecific, revealing a markedly thickened, compact stratum

TABLE 97-1

### Genodermatoses Diagnosed Prenatally Using Fetal Skin Samples

Epidermolysis bullosa
Junctional
Recessive dystrophic
Dominant dystrophic
Epidermolysis bullosa simplex (general)
Epidermolysis bullosa simplex Dowling-Meara
Unidentified forms
Keratinization disorders
Bullous congenital ichthyosiform erythroderma
Nonbullous congenital ichthyosiform erythroderma/ lamellar ichthyosis
Harlequin ichthyosis
Sjögren-Larsson syndrome
Pigment disorders
Tyrosinase-negative oculocutaneous albinism
Congenital nevus
Incontinentia pigmenti
Disorders of epidermal appendages
X-linked hypohidrotic ectodermal dysplasia
Autosomal-recessive anhidrotic ectodermal dysplasia
Other disorders
Tay syndrome
Chédiak-Higashi syndrome
Griscelli disease
Restrictive dermopathy

Adapted from Holbrook et al, 1993.

corneum. Nonetheless, these infants have a very ineffective barrier against transepidermal water loss and invasion of pathogenic microbes, with accompanying temperature instability.

#### Causes

Several genetically distinct outcomes have been reported for the collodion baby phenotype (see Table 97-1). Two thirds of these infants have nonbullous ichthyosiform erythroderma. Fifty percent of affected infants have no family history suggestive of ichthyosis (Pongprasit, 1993).

#### Diagnosis

Skin biopsy can be helpful, but is not likely to be specific until after the collodion appearance has resolved. Diagnostic studies should be carefully selected, based on the evolution of the cutaneous findings, associated abnormalities, and family history (Table 97-2). Several outcomes have been reported, including complete healing without sequelae (Frenk and de Techtermann, 1992; Shwayder and Ott, 1991). A prolonged period of observation may be required to determine the precise diagnosis and prognosis. As soon as a definite diagnosis has been made, genetic counseling should be provided.

#### Treatment

Complications include marked temperature instability, defective barrier function, increased insensible water loss predisposing to hypernatremic dehydration (Buyse et al, 1993), pneumonia secondary to aspiration of squamous

**FIGURE 97-1.** Blaschko's lines are a distinct linear and whorled pattern, to be distinguished from dermatomes or skin tension lines, characterized by midline demarcation with a central V. This pattern is the cutaneous clinical manifestation of a variety of mosaic genetic conditions.

material in the amniotic fluid, and cutaneous infections from gram-positive organisms and *Candida albicans*.

Treatment consists of aggressive supportive care. Infants must be placed in a highly humidified isolette. Fluid and electrolyte balance must be closely monitored. A high index of suspicion must be maintained for signs of cutaneous or systemic infection. Overzealous administration of antibiotics, however, may lead to gram-negative infections and subsequent septicemia. Topical skin care should include application of a bland occlusive ointment emollient every 6 to 8 hours until the hyperkeratosis has resolved. Potentially toxic topical agents should be avoided because of the increased risk of percutaneous absorption. Manual débridement is not indicated. The eyes should be protected with a bland lubricating ointment; aggressive surgical management of ectropion is almost never necessary. Systemic retinoids have not been useful (Waisman et al, 1989). With

TABLE 97-2

**Collodion Baby: Differential Diagnosis and Laboratory Evaluation**

Diagnosis	Inheritance	Associated Abnormalities	Diagnostic Tests*
Nonbullous ichthyosiform erythroderma (>60%)	AR, AD		Histology is nonspecific; fetal skin biopsy is unreliable; the gene defect has not been identified
Lamellar ichthyosis	AR, AD	Persistent ectropion	Histology is nonspecific; fetal skin biopsy is unreliable; the gene defect has been identified
X-linked ichthyosis	X-linked recessive	Maternal failure to initiate labor; hypogonadism, undescended testes; corneal opacities (carrier females and affected males)	Histology is nonspecific; decreased serum cholesterol sulfate and steroid sulfatase activity; the gene defect has been mapped to Xp22.3
Netherton syndrome	Sporadic	Ichthyosis linearis circumflexa, atopic diathesis, impaired cellular immunity	Histology is nonspecific; microscopic examination of hair shaft reveals pathognomonic trichorrhexis invagina
Gaucher disease	AR	Hepatosplenomegaly, thrombocytopenia, neurologic abnormalities	Liver biopsy; beta-glucocerebrosidase activity; the gene defect has been mapped to 1q21 and sequenced
Trichothiodystrophy (Tay syndrome)	AR	Progeric facies, neurologic abnormalities, hypogonadism, cataracts, dental problems	Hair analyses: polarizing light microscopic examination reveals characteristic banding; there is decreased content of sulfur-rich matrix proteins
Sjögren-Larsson syndrome	AR	Spasticity, retardation, seizures	Pathognomonic retinal changes; fibroblast culture for fatty alcohol oxidoreductase activity
No detectable abnormality (lamellar exfoliation of the newborn)	AR, sporadic		Watchful waiting

\*In the immediate neonatal period, skin biopsy may be nonspecific. Histologic evaluation may be postponed until after age 3 to 6 months.

AD, autosomal dominant; AR, autosomal recessive.

Data on diagnostic tests from Paller AS: Laboratory tests for ichthyosis. *Derm Clinics* 12:99-107, 1994.

optimal supportive care, the thickened stratum corneum usually resolves in 2 to 4 weeks but can persist, especially in infants with lamellar ichthyosis.

### **Harlequin Ichthyosis**

This rare congenital abnormality has a more striking appearance and a graver prognosis than those reported for collodion baby. Most infants have been stillborn or died in infancy. Survival beyond infancy has only recently been possible. The harlequin phenotype is inherited as an autosomal recessive trait; several biochemical defects probably underlie the clinical condition.

#### **Clinical Findings**

The clinical features are unforgettable. The cutaneous scale is firm and plate-like, distorting and flattening the nose and ears. Skin rigidity also causes deep fissures, marked ectropion, eclabium, and pseudocontractures of all joints. Chemosis of the conjunctivae obscures the globes. The nails and hair are hypoplastic or absent (Fig. 97-3). Primary extracutaneous abnormalities are not prominent.

#### **Diagnosis**

The diagnosis is made by the pathognomonic appearance. The light microscopic examination always demonstrates compact hyperkeratosis. Additional light and electron microscopic abnormalities of the stratum corneum have not been identified consistently, supporting the theory that harlequin ichthyosis may represent a common phenotype for several different genetic errors of cornification (Hashimoto et al, 1993).

#### **Causes**

The cause of harlequin ichthyosis is unknown. Although abnormalities of keratinization and epidermal lipid metabolism have been reported, few affected infants have been studied, and no single defect has been identified consistently (Dale and Kam, 1993).

#### **Prognosis and Treatment**

Treatment consists of supportive care in a humid, temperature-controlled environment and frequent application of topical emollients to the skin and mucosal surfaces, as for collodion baby (Prasad et al, 1994). Nevertheless, infants given these therapies almost invariably succumb to their

**FIGURE 97-3.** Collodion baby. Note the ectropion, eclabium, and areas of rupture in the membrane over the anterior thorax.

disease from sepsis, inability to feed, and inadequate ventilation. Survival beyond 6 weeks was extremely unusual prior to the use of oral retinoids. Recent reports have documented successful therapy of several affected infants using oral retinoids, with improved quality of life and survival well into childhood. Etretinate has been used most often in the past, at doses of 1 mg/kg/day. Although FDA approval of this drug has been withdrawn, Isotretinoin has been used at a dose of 0.5 mg/kg. Infants receiving retinoids must be monitored for toxic effects. All survivors have had severe ichthyosis as an outcome; some have intellectual impairment. Genetic counseling for the families of these infants is mandatory. Prenatal diagnosis may be made by fetal skin biopsy (Holbrook et al, 1993).

### **Epidermolytic Hyperkeratosis (Congenital Bullous Ichthyosiform Erythroderma)**

Epidermolytic hyperkeratosis (EHK) is rare, with an estimated incidence of 1/250,000. Neonates with EHK are born with generalized erythroderma and blistering. Their clinical appearance shares cutaneous features of other infantile bullous disorders, especially epidermolysis bullosa (EB). Molecular defects responsible for EHK have recently been identified, proving biochemical similarities between EHK, EB simplex, and other disorders of keratinization.

#### **Clinical Findings**

Infants may be born with generalized erythroderma and blistering. Hyperkeratosis may not be readily apparent. The neonatal course is complicated by temperature insta-

bility, susceptibility to hypernatremia, and sepsis, as in the other severe neonatal ichthyoses. With time, the skin changes evolve to include characteristic ridged scales, accentuated in the flexural areas. Palms and soles usually are involved. Excessive bacterial colonization often causes a distressingly foul odor. There are no extracutaneous manifestations.

#### **Diagnosis**

There is significant clinical similarity to other bullous disorders of infancy, including EB, staphylococcal scalded skin syndrome (SSSS), and toxic epidermal necrosis (TEN). Precise diagnosis can be lifesaving. Skin biopsy should be performed emergently, with examination of frozen sections. The histologic features of EHK are distinctive, showing intercellular edema and coarse, clumped material in the upper granular layers of the epidermis. Prenatal diagnosis is possible by means of fetal skin biopsy (Holbrook et al, 1993).

#### **Causes**

EHK is transmitted in an autosomal dominant fashion, with a high rate of spontaneous mutation. Ultrastructural analysis of skin from affected patients suggests an abnormality of keratin filaments in the suprabasal cells. Molecular analysis of affected families has identified genetic mutations in the genes encoding the synthesis of the keratin filaments that are preferentially expressed in the superficial epidermis, *K1* (located within the type I keratin gene cluster at chromosome 17q) and *K10* (located within the type II keratin gene cluster at chromosome 12q) (Francis, 1994; Nirunskisiri et al, 1995; Smack et al, 1994; Steijlen et al, 1994a). The disorder also can be expressed in mosaic fashion as an epidermal nevus oriented along the lines of Blaschko (Paller et al, 1994). Prenatal studies for EHK may be indicated for the offspring of parents with extensive epidermal nevi.

#### **Prognosis and Treatment**

Infants with widespread blistering should be managed according to the same principles and techniques used for collodion babies. Attention to gentle handling will minimize further trauma. Application of a nonadhesive bio-occlusive dressing (e.g., hydrogel, foam) will promote healing of denuded areas. Infants should be closely monitored for the development of secondary infection.

### **Nonbullous Congenital Ichthyosiform Erythroderma/Lamellar Ichthyosis**

The nonbullous form of infantile ichthyosiform skin disease, as distinct from the bullous variety (EHK), initially was characterized by its severity and autosomal recessive inheritance pattern. The term *nonbullous congenital ichthyosiform erythroderma* (NCIE) generally refers to a milder clinical variant. Ultrastructural differences have been described in skin biopsy specimens. The phenotypically more severe lamellar ichthyosis has proved to be genetically distinct as well (Russell et al, 1995).

### Clinical Findings

These conditions are characterized by congenital erythroderma and a varying degree of generalized scaling. Face, flexural sites, palms, and soles are also involved. A majority of collodion babies have these types of ichthyosis. In lamellar ichthyosis, the scales evolve to be thick, dark, and plate-like (Fig. 97-4). Facial involvement causes chronic ectropion. Hair growth may be sparse, and nails may be dystrophic. Children with NCIE have generalized erythema with finer, white scales. There is no associated ectropion. Secondary cutaneous infections with bacteria, yeasts, and dermatophytes are common complications.

### Diagnosis

Before genetic advances, the diagnosis of these forms of ichthyosis had been based on clinical features alone. Skin biopsy is nonspecific; a normal granular layer is present. The differential diagnosis includes other causes of erythroderma and collodion baby (see Chapter 96). Prenatal diagnosis is possible for affected families (Holbrook et al, 1993). For patients without a previously defined family history, the appropriate laboratory assessment can be arranged through the National Registry for Ichthyosis and Related Disorders (see earlier).

### Causes

A majority of cases are inherited in an autosomal recessive fashion, but an autosomal dominant form of lamellar ichthyosis also has been described. In 1995, a common locus of genetic mutations was identified in several families with recessive lamellar ichthyosis (Russell et al, 1995). The linked defects, located on chromosome 14, result in production of abnormal transglutaminase-1. This enzyme normally promotes cross-linking of intracellular proteins in the stratum corneum during terminal differentiation (Huber et al, 1995; Russell et al, 1995). New research has revealed genetic heterogeneity with two other loci on chromosomes 2 and 19. Additionally, a locus on chromosome 3 was identified that was clinically consistent with NCIE (Fischer et al, 2000).

### Prognosis and Treatment

The same management principles recommended for neonates presenting with the collodion baby phenotype can be applied to infants with erythroderma, although their neonatal course is marked by fewer complications. The mainstay of therapy for children with lamellar ichthyosis is the use of topical emollients and keratolytic agents. Successful treatment with topical calcipotriol has been described (Delfino et al, 1994; Russell and Young, 1994). Any topically applied agent will be transcutaneously absorbed to a much higher degree than through normal skin; dosing must be carefully monitored (Abdel-Magid and el-Awad, 1994; Luckner, 1994). Treatment with systemic retinoids has had variable success (Steijlen et al, 1994b; Waisman et al, 1989).

### Ichthyosiform Syndromes

Several syndromes manifesting in the neonatal period have ichthyosis as a major feature.

#### **Recessive X-linked Ichthyosis**

Recessive X-linked ichthyosis (RXLI) is an uncommon condition, affecting 1 in 6000 males. Signs of the disorder are present at birth in one fifth of affected infants; 85% develop skin changes by 3 months of age. The characteristic cutaneous finding is coarse brownish scaling, most prominent on the neck and extensor extremities. The palms and soles are spared. Extracutaneous manifestations include hypogonadism and cryptorchidism, present in up to 25% of affected males. Severely affected males may have short stature and mental retardation, a variant that has been referred to as Rud syndrome. Characteristic corneal opacities are seen in affected males and heterozygote females but usually not until late childhood or adolescence. Carrier females experience failure to initiate labor or prolonged labor. Light microscopic and ultrastructural findings in skin biopsy specimens are unremarkable. The

**FIGURE 97-4.** Large dark scales characteristic of lamellar ichthyosis on the leg of an affected infant.

pathogenesis of RXLI is aberrant production of the enzyme steroid sulfatase (a form of arylsulfatase C), with accumulation of cholesterol sulfate (Williams, 1986). The genetic abnormality has been localized to the distal short arm of the X chromosome (Xp22.3).

### ***Netherton Syndrome/Ichthyosis Linearis Circumflexa***

Netherton syndrome is a rare, autosomal recessive condition. It often manifests at birth as ichthyosiform erythroderma, with flexural accentuation. The characteristic migratory, polycyclic lesions with a peripheral double-edged scale, referred to as *ichthyosis linearis circumflexa*, do not appear until after age 2 years. The syndrome is characterized by congenital ichthyosis, hair shaft defects (principally trichorrhexis invaginata), and atopic features (pruritus, hay fever, facial angioedema, and elevated immunoglobulin E [IgE]), but until the advent of genetic testing, diagnosis in affected children often was not possible for the first several years of life (Judge et al, 1994b). Generalized aminoaciduria and impaired cellular immunity also have been reported. This distinctive pattern of ichthyosis linearis circumflexa can also manifest as an isolated cutaneous condition. Recently, pathogenic mutations in Netherton syndrome were localized to the *SPINK5* gene on chromosome 5q32, which encodes the serine protease inhibitor LEKTI (Chavanas et al, 2000). Subsequently, prenatal testing for the disorder was successfully attempted (Müller et al, 2002; Sprecher et al, 2001).

### ***Sjögren-Larsson Syndrome***

Sjögren-Larsson syndrome, inherited as an autosomal recessive disorder, usually manifests at birth with ichthyosiform erythroderma. The syndrome includes features that become evident only after the neonatal period: spastic diplegia, characteristic retinal lesions (“glistening dots”), and mental retardation. The diagnosis is supported by finding reduced or absent enzymatic activity of fatty aldehyde dehydrogenase from cultured skin fibroblasts, amniocytes, or chorionic cells. The genetic disorder that causes Sjögren-Larsson syndrome has been mapped to a locus on chromosome 17p11.2 that codes for a fatty aldehyde dehydrogenase (De Laurenzi et al, 1996).

### ***Chondroplasia Punctata Syndromes (Conradi and Conradi-Hünemann Syndromes)***

The chondroplasia punctata syndromes are a loosely defined group of syndromes sharing distinctive skin and bone abnormalities that are present at birth but may disappear with time. The skin lesions consist of patterned hyperkeratosis along the lines of Blaschko. Orthopedic abnormalities (including asymmetrical shortening of the long bones) prompt radiologic evaluation that reveals chondrodysplasia punctata, characterized by punctate calcifications of the epiphyses and cartilage. Abnormal facies

and cataracts are associated features. Autosomal dominant, autosomal recessive, and X-linked dominant forms have been reported. The genetic abnormality associated with X-linked dominant Conradi syndrome has now been mapped to the *EBP* gene locus at Xp11.22-p11.23, which codes for a sterol isomerase (Braverman et al, 1999; Derry et al, 1999).

### ***CHILD Syndrome***

CHILD syndrome is characterized by a striking phenotype consisting of congenital hemidysplasia, unilateral ichthyosiform erythroderma, and limb defects and also is known as *unilateral congenital ichthyosiform erythroderma*. CHILD syndrome is an X-linked disorder that shares some features with the X-linked dominant Conradi syndrome. Most cases of CHILD syndrome probably are caused by a mutation of the NAD(P)H steroid dehydrogenase-like (NSDHL) protein gene, which has been mapped to Xq28 (Grange et al, 2000). This steroid dehydrogenase functions upstream of the sterol isomerase, which is defective in X-linked dominant Conradi syndrome in the cholesterol biosynthesis pathway. There have also been cases of mutations in the same *EBP* gene of X-linked Conradi syndrome that also included CHILD syndrome (Traupe and Has, 2000).

### ***Keratitis-Ichthyosis-Deafness Syndrome***

Keratitis-ichthyosis-deafness (KID) syndrome is a rare disorder of autosomal dominant inheritance that consists of congenital ichthyosiform erythroderma with characteristic pebbly palmoplantar thickening; abnormalities of the nails, hair, and teeth; vascularizing keratitis; and sensorineural deafness. A few affected patients have died in infancy from overwhelming sepsis (Caceres-Rios et al, 1996). Recent evidence points to a mutation in connexin 26 as the pathogenesis of this disorder (van Steensel et al, 2002).

### ***Neutral Lipid Storage Disease***

Neutral lipid storage disease, or Chanarin-Dorfman disease, consists of congenital ichthyosiform erythroderma, myopathy, neurosensory deafness, and cataracts. Inheritance is autosomal recessive. Vacuolated leukocytes from lipid droplets, seen on peripheral smear, help establish the diagnosis (Judge et al, 1994a). This disease is characterized by an intracellular accumulation of triacylglycerol droplets. Mutations in a newly discovered protein of the esterase/lipase/thioesterase subfamily, CGI-58, encoded by the *CDS* locus on chromosome 3p21 appear to be the cause of this disease (Lefèvre et al, 2001).

### ***Trichothiodystrophy***

Trichothiodystrophy (TTD) is a disorder of autosomal recessive inheritance that includes a spectrum of ectodermal abnormalities: congenital ichthyosis (sometimes manifesting

initially as collodion baby), brittle hair, and short stature (Kousseff, 1991). More severely affected patients have a constellation of features that has been referred to as *Tay syndrome*. These features include abnormal dentition, cataracts, nail dystrophy, progeric facies, and photosensitivity, with an increased incidence of skin cancers and a wide variety of central nervous system (CNS) abnormalities. Diagnosis is supported by detection of characteristic alternating light and dark bands within the hair shaft on examination under polarizing microscopy. Further analyses of hair and nails reveal a decrease in the sulfur-rich proteins (Itin and Pittelkow, 1990).

The genetic mutations that cause TTD are the subject of active research. Two genes implicated in TTD, *XPB* and *XPD*, have been found to encode DNA helicase subunits. Other mutations in these two genes can result in xeroderma pigmentosum, or Cockayne syndrome. *XPB* has been localized to chromosome 2q21, and *XPD* has been localized to 19q13.2-q13.3. There is also evidence that a mutation in an unlocalized third gene, *TTDA*, also may cause TTD (van Brabant et al, 2000).

### Primary Cutaneous Ichthyoses

Primary cutaneous ichthyoses are a group of familial disorders that have no prominent extracutaneous manifestations. Lamellar ichthyosis, congenital nonbullous ichthyosiform erythroderma, and EHK also are primary cutaneous ichthyoses.

#### *Ichthyosis Vulgaris*

Ichthyosis vulgaris is the most common form of ichthyosis, with an estimated incidence of 1/250. It is inherited as an autosomal dominant trait. Onset is usually after the first 3 months of life. Scaling is most prominent on the extensor surfaces of the limbs. The palms and soles also are affected. Affected persons often have coexisting keratosis pilaris and atopic dermatitis (Rabinowitz and Esterly, 1994). Skin biopsy distinguishes ichthyosis vulgaris from the other forms of ichthyosis by revealing small or absent keratohyalin granules. A major component of these granules, profilaggrin, is reduced or undetectable in the skin of affected persons (Nirunskis et al, 1995).

#### *Erythrokeratoderma Variabilis*

Erythrokeratoderma variabilis also is a very rare type of ichthyosis that can present in infancy; it usually is inherited in an autosomal dominant fashion, although a probable case of autosomal recessive inheritance has been reported (Armstrong et al, 1997). Affected persons have transient migratory areas of discrete macular erythema as well as fixed hyperkeratotic plaques. A mutation in the connexin 31 gene, which codes for the gap junction protein  $\beta 3$ , was reported as the cause of erythrokeratoderma variabilis, but a subsequent case was shown to not have a mutated connexin 31 gene (Wilgoss et al, 1999).

### Prognosis and Treatment for the Ichthyoses

It is important to distinguish among the various forms of ichthyosis so that the physician can offer a prognosis and appropriate genetic counseling to the family. The prognosis is related to the severity of the condition and the type of ichthyosis. The clinical signs and pedigree data sometimes provide sufficient information to make a diagnosis. Skin biopsy for light microscopy is diagnostic only for EHK and ichthyosis vulgaris. Other general screening laboratory tests are equally nonspecific. Unfortunately, a period of observation beyond the first 4 weeks of life is frequently needed, and laboratory confirmation of the correct diagnosis requires specialized studies (Holbrook et al, 1993).

Standard therapy begins with topical care designed to hydrate the stratum corneum. Frequent, brief tepid water baths should be followed immediately by liberal application of a bland ointment or cream emollient, such as petrolatum, Aquaphor, or Eucerin. Emollients containing keratolytics such as urea (10% to 25%), salicylic acid, propylene glycol, and alpha-hydroxy acids also are effective but are recommended only after infancy because of the risk of toxicity associated with increased percutaneous absorption. Irritating soaps and detergents should be avoided. Topical calcipotriol has been safe and effective as an agent for short-term therapy in adults with a variety of ichthyoses (Kragballe et al, 1995).

### Oculocutaneous Albinism

The term *oculocutaneous albinism* (OCA) refers to a group of congenital disorders that are clinically manifested by an absence of pigment of the skin, hair, and eyes, with associated photophobia and nystagmus. All races are affected; estimates of gene frequency vary depending on the population under consideration. As with many genetic disorders, the incidence of affected persons is increased in certain racial isolates in which there is a high percentage of consanguineous marriages (Witkop et al, 1989).

#### Causes

All forms of OCA but one are inherited in an autosomal recessive fashion. The characteristic pigmentary changes are due to a spectrum of biochemical defects that interfere with melanin synthesis or transport. Three types of oculocutaneous albinism have been mapped to specific chromosomal regions that code for regulatory proteins in the transport and synthesis of tyrosine, a precursor in the melanin synthesis pathway (Oetting and King, 1994). OCA type 1 results from mutations in the gene that codes for tyrosinase (locus 11q14-q21). Tyrosinase is a copper-containing enzyme that catalyzes the two rate-limiting steps in the melanin biosynthetic pathway, and patients with homozygous mutations have a lifelong inability to produce melanin in the eyes, hair, and skin. Over 90 different mutations have been identified (Nakamura et al, 2002). OCA type 2, the most common form of OCA, results from mutations in the *P* gene. Recent findings suggest that the *p* protein plays a major role in modulating the intracellular transport of tyrosinase (Toyofuku et al,

2002). OCA type 3 is caused by mutations in the tyrosinase-related protein 1 gene (*Tyrrp1*). The encoded protein functions to maintain stability of tyrosinase (Sarangerajan and Boissy, 2001). Recent research suggests other genetic mutations may cause a fourth form of OCA (Newton et al, 2001).

### Diagnosis

OCA type 1 can be distinguished from OCA types 2 and 3 on the basis of subtle clinical differences and the presence or absence of tyrosinase activity. OCA type 1 is the tyrosinase-negative variant and can be diagnosed prenatally by fetal skin biopsy (Holbrook et al, 1993). It results from any of several defects in the tyrosinase gene (Tomita, 1994). In type 2 and type 3 OCA, tyrosinase activity is positive. Genetic testing may be necessary to distinguish OCA type 2 from type 3. Oculocutaneous albinism should be distinguished from simple ocular albinism, which has sex-linked, autosomal dominant, and autosomal recessive forms.

### Clinical Findings

Affected infants, regardless of their familial skin type, have a decrease in skin pigment. Hair and iris pigmentation can vary, depending on the genotype. Photophobia and nystagmus of varying degrees are also type specific. Visual acuity is almost always impaired. Patients with tyrosinase-negative OCA have the most severe form of visual impairment. Associated abnormalities may include hemorrhagic diathesis (Hermansky-Pudlak syndrome), small stature, and defective mentation. Deafness can occur in association with oculocutaneous albinism as well as with a number of other pigmentary disorders (Konigsmark, 1972).

### Prognosis and Treatment

The most significant associated problems are visual impairment and the increased risk of sun-induced carcinogenesis. Treatment is supportive. Religious use of broad-spectrum sunblock with the highest available sun protection factor (SPF) is mandatory to protect against excessive exposure to sunlight. The safest approach for infants is zinc oxide ointment, sun-protective clothing [Sun Precautions, Seattle, WA; telephone: (800) 882-7860; Web site: [www.sunprecautions.com](http://www.sunprecautions.com)], and sun avoidance. Persons with tyrosinase-positive albinism accumulate pigment with increasing age, decreasing the risk of sun-induced complications. The National Organization for Albinism and Hypopigmentation (NOAH) can provide additional information and support for affected families (see Resources section at the end of the chapter).

## Piebaldism

Piebaldism is an autosomal dominant congenital leukoderma, characterized by a white forelock. Histologic studies show an absence of melanocytes in the depigmented areas of skin and normal melanocytes in the uninvolved skin (Jimbow et al, 1975). The molecular basis of the disease has been identified as a defect of the *c-kit* proto-oncogene. This gene encodes the cell surface receptor

transmembrane tyrosine kinase for an embryonic growth factor. When *c-kit* function is reduced, the migration of melanocytes is curtailed during embryogenesis (Tomita, 1994).

### Clinical Findings

A white forelock is present in 90% of cases. Other areas of the ventral skin may also be devoid of pigment, including the central forehead, chin, and trunk, with relative sparing of the dorsal surface. Eyebrows and midarm and midleg skin may also be depigmented. Within these areas, smaller, normally pigmented or hyperpigmented patches may be evident (Fig. 97-5).

### Diagnosis

Piebaldism is readily differentiated from albinism, in which the absence of pigment is uniform. Vitiligo may have a similar appearance, but it is not congenital and usually does not remain fixed. Occasional families may have associated defects such as sensorineural deafness and mental retardation (Telfer et al, 1971). Piebaldism is unrelated to Waardenburg syndrome, an autosomal dominant condition that features a white forelock, widened nasal bridge, and cochlear deafness.

### Prognosis and Treatment

The leukoderma and white forelock remain constant throughout life. Cosmetic camouflage is a treatment option suitable for infants and children. Surgical options are evolving.

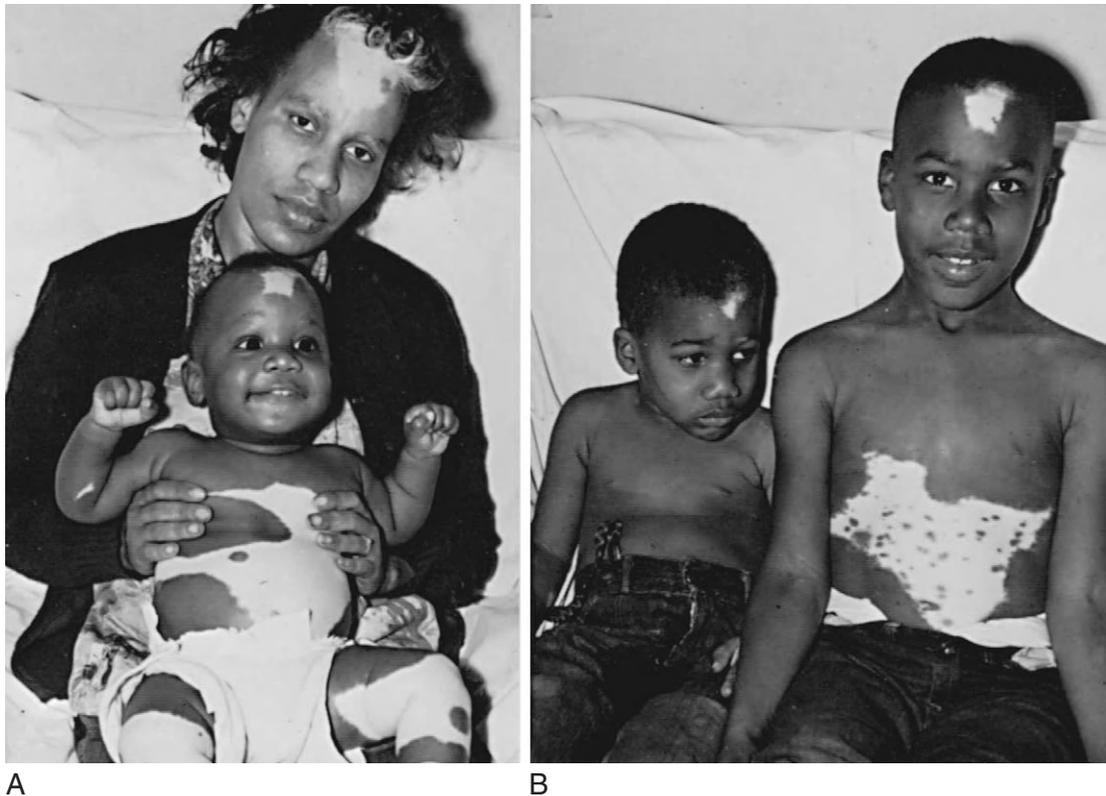

## Aplasia Cutis Congenita

The congenital absence of skin is a cutaneous anomaly most often affecting the scalp but occasionally involving the trunk and extremities.

### Causes

Several distinct subtypes of aplasia cutis have been described based on the distribution, mode of inheritance, and associated abnormalities (Frieden, 1986). Most cases of aplasia cutis congenita occur sporadically; autosomal dominant and autosomal recessive modes of transmission also have been well documented (Sybert, 1985). Associated abnormalities include cleft lip and palate, limb anomalies, cutaneous organoid nevi, and EB. Aplasia cutis may overlie embryologic malformations such as meningocele and spinal dysraphia, omphalocele, and gastroschisis (Frieden, 1986; Sybert, 1985). In addition, scalp defects are associated with specific teratogens (methimazole, intrauterine varicella, herpes simplex) and malformation syndromes (trisomy 13, Johanson-Blizzard syndrome, amniotic band disruption complex, and the ectodermal dysplasias). Extensive aplasia cutis has been associated with elevated alpha-fetoprotein in maternal serum and amniotic fluid (Gerber et al, 1993).

The cause of aplasia cutis congenita is unknown. Basically, it is a phenotypic physical finding signifying disruption of the skin in utero attributable to any of numerous causes. Findings of a twin fetus papyraceus or a placental

A

B

**FIGURE 97-5.** A, Mother and child with piebaldism. Both have patches on the forehead, although of different sizes and shapes. The areas of nonpigmentation on the infant's trunk and extremities are unusually extensive. B, Siblings with different degrees of piebaldism. (From Jahn HM, McIntire MS: *Am J Dis Child* 88:481, 1954. © American Medical Association.)

infant have suggested vascular thrombosis as a cause in infants with lesions on the trunk and limbs (Levin et al, 1980).

#### Clinical Findings

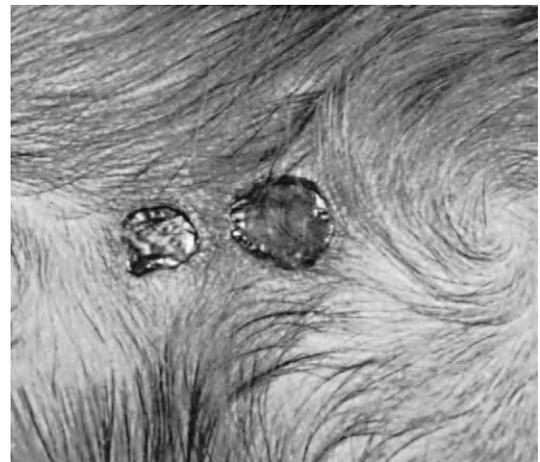

The defect is usually along the midline of the scalp in the parietal or occipital area. Lesions are sharply margined and may manifest as ulcers, bullae, or scars. Lesions may be solitary or multiple, measuring up to several centimeters in diameter (Fig. 97-6). Up to 30% of affected infants have underlying defects of the calvaria. Multiple defects, particularly those on the trunk and extremities, may be strikingly symmetrical in distribution (Levin et al, 1980). Larger defects are often deeper and may extend to the dura or meninges. These may be complicated by meningitis, hemorrhage (which can be fatal), or venous thrombosis.

Histologic examination of tissue from the defect demonstrates an absence of epidermis and a diminished number of appendageal structures and dermal elastic fibers or, in deeper lesions, the absence of all layers of the integument. There is no evidence of inflammation or pathogenic organisms.

#### Prognosis and Treatment

Cutaneous and bony lesions can heal spontaneously over a period of weeks to months. A hypertrophic or atrophic patch of alopecia remains. Patients with larger and deeper lesions must be observed for the possibility

of a complicating meningitis. Prophylactic excision with repair should be considered in these cases. Lesions that fail to heal or produce cosmetically unacceptable scars can be excised with primary closure (Kosnik and Sayers, 1975).

**FIGURE 97-6.** Skin is absent in two sharply margined areas on the scalp of a normal newborn male infant whose mother's labor and delivery were normal. The defects extended to the subcutaneous tissue and healed in 3 weeks with the formation of thin, white atrophic scars.

## Incontinentia Pigmenti

Incontinentia pigmenti (IP), also known as the Bloch-Sulzberger syndrome, is a disorder of the developing neuroectoderm, characterized by three distinctive, transient stages of cutaneous lesions and variable persistent abnormalities of the CNS, eyes, teeth, hair, and nails.

### Causes

IP is inherited in an X-linked dominant fashion. Surviving females are mosaics, whereas most hemizygous males do not survive embryogenesis. Molecular research points to mutations at one genetic locus at Xq28 as the cause of all true cases of IP. The nuclear factor *kB* essential modulator gene (*NEMO*) codes for a transcription factor. Eighty percent of IP cases were found to result from a single mutation (Berlin et al, 2002).

### Clinical Findings

The diagnosis of IP is made by cutaneous examination. Most patients exhibit three stages of skin lesions that persist for varying periods (O'Brien and Feingold, 1985). The *vesiculobullous* phase presents at birth and generally lasts for several months. It is characterized by widespread inflammatory vesicular lesions on the scalp, trunk, and extremities in a whorled and linear distribution along the lines of Blaschko (Fig. 97-7A). The infant is otherwise well, although markedly elevated leukocyte counts and

peripheral eosinophilia with as much as 79% eosinophils may be associated (Berlin et al, 2002). The vesicular phase evolves into a *verrucous* phase, in which warty lesions appear in roughly the same distribution as the blisters but are most pronounced on the hands and feet. The third stage is characterized by macular gray or brown pigmentation distributed along Blaschko's lines, independent of the sites of previous lesions (see Fig. 97-7B). The pigmentary lesions usually fade in later years and may disappear by adulthood. Rarely, the stage three pigmentary changes are present at birth, and the first two stages are never evident (Lerer et al, 1973). Fourth-stage lesions, seen in some affected women, consist of hypopigmented, atrophic, anhidrotic streaks, usually localized to the legs (Moss and Ince, 1987).

Eighty percent of affected persons have extracutaneous involvement, including CNS aberrations (seizures, microcephaly, retardation, and spastic paralysis), patchy alopecia, defective dentition, ocular abnormalities, and less commonly, bone defects (Carney, 1976).

### Diagnosis

Infants with IP usually present with blisters. The linear distribution of blisters is often so characteristic that it permits instant recognition of the disorder. But other causes of blisters must be considered in the differential diagnosis (see Chapter 96). Skin biopsy during the bullous phase will show intraepidermal vesicles filled with eosinophils.

A

B

**FIGURE 97-7.** Incontinentia pigmenti. **A**, Inflammatory vesicular and crusted lesions on the legs. **B**, Whorled pigmentation developing on the trunk of a 1-month-old infant, who still has inflammatory lesions on the limbs.

These features are not pathognomonic but help exclude more ominous causes of neonatal blistering. Clinicians should refer patients for genetic testing to the DNA Diagnostic Laboratory at Baylor College of Medicine (see under “Incontinentia Pigmenti” in Resources section).

### Prognosis and Treatment

Treatment of the skin lesions is not necessary. Occasionally, vesicular lesions become extremely inflamed or secondarily infected. Patients should be monitored for the development of other anomalies, especially of the eyes, teeth, and CNS. Genetic counseling is indicated. Two IP support groups for patients and their families are the Incontinentia Pigmenti International Foundation and the Incontinentia Pigmenti Support Network (see Resources section).

## Cutis Laxa

Cutis laxa is a rare, heterogeneous group of genetic abnormalities of connective tissue with striking cutaneous features. Autosomal dominant, autosomal recessive, and X-linked forms have been described (Beighton, 1972; Byers et al, 1980). Cutis laxa-like skin changes can also be found in other disorders (e.g., combined immunodeficiency disease, the Prader-Willi and Langer-Giedion syndromes).

### Clinical Features

Cutis laxa-like skin hangs in pendulous folds, producing a facies with a hooked nose, everted nostrils, a long upper lip, sagging cheeks, and a prematurely aged appearance (Fig. 97-8). The infant may have a hoarse cry due to redundant laryngeal tissue. Persons with the autosomal dominant form of cutis laxa suffer few ill effects, apart from their altered appearance, and enjoy good health and a normal life span. Pulmonary and cardiovascular manifestations are absent or minimal. In contrast, patients with the recessive form of the disorder are often seriously compromised and may die in childhood of pulmonary or cardiovascular complications. Systemic manifestations include diverticula of the gastrointestinal and urogenital tracts, rectal prolapse, multiple hernias, pulmonary emphysema, and cardiac disease (Mehregan et al, 1978). A few infants have been reported who manifested additional defects, such as skeletal anomalies, dislocation of the hips, and intrauterine growth retardation (Sakati et al, 1983).

### Diagnosis

The clinical manifestations of cutis laxa can be attributed to abnormalities of elastin. Elastic fibers are diminished in the papillary and upper dermis, whereas those in the lower dermis undergo fragmentation and granular degeneration (Mehregan et al, 1978). Similar changes occur in the elastic tissue of affected viscera. Autosomal recessive cutis laxa has been associated with a deficiency of lysyl oxidase, a copper-dependent enzyme mapped to chromosome 5 (Khakoo et al, 1997). The X-linked form has been associated with abnormal intracellular copper metabolism, with a decrease in the activity of lysyl oxidase. This form of cutis laxa, once classified as type IX Ehlers-Danlos syndrome,

**FIGURE 97-8.** Newborn infant with clinical features of Menkes syndrome and cutis laxa.

was redefined as occipital horn syndrome, an X-linked recessive condition allelic to Menkes syndrome (Beighton et al, 1988; Byers, 1994; Goldsmith, 1990) (see Fig. 97-8).

### Treatment

Plastic surgery can improve the physical appearance of patients with cutis laxa (Thomas et al, 1993). The internal manifestations are not amenable to therapy.

## Ehlers-Danlos Syndrome

The Ehlers-Danlos syndrome (EDS) is another heterogeneous group of inherited connective tissue disorders. In contrast to patients with cutis laxa, those with EDS have skin that is hyperextensible rather than loose; when stretched, the skin readily snaps back into place. Skin fragility is another feature, leading to easy bruising and bleeding, gaping wounds, and numerous cigarette paper-like scars. Joint hypermobility is another major manifestation. The classification of EDS is evolving, and the latest classification scheme now identifies six major types: the classic type, the hypermobility type, the vascular type, the kyphoscoliosis type, the arthrochalasia type, and the dermatosparaxis type. The kyphoscoliosis and dermatosparaxis types are inherited in an autosomal recessive fashion, whereas inheritance for the other four types is autosomal dominant. In addition, there are other known cases of EDS that do not fit into one of these types and await further characterization (Beighton et al, 1998). Persons with the vascular type of EDS (type IV by previous classification) can be easily distinguished from those with the other forms by their thin, translucent skin, marked bruising, and normal range of motion. It is especially important to identify this group because of its life-threatening complications (Byers, 1994).

### Causes

All forms of EDS are believed to be due to defects in the biogenesis of collagen. The vascular type is characterized by a variety of defects in the synthesis of type III collagen, the kyphoscoliosis type by lysyl hydroxylase deficiency, the

arthrochalasia type by defective processing of type I collagen, and the dermatosparaxis type by procollagen N-proteinase deficiency. These specific defects can be identified by culture of dermal fibroblasts from a skin biopsy.

### Treatment

Recognition of the correct subtype is important for prognosis. The vascular type of EDS is particularly important to identify because of the life-threatening association with arterial, bowel, and uterine ruptures. There is no effective treatment for the various forms of EDS. Affected patients tolerate surgical procedures poorly because of difficulty in healing and frequent dehiscence of surgical wounds. Repair of cutaneous wounds may require the services of a plastic surgeon, and progressive joint disease will require ongoing orthopedic care. The Ehlers-Danlos National Foundation can provide additional information and support for affected families (see Resources section at the end of the chapter).

## Epidermolysis Bullosa

Epidermolysis bullosa (EB) is a diverse group of diseases that is characterized by skin blistering. Classification is based on clinical characteristics, inheritance pattern, and the level of cleavage within the skin, as determined by skin biopsy. This prominent histologic feature defines three main groups: simplex (cleavage within the basal cells of the epidermis), junctional (within the lamina lucida of the basement membrane zone), and dystrophic (beneath the lamina lucida of the basement membrane). At each level, there are several protein components that contribute to skin integrity. These molecules all are expressed in utero during the first trimester, allowing prenatal diagnosis by skin biopsy (Holbrook et al, 1993). Further progress in the field has led to a simplified classification system that recognizes 10 major subtypes; three major EB types, epidermolysis bullosa simplex (EBS), junctional epidermolysis bullosa (JEB), and dystrophic epidermolysis bullosa (DEB); and 11 minor subtypes. (Fine et al, 2000). Research efforts have been greatly enhanced by the Dystrophic Epidermolysis Bullosa Research Association of America (DEBRA) (see Resources section) and the National Epidermolysis Bullosa Registry (see Resources section) (Fine et al, 1994). Identification of the molecular basis of a number of EB genotypes has not only facilitated prenatal and postnatal diagnoses but has also provided insight into the pathogenesis of blistering diseases, as well as the basic mechanisms of epithelial and basement membrane integrity.

### Epidermolysis Bullosa Simplex

EB simplex features blisters that arise within the basal layer of the epidermis. For this reason, the lesions of EB simplex do not scar. Four major subtypes and several minor subtypes have been recognized (Fine et al, 2000). The molecular defects of EB simplex have been localized to the genes encoding specific keratins, *K14* (located on chromosome 17) and *K5* (located on chromosome 12), except for EB with muscular dystrophy, which is due to a defect in plectin. Keratins *K5* and *K14* are expressed predominantly in the basal cells of the epidermis, and these

disorders are closely related to epidermolytic hyperkeratosis (Francis, 1994) (see earlier section on ichthyoses). The four major subtypes are described next.

#### ***Epidermolysis Bullosa Simplex, Koebner Subtype***

ES simplex, Koebner subtype (EBS-K), inherited as an autosomal dominant trait, is present at birth or early in infancy. Bullae arise most frequently over pressure points, such as the elbows and knees, as well as on the legs, feet, and hands. Mucous membrane involvement occurs primarily during infancy. The extensive erosions that sometimes result from the trauma of birth may be mistaken for aplasia cutis. Nails may be lost but almost always regrow. The prognosis is relatively good, and the propensity to blister may decrease with age.

#### ***Epidermolysis Bullosa Simplex, Dowling-Meara Subtype***

EB simplex, Dowling-Meara subtype (EBS-DM), is inherited as an autosomal dominant trait and causes generalized, often extensive blistering in the neonatal period and early years of life. Herpetiform grouping of the blisters is characteristic. Additional findings include nail dystrophy, palmoplantar keratoderma as a late feature, and improvement with age.

#### ***Epidermolysis Bullosa Simplex, Weber-Cockayne Subtype***

EB simplex, Weber-Cockayne subtype (EBS-WC), is inherited in autosomal dominant fashion and usually does not manifest during the neonatal period. The blisters in this disease usually are limited to the hands and feet, although they occasionally occur elsewhere on the body.

#### ***Epidermolysis Bullosa Simplex with Muscular Dystrophy***

EB simplex with muscular dystrophy (EBS-MD) is a rare variant that is inherited in an autosomal recessive fashion. Affected persons usually demonstrate blisters on the skin and mucous membranes at birth or shortly thereafter. EBS-MD is associated with tooth enamel hypoplasia and nail dystrophy. Progressive muscular dystrophy usually occurs later in life (Shimizu et al, 1999).

### Junctional Epidermolysis Bullosa

Junctional EB (JEB) is characterized by cleavage within the lamina lucida of the basement membrane zone. Three major subtypes are now recognized: JEB, Herlitz subtype; JEB, non-Herlitz subtype; and JEB with pyloric atresia. Molecular defects have been recognized within several proteins found in the basement membrane zone, including laminin-5, type XVII collagen, and the  $\alpha_6\beta_4$ -integrin complex. Several subtypes of JEB are relatively localized and benign (Fine et al, 2000). The major subtypes are described next.

### ***Junctional Epidermolysis Bullosa, Herlitz Subtype***

JEB, Herlitz type (JEB-H), was formerly known as EB gravis or letalis because many affected patients die in infancy. Generalized blistering is noted at birth. Persons with this form of JEB can, however, exhibit a spectrum of severity. Bullae and moist erosions occur on the scalp, in the perioral area, and over pressure points elsewhere on the body (Fig. 97–9A). Some of these erosions become the sites of vegetating granulomas, a pathognomonic finding. The hands and feet are relatively spared, and digital fusion, inevitable in the recessive dystrophic type of EB, does not occur. Nails are affected and may be lost permanently. Defective dentition is the rule, but mucous membrane erosions are inconspicuous and rarely cause problems. Laryngeal involvement can occur in childhood, manifested as hoarseness or stridor. These patients grow poorly, appear malnourished, and have chronic recalcitrant anemia.

### ***Junctional Epidermolysis Bullosa, Non-Herlitz Subtype***

JEB, non-Herlitz subtype (JEB-nH), is a disorder of autosomal recessive inheritance that carries the best prognosis of the major subtypes, with affected persons often surviving into adulthood. Onset is usually at birth, with generalized blistering; dystrophic nails or absence of nails is common (Fine et al, 2000).

### ***Junctional Epidermolysis Bullosa with Pyloric Atresia***

JEB with pyloric atresia (JEB-PA) is a rare, autosomal recessively inherited disease characterized by mucocutaneous fragility. JEB-PA is usually fatal in the first few

weeks of life, although mild cases have been reported. Polyhydramnios seen at ultrasound examination may be the first clue to gastric outlet obstruction. Generalized blistering and ulcerations of skin and mucous membranes usually are evident at birth. The urinary tract frequently is involved, stenosis being a common complication for survivors (Mellerio et al, 1998).

### ***Dystrophic Epidermolysis Bullosa***

Dystrophic EB is characterized by subepidermal blistering, below the level of the lamina densa of the basement membrane. The anchoring fibrils that link the lower part of the basement membrane to the papillary dermis are composed of type VII collagen. Mutations of the gene that codes for type VII collagen have been identified in most forms of dystrophic EB. This group of diseases is characterized clinically by milia and scarring at the sites of healed blisters. There are three major subtypes and several minor subtypes. All are present at birth (Fine et al, 1991b). Prenatal diagnosis as early as 8 to 10 weeks is possible by molecular techniques for some families. The three major subtypes are described next, as well as one of the more distinctive minor subtypes.

### ***Dominant Dystrophic Epidermolysis Bullosa***

Dominant dystrophic EB (DDEB) is a relatively mild form, inherited as an autosomal dominant trait. Generalized blistering usually is noted at birth. In some cases, blistering may appear only on the hands, feet, elbows, or knees; this pattern is usually due to mechanical trauma. Rarely does scarring cause immobility and deformity of the hands and feet. Small cysts or milia are seen at sites of scarring. There may be mild involvement of the mucous

A

B

**FIGURE 97–9.** **A**, Multiple moist erosions characteristic of junctional epidermolysis bullosa. Note involvement of fingers and perioral skin. **B**, Large bullae on the feet of an infant with a scarring form of epidermolysis bullosa.

membranes; nails may be thick, dystrophic, or destroyed. Some persons affected by this form of EB may note the presence of small, firm, flesh-colored or white skin elevations that appear spontaneously on the trunk and extremities, called *albopapuloid lesions*.

The Cockayne-Touraine and Pasini types of EB formerly were considered to represent two generalized forms of dominant dystrophic EB but are now included within DDEB in the new classification system. The bullae are subepidermal and heal with scarring, but the process may be relatively limited, involving mainly hands, feet (see Fig. 97–9B), and skin over bony protuberances, or may be generalized, particularly in the Pasini variant. Nails may be lost. Milia are common and may appear in profusion in the soft, wrinkled scars; pigmentary changes also are usual. Mucous membrane lesions, if present, are mild, and general health may be unimpaired. The appearance of albopapuloid lesions on the trunk during adolescence is a unique feature of the Pasini variant.

### **Transient Bullous Dermolysis of the Newborn**

The rare variant transient bullous dermolysis of the newborn was first reported in 1985. Autosomal dominant and recessive forms have been described. The dominant form is now thought to be a form of DDEB. Affected neonates present with alarming acral or generalized blistering that heals with scars. Histologic analyses have localized the abnormality to the precursors of the anchoring fibrils, and genetic studies have shown mutations in a gene that codes for type VII collagen in some cases (Hammami-Hauasli et al, 1998). This condition is unique among the subsets of EB because it spontaneously resolves within the first years of life.

### **Recessive Dystrophic Epidermolysis Bullosa, Hallopeau-Siemens Subtype**

Recessive dystrophic EB, Hallopeau-Siemens subtype, is the more severe form of recessive dystrophic EB. Infants with Hallopeau-Siemens EB often have extensive denuded lesions at birth and during the neonatal period. Bullae may be hemorrhagic and occur on all surfaces, including the hands and feet; loss of the nails is usual. Over subsequent years the mobility of the fingers and toes becomes severely impaired as fusion of digits, bone resorption, and the inevitable mitten-like deformity of the hands and feet ensue. Mucous membrane involvement may be severe, resulting in esophageal strictures and serious impairment of nutrition due to the restriction of oral intake. These bullae are subepidermal and always eventuate in scarring. Affected persons have a markedly increased risk of skin cancer, with a 39.6% cumulative risk of developing squamous cell carcinoma and a 2.5% cumulative risk of developing malignant melanoma by age 30 (Fine et al, 2000). Electron microscopy reveals diminished or absent anchoring fibrils associated with marked degeneration of type VII collagen in the papillary portion of the dermis. Also evident is excess abnormal collagenase in fibroblast cultures.

### **Recessive Dystrophic Epidermolysis Bullosa, Non-Hallopeau-Siemens Subtype**

Recessive dystrophic EB, non-Hallopeau-Siemens subtype, is the less severe form of recessive dystrophic EB. It is characterized by onset at birth, generalized blisters to include the mucosal surfaces, atrophic scarring over bony prominences and either nail loss or nail dystrophy. Milia, mild finger flexion contractures, albopapuloid lesions, dental disease, and external ear involvement also are often seen. According to one report, affected patients also have an increased risk of squamous cell carcinoma of about 14% by age 30 (Fine et al, 2000).

## **Diagnosis and Treatment of Epidermolysis Bullosa**

### **Diagnosis**

Arriving at the correct diagnosis can be difficult, especially in the neonatal period. The differential diagnosis includes the spectrum of blisters and bullae outlined in Chapter 96. The distribution of blisters can be a clue. In EB, the earliest lesions occur on points of friction, such as the heels, wrists, knees, and sacrum. The fluid within the bullae is likely to be clear or hemorrhagic, rather than purulent. A careful family history for blistering diseases should be obtained. The most precise diagnostic tool is a carefully performed skin biopsy to obtain specimens for immunofluorescence mapping and ultrastructural study. The sample for immunofluorescence should be obtained from normal or perilesional skin, excluding the palms or soles, and placed in Zeus or Michel transport medium. The ideal specimen for electron microscopy is a new spontaneous or induced blister preserved in glutaraldehyde (Fine et al, 1994). After the diagnosis of simplex, junctional, or dystrophic EB is made, further subclassification can be difficult during infancy for subsets without a defined genotype. In these patients without relevant family history, distinguishing clinical features may take months or years to develop.

### **Treatment**

To date, the mainstay of therapy for this group of disorders is supportive. The infant should be protected from frictional trauma; direct pressure is tolerated. Latex gloves can stick to the skin and should be lubricated with petrolatum. Bedding should be of a soft material. Dressing changes should be performed daily. Adequate premedication for pain control should be given. Bathing may have to be restricted to avoid excessive handling. Compresses with normal saline or Burow solution for eroded areas may be helpful in some instances. Tepid compresses should be used, because warm temperatures increase the tendency to blister. Intact blisters should be lanced with an adequate incision to drain the fluid, while the roof is maintained as a “biologic dressing.” Wounds should be covered with petrolatum-impregnated gauze. Topical antibiotics may promote healing, but content and quantity should be carefully monitored in young infants (see Chapter 98). Topical mupirocin is the antibiotic of choice at several EB centers; bacterial resistance has been reported in chronic users with EB. Commercially available

nonadhesive dressings are simpler to use and more effective than plain gauze wraps. Exudry pads, secured with Surginet or conforming gauze, are recommended for draining wounds on the body. Omiderm (Doak Pharmaceuticals) is a nonadhesive polyurethane dressing that provides an excellent barrier for moist wounds on the face and hands. Adhesive tape should never be applied, because large areas of epidermis may be torn off with its removal. Dressing should be applied to blistered areas only to maximize the infant's tactile stimulation. For the newborn, environmental temperature must be carefully monitored; overheating may result in extensive blistering. For patients with mucous membrane involvement, soft nipples, bulb syringes, and devices used for feeding infants with cleft palates should be used. Chronic serosanguineous drainage and gastrointestinal involvement often result in poor nutritional status. Iron deficiency anemia is another common complication in infants with severe disease. Routine use of aggressive nutritional supplementation is recommended. After discharge, cribs, high chairs, and infant seats should be well padded, and only soft toys offered for play (Gibbons, 1990).

Caregivers should be given anticipatory guidance about protective measures, wound care, and nutrition. The practitioner should encourage contact with DEBRA, a privately funded organization that is an excellent resource for affected families. DEBRA can provide practical information for day-to-day care and direct families to the appropriate regional center for specialized care (see Resources section). To register newly diagnosed patients, clinicians should contact the National Epidermolysis Bullosa Registry (see Resources section).

### Neonatal Lupus Erythematosus

Neonatal lupus erythematosus (NLE) is an uncommon immune-mediated disease that results from transplacental transfer of maternal immunoglobulin G (IgG) antinuclear antibodies. It manifests within the first 2 months of life. Infants present with a spectrum of signs, including transient cutaneous lesions, thrombocytopenia, hepatitis, and/or congenital heart blocks; all affected infants have serologic evidence of lupus erythematosus during the first few months of life (Lee, 1993; Lee and Weston, 1984; Provost et al, 1987).

#### Causes

NLE is always marked by the presence of anti-Ro (SS-A), anti-La (SS-B), and/or anti-U<sub>1</sub>RNP autoantibodies in the mother and infant. With the exception of congenital heart block, most of the manifestations of neonatal lupus resolve with the disappearance of maternal antibodies, suggesting an important role for these antibodies in pathogenesis. An association with HLA-DR3 in the mother but not the infant also has been documented (Lee and Weston, 1984). Ro-positive HLA-DR2 mothers, in contrast, produce unaffected infants (Provost et al, 1987).

#### Clinical Findings

Half of the affected infants have skin lesions. These may be present with or without evidence of systemic disease (Hardy et al, 1979). Skin lesions are typically annular erythematous scaling plaques (Fig. 97-10), with a predilection

**FIGURE 97-10.** Newborn with cutaneous lesions of neonatal lupus erythematosus.

for sun-exposed areas. These begin to resolve at about 6 months, concurrent with the disappearance of maternal antibodies. Persistent telangiectatic matting in a characteristic distribution, involving the scalp, lips, and vulva, also has been described (Fig. 97-11) (Thornton et al, 1995).

**FIGURE 97-11.** Telangiectatic matting of the scalp, lips, and groin is a recently recognized cutaneous marker of neonatal lupus.

### Diagnosis

The skin lesions of NLE can be mistaken for several cutaneous disorders including syphilis, seborrheic dermatitis, dermatophytosis, atopic dermatitis, and psoriasis. Skin biopsy may demonstrate the histopathologic features of lupus. More reliable, however, is the detection of Ro (SS-A) and/or La (SS-B) antibody in serum from the infant and the mother.

The North American Collaborative Study of NLE is an ongoing prospective study of all aspects of the disease. To arrange for enrollment and serologic testing of patients, clinicians should contact study investigators (see under “Neonatal Lupus Erythematosus” in Resources section).

### Prognosis and Treatment

Affected infants should be protected from sources of ultraviolet light (sunlight and daylight fluorescent bulbs) by application of a broad-spectrum sunscreen such as titanium dioxide, zinc oxide, and sun-protective clothing [Sun Precautions, Seattle, Washington; telephone: (800) 882-7860]. Active skin lesions may be treated with a topical corticosteroid.

The prognosis is excellent, except in affected infants who develop congenital heart block. Most infants with congenital heart block will require a pacemaker, and death will occur in about 20% (Tseng and Buyon, 1997).

It is important to recognize that asymptomatic mothers are at risk for development of disorders associated with their serologic abnormalities (e.g., Sjögren syndrome, subacute cutaneous lupus, systemic lupus erythematosus). There is a 25% risk of involvement for each subsequent pregnancy (Gawkrodger and Beveridge, 1984; McCune et al, 1987).

## Ectodermal Dysplasias

The ectodermal dysplasias (EDs) are a heterogeneous group of inherited disorders characterized by defects in the development of two or more structures of ectodermal origin. The major structures involved are hair follicles, nails, teeth, and sweat glands; sebaceous glands, conjunctivae, and/or the lens also may be affected. A formal classification system has been created for the EDs, based on the specific structures affected (Pinheiro and Freire-Maia, 1994). One hundred fifty-four syndromes have been included in this grouping. Several of these, such as incontinentia pigmenti and syndromes associated with ichthyosis, have not been traditionally regarded as ED. Many others have been reported rarely. The National Foundation for Ectodermal Dysplasias (NFED) is a privately funded organization committed to locating affected families and providing them with information and support (see Resources section). The NFED also coordinates and funds research efforts.

Three of the more well-characterized types of ED are described next.

### Hypohidrotic Ectodermal Dysplasia

Hypohidrotic ED, inherited as an X-linked recessive disorder, was the first type of ED described, as Christ-Siemens-Touraine syndrome. It was previously referred to

as “anhidrotic,” but affected persons may have a limited capacity to sweat, and the preferred descriptor is *hypohidrotic*. This type of ED occurs in 1 in 100,000 male births and manifests during the first year of life. The most serious problem is diminution of the sweating response due to rudimentary or absent eccrine sweat glands, which results in marked heat intolerance and episodes of hyperpyrexia, frequently misinterpreted as fever of unknown origin (Richards and Kaplan, 1969). If ED is not considered in the differential diagnosis, these infants may be subjected to numerous unnecessary hospitalizations and tests.

### Clinical Features

Patients with hypohidrotic ED have several characteristic features that may be subtle in the newborn. One common neonatal sign is severe peeling or scaling skin. This skin change, which can be misconstrued as an indication of postmaturity, may provide a valuable clue to the diagnosis (Executive and Scientific Advisory Boards of the NFED, 1989). Thereafter, the skin may appear relatively pale and dry, with a prominent venous pattern over most of the body, but hyperpigmented and wrinkled in the periorbital area (Fig. 97–12).

The craniofacial characteristics of frontal bossing, depression of the midface, flattened nasal bridge, thick protruding lips, and prominent chin may not be readily apparent in the newborn. Likewise, the sparse, unruly, light-colored hair and scanty brows and lashes also are difficult to appreciate in the first few months. The changes in dentition cannot, of course, be detected until late infancy. Hypodontia with conical, poorly formed teeth is the rule; these changes can be identified on dental panoramic radiographs prior to eruption of the teeth. Atrophic rhinitis, diminished lacrimation, hoarseness, and hypoplasia or absence of mucous glands in nasotracheobronchial passages are also frequent findings in these patients (Reed et al, 1970). If the diagnosis is in doubt, palmar skin biopsy may demonstrate absent or hypoplastic eccrine sweat glands. Techniques used to elicit sweating, such as pilocarpine iontophoresis or examination of the

**FIGURE 97-12.** Girl with fully expressed anhidrotic ectodermal dysplasia. Note the sparse wispy hair, hyperpigmentation around the eyes, depressed nasal bridge, and protruding lips and ears.

sweat pores on the palm with *O*-phthalaldehyde, also can be utilized to demonstrate the defect (Esterly et al, 1973). Atopic dermatitis occurs frequently in these children (Reed et al, 1970), as well as a decrease in T-cell function (Davis and Solomon, 1976).

Hypohidrotic ED is transmitted as an X-linked recessive trait. The gene has been localized to Xq11.21.1. First-trimester prenatal diagnosis is possible (Zonana et al, 1990). All affected males fully express the disease, whereas carrier females have variable expression of the clinical signs. This expression can be explained by the inactivation of a random percentage of abnormal X chromosomes. In these females, hypohidrosis can be demonstrated in areas of skin marking the lines of Blaschko (see the section on mosaicism) (Bologna et al, 1994; Crump and Danks, 1971; Esterly et al, 1973; Gorlin et al, 1970).

Once the diagnosis is made, it is important to educate parents so that these children are protected from overheating. Defective lacrimation can be palliated by the use of artificial tears. The nasal mucosa should be treated with saline drops or irrigation followed by application of petrolatum. Regular dental evaluations should be started early in life and dentures fitted to promote good nutrition, articulation, and normal appearance before the child starts school. Some of these children also choose a wig and reconstructive procedures later in life to improve facial configuration.

### Hidrotic Ectodermal Dysplasia

Hidrotic ED, also known as Clouston syndrome, is an autosomal dominant condition. Affected individuals have characteristic abnormalities of skin, hair, and nails, whereas eccrine and sebaceous functions and dentition are normal. The phenotype is easily recognizable in early childhood, with features including thickened, conical nails and widening of the distal periungual area with cerebriiform furrowing. The skin over the joints often is hyperpigmented. The degree of alopecia is variable. The genetic abnormality in hidrotic ED has been mapped to the *GJB6* gene at 13q11-q12.1 encoding connexin 30 (Lamartine et al, 2000).

### Ectodermal Dysplasia–Ectrodactyly–Cleft Lip/Palate Syndrome

The ectodermal dysplasia–ectrodactyly–cleft lip/palate (EEC) syndrome is an autosomal dominant condition featuring ectodermal dysplasia (including dental, ocular, nail, and hair defects), ectrodactyly (lobster-claw deformity of the hand), and cleft lip/palate. The cutaneous and appendageal anomalies include diffuse hypopigmentation affecting both skin and hair, scanty scalp hair and eyebrows, dystrophic nails, and small teeth with enamel hypoplasia. Sweating appears to be intact, and sweat glands are present on skin biopsy. The clefting of the lip is usually complete and bilateral, and the palate has a median cleft. Dry granulomatous lesions in the corners of the mouth often are secondarily infected with *Candida albicans*. Other findings include lacrimal duct scarring, blepharitis and conjunctivitis, xerostomia, conductive hearing loss, and mental retardation. EEC syndrome is caused by

a mutation in the *p63* gene located at 3q27. The *p63* gene, a homologue of the tumor suppressor *p53* gene, is highly expressed in the basal layer of many epithelial tissues (Celli et al, 1999).

## Infections of the Skin\*

Elisabeth G. Richard, Bernard A. Cohen,  
and Elaine C. Siegfried

As a group of potentially life-threatening and often easily treatable diseases, infections are often suspected first in a neonate with skin lesions. Recognition of characteristic morphologic features, aided by a few easily performed tests, will greatly enhance correct diagnosis and early initiation of appropriate therapy of the most common cutaneous infections. In this chapter, we confine our discussion to disease caused by the most common pathogens responsible for neonatal infections that manifest with skin lesions: *Staphylococcus aureus*, *Streptococcus* species, *Candida albicans*, and herpes simplex virus (HSV).

### STAPHYLOCOCCUS AUREUS INFECTIONS

*S. aureus* is a ubiquitous organism, harbored as a commensal organism by greater than 30% of the general population (Ladhani, 2000). Colonization of the anterior nares and perineum is common, with frequent hand carriage (Dancer and Noble, 1991). This bacterial species is responsible for a variety of skin lesions. Infants become colonized with *S. aureus* during the first few weeks of life, following inoculation at the perineum or from handling. Cutaneous signs of *S. aureus* infection are mediated by local or circulating bacterial toxins that act directly on components of the epidermal keratinocytes, or as “superantigens” to stimulate exuberant immunologic responses (Tokura et al, 1994).

#### Bullous Impetigo

Impetigo is a group of superficial skin infections caused by group A streptococci or *S. aureus*, or both. Lesions caused by *S. aureus* can be primarily vesicular and thus are referred to as bullous impetigo. This form of impetigo can occur in nursery-based, epidemic patterns, often attributed to nasal carriage of *S. aureus*.

#### Clinical Findings

Impetigo is one of the most common neonatal skin infections. It occurs during the latter part of the first week or as late as the second week of life, manifested as vesicles or pustules on an erythematous base, most often seen in

the periumbilical area, diaper area, or skin folds. Because the blisters are superficial, intact lesions are usually less than 1 cm in diameter. Larger lesions are flaccid and rupture so easily that they are usually seen as erosions, with a red moist base that develops a thin, varnish-like crust (Fig. 98–1). These lesions heal rapidly without scarring. Lesions are usually not closely grouped, differentiating them from the vesicles of herpes simplex infection.

#### Etiology

*S. aureus* is the primary cause of both bullous and nonbullous impetigo. Group A streptococci usually are associated with the nonbullous form, especially affecting patients with atopic dermatitis. Bullous impetigo is caused by toxigenic strains of coagulase-positive hemolytic *S. aureus*. Most often, the organism can be classified as one of the group II phage types. The incubation period is 1 to 10 days. Skin lesions are the result of local production of an epidermolytic exotoxin that cleaves a desmosomal protein connecting cells in the granular layer of the epidermis, producing superficial blisters. This is the same toxin produced in staphylococcal scalded skin syndrome (Amagi et al, 2000; Yamaguchi et al, 2002).

#### Epidemiology

Persons with skin lesions are highly contagious, but the disease also can be transmitted by asymptomatic carriers. The anterior nares of 30% of the general population are colonized with *S. aureus*, providing a reservoir for hand carriage and nosocomial spread (Doebbeling, 1994; Kragballe et al, 1995). Colonization of health care workers by methicillin-resistant strains poses a potentially serious problem, and outpatient studies now demonstrate methicillin-resistant strains collected in the community (Yamaguchi et al, 2002).

Sporadic cases of impetigo are common, but many nursery epidemics have been reported and should be treated aggressively (Dave et al, 1994). Infected infants may not develop skin lesions until after discharge, so infection control surveillance should include all exposed patients. Overcrowding, insufficient nursery personnel, and inadequate hand washing contribute to nosocomial spread. Treatment of the umbilical cord with an antimicrobial agent has been shown to control epidemic *S. aureus* infections in the neonatal intensive care unit (NICU) (Haley et al, 1995). In the setting of an outbreak, nursery personnel should be surveyed for colonization of the hands and nares. Application of mupirocin ointment to the anterior nares twice daily for 5 days will eliminate nasal carriage for up to 1 year (Doebbeling et al, 1994). Effective hand washing can prevent nosocomial spread; chlorhexidine is among the safest and most effective antimicrobial cleansers for hospital use (Doebbeling et al, 1992).

#### Diagnosis

The diagnosis is supported by the presence of gram-positive cocci in clusters on Gram stain of the contents from an intact pustule and confirmed by bacterial culture.

\*This chapter includes material from the previous edition, to which Nancy B. Esterly, MD, contributed.

**FIGURE 98-1.** Bullous impetigo. Multiple intact and ruptured bullae on the abdomen, hip, and thigh of a newborn infant. No underlying erythema is present.

### Treatment

Bullous impetigo is benign if treated early, but local proliferation with exotoxin production or dissemination can be life-threatening. Treatment should be instituted promptly, and strict isolation maintained until the lesions have resolved. Infants should be closely monitored, and a high index of suspicion maintained for evidence of systemic disease. Infants with periumbilical lesions are at risk for bacterial omphalitis. Extremely limited infections may be treated with topical mupirocin, but this form of therapy should be used with caution in neonates. Application of compresses with sterile water, normal saline, or Burow solution every few hours helps desiccate blisters. More extensive lesions require a systemically administered penicillinase-resistant antibiotic for 7 to 10 days. Sensitivities of the organism cultured should ultimately determine the choice of antibiotics, especially with the rising incidence of methicillin-resistant strains.

### Staphylococcal Scalded Skin Syndrome

Staphylococcal scalded skin syndrome (SSSS) occurs as a generalized manifestation of a circulating toxin produced by *S. aureus* that specifically cleaves cell-to-cell adhesion proteins in the epidermis. Affected infants are erythrodermic, a striking cutaneous finding that suggests a long list of differential diagnostic possibilities. Early diagnosis and treatment of SSSS can be lifesaving.

### Clinical Findings

Affected infants demonstrate abrupt onset of temperature instability and irritability with generalized skin tenderness and erythema that most often starts on the face and spreads rapidly. Erythema often is accentuated in skin folds. Facial edema, conjunctivitis, and crusting around the eyes, nose, and mouth give the infant a characteristic “sad mask” appearance. Flaccid bullae may develop, followed by widespread exfoliation (Fig. 98-2) involving the entire skin surface within hours to days. Blistering is easily elicited by light stroking of intact skin, a diagnostic feature referred to as a Nikolsky sign. When blisters rupture, the skin peels off in sheets, leaving a painful moist, red base. Widespread skin involvement can exacerbate fluid and

**FIGURE 98-2.** Staphylococcal scalded skin syndrome (Ritter disease). Intense erythema and peeling of large areas of epidermis are seen.

electrolyte problems (Frieden, 1989). Whereas in bullous impetigo *S. aureus* is identifiable in the blisters, in SSSS *S. aureus* is present at a primary distant site such as the nose, mouth, or conjunctiva.

SSSS must be distinguished from toxic epidermal necrolysis, a life-threatening condition involving full-thickness epidermal necrosis, most commonly due to a drug reaction. Intraoral mucosal involvement is rare in SSSS but can be striking in toxic epidermal necrolysis.

### Etiology

The signs and symptoms of SSSS are the result of circulating epidermolytic toxin, produced from an often subclinical focus of *S. aureus* infection. Fresh skin lesions do not contain bacteria, and the blisters are culture negative. Two distinct epidermolytic toxins have been identified in SSSS, produced by toxigenic strains of *S. aureus*, phage group I, II, or III. Approximately 5% of *S. aureus* isolates produce the toxins (Farrell, 1999). The exotoxin cleaves desmosomal proteins within the epidermal granular layer, resulting in blisters (Amagi et al, 2002; Resnick, 1992). Superantigenic stimulation of cytokine production also has been demonstrated (Dave et al, 1994).

### Diagnosis

If the diagnosis is in doubt, skin biopsy prepared for frozen section can be examined emergently. The presence of an intraepidermal rather than full-thickness blister will distinguish SSSS from toxic epidermal necrolysis, allowing rapid initiation of appropriate therapy. Other conditions can be ruled out by examination of formalin-fixed sections. If the clinical impression is strong, surveillance samples will define the primary focus of infection. Gram staining

may be performed emergently; cultures will confirm the diagnosis. Common sites of primary infection are the nasopharynx, umbilicus, and ocular conjunctivae; the urine also may demonstrate organisms. Bullous lesions do not contain organisms. Blood culture specimens should be obtained because sepsis, although uncommon, may occur. Phage typing may be of interest in epidemics.

### Treatment

Systemic administration of a penicillinase-resistant penicillin is the therapy of choice. Fluid and electrolyte replacement and measures for maintenance of normal body temperature may be required. Approximately 2 to 3 days after initiation of therapy, the denuded areas become dry, and a flaky desquamation ensues. Crusted and denuded areas may be treated with compresses of Burow or normal saline solution. Application of a bland ointment emollient may accelerate the return of the skin to normal during the flaky desquamative phase. Resolution occurs in another 3 to 5 days. Because the intraepidermal cleavage plane is at the level of the granular layer, scarring occurs only in instances of secondary complications (Frieden, 1989).

## STREPTOCOCCUS SPECIES INFECTIONS

Cutaneous streptococcal infections occur in the newborn but are less common than staphylococcal infections. Group A streptococci have been reported to cause disease of epidemic proportions (Dillon, 1966; Peter and Hazard, 1975) following the introduction of the organism into the nursery by maternal carriers or nursery personnel. The umbilicus is a frequent site of infection. Conjunctivitis, paronychia, vaginitis, and an erysipelas-like eruption also have been described (Dillon, 1966; Geil et al, 1970; Isenberg et al, 1984). Because sepsis and meningitis may result, infected infants should be treated promptly, and strict isolation should be instituted. As with staphylococcal infection, serious efforts should be made to identify the source of the organism. Several nursery outbreaks have been difficult to terminate because colonized infants may show little evidence of disease (Lehtonen et al, 1984). Isolation and treatment of infected infants, disinfection of the umbilical stump as the most likely reservoir of the organism, and penicillin prophylaxis for carriers and exposed infants have been the most effective measures. The infections respond readily to penicillin, which should be administered over a 10-day course.

Group B streptococci are now one of the most frequently encountered pathogens in the newborn nursery. Early-onset disease (during the first week of life), probably acquired in utero or during delivery, most commonly becomes manifest as septicemia with respiratory distress and shock. Late-onset disease (after the first week of life) is acquired post partum and more often takes on the form of meningitis. Patients with early-onset disease may harbor the organism on the skin; however, the presence of this agent on the skin is short-lived compared with other sites (Baker, 1977).

Skin infections caused by group B streptococci are uncommon but have been documented (Belgaumkar, 1975; Hebert and Esterly, 1986; Howard and McCrackin, 1974). Vesiculopustular lesions, cellulitis, and small abscesses all

have been noted. A 10-day course of procaine penicillin is considered the treatment of choice.

## CANDIDA ALBICANS INFECTIONS

*C. albicans* is a frequent pathogen of the female genital tract, especially during pregnancy. Infantile infection may be acquired in utero, during delivery, or postnatally.

### Thrush

#### Clinical Findings

*C. albicans* colonizes the oral cavity and gastrointestinal tract of most neonates, with peak incidence of thrush occurring at 4 weeks of age (Russell and Lay, 1973). The lesions are readily recognized as asymptomatic to moderately painful plaques of white, friable material on an erythematous base over the tongue, palate, buccal mucosa, and gingivae. Candidal infection in the breast-feeding mother-infant dyad is a significant problem, as it can cause considerable pain in the mother and subsequently may lead to premature weaning. Infection frequently recurs and may become chronic (Brent, 2001).

#### Diagnosis

Presumptive diagnosis often is made by physical examination and history, but microscopic examination of scrapings suspended in 10% potassium hydroxide for yeast and pseudohyphal forms is useful. The diagnosis may be confirmed by identification of the organism on culture.

#### Treatment

Nystatin is an antibiotic derived from *Streptomyces noursei* with activity against *Candida* but not dermatophytes. Oral lesions usually respond promptly to a course of nystatin suspension, 100,000 to 200,000 units, administered by mouth four times daily for 14 to 21 days. In refractory cases, an increased dosage of nystatin or systemic therapy may have to be instituted (Hebert and Esterly, 1986). If the breast-feeding mother is affected, treatment of the mother with nystatin cream or oral fluconazole may be indicated. Gentian (crystal) violet is a triphenylmethane antiseptic dye effective against *Candida* species. In a 0.5% or 1% aqueous solution it has been a time-honored, safe, and effective treatment for thrush. Gentian violet is infamous for deep purple staining of the skin, which is transient. Prolonged use of gentian violet has been associated with nausea, vomiting, diarrhea, and mucosal ulceration. Carcinogenicity in mice has been reported (Rosenkranz and Carr, 1971).

### Neonatal and Cutaneous Candidiasis

Neonatal candidiasis manifests 3 to 7 days after birth with mucocutaneous lesions. Infection can be localized or generalized and is usually acquired during birth through an infected birth canal. The disease is rarely invasive in healthy full-term infants.

### Clinical Findings

Localized cutaneous candidal infections are common in infants. Intertriginous areas, particularly the neck folds, axillae, and diaper area (Fig. 98–3A), are most frequently affected. Nails and periungual areas also are sites of predilection. Characteristic primary lesions are tiny vesicopustules that erode and merge, forming bright, erythematous, scaly plaques, often with a scalloped edge. “Satellite” pustules are commonly seen, but by no means are they pathognomonic for this condition. *Oral infection* (thrush) often is seen in neonatal candidiasis following swallowing of infected fluids (Waguespack-LaBiche et al, 1999).

Disseminated neonatal candidiasis can occur as a result of spread from an untreated localized site or by widespread inoculation during the process of birth via passage through an infected birth canal (see Fig. 98–3B). Generalized scaling is the dominant feature, but a careful search may reveal primary vesicopustules and periungual or nail involvement as helpful diagnostic clues (Gibney and Siegfried, 1996). Skin lesions usually resolve with desquamation within 1 to 2 weeks (Darmstadt et al, 2000).

### Diagnosis

The differential diagnosis includes conditions that cause blisters and pustules. A potassium hydroxide preparation that reveals budding yeasts and pseudohyphal forms is the easiest and most cost-effective initial step in establishing the diagnosis. Calcofluor white stain and immunofluorescence microscopy is a more sensitive rapid technique. Positive results on cultures from an intact pustule, skin scrapings, or skin biopsy tissue also support the diagnosis. Cultures of blood, urine, and cerebrospinal fluid are usually negative; however, they are indicated when systemic disease is suspected and in all preterm infants.

### Treatment

The eruption may resolve spontaneously or may become more widespread if left untreated. Localized cutaneous

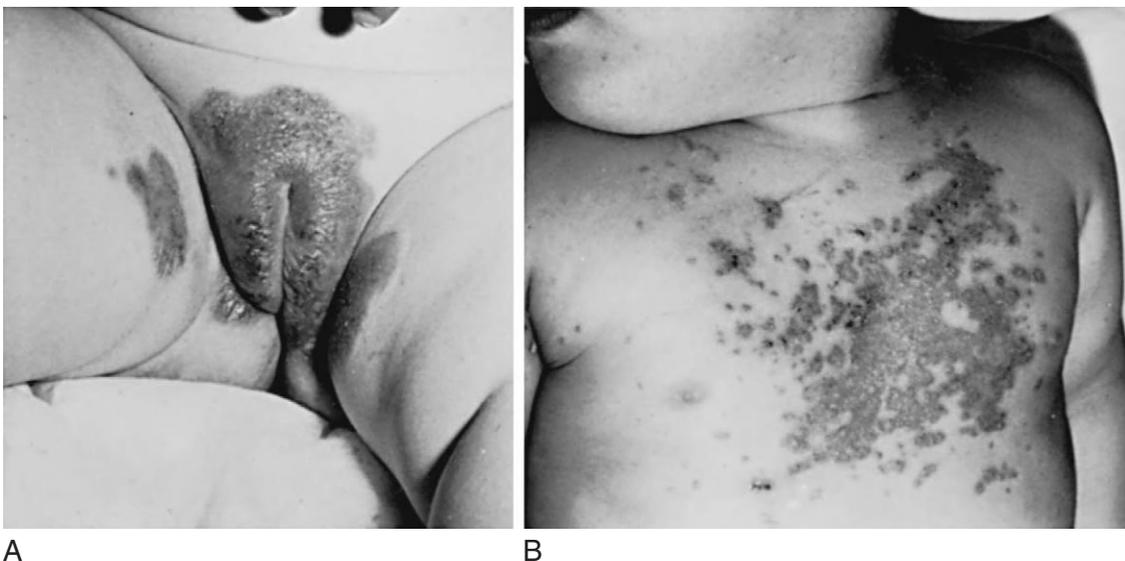

candidiasis in an otherwise healthy infant is most easily treated with a topical candidicidal agent, such as nystatin, one of the imidazoles (e.g., miconazole, clotrimazole, ketoconazole), or ciclopirox olamine. Nystatin in an ointment vehicle may be the least irritating.

### Congenital and Disseminated Candidiasis

Congenital candidiasis is assumed to result from ascending intrauterine infection and usually is noted at birth. This form typically is seen in compromised, premature infants. Disseminated candidiasis also can be acquired during the neonatal period, with 10% of NICU infants becoming colonized in the first week of life. *Candida* septicemia represents 10% to 16% of all cases of sepsis in the NICU, and early recognition and appropriate therapy are lifesaving (Gibney and Siegfried, 1996; Leibovitz, 2002). The estimated crude mortality rate for candidemia is 38% to 75% (Lupetti et al, 2002).

### Clinical Findings

Lesions of congenital candidiasis can be seen on the placenta and fetal membranes, including characteristic granulomas of the umbilical cord (Hebert and Esterly, 1986; Schirar et al, 1974). The cord lesions are multiple yellow-white papules, usually measuring 1 to 3 mm in diameter. The cutaneous eruption of congenital cutaneous candidiasis may be sparse or widespread and consists of papules and vesicopustules on an erythematous base. The face is relatively spared, as are the oral mucous membranes, and there is no predilection for the diaper area. Palmar and plantar pustules, paronychia, and nail dystrophy help distinguish this condition from more common, benign neonatal dermatoses (Fig. 98–4). Bullae and desquamation usually are late features (Fig. 98–5). Very low-birth-weight infants may present with a less specific, scalded skin–like dermatitis due to the organism’s penetration of the immature, compromised epidermal barrier, leading to invasive disease.

**FIGURE 98-3.** A, Sharply demarcated erythematous, scaly candidal rash in the groin. B, Candidal eruption on the central chest of an infant.

**FIGURE 98-4.** Congenital cutaneous candidiasis, pustular stage, in a 6-day-old infant. A maculopapular rash was present at birth. (Courtesy of P. J. Kozinn, N. Rudolf, A. A. Tariq, M. R. Reale, and P. K. Goldberg.)

Systemic involvement occurs via hematogenous or lymphatic spread, most frequently involving the kidney, central nervous system (CNS), and skeletal system. Pneumonia may result from aspiration of infected amniotic fluid and manifests with respiratory distress. Laboratory features include an elevated white blood cell count with a left shift reaching the level of a leukemoid reaction (e.g., 120,000/mm<sup>3</sup>). In addition, persistent hyperglycemia and glycosuria may be present (Darmstadt et al, 2000).

Risk factors for congenital systemic infection include birth weight of less than 1500 g, indwelling catheters, antibiotic therapy, steroid administration, and hyperalimentation. The indication for parenteral therapy may be stronger in infants with these risk factors (Botas et al, 1995; Johnson et al, 1984).

**FIGURE 98-5.** An 8-day-old infant with a generalized erythematous, scaly eruption sparing only the face and scalp. Oral mucosa was not involved. Hyphae and budding yeasts were seen on potassium hydroxide preparation, and *Candida albicans* was cultured from the lesions. The infant's mother had candidal vaginitis during the pregnancy.

### Etiology

Congenital candidiasis is presumed to invade as an ascending infection, crossing the fetal membrane and infecting surfaces that come in contact with amniotic fluid. Disease may be limited to chorioamnionitis and funisitis. Infection also may occur in neonates born to mothers with an intrauterine foreign body such as an intrauterine device (IUD) or a cervical cerclage ring (Darmstadt et al, 2000). Symptomatic vaginitis, chorioamnionitis, and ruptured membranes have no prognostic value for congenital disease (Gibney and Siegfried, 1996; Johnson et al, 1984). Nosocomial acquisition of disseminated disease may be attributed to cluster outbreaks with patient-to-patient spread or caused by horizontal transmission via hospital personnel. Most neonatal fungal infections are caused by *C. albicans* and *Candida parapsilosis*. In recent years, trends indicate a shift toward infection with *C. parapsilosis*, which has a lower associated mortality rate than that for candidemia due to *C. albicans*.

### Diagnosis

The differential diagnosis includes several other neonatal vesiculopustular eruptions that range from benign, self-limited cutaneous processes to rapidly progressive, life-threatening disease. Early and correct diagnosis is essential. Organisms from skin usually are demonstrable on potassium hydroxide or calcofluor white preparations and cultures of scrapings from involved skin. Disseminated disease can be difficult to diagnose. Respiratory distress and infiltrates on chest radiograph will obscure evidence of *Candida* pneumonia because hyaline membrane disease often occurs in the same patient population. Ophthalmologic examination, chest radiograph, and blood, urine, and cerebrospinal fluid cultures may be helpful, but negative findings are not uncommon in disseminated candidiasis (Johnson et al, 1984). Histologic examination of specimens from the placenta and umbilical cord prepared with the appropriate stains may demonstrate fungal elements. Urinalysis positive for budding yeast or urine culture positive for *C. albicans* may be quickly dismissed as being due to

contaminants, but such findings are strongly associated with systemic disease in infants at risk. The diagnosis of disseminated candidiasis can be expedited by a positive touch preparation of a punch biopsy specimen. Using this technique, the practitioner firmly imprints the dermal side of the specimen on a microscope slide and then looks for yeast after potassium hydroxide preparation or Gram staining (Held et al, 1988).

### Prognosis and Treatment

Systemic infection with *C. albicans* in premature infants is a serious infection with high morbidity and mortality rates (Johnson et al, 1984). Congenital or acquired candidiasis warrants parenteral antifungal therapy (e.g., with amphotericin B) for infants with any of the following risk factors for disseminated disease: (1) evidence of respiratory distress or sepsis in the immediate neonatal period; (2) birth weight of less than 1500 g; (3) treatment with broad-spectrum antibiotics or corticosteroids; (4) extensive instrumentation during delivery or invasive procedures in the neonatal period; (5) positive systemic cultures; (6) evidence of altered immune response; and (7) birth at less than 27 weeks of gestational age. A critical factor for survival in systemic candidiasis is not limited extent of infection but the early initiation of antifungal therapy (Botas et al, 1995; Johnson et al, 1984). Healthy infants without visceral involvement respond rapidly to topical anticandidal agents (Gibney and Siegfried, 1996).

## HERPES SIMPLEX VIRUS INFECTION

Early recognition and prompt initiation of therapy for neonatal herpes are critical. The consequences of delaying antiviral therapy can be devastating.

### Clinical Findings

Onset of symptoms usually occurs at 1 to 2 weeks for most neonates, but congenital lesions have been reported (Salvador et al, 1994). Infection is categorized by extent of disease, as follows: skin-eye-mucosae (SEM) disease, CNS disease, and disseminated disease. Only one third of infants present with cutaneous involvement (Frieden, 1989), although more than 80% develop typical skin lesions during the course of their disease (Overall, 1994). Characteristic skin lesions begin as isolated or grouped, tense vesicles on an erythematous base and evolve into pustules, crusts, or small erosions over several days. Forty percent of infected infants have SEM disease. With early treatment, these infants have an excellent prognosis; if the infection is left untreated, it will progress in 75% of cases (Arvin and Prober, 1992). Thirty-five percent of infected infants have CNS disease, with a high incidence of developmental abnormalities. One fourth of the infants present with evidence of disseminated disease (e.g., sepsis, liver dysfunction, coagulopathy, respiratory distress). For this group, the prognosis is poor, with a 60% mortality rate and a 40% risk of long-term neurologic impairment in survivors (Arvin and Prober, 1992; Whitley, 1994).

Infants infected in utero have a distinctive clinical presentation. Skin lesions are almost always present at birth and include widespread erosions and bullae, scars,

and scalp lesions that resemble those of aplasia cutis. Other frequent findings include chorioretinitis, microcephaly, hydranencephaly, and microphthalmia (Arvin and Prober, 1992).

### Etiology

A majority of cases of neonatal herpes simplex are the result of vertical transmission. Two thirds of cases are caused by HSV-2 and one third by HSV-1. The usual route of infection is via intrapartum contact with genital mucosa, but ascending infection accounts for 5% of cases of neonatal herpes. Infants who become infected in utero are more often premature or small for gestational age, with more widespread and severe disease (Arvin and Prober, 1992).

### Epidemiology

The incidence of neonatal HSV infection is 1/500 to 1/7500 live births. One half of infected infants are born to mothers with primary infections. These women, who are usually without active lesions, have a 50% risk of transmitting disease to their newborns. One half of infants with neonatal herpes are born to mothers with recurrent genital herpes, generally from HSV-2. Most of these women also are asymptomatic at the time of delivery and may have no known history of genital herpes. In this group, the risk of transmitting infection is only 2.5%.

### Diagnosis

A high index of suspicion is required. The differential diagnosis includes the causes of vesicles and pustules in the newborn outlined in Chapter 96. Tzanck smears, viral cultures, and direct fluorescent antibody detection are the most widely used tests to detect herpes infection. The diagnostic yield for each is variable, largely influenced by the age, quality, and handling of the specimen. Optimally, skin scrapings should be obtained from the base of a fresh vesicle. Other sites should be sampled as well, especially in infants suspected of having CNS or disseminated disease. Tzanck smear analysis is rapid and readily available but will reveal characteristic multinucleated giant cells in only 50% of HSV infections (Nahass et al, 1995). Immunofluorescence is 90% to 95% sensitive and specific but requires a specialized laboratory. Viral culture yields positive results for 80% of specimens by 24 hours and for 90% by 48 hours, under optimal conditions of handling and transport. Molecular diagnosis by polymerase chain reaction assay can detect HSV from specimens that would be suboptimal for the other methods (e.g., Tzanck smears, crusts, paraffin-fixed biopsy specimens). Diagnostic polymerase chain reaction assay may be the easiest means of diagnosing HSV infection in the future; however, limitations include the lack of standardization of methodologies, adversely affecting the clinician's ability to interpret results (Kimberlin, 2001; Nahass et al, 1992, 1995).

### Treatment

Early treatment with antiviral agents is critical to decrease the risk of serious complications and death. When diagnostic confirmation is delayed in suspected cases, presumptive therapy should be started. This therapy includes

strict isolation and prompt administration of parenteral antiviral therapy. Recent studies indicate that a 21-day course with high-dose (60 mg/kg/day) intravenous acyclovir is more effective at decreasing morbidity and mortality than standard doses (30 mg/kg/day). Adverse effects of high-dose therapy have included temporary neutropenia (Kimberlin et al, 2001). Vidarabine also is effective in preventing severe disease in infants with SEM disease. Treatment is much less effective for infants with more widespread herpes infection (Arvin and Prober, 1992). Morbidity in CNS disease and disseminated disease remains high, with corresponding mortality rates of 15% and 57%, respectively (Jacobs, 1998). Concomitant administration of immunoglobulin products may improve disease outcome for these infants (Whitley, 1994).

Strategies to prevent vertical transmission include cesarean delivery, serologic screening of pregnant women, prophylactic antiviral therapy, and maternal vaccination. Delivery via cesarean section for women with active lesions or prodromal symptoms and prophylactic antiviral treatment for women with gestational HSV are the currently accepted approaches (Enright and Prober, 2002). Because a direct correlation exists between the development of neurologic deficits and the frequency of recurrent cutaneous HSV, the use of suppressive oral acyclovir therapy following acute neonatal SEM disease is under way with the hope that such treatment will limit long-term morbidity (Kimberlin et al, 1996).

## Common Newborn Dermatoses\*

Rebecca A. Kazin, Bernard A. Cohen, and Elaine C. Siegfried

This chapter describes a group of cutaneous disorders that are unique to neonates. All of these disorders have well-recognized clinical and/or histologic features. Most are asymptomatic and self-limited, so rigorous searches have not been made for precise pathogeneses or definitive therapies. These common neonatal dermatoses may be mistaken for more serious diseases, and serious diseases may be mistaken for common neonatal dermatoses. For this reason, verification of the correct diagnosis can obviate the initiation of aggressive workup and treatment. In other cases, it can be lifesaving. Important considerations in the differential diagnosis based on clinical morphology are outlined in Chapter 96.

### ERYTHEMA TOXICUM NEONATORUM

#### Clinical Findings

Erythema toxicum is an inflammatory cutaneous disease of unknown origin that affects about half of all full-term newborns (Berg and Solomon, 1987). It occurs less frequently among preterm infants (Carr et al, 1966; Taylor and Bondurant, 1957). In a majority of infants, the lesions develop between 1 and 3 days of age, but they may appear as late as 3 weeks. No predilection of the disorder for race, gender, season, or geographic location has been reported.

Affected infants appear healthy. The basic skin lesion is a small (1 to 3 mm in diameter) papule that evolves into a pustule, with a prominent halo of erythema, that has been likened to a flea bite. Individual lesions may persist only a few hours, but the eruption lasts for several days or, rarely, for several weeks. The number of lesions present may vary from a few to dozens. The trunk is the most frequent site of predilection, but the face and extremities also may be involved. Palms and soles are almost always spared. Several lesions may coalesce into plaques measuring several centimeters in diameter (Fig. 99-1).

#### Diagnosis

A Wright-stained smear of pustule contents reveals large numbers of eosinophils, which supports the diagnosis. Skin biopsy may be necessary in clinically atypical cases.

Histologic features consist of eosinophil-filled intraepidermal vesicles and a mixed intradermal inflammatory infiltrate that tends to localize around the superficial portion of the pilosebaceous follicle.

Considerations in the differential diagnosis include other benign, self-limited disorders such as transient neonatal pustular melanosis, miliaria, infantile acropustulosis, and eosinophilic pustular folliculitis, as well as infections such as bacterial folliculitis, bullous impetigo, candidiasis, herpes, and scabies. Urticaria pigmentosa and incontinentia pigmenti are more serious disorders that can be mistaken for erythema toxicum. The diagnostic workup outlined in Chapter 96 can differentiate among these conditions.

#### Etiology

Erythema toxicum is a benign inflammatory disease of unknown cause. The eosinophilic infiltrate suggests that erythema toxicum is a hypersensitivity response, but studies attempting to incriminate chemical or microbiologic substances, acquired either transplacentally or vaginally from the mother, such as drugs, topical irritants, sebum, and milk, have failed to provide support for this hypothesis (Bassukas, 1992). At a molecular level, there appears to be an accumulation and activation of immune cells in these lesions as seen by immunohistochemical staining of punch biopsies from cutaneous lesions. Monoclonal antibodies placed in lesional skin detected E-selectin in the vessel wall as well as dendritic cells, eosinophils, macrophages, and E-selectin-expressing cells in these affected areas, whereas uninvolved skin demonstrated reduced or absent immunologic activity (Marchini et al, 2001).

#### Treatment and Prognosis

Erythema toxicum is asymptomatic, resolves spontaneously, and requires no treatment. A prolonged course and recurrence are rare. Once the diagnosis is confirmed, anticipatory guidance and reassurance should be provided to parents.

### TRANSIENT NEONATAL PUSTULAR MELANOSIS

#### Clinical Findings

This benign disorder is present at birth in 5% of African-American and in 1% of white infants (Ramamurthy et al, 1976). Characteristic lesions are small, superficial pustules that rupture easily, leaving a collarette of fine scale and hyperpigmented macules (Fig. 99-2). The lesions may be profuse or sparse and can involve all body surfaces, including the palms, soles, and scalp (Fig. 99-3). The pustules last about 48 hours; the macules may persist for several months.

#### Diagnosis

Affected infants are otherwise well. A Wright-stained smear of pustule contents revealing keratinous debris and variable numbers of polymorphonuclear neutrophils with few or no eosinophils supports the diagnosis. Gram stain and bacterial cultures obtained from intact pustules uniformly fail to disclose the presence of organisms. The differential diagnosis includes the conditions listed for erythema toxicum.

\*This chapter includes material from the previous edition, to which Nancy B. Esterly, MD, contributed.

**FIGURE 99-1.** Florid lesions of erythema toxicum on the back of a newborn infant. The pustules are large and surrounded by an erythematous halo. Smears of the pustular contents showed only eosinophils.

#### Etiology

The cause of transient neonatal pustular melanosis is unknown. A prospective study reported that 17 infants with typical congenital lesions subsequently developed lesions of erythema toxicum, linking the two conditions (Ferrandiz et al, 1992).

#### Treatment

The disorder is asymptomatic and self-limited. Once the diagnosis is confirmed, further therapy is not required.

**FIGURE 99-2.** Numerous superficial pustules on the neck and back of a 1-day-old infant. A few pustules have ruptured, leaving a collarette of scales.

**FIGURE 99-3.** Transient neonatal pustular melanosis. Hyperpigmented macules on the lower back and buttocks, some of which are encircled by scales. (From Ramamurthy RS, Reveri M, Esterly NB, et al: Transient neonatal pustular melanosis. *J Pediatr* 88:831, 1976.)

### MILIA, EPSTEIN PEARLS, AND SEBACEOUS HYPERPLASIA

#### Clinical Findings

*Milia* (a single lesion is a *milium*) are found in 40% of full-term infants (Gordon, 1959). They are single or sparsely scattered 1- to 2-mm pearly lesions that occur on the face. The sites of predilection are the cheeks, forehead, and chin (Fig. 99-4). Large milia (greater than 2 mm in diameter) are found in infants with type I oral-facial-digital syndrome (Solomon et al, 1970). Rarely, milia may occur in unusual sites, such as on the arms, legs, or foreskin.

*Epstein pearls* are milia that occur in the oral mucosa. These tiny cystic lesions occur in about 85% of newborn infants and usually are found on the palate, particularly along the midpalatine raphe and at the junction of the hard and soft palates. They usually are grouped, firm, and movable and appear opaque and white.

#### Diagnosis

Histologically, a milium is an invagination of epidermal tissue, arising from the pilosebaceous apparatus of vellus

**FIGURE 99-4.** Numerous grouped milia on the chin of a newborn infant.

hair, which forms a cyst filled with several layers of keratin-producing cells. The expressed contents of milial cysts resemble tiny white pearls and consist mostly of keratinocyte debris, a useful diagnostic feature.

Milia may be mistaken for *sebaceous gland hyperplasia*, which occur in the same distribution. The papules of sebaceous gland hyperplasia are smaller (pinpoint) and more yellow and contain sebaceous lipids. Milia usually exfoliate spontaneously within 1 month. Epstein pearls are self-limited but may take several months to resolve. Sebaceous hyperplasia also resolves spontaneously within the first few weeks of life.

## MILIARIA

### Clinical Findings

Miliaria neonatorum is a vesicular or pustular dermatitis arising from the eccrine duct. Four clinical variants have been described, their appearances influenced by the site of obstruction within the duct. *Miliaria crystallina* (sudamina) consists of very superficial, clear, thin-walled, non-inflammatory vesicles that rupture easily. The vesicle is localized within the stratum corneum. *Miliaria rubra* (prickly heat) consists of small, erythematous, grouped papules often localized to skin folds and areas covered by clothing. These lesions arise within the deeper levels of the epidermis and are accompanied by inflammation. The papules may become pustular if there is a prominent inflammatory component or secondary bacterial infection, a condition sometimes referred to as *miliaria pustulosa*. *Miliaria profunda* is a mildly inflammatory papular eruption that arises within the dermal portion of the eccrine duct.

### Etiology

Miliaria is believed to be caused by sweat accumulation into obstructed eccrine ducts. Obstruction of the eccrine duct in adults has been reported to result from a variety of triggers such as cutaneous injury, excessive hydration of the stratum corneum, or overgrowth of microbes (Fitzpatrick, 1990). Premature and even full-term neonates have a full complement of eccrine glands, distributed in greater density than after growth with concomitant increase in skin surface area (Jordan and Blaney, 1982). Immature, incompletely canalized eccrine ducts could predispose the newborn to miliaria (Straka et al, 1991). Overheating from excessive bundling and phototherapy probably contribute to its pathogenesis. The widespread availability of environmental temperature control probably has decreased the incidence of this condition.

Recurrent episodes of pustular miliaria rubra could signal the rare condition type I pseudohypoaldosteronism. This potentially fatal condition of autosomal recessive inheritance is a disorder of mineralocorticoid resistance that leads to salt-wasting crises through the eccrine ducts. If this condition is suspected, an appropriate serologic workup should be initiated. (Urbatsch and Paller, 2002)

### Diagnosis

The differential diagnosis of miliaria includes the conditions listed previously for erythema toxicum. Wright stain of vesicle contents from miliaria crystallina will show few

cells; that of miliaria rubra will usually reveal a majority of lymphocytes. If screening studies are nondiagnostic, a skin biopsy will be confirmatory (Fitzpatrick, 1990).

### Treatment

Lesions rapidly resolve after the infant's environmental temperature is reduced. Application of occlusive emollients may exacerbate the eruption.

## ACNE

### Clinical Findings

The appearance of acne in infancy is similar to that of typical acne vulgaris of adolescence. The spectrum of lesions includes comedones, inflammatory papules, pustules, and rarely, cysts, generally limited to the face (Fig. 99-5). Comedones are an easily recognized, pathognomonic feature of acne.

The condition occurs in up to 20% of infants and is more common in boys. Acne occurs in a bimodal distribution during infancy. Early-onset *neonatal acne* occurs after 1 to 2 weeks of age and usually resolves spontaneously by 3 months. *Infantile acne* appears after 3 to 6 months and may persist for years.

### Etiology

The pathophysiologic features of acne are similar at all ages. Important components are the increased size and activity of sebaceous glands, which are influenced by circulating levels of adrenal and gonadal androgens, of both endogenous and maternal origins. The role of *Propionibacterium acnes* in the pathogenesis of infantile acne has not been studied. This lipophilic, anaerobic gram-positive rod plays an important role in the pathogenesis of inflammatory lesions in adolescent acne. A family history of acne is common, and affected infants have a higher risk of developing severe acne later in life (Hellier, 1954), suggesting a genetic predisposition (Forest et al, 1973).

In the past few years, a potential etiologic factor of noncomedonal neonatal acne, or cephalic pustulosis, has been identified. *Malassezia* is a lipophilic yeast that is part of the normal flora of adult skin; a variety of factors,

**FIGURE 99-5.** Papules, pustules, and comedones (diagnostic of acne) on the chin and cheeks of a male infant.

including sebaceous gland activity, humidity, heredity, and corticosteroid treatment, may be influential in allowing it to become an opportunistic pathogen. Recently, several investigators have examined the connection between *Malassezia* and neonatal acne. Findings include the rapid progressive skin colonization of neonates by *Malassezia* species as seen on smear and culture examination, specifically *Malassezia sympodialis* and *Malassezia globosa*; higher rates of skin colonization by *Malassezia* in more severe cases of cephalic pustulosis; and isolation of *M. sympodialis* in the neonatal pustules (Bernier et al, 2002; Niamba et al, 1998). In a study conducted to explore this association, 8 of 13 patients (61%) with pustules positive for *Malassezia* showed a favorable response to treatment with 2% ketoconazole (Rapelano et al, 1996.)

However, contrary evidence exists, including lack of complete correlation between *Malassezia* and neonatal acne. Other studies have identified patients with neonatal acne in whom *Malassezia* was not found, as well as patients without acne whose pustule cultures were positive for *Malassezia* (Katsambas et al, 1999). Therefore, further investigation is needed to clarify cephalic pustulosis and neonatal acne and to specifically address the possibility that these inconsistencies could be explained by methodologic or pathologic variation, or that *Malassezia* may be one part of a multifactorial process, or that some cases of neonatal acne are not cephalic pustulosis but true comedonal disease (Bergman and Eichenfield, 2002.)

### Diagnosis

Considerations in the differential diagnosis include the papular and pustular disorders listed previously, but the diagnosis of acne can almost always be made by clinical inspection. No other disorder features comedones. Infants with severe or persistent acne should be evaluated for androgenic endocrinopathy.

### Treatment

Aggressive treatment of neonatal acne is rarely required. For initial therapy, topical 2% erythromycin or 2.5% or 5% benzoyl peroxide may be applied daily. Tretinoin and more potent formulations of benzoyl peroxide may be irritating. In more severe cases, a course of enteral erythromycin may be added, in divided doses of 30 to 50 mg/kg/day. Creams, ointments, and topical steroids may exacerbate the condition. If *Malassezia* is isolated or suspected, an antifungal agent may be efficacious (Rapelano et al, 1996.)

## INFANTILE ECZEMA

The term *eczema* is derived from a Greek term meaning “to boil over.” It refers to a clinical and histologic cutaneous phenotype characterized by erythema, edema, and scaling, often accompanied by crusting and, in severe cases, blistering. The histologic hallmark of acute eczema is epidermal intercellular edema (i.e., spongiosis). Epidermal thickening is present in chronic eczema. A mixed perivascular inflammatory infiltrate usually is seen within the papillary dermis.

Different types of eczema can be defined by a spectrum of unifying clinical features. When a patient presents

in infancy with widespread eczema, a precise diagnosis sometimes requires a period of observation. Two common eczematous conditions manifest in otherwise healthy infants: seborrheic dermatitis and atopic dermatitis (AD). These diseases differ in pathogenesis, distribution of skin involvement, prognosis, and range of therapeutic options. Infants with widespread eczema who are not otherwise healthy and those with prominent, erosive periorificial involvement should be evaluated for associated nutritional, metabolic, or immunologic abnormalities. A more extensive differential diagnosis is detailed under “Erythroderma” in Chapter 96.

## Seborrheic Dermatitis

### Clinical Findings

Infantile seborrheic dermatitis is characterized by greasy yellow scales on an erythematous base and minimal pruritus. Onset usually is within the first 2 months of life. The most common sites of involvement are the face, scalp, and diaper area. The condition may be localized or disseminated. Flexural areas such as the posterior auricular sulcus, neck, axillae, and inguinal folds also can be affected. Hypopigmentation is often striking in dark-skinned infants (Fig. 99–6). In severe cases, fissures may develop and become secondarily infected.

### Causes

*Pityrosporum ovale* is a lipophilic yeast that is commonly present on normal skin, increasing in density during and after puberty. The mycelial form has been identified as a causative agent in tinea versicolor. For a century, the yeast form has been linked to adult seborrheic dermatitis. Therapeutic trials with yeast-inhibiting agents have supported a causal role (Straka et al, 1991). There is a higher incidence of seborrheic dermatitis in immunocompromised patients, especially those with acquired immunodeficiency syndrome (AIDS) (Prose, 1991). The association between *P. ovale* and infantile seborrheic dermatitis also has been confirmed (Broberg and Faergemann, 1989; Ruiz-Maldonado et al, 1989). The pathogenesis of the disorder, and the reasons carriers remain asymptomatic and immunocompromised persons can be more severely affected, remain unclear.

**FIGURE 99–6.** Infant with seborrheic eczema on the face and neck and in the axillae. Note the scaling and hypopigmentation. Temporary hypopigmentation is common in African-American infants with this disorder.

### Treatment

Infantile seborrheic dermatitis spontaneously resolves by the end of the first year of life. For infants with disfiguring or symptomatic disease, there are several therapeutic alternatives. Topical agents effective against *P. ovale* include topical ketoconazole, in a cream or shampoo base (Cutsem et al, 1990), shampoos containing 1% zinc pyrithione or 1% to 2.5% selenium sulfide, and propylene glycol (Faergemann, 1988). Propylene glycol is a hygroscopic preservative, with antimycotic activity against *P. ovale*, that has been widely used for more than a century in foods and cosmetics. It is commercially available as a 1.5% soapless cleanser (Cetaphil lotion, Galderma Laboratories, Inc., Fort Worth, Texas). The safety and efficacy for none of these products have been established in infants. Nevertheless, widespread availability and popular use have not produced reports of toxicity. Brief application with daily bathing usually is effective and limits excessive percutaneous absorption. Daily application of 0.5% to 1% hydrocortisone cream is another short-term alternative.

## Atopic Dermatitis

### Clinical Findings

AD is a chronic, severely pruritic, familial disorder defined by a spectrum of defined cutaneous and extracutaneous manifestations (Hanifin, 1991; Paller, 1991). In 60% of cases, signs and symptoms begin in infancy; up to 10% of 1-year-old children are affected (Kay et al, 1994). The most easily recognized of the diagnostic criteria for AD may not be present until early childhood. These criteria include onset of rash before the age of 2 years, flexural skin lesions, asthma or hay fever, and generalized dry skin (Williams et al, 1994). AD and seborrheic dermatitis share clinical features, often making correct diagnosis difficult during the neonatal period. A common feature that may distinguish one from the other form is involvement of the diaper area. This area is often dramatically spared in infants with AD and is primarily involved in infants with seborrheic dermatitis.

### Etiology

Atopic disease has been clinically recognized since 1916; however, its pathogenesis remains elusive. Recent investigations of the mechanisms and treatment of AD have focused on immune alterations. Blood eosinophilia, overproduction of immunoglobulin E (IgE), and a diminished cell-mediated delayed-type hypersensitivity response are common features. Other, in vitro immune abnormalities have been described, including alterations in monocyte cyclic AMP (cAMP) production, increased histamine release by basophils and mast cells, abnormal differentiation of antigen-presenting cells, increased serum levels of eosinophil cationic protein and interleukin-4 (IL-4), and diminished production of interferon gamma by circulating lymphocytes (Hanifin, 1991; Hanifin et al, 1993). These data support a hypothesis regarding the basic immune dysregulation causing AD. The theory assumes an imbalance of T-cell subsets, with inhibition of the cells that produce interferon- $\gamma$  (T<sub>H</sub>1 helper T cells) and a relative activation of the cells that produce IL-4 (T<sub>H</sub>2 helper

T cells). These assumed outcomes are believed to potentiate a vicious circle of enhanced production of IgE, eosinophilia, mast cell proliferation, release of histamine by basophils and mast cells, and further expansion of T<sub>H</sub>2 cells (Hanifin, 1991; Hanifin et al, 1993).

*Staphylococcus aureus* plays an important role in the exacerbation of AD. Ninety percent of affected patients carry this microbe on their skin, and a course of antistaphylococcal antibiotics augments therapy during clinical flares. Staphylococcal exotoxins act as superantigens capable of stimulating a wide variety of T-cell responses (Leung et al, 1995).

Food and environmental allergens play a role in the minority of patients (Hanifin, 1991). Prolonged breastfeeding and delayed exposure to diverse solid foods may protect against AD, especially in infants with a strong family history of atopic disease (Zeiger, 1994).

### Treatment

The goal of treatment is to control signs and symptoms. A definitive cure is not yet available, but spontaneous improvement occurs before puberty in 40% of patients (Hanifin, 1991). Maintenance therapy aims to hydrate the skin, reduce inflammation, control pruritus, and eliminate inciting factors. These goals are achieved with once- or twice-daily bathing with a mild antimicrobial cleanser, sparing application of topical corticosteroids, and liberal application of a bland ointment emollient. Addition of systemic antistaphylococcal antibiotics is sometimes necessary.

Both tacrolimus 0.03% ointment and pimecrolimus 1% cream, nonsteroidal selective inhibitors of inflammatory cytokines, have been approved for the treatment of atopic dermatitis in children older than 24 months. However, studies support the safe use of both agents in infants as young as 3 months.

Infants with AD have a relative cutaneous anergy and are at increased risk for the development of cutaneous bacterial, yeast, fungal, and viral infections. A high index of suspicion for secondary infection must be maintained.

## DIAPER DERMATITIS

### Etiology

Although diaper dermatitis, described over a century ago, has been widely studied, the cause, true prevalence, and optimal treatment are still issues of debate. A majority of infants has episodes of diaper dermatitis, most commonly between 6 and 12 months of age (Jordan and Blaney, 1982). For decades, the condition was believed to be due primarily to the effects of ammonia. However, objective studies did not support this theory (Leyden et al, 1977). Many factors contribute to the pathogenesis of diaper dermatitis, but the nidus of the problem begins with occlusion, excessive hydration, friction, and maceration. Once skin barrier function has been compromised, irritants (urine, fecal lipases, proteases, bile salts) and microorganisms (urease-splitting bacteria, *S. aureus*, beta-hemolytic streptococci, *Pseudomonas* species, *Candida albicans*) exacerbate the problem. Exogenous irritants, such as soaps, commercial diaper wipes, and a myriad of

over-the-counter topical products, can perpetuate the process in susceptible infants.

### Treatment

Clearly, the most important steps in preventing diaper dermatitis are maintaining skin barrier function and hygiene and preventing irritation. Traditionally, an effective but labor-intensive approach has been frequent diaper changes with gentle cleansing, thorough drying, and limited use of occlusive plastic or rubber diaper covers. This practice has been greatly simplified by the introduction of disposable diapers.

The first disposable diapers were marketed in 1963. Initially, the absorbent core was composed primarily of cellulose fluff. Subsequently, several conflicting studies were done to evaluate the incidence of diaper dermatitis in infants wearing cloth versus disposable diapers (Jordan and Blaney, 1982). In the mid-1980s, a superabsorbent core material was developed, containing a cross-linked sodium polyacrylate. Upon contact with fluid, this material undergoes a transformation to allow it to hold fluid within a gel and has the capacity to absorb many times its own weight. Several studies have concluded that superabsorbent diapers are superior to cloth diapers in preventing diaper dermatitis (Lane et al, 1990). In addition, superabsorbent diapers may prevent occult fecal contamination of clothing and fomites in daycare settings (Rory et al, 1991).

Routine use of topical preparations to prevent diaper dermatitis is not necessary in infants with normal skin. For some of these products, additional risks have been recognized. Additives have the potential to cause contact sensitization or irritation. Powders applied vigorously enough to raise a cloud pose an aspiration hazard. This is especially true for talc, which can cause irritant pneumonitis. Talc (mainly hydrous magnesium silicate) also may cause granulomatous reactions when applied to wounds.

Appropriate treatment of diaper dermatitis begins with correct diagnosis of the underlying cause. Most infants develop acute diaper dermatitis as a result of the factors described previously. However, other primary pathologic processes must be considered for any infant with chronic, severe, or recurrent diaper rash. Primary cutaneous diseases that may manifest with diaper rash include allergic contact dermatitis, seborrheic dermatitis, psoriasis, and candidiasis. Several uncommon causes of diaper dermatitis such as histiocytosis, congenital syphilis, bullous pemphigoid, and staphylococcal scalded skin syndrome have serious implications (Kazaks, 2000).

Mild to moderate, common diaper dermatitis should be treated initially with traditional frequent diaper changes and/or leaving the area exposed. A temporary switch to superabsorbent diapers may be helpful for infants diapered with cloth. All potential irritants or sensitizers should be discontinued. Commercial diaper wipes are an often-overlooked, common source of these substances. Washcloths, dampened paper towels, and mineral oil-soaked cotton balls are safe alternatives. Zinc oxide ointment and zinc paste are inexpensive, bland, protective agents with antiseptic and astringent properties. Zinc also may play a role in wound healing (Maitra and Dorani, 1992; Okada et al, 1990; Rackett et al, 1993). Some caregivers may object to

the difficulty in removing zinc oxide preparations. They should be reassured that it is not necessary to remove the salve. If a parent or clinician needs to remove zinc oxide to assess the skin, this can be easily accomplished with the help of mineral oil.

If there is no objective evidence of candidiasis, a short course of a topical low-potency corticosteroid may be beneficial. A topical anticandidal agent should be used when potassium hydroxide preparation or culture suggests yeast infection. Combination products containing potent topical corticosteroids and antifungal agents are less effective than an antifungal used alone (Reynolds et al, 1991). Widespread use of one such product combining a potent, fluorinated topical corticosteroid, 0.05% betamethasone dipropionate, with 1% clotrimazole (Lotrisone), applied under the occlusion of a diaper, has resulted in reports of skin atrophy, striae, and even adrenal suppression (Barkley, 1987). Clotrimazole and a similar product combining 0.1% triamcinolone acetonide and nystatin (Mycolog II) are contraindicated for the treatment of diaper dermatitis.

## HARLEQUIN COLOR CHANGE

Harlequin color change should not be confused with an entirely different disorder called *harlequin fetus*. Harlequin color change, first described in 1952, usually occurs during the first 4 days of life (Mortensen and Stougard-Andresen, 1959). It is characterized by reddening of one half of the body and simultaneous blanching of the other half. A sharp, midline demarcation runs from the center of the forehead down the face and trunk. Occasionally, the line of demarcation may be incomplete, sparing the face and genitalia. Turning the body from one side to the other accentuates blanching of the upper half and reddening of the lower half. There is no accompanying change in respiratory rate, pupillary reflexes, muscle tone, or response to external stimuli. The total duration of these episodes may range from a few minutes to several hours. Harlequin color change occurs most frequently in low-birth-weight infants but may be seen in up to 10% of term infants. The physiologic basis of the phenomenon has not been defined. It has no pathologic significance, requires no treatment, and can be expected to disappear no later than the third week of life.

## SUBCUTANEOUS FAT NECROSIS

### Clinical Findings

Subcutaneous fat necrosis affects full-term infants who have experienced perinatal distress. Lesions usually appear within the first 2 weeks of life. They may be single or multiple, are poorly circumscribed, and often are tender nodules or plaques that are initially firm with a dusky reddish-purple hue. They are located most often in areas in which a fat pad is present: buttocks, back, arms, and thighs (Fig. 99-7). With time, subcutaneous calcification may develop, with subsequent drainage and resultant scarring. The most serious association is hypercalcemia. Infants with hypercalcemia may be asymptomatic, so the incidence and time course have not been well documented (Cook and Stone, 1992). Symptoms include irritability, vomiting, poor feeding, and failure to thrive.

**FIGURE 99-7.** Rear view of a newborn showing several large discolored areas of subcutaneous fat necrosis. They were irregular in size and shape, felt firm to palpation, and were not hot or tender.

### Causes

The development of subcutaneous fat necrosis has been related to ischemic injury from obstetric trauma, intrauterine asphyxia (Chen et al, 1981), and hypothermia. Skin biopsy from a well-developed lesion will reveal a subcutaneous granulomatous infiltrate with multinucleated giant cells. Damaged lipocytes contain characteristic needle-shaped clefts. Soft tissue necrosis and inflammation may stimulate local production of 1,25-dihydroxyvitamin D<sub>3</sub>, resulting in hypercalcemia (Cook and Stone, 1992).

### Treatment

In most infants, the process is self-limited; resolution occurs over a period of weeks to months. Some experts recommend careful needle aspiration of fluctuant areas to reduce scarring (Hurwitz, 1985). Infants should be followed closely for the development of hypercalcemia for the first 6 weeks of life. Hypercalcemic infants should be managed initially with hydration and furosemide-induced diuresis. Restriction of oral calcium and vitamin D intake and the administration of systemic corticosteroids may be necessary (Cook and Stone, 1992; Norwood-Galloway et al, 1987). However, this approach may only be partially successful, and persistent hypercalcemia with its associated morbidity may ensue. Bisphosphonate agents, specifically etidronate, have recently been discussed for use as possible last resort agents to control the persistent hypercalcemia that can be secondary to subcutaneous fat necrosis. In one case report, a newborn with subcutaneous fat necrosis refractory to conservative management had etidronate added to his regimen. After initiation of the drug, the patient's urinary calcium levels soon normalized. It was postulated that the mechanism of lowering the serum and urinary calcium by etidronate was primarily a decrease in bone resorption. (Rice and Rivkees, 1999.)

Other investigators have commented on the limited use of bisphosphonates in children and question whether the hypercalcemia of subcutaneous fat necrosis is secondary to enhanced bone resorption or intestinal absorption. Controlled trials have been recommended before the use of these agents for this indication can be recommended (Bachrach and Lum, 1999). Of note, in the case study, etidronate had to be stopped because of a rash severe enough to be of clinical concern. Physicians must be aware of possible bisphosphonate-induced hypersensitivity reactions and stop the agent if suspected (Rice and Rivkees, 1999).

## SCLEREMA NEONATORUM

The lesions of subcutaneous fat necrosis are histologically similar to those of sclerema neonatorum, thereby potentially raising unnecessary concern for stable, full-term infants with localized skin lesions. Sclerema neonatorum is a diffuse, systemic process with a grave prognosis (Fretzin and Arias, 1987).

### Clinical Findings

Sclerema neonatorum occurs in debilitated or preterm neonates. It manifests with widespread, stone-hard, nonpitting cutaneous induration. The skin appears pale and waxy, shaping the face in mask-like expression (Fig. 99-8); the joints are stiff. Associated metabolic acidosis, hypoglycemia, hyperkalemia, hyponatremia, and azotemia may occur.

### Etiology

The disorder has been associated with prematurity, low birth weight, asphyxia, and hypothermia (Ji et al, 1993).

**FIGURE 99-8.** Sclerema neonatorum. Note the mask-like facial expression, "pseudotrismus" of the partially immobilized mouth, and thickening of the skin over the face, arms, and hands. (From the Collection of the American Academy of Pediatrics. Reproduced with permission of the officers of the Academy.)

The histologic changes of sclerema are not specific. Fat necrosis with crystallization may be seen; thinning of the epidermis and dermal and subcutaneous fibrosis with edema and thickening of the interlobular septa are more conspicuous features (Dasgupta et al, 1993).

The mechanism responsible for sclerema is unknown. Biochemical and crystalline changes in the subcutaneous fat of affected infants have suggested a decrease in the enzymatic desaturation of triglycerides (Horsefield and Yardley, 1965; Kellum et al, 1968).

### Treatment

The treatment of sclerema neonatorum is supportive care. Corticosteroid therapy has not been effective in altering the 30% to 60% mortality rate (Levin et al, 1965).

## Cutaneous Congenital Defects\*

Alison Z. Young, Bernard A. Cohen, and Elaine C. Siegfried

The spectrum of congenital cutaneous defects can be organized by tissue of origin or location within the skin. This spectrum is summarized in Table 100–1. However, in many cases the clinical appearance is not diagnostic for the specific condition or even the tissue type. An overview of differential diagnosis by clinical appearance is included in Chapter 96.

This chapter presents information on the most common and clinically significant congenital cutaneous defects.

### VASCULAR DEFECTS

Precise diagnosis and appropriate management of the cutaneous vascular defects have been confounded by tremendous confusion in nomenclature and poor understanding of the pathogenesis of the different conditions within this group. For example, the term *hemangioma* has been used indiscriminately to refer to lesions that differ considerably in morphology, behavior, and prognosis. The classification system proposed by Mulliken and Glowacki in 1982 is accepted as the official classification scheme for congenital vascular defects by the International Society for the Study of Vascular Anomalies (Hand and Frieden, 2002). This scheme separates vascular lesions of infants and children into two major categories: hemangiomas and malformations (Mulliken and Young, 1988). A *hemangioma*, by definition, is a benign tumor of vascular endothelium, characterized by a proliferative phase and an involutional phase (Fig. 100–1A). In contrast, a *malformation* is a developmental anomaly generated from a single vascular component or from a combination of vascular components: capillary, venous, arterial, or lymphatic. These two groups can be further differentiated according to clinical, cellular, hematologic, radiologic, and skeletal characteristics (Table 100–2).

#### Hemangiomas

Hemangiomas are the most common tumors of infancy; mature lesions have been noted in 10% to 12% of 1-year-old infants. They occur sporadically, most often as single lesions. For unclear reasons, hemangiomas are more common in premature infants. The male-to-female ratio in term infants is 1:3 (Esterly, 1995).

\*This chapter includes material from the previous edition, to which Nancy B. Esterly, MD, contributed.

#### Clinical Findings

Typically, hemangiomas are not clinically apparent at birth but present within the first month of life as a faint blush or area of pallor, a change known as a *precursor lesion*. Most hemangiomas grow rapidly in the first 3 to 6 months; the rate and extent of growth are impossible to predict. The clinical appearance is dictated by the depth of the tumor. Superficial lesions are cherry red and sharply circumscribed. This type of hemangioma has been referred to as a “strawberry,” “capillary,” “plane,” or “planotuberous” hemangioma. Lesions that are confined to the deep dermis and subcutis appear bluish and dome-shaped. This subset has been referred to as “cavernous” or “nodose.” Most lesions have both superficial and deep components. The added descriptors have no functional or prognostic significance, with one possible exception: The superficial component may herald residual change in skin texture, whereas the deep component may leave excess fibrofatty tissue. The growth phase usually slows after 6 months and ends by 12 months of age, followed by gradual involution. Flattening occurs by age 5 in half the cases, and by age 9 in an additional 40% (Esterly, 1995). Parents are frequently concerned about the risk of hemorrhage and should be reassured that this rarely occurs. Several other complications are possible, however, and the more serious sequelae are described next.

**Obstruction.** A hemangioma that obstructs just one eye can pose a significant threat to visual development by limiting the visual field or compressing the globe. Obstruction of both external ear canals will impair development of hearing. A lesion encompassing the beard area may indicate upper airway involvement, which should be considered life-threatening.

**Ulceration.** This occurs in 5% of hemangiomas (Morelli et al, 1991, 1994; Mulliken et al, 1995), most often in those located in areas of friction (skin folds, diaper area), as well as in rapidly growing or involuting lesions. Ulcerated hemangiomas are painful and at risk for secondary infection.

**Disfigurement.** During the first year of life, the presence of a prominent hemangioma can elicit a disturbing amount of unwanted attention. Many parents require emotional support through this time. In addition to the transient disfigurement, lesions of the central face, and those with a significant superficial component, predispose the affected child to permanent scarring.

**Kasabach-Merritt Syndrome.** This syndrome was originally described as a complication of infantile hemangioma but may in fact be associated with kaposiform hemangioendothelioma (Cooper et al, 2002). The lesion consists of a rapidly expanding vascular tumor with compression and invasion of surrounding structures as well as primary platelet trapping and resultant consumptive coagulopathy. The mortality rate is 30% to 40%.

**Central Nervous System (CNS) Anomalies.** Large facial hemangiomas may be associated with posterior fossa malformations along with arterial anomalies/hemangiomas,

TABLE 100-1

## Spectrum of Congenital Cutaneous Defects

## Vascular Defects

Hemangiomas

Malformations: lymphatic, venous, arterial, capillary, mixed

## Hypopigmented Lesions

Ash-leaf macules, confetti-like macules

Linear and whorled hypomelanosis

Nevus depigmentosus

Nevus anemicus

Hemangioma precursor

## Melanin-Containing Lesions

Nevocellular nevi

Melanoma

Lentigines

Café-au-lait macules

Nevus spilus

Mongolian spots

Nevus of Ota and nevus of Ito

## Tumors of Epithelial Origin

Epidermal (keratinocytic) nevi/sebaceous nevi-nevus unius lateris, nevus verrucosus, ichthyosis hystrix

Nevus comedonicus

Pilomatrixoma

Porokeratosis of Mibelli

## Dermal Tumors

Connective tissue nevi: collagen, elastic tissue

Digital fibroma

## Tumors of Extracutaneous Origin

Cutaneous mastocytosis: urticaria pigmentosa, solitary mastocytoma, diffuse cutaneous mastocytosis

Juvenile xanthogranuloma

Lipoma

Osteoma cutis

Nasal glioma

Dermoid cyst

Meningioma

coarctation of the aorta and other cardiac defects, and eye abnormalities—the PHACE syndrome (Coats et al, 1999; Frieden et al, 1996; Rossi et al, 2001).

**Spinal Dysraphism.** Sacral and lumbar hemangiomas may reveal spinal dysraphism, including tethered spinal cord and lipomyelomeningocele (Albright et al, 1989; Laurent et al, 1998; Tavafoghi et al, 1978).

**Genitourinary Abnormalities.** Sacral hemangiomas also may be associated with imperforate anus, renal anomalies, or abnormalities of the external genitalia (Goldberg et al, 1986).

**Visceral Involvement.** Diffuse neonatal hemangiomatosis manifests as widely scattered, small superficial hemangiomas. Infants with this pattern of cutaneous involvement may have a “benign” variant (i.e., lesions limited to skin). However, associated hemangiomatosis of the liver, gastro-

intestinal tract, lungs, and/or CNS can be complicated by visceral hemorrhage, hepatomegaly, high-output cardiac decompensation, or unexplained anemia or thrombocytopenia, with a significant mortality rate (Byard et al, 1991). Congestive heart failure also can occur with a large, isolated cutaneous hemangioma (Mulliken et al, 1995).

### Diagnosis

In most cases, a hemangioma can be diagnosed by its clinical appearance and pattern of evolution. A vascular lesion that is not obvious at birth, begins as a precursor noted during the first month of life, and exhibits rapid growth is undoubtedly a hemangioma. A lesion that deviates from this typical picture presents a diagnostic dilemma. Considerations in the differential diagnosis include atypical hemangioma, vascular malformation, and a nonvascular mimic. Doppler ultrasound examination is an easily performed test that may help to distinguish between a hemangioma and a high-flow malformation. Other

TABLE 100-2

## Characteristics of Vascular Birthmarks

Hemangioma	Malformation
<b>Clinical</b>	
Usually nothing seen at birth, 30 percent present as red macule	All present at birth; may not be evident
Rapid postnatal proliferation and slow involution	Commensurate growth; may expand as a result of trauma, sepsis, hormonal modulation
Female : male 3 : 1	Female : male 1 : 1
<b>Cellular</b>	
Plump endothelium, increased turnover	Flat endothelium, slow turnover
Increased mast cells	Normal mast cell count
Multilaminated basement membrane	Normal thin basement membrane
Capillary tubule formation in vitro	Poor endothelial growth in vitro
<b>Hematologic</b>	
Primary platelet trapping; thrombocytopenia (Kasabach-Merritt syndrome)	Primary stasis (venous); localized consumptive coagulopathy
<b>Radiologic</b>	
Angiographic findings; well-circumscribed, intense lobular-parenchymal staining with equatorial vessels	Angiographic findings: diffuse, no parenchyma Low-flow: phleboliths, ectatic channels High-flow: enlarged, tortuous arteries with arteriovenous shunting
<b>Skeletal</b>	
Infrequent “mass effect” on adjacent bone; hypertrophy rare	Low-flow: distortion, hypertrophy, or hypoplasia High-flow: destruction, distortion, or hypertrophy

From Mulliken JB, Young AE: Vascular Birthmarks, Hemangiomas and Malformations. Philadelphia, W. B. Saunders, 1988, p 35.

imaging modalities—magnetic resonance imaging (MRI) or angiography—may be indicated for large or obstructive lesions (e.g., ocular, upper airway) to help define the extent of involvement or associated abnormalities (Baker et al, 1993; Esterly, 1995). Skin biopsy is diagnostic for nonvascular tumors, which can mimic vascular birthmarks (e.g., pilomatrixoma, juvenile xanthogranuloma, Langerhans cell histiocytosis, infantile myofibromatosis).

### Pathogenesis

Hemangiomas in the proliferative phase are composed of syncytial aggregates of endothelial cells. These cells, like mature endothelial cells, express alkaline phosphatase, factor VIII antigen, and CD31 PECAM (platelet endothelial cell adhesion molecule), as well as Weibel-Palade bodies on electron microscopy, but <sup>3</sup>H labeling demonstrates active proliferation. Other histologic features that distinguish proliferating hemangiomas from malformations are the pres-

ence of multilaminar basement membranes bordering the endothelial syncytia, large numbers of mast cells (Esterly, 1995), and increased expression of other immunohistochemical markers, including proliferating cell nuclear antigen, (PCNA), vascular endothelial cell growth factor (VEGF), type IV collagenase, urokinase, and basic fibroblast growth factor (bFGF) (Takahashi et al, 1994). Elevated bFGF can be detected in urine from infants with hemangiomas, which may prove to be a useful diagnostic marker (Mulliken et al, 1995). Angiogenesis is a process that allows new blood vessel formation. It plays an important role in the growth of all vascular tumors, including hemangiomas. Identification of the basic processes that contribute to angiogenesis and effective angiogenesis inhibitors will provide insight into the pathogenesis and a more ideal therapy for hemangiomas (Morelli, 1993; Mulliken, 1991; O'Reilly et al, 1995).

It appears that hemangiomas constitute clonal expansions of endothelial cells, suggesting that these tumors are caused by somatic mutations in one or more genes regulating endothelial cell proliferation (Boye et al, 2001). Recently, it has been shown that Tie2 and its ligands angiopoietin-1 and angiopoietin-2 may be involved in the pathogenesis of hemangiomas (Yu et al, 2001).

### Treatment

Eighty percent of hemangiomas are ultimately uncomplicated, and it is impossible to predict which ones will develop problems (Mulliken et al, 1995). For a majority of lesions, the initial treatment of choice is “active nonintervention.” During the phase of rapid proliferation, patients with uncomplicated hemangiomas should be examined at 2- to 4-week intervals to evaluate degree of growth and development of problems. During this phase, parents often are anxious and require ongoing, directed anticipatory guidance. A common concern is the risk of significant hemorrhage. This is rare. Minor episodes of bleeding can result from trauma and respond to short-term compression, like any superficial wound. Demonstration of before-and-after photographs of growing and involuted lesions in other children helps diminish concern. Local compression of accessible lesions (Mangus, 1973) may control growth and promote comfort. Coban dressing is a conveniently applied self-adhesive compressive wrap that easily provides compression (Kaplan and Paller, 1995).

Decades of aggressive therapy followed by suboptimal outcome from the 1940s through the 1960s were followed by a passive approach to the treatment of minimally complicated hemangiomas. The dogma has been to avoid treatment because children whose hemangiomas were allowed to involute spontaneously had less severe scarring than those subjected to cold steel excision or ionizing radiation. However, up to 20% of hemangiomas leave permanent skin changes that can be disfiguring (Enjolras and Mulliken, 1993). Psychological and social problems may result from facial or other visible deformities. Early intervention should be considered for lesions with a higher potential for complications. Such lesions include hemangiomas of the periorbital area, central face, skin folds, and hands, and those with a pattern suggestive of visceral involvement (large or multiple lesions or those encompassing the “beard area”). Newer therapeutic approaches are

aimed at minimizing growth or speeding resolution without the risk of additional scarring. At present, the benefits of newer approaches to therapy outweigh the risks in many cases. Early initiation of therapy, aimed at preventing growth, is easier and probably more effective than therapy that is delayed until maximal growth has been reached. Treatment options include pulsed dye laser, corticosteroids, and  $\alpha$ -interferon, alone or in combination.

Several small uncontrolled studies have indicated that early treatment with yellow pulsed-dye laser can prevent growth of the superficial, but not the deep, component of proliferating hemangiomas. Laser treatment of persistent hemangiomas may hasten or ensure resolution (Ashinoff and Geronemus, 1991, 1993; Barlow et al, 1996; Garden et al, 1992; Glassberg et al, 1989; Haywood et al, 2000; Poetke et al, 2000; Scheepers and Quaba, 1995; Sherwood and Tan, 1990; Waner et al, 1994; Wheeland, 1995). However, because the magnitude of growth, timing of involution, and degree of sequelae are variable and unpredictable, large, prospective, controlled studies are necessary to determine the laser's true efficacy and long-term effects. A recent prospective, randomized controlled study of 121 infants has shown that pulsed-dye laser treatment in uncomplicated hemangiomas is no better than watchful waiting (Batta et al, 2002).

Corticosteroids may be administered by topical application, intralesional injection, or enteral/parenteral dosing. Each route utilizes corticosteroid preparations of different potency and duration of action. True comparative efficacy studies would be impossible. Experience is greatest with systemic administration, considered to be the optimal regimen by some experts; the recommended regimen is oral prednisone or prednisolone, 2 to 4 mg/kg/day as a single morning dose or in divided doses (Esterly, 1995; Mulliken et al, 1995). Within 1 to 2 weeks, 30% of hemangiomas will show dramatic response; 40% will respond equivocally. In patients with slower-responding lesions, slowly tapering therapy is required through the proliferative phase. If no response is detected, the medication should be rapidly tapered after 2 weeks.

Intralesional injections may be preferred for well-localized hemangiomas, including those involving the eyelid. Colloidal suspensions of triamcinolone and dexamethasone or betamethasone in 1:1 mixtures are used. Large doses are administered, in the range of 40 mg triamcinolone plus 6 mg of betamethasone in 2 mL of suspension (Kushner, 1979). Administration of this dose to a 5-kg infant is equivalent to 20 mg/kg of prednisone given as a single dose, which may ultimately allow for a lower total systemic dose. Complications include cutaneous atrophy and skin necrosis.

The paucity of information on the treatment of hemangiomas with topical steroids suggests that this route of administration has been ineffective. However, application of newer, more potent topical preparations may prove to be beneficial (Magana et al, 1994).

Recombinant interferon alfa-2a may be an effective agent for therapy for life-threatening hemangiomas that are unresponsive to corticosteroids (Mulliken et al, 1995). Regression is not as dramatic as seen in corticosteroid-responsive lesions, making this form of therapy inadequate for vision-threatening hemangiomas; however, it is especially effective for Kasabach-Merritt syndrome. Interferon alfa-2a is administered by subcutaneous injection, in a dose in the

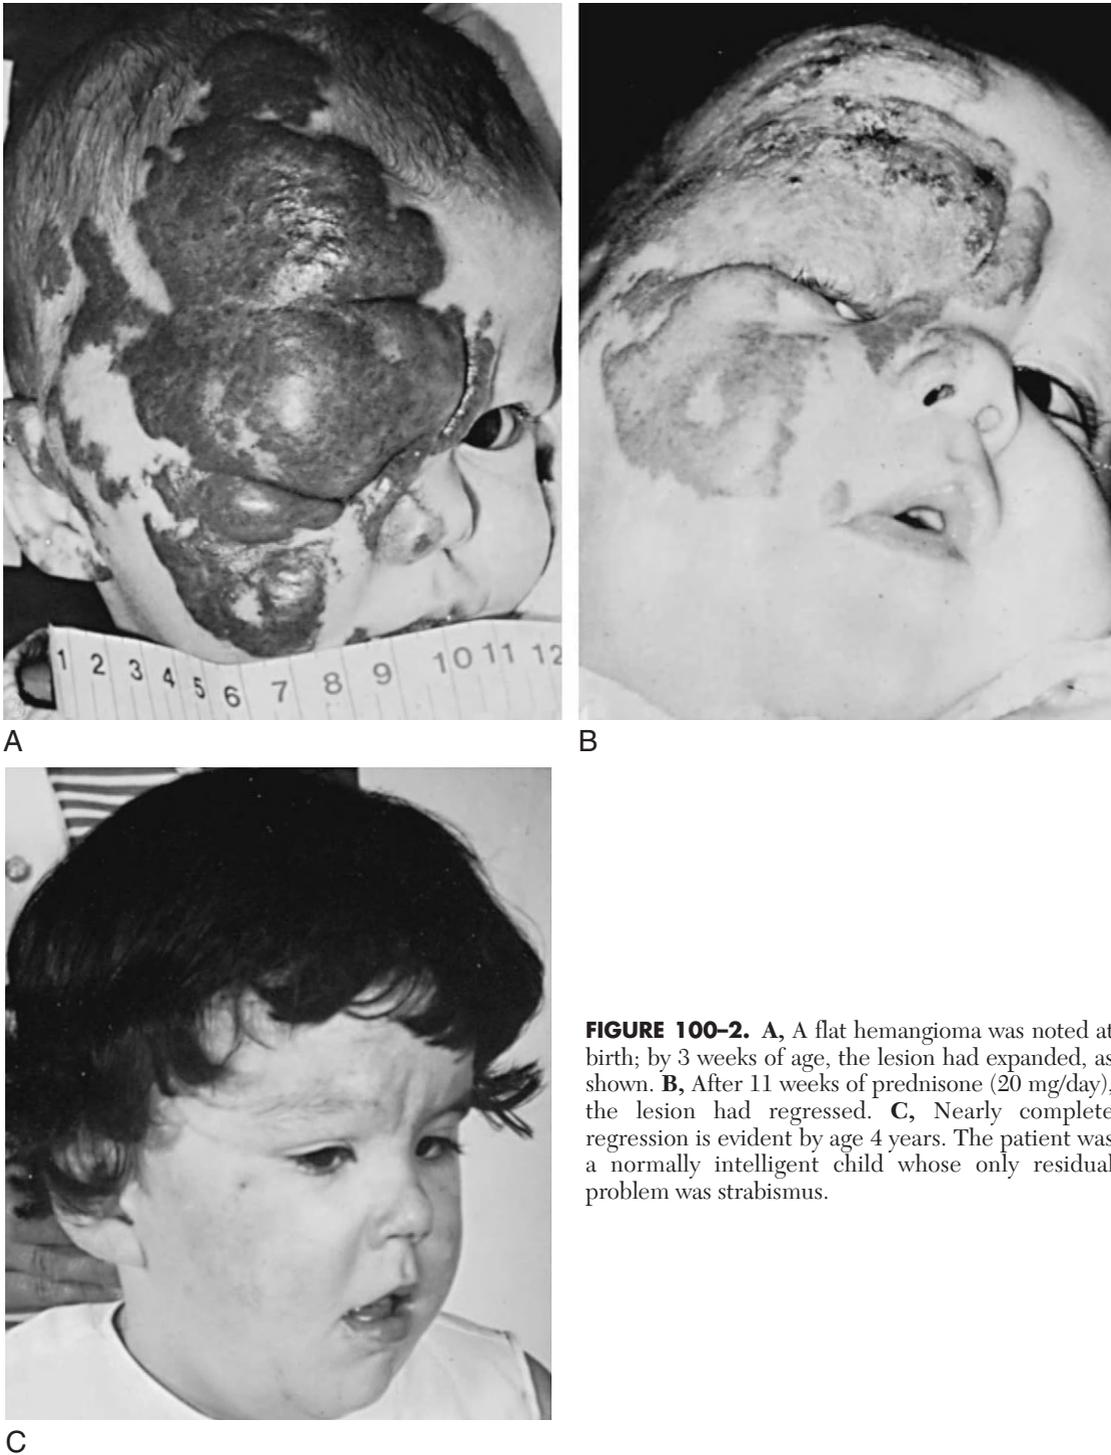

range of 3 million units/m<sup>2</sup>/day. Treatment must be continued for 6 to 10 months. Side effects include fevers of up to 39° C, reversible elevations in liver transaminases, neutropenia, and anemia (Esterly, 1995; Mulliken et al, 1995).

Angiogenesis inhibitors offer promise for more predictably effective therapy in the future. Candidates include interleukin-12 (Voest et al, 1995) and AGM-1470 (a derivative of the fungal product fumagillin) (O'Reilly et al, 1995). Interferon- $\alpha$  has both antitumor and antiangiogenic effects. A recent report has shown that a bFGF-overexpressing low-grade tumor can respond to interferon alfa-2b in a manner similar to that seen for life-threatening infantile hemangiomas, most likely secondary to inhibition of bFGF-mediated tumor angiogenesis by interferon alfa-2b. Measurement of urinary bFGF levels may provide an objective method for monitoring treatment response and guiding interferon- $\alpha$  dosage (Marler et al, 2002).

Ulceration is a therapeutic challenge that may be treated initially with the appropriate occlusive dressing. The choice of dressing and frequency of changes are dictated by the amount of exudate produced. Coban dressing is ideally suited to secure dressings over hemangiomas on the extremities (Kaplan and Paller, 1995). For sites that are difficult to dress, frequent, liberal application of zinc oxide paste is effective. To inspect the skin, zinc oxide is easily removed with mineral oil. Healing, pain relief, and involutinal effects of a polyurethane film in eight cases with ulcerative hemangiomas have been reported (Oranje et al, 2000). Agents for pain control should be prescribed. Alternating doses of acetaminophen and ibuprofen usually are sufficient, but overuse of the latter may increase the risk of bleeding and cause pain from gastrointestinal upset that can be difficult to distinguish from the pain associated with ulceration. A high index of suspicion should be maintained for secondary infection, with a low threshold for use of either topical or systemic antibiotic therapy. If conservative therapy is unsuccessful, yellow light laser may relieve pain and speed reepithelialization (Achauer and Vander Kam, 1991; Morelli et al, 1991, 1994). The ulcers will heal but will inevitably leave scars.

A hemangioma that interferes with the visual axis should be treated aggressively. Evaluation by an experienced pediatric ophthalmologist is recommended. A hemangioma that limits the visual field but does not distort the globe may be treated by patching the contralateral eye. More complicated lesions may be treated initially with corticosteroids: topical, enterally administered, or intralesional. The intralesional route of administration carries the risk of embolic occlusion of the retinal arteries. This tragic adverse effect can occur ipsilaterally, contralaterally, or bilaterally (Brown et al, 1972; Fost and Esterly, 1968; Zuniga et al, 1987) (Fig. 100-2). Surgical excision should be considered for vision-threatening hemangiomas that fail to respond to corticosteroids (Mulliken et al, 1995; Walker et al, 1994).

There is no uniformly successful therapy for seriously complicated or life-threatening hemangiomas. Reported treatment options include high-dose corticosteroids, aspirin, dipyridamole, interferon- $\alpha$ , cold steel excision, sclerotherapy, arterial embolization, cyclophosphamide, bleomycin, and vincristine (Enjolras et al, 1990; Esterly, 1995; Mulliken et al, 1995; Payarols et al, 1995; Sarihan

**FIGURE 100-2.** **A,** A flat hemangioma was noted at birth; by 3 weeks of age, the lesion had expanded, as shown. **B,** After 11 weeks of prednisone (20 mg/day), the lesion had regressed. **C,** Nearly complete regression is evident by age 4 years. The patient was a normally intelligent child whose only residual problem was strabismus.

et al, 1997). All carry significant risks. The use of ionizing radiation is justified for alarming-looking hemangiomas that have been unresponsive to other therapeutic modalities and are inoperable.

### Vascular Malformations

Vascular malformations may be indistinguishable from hemangiomas by clinical and light microscopic examination; however, they are biologically distinct lesions.

### Clinical Findings

Malformations are true structural anomalies, composed of one or more types of vessels—capillaries, veins, arteries, and/or lymphatics. Unlike hemangiomas, they are always present at birth. They affect males and females equally. Growth is commensurate with the child's growth, although the lesion may expand as a result of local thrombosis or inflammation. Primary platelet trapping with consumptive coagulopathy (e.g., Kasabach-Merritt syndrome) does not occur. Local skeletal or soft tissue destruction or hypertrophy

is common. Spontaneous resolution is not expected except in one specific malformation, the salmon patch. Vascular malformations occur either as isolated cutaneous defects or in association with a variety of well-defined syndromes. The more common variations are described next.

**Salmon Patch.** The glabellar salmon patch (macular stain, nevus simplex), also known as an “angel’s kiss,” is a bilaterally symmetrical superficial capillary defect. It is the most common vascular malformation and the only one that almost always fades spontaneously. A similar lesion in the nuchal area, the “stork bite,” usually is persistent. Large lesions may also involve the eyelids and alae nasi. Prominent glabellar salmon patches are associated with dysmorphic syndromes including Beckwith-Wiedemann syndrome and fetal alcohol syndrome (Burns et al, 1991).

**Nevus Flammeus (Port-Wine Stain).** This asymmetrical postcapillary venule malformation occurs in 0.3% of neonates. A majority are isolated cutaneous lesions. At birth they are pink, macular, and blanchable. With time, most lesions darken; papulonodular surface change and ipsilateral soft tissue or even bone hypertrophy may occur. Facial nevus flammeus is a distribution that includes the forehead or upper eyelid and may be associated with buphthalmos or glaucoma. Emergent ophthalmologic examination is indicated for affected infants.

**Sturge-Weber syndrome (SWS)** is a triad of facial nevus flammeus, leptomenigeal vascular malformation, and glaucoma that occurs sporadically. The classic finding of double-contoured (tram-line) calcifications on a skull film is not seen during infancy; this sign develops during childhood. CNS lesions are most reliably detected by MRI after 6 months of age. SWS occurs in less than 30% of infants with facial port-wine stains; the risk is increased in infants with more extensive lesions (Tallman et al, 1991). The degree of CNS involvement is variable in SWS, ranging from subclinical lesions to intractable seizures and intellectual impairment. Two national organizations have been established to serve the needs of patients and their families:

National Vascular Malformations Foundation, Inc., 8320  
Nightingale, Dearborn Heights, MI 48127  
The Sturge-Weber Foundation, P.O. Box 460931, Aurora,  
CO 80046

**Arterial/Lymph/Venous Malformation.** This category includes a spectrum of isolated cutaneous vascular anomalies that have been given a variety of clinically descriptive names. These multifarious names do not offer insight into pathogenesis or natural history, and some experts advocate for a more simple classification based on the type of anomalous vessel (Mulliken and Young, 1988). Thus, categories would include pure lymphangiomas (e.g., “cystic hygroma,” lymphangioma circumscriptum), arteriovenous malformations, and venous malformations.

These lesions do not resolve spontaneously. Corticosteroid therapy is not beneficial. Complications are related to the flow rate and extent of the lesion. Localized thrombosis and phlebitis occur in low-flow lesions; high-

flow lesions can cause significant bleeding, destructive interosseous changes, and high-output cardiac failure (Mulliken and Young, 1988).

**Cutis Marmorata Telangiectatica Congenita.** Cutis marmorata telangiectatica congenita (CMTC) is a distinct, reticulated capillary-venous malformation. CMTC can occur as a single isolated patch or involve an extensive area. With time, associated atrophy and ulceration may occur. The larger lesions may have ipsilateral hypertrophy or hypotrophy of the affected limb.

**Klippel-Trénaunay and Parkes Weber Syndromes.** These are clinically defined, sporadic conditions consisting of extensive nevus flammeus, most often occurring unilaterally on the lower extremity, associated with venous varicosities and progressive ipsilateral limb hypertrophy. Some authors differentiate Parkes Weber syndrome, which also includes an arteriovenous fistula and its associated constellation of complications, as a discrete entity.

**Cobb Syndrome.** This is a sporadic condition consisting of a posterior truncal nevus flammeus overlying a vascular abnormality that involves the spinal cord.

**Bonnet-Dechaume-Blanc Syndrome.** This condition (also known as *Wyburn-Mason syndrome*) consists of a facial port-wine stain overlying a retinal and intracranial arteriovenous malformation. The retinal lesion appears as dilated, tortuous retinal vessels on routine ophthalmoscopy. Cranial bruit, mild proptosis, and conjunctival hyperemia may be present.

**Blue Rubber Bleb Nevus Syndrome.** This condition, inherited as an autosomal dominant trait, is characterized by venous malformations of the skin and gastrointestinal tract associated with bleeding and iron deficiency anemia. Numerous lesions may be present at birth. They are blue macules or nodules that range in size from 1 mm to several centimeters, resembling the “blueberry muffin” lesions of congenital TORCH (*toxoplasmosis, other infections, rubella, cytomegalovirus, herpes simplex*) infection, but are easily compressible. They may be tender to palpation or surmounted by droplets of sweat.

**Maffucci Syndrome.** This sporadic condition consists of mixed vascular malformations and characteristic enchondromas. In 25% of the cases, manifestations are present at birth or in early infancy.

**Bannayan-Riley-Ruvalcaba Syndrome.** The abnormalities included in this category are vascular malformations, macrocephaly, and lipomas. In combination with other features, separate conditions have been described: Bannayan-Zonana, Riley-Smith, and Ruvalcaba-Myhre-Smith syndromes. The usual inheritance pattern is autosomal dominant.

**Lymphedema.** *Lymphedema* is a term used to describe diffuse soft tissue swelling characterized by firm, pitting edema. Lymphedema can occur in the setting of anomalous

lymphatic drainage. Congenital variants have been reported. Females are affected more frequently than males. The lower limbs are the most commonly affected sites, but other sites also may be involved, and rarely, chylothorax or ascites may be present. *Milroy disease* is an autosomal dominant condition that manifests with progressive lymphedema of the lower extremities. Lymphedema of the extremities occurs in Turner (XO) syndrome.

### Treatment

Treatment for an uncomplicated capillary malformation is aimed at minimizing disfigurement. With time, these lesions thicken and develop irregular surface changes, often with friable nodules. In 1986, the yellow-light pulsed-dye laser was approved by the Food and Drug Administration (FDA) for the treatment of nevus flammeus, as early as the neonatal period. The copper vapor laser and the argon-pumped tunable dye laser also are yellow light lasers. Most of the published data on laser treatment of port-wine stains in children is from studies utilizing the pulsed-dye laser. Children require an average of four or five pulsed-dye laser treatments for maximal lightening. The best results have been seen in children younger than 4 years of age. In this age group, 20% can expect 95% clearing (Goldman et al, 1993). Pulsed-dye laser therapy is less effective for facial port-wine stains that are close to midline or those on the extremities (Garden and Bakus, 1993; Renfro and Geronemus, 1993). A recent study comparing the effects of the pulsed-dye laser with those of the argon-pumped dye laser for the treatment of port-wine stains has shown that the pulsed-dye laser is clinically superior to the argon-pumped dye laser (Edstrom et al, 2002). Laser therapy can yield remarkable improvement for many port-wine stains, minimizing the emotional pain that accompanies facial disfigurement. Unfortunately, none of the currently available lasers is capable of permanently erasing port-wine stains in a majority of patients. Attempts to optimize laser treatment efficacy include using the pulsed-dye laser at higher fluences in conjunction with cryogen spray cooling, the effects of which are still unclear (Kelly et al, 2002). The range of skin conditions that may benefit from yellow-light laser therapy is expanding rapidly to include a variety of skin lesions with vascular components.

## HYPOPIGMENTED LESIONS

Localized areas of hypopigmentation on the skin of the newborn infant may be isolated phenomena, or they may be markers of extracutaneous abnormalities. The degree of hypopigmentation and the distribution of the defect help distinguish among the different conditions.

### Definition

A distinction must first be made between complete *depigmentation* and *hypopigmentation*. A depigmenting condition produces pure white lesions that are devoid of normal melanocytes. Even in fair-skinned infants, the lesions can be easily seen in ordinary daylight. This

group of disorders includes tyrosinase-negative albinism and piebaldism, as well as vitiligo, which is rarely seen in infancy. A hypopigmented lesion often is subtly lighter in color than the surrounding skin. Histologic examination reveals a normal number of melanocytes. In fair-skinned children, these lesions may require Wood's lamp illumination to become obvious. This group includes anomalies with a deficient amount of either of the skin's pigments: melanin or hemoglobin. The ash-leaf macules and "confetti-like" lesions of tuberous sclerosis (Fig. 100-3), the linear and whorled patterning associated with hypomelanosis of Ito (Fig. 100-4A), and simple nevus depigmentosus are hypomelanotic lesions (see Fig. 100-4B). Nevus anemicus and hemangioma precursors are areas of pallor that result from diminished superficial blood flow.

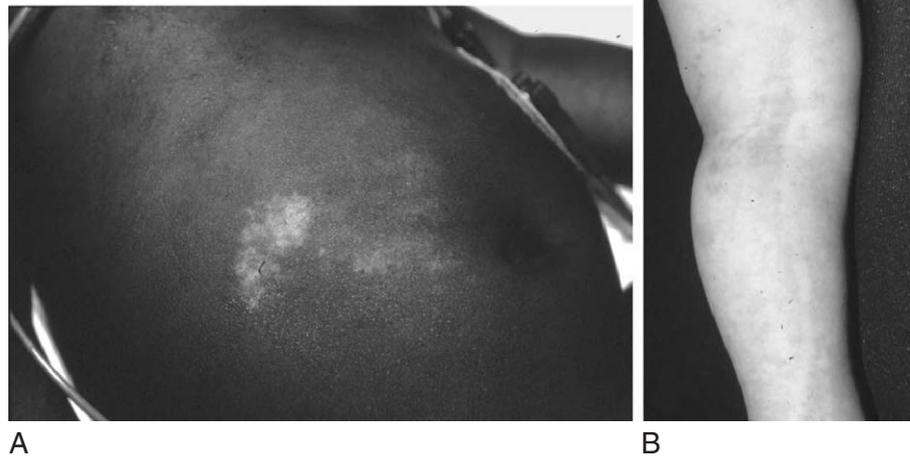

### Ash-Leaf Macules

Ash-leaf macules are small oval areas of hypopigmentation, named for their similarity in size and shape to a leaflet from a European mountain ash tree. They are one of the few congenital markers for infants with tuberous sclerosis. Tuberous sclerosis complex (TSC) is a disorder of autosomal dominant inheritance with variable clinical manifestations characterized by the development of benign and malignant tumors in a variety of tissues: skin, CNS, and kidney. Serious complications of tuberous sclerosis include hamartomas of the lung and kidney and congenital rhabdomyomas of the heart. The diagnosis is currently made by meeting a set of diagnostic criteria, but a majority of manifestations are not present in infancy (Gomez, 1991; Janniger and Schwartz, 1993; Zvulunov and Esterly, 1995). Abnormalities at two different genetic loci have been identified in kindreds with TSC (Wienecke et al, 1995). The two genetic loci are *TSC1* on chromosome 9q and *TSC2* on chromosome 16p, and the gene products are hamartin and tuberlin, respectively. Both hamartin and tuberlin are expressed in neurons and astrocytes, where they physically interact (Gutmann et al, 2000).

**FIGURE 100-3.** White ash-leaf macule on the back of a patient with tuberous sclerosis.

**FIGURE 100-4.** Nevus depigmentosus is an isolated congenital skin lesion that presents as a hypomelanotic polygonal macule (A) or in a linear Blaschko distribution (B).

### Hypomelanosis of Ito

The term *hypomelanosis of Ito* has been used as a diagnosis for a genetic disorder marked by a striking linear and whorled pattern of cutaneous pigment change oriented along the lines of Blaschko. Affected persons may have areas that are hyperpigmented or hypopigmented, or both. The pattern may be congenital or become apparent after birth.

This condition is a form of genetic mosaicism. In a subset of affected persons, karyotype abnormalities are demonstrable in tissue from affected sites. In a majority of reported cases, the patients have extracutaneous abnormalities (CNS, ocular, cardiac, and skeletal) (Alvarez et al, 1993; Dereser-Dennl et al, 2000; Devriendt et al, 1998; Tunca et al, 2000). Patterned pigment change confined to skin probably is a more common occurrence. For persons so affected, the term *linear and whorled nevoid melanosis* may be more appropriate. Chromosomal analysis from separate tissues (e.g., blood and skin) is indicated for children with extensive skin lesions or evidence of extracutaneous involvement (Sybert, 1994).

### MELANIN-CONTAINING LESIONS

Brown lesions usually reflect an increased number of melanocytic cells or an excess of melanin. Brown coloration also can be associated with a thickened epidermis. It may be difficult to distinguish among the lesions in this category without histopathologic examination. A majority of congenital brown lesions are isolated and benign, but it is important to recognize those that are syndrome-associated or potentially life-threatening (see Chapter 96 for a differential diagnosis).

In general, skin biopsy of a congenital pigmented lesion can be postponed until after the neonatal period. The one exception is a nodular lesion suggestive of melanoma.

### Nevocellular Nevi

The category of nevocellular nevi includes congenital or acquired nevomelanocytic neoplasms. Nevomelanocytes are dendritic cells of neural crest origin. Nevocellular nevi traditionally have been categorized by the histologic position of the tumor nests within the skin. *Junctional nevi* are the most superficial, located at the junction between the epidermis and dermis. These lesions appear clinically as macules. *Intradermal nevi* are located deep to the dermoepidermal junction and are usually papular. *“Blue” nevi* are a variant located in the deep dermis, made up of cells that have elongated, neural features. *Compound nevi* have both junctional and dermal nests of nevomelanocytes.

Melanocytic nevi can be further divided into categories based on size: small (less than 1.5 cm in greatest diameter), large (2 to 20 cm), and giant (greater than 20 cm in diameter, or 120 cm<sup>2</sup> surface area) (Zitelli et al, 1984); and time of onset: congenital, early-onset (before the age of 2 years), and acquired. Diagnostic histologic features have been described for congenital and acquired lesions, but these features may be found in both types.

Large, multiple, or congenital melanocytic nevi have been reported in association with several syndromes (Marghoob et al, 1993) (Table 100-3).

### Congenital Nevocellular Nevi

Congenital nevocytic nevi are common and generally of little or no consequence. However, the infrequent but devastating association with malignant melanoma has made management a controversial issue.

Small congenital nevi measure less than 1.5 cm in diameter at birth (Fig. 100-5). Truly congenital lesions are present in 1% of white infants and in 2% to 3% of African-American infants surveyed in the nursery (Osburn et al, 1987). There is a risk of malignancy associated with small nevi, but it may never be well defined. A distinct

TABLE 100-3

## Syndromes Associated with Melanocytic Nevi

Associated with:	Other Key Features
<b>Congenital Nevi</b>	
Carney syndrome (including LAMB and NAME syndromes)	Cardiac and cutaneous myxomas, endocrine abnormalities
Epidermal (linear sebaceous) nevus syndrome	Linear epidermal/sebaceous nevi, central nervous system and musculoskeletal defects
Neurocutaneous melanosis	Leptomeningeal melanocytosis and obstructive hydrocephalus
Neurofibromatosis type I	Cutaneous and plexiform neurofibromas, café-au-lait spots, Lisch nodules
Premature aging syndrome	Premature aging, short stature, bird-like facies, deafness
Occult spinal dysraphism/tethered cord	Spinal cord abnormalities, lipomas, vascular malformations
Malformations associated with congenital melanocytic nevi	
<b>Acquired Nevi</b>	
Dysplastic nevus (atypical mole) syndrome	Increased incidence of cutaneous melanoma
Langer-Giedion syndrome	Distinctive facies, cone-shaped epiphyses, multiple exostoses
<b>Congenital and/or Acquired Nevi</b>	
EEC syndrome	Ectrodactyly, ectodermal dysplasia, cleft lip/palate, ocular abnormalities
Goeminne syndrome	Muscular torticollis, spontaneous keloids, genitourinary abnormalities
Kuskokwim syndrome	Skeletal abnormalities, joint contractures, muscle atrophy/hypertrophy
Noonan syndrome	Webbed neck, heart defects, multiple other anomalies
Turner syndrome	Webbed neck, heart defects, multiple other anomalies, X-chromosome defect
Tricho-odonto-onychial dysplasia	Hypotrichosis, enamel defects, nail dystrophy

From Marghoob AA, Orlo SJ, Kopf AW: Syndromes associated with melanocytic nevi. *J Am Acad Dermatol* 29:373-388, 1993.

subset of melanocytic nevi in children, “early-onset nevi,” has recently been recognized. These lesions are not necessarily congenital, appearing during the first 2 years of life. Early-onset nevi have been observed in 25% of children specifically examined for them. Twenty percent to 50% of melanomas arising in children and young adults may be associated with this type of nevus (Williams, 1993; Williams and Pennella, 1994). The frequency of congenital melanocytic nevi (CMN) is paradoxically increased in African-Americans, who have a much lower risk of melanoma (Shpall et al, 1994). The risk of melanoma associated with these very common pigmented skin lesions must be well below that in children with giant con-

**FIGURE 100-5.** Dark brown irregular congenital nevus on the limb of an infant.

genital nevi and possibly no higher than the 1% lifetime risk of malignant melanoma in the general white population. A decision about surgical removal of these lesions must be made on a case-by-case basis.

Large, giant or “garment” congenital nevi measure at least 20 cm or cover an entire body part (Fig. 100-6). These lesions are rare, occurring in less than 1 in 20,000 neonates, and have a much greater potential for malignant degeneration. The cumulative risk of malignancy is estimated to be 2% to 15% over a lifetime, with a bimodal pattern of occurrence, either before age 3 or after puberty (Kuflik and Janniger, 1994; Williams and Pennella, 1994).

Conservative management of large congenital nevi by surveillance alone is complicated by the presence of features that strongly suggest melanoma. Most of these nevi have an irregular surface appearance from birth and are variably thickened, hairy, verrucous, or nodular. Smaller, widely scattered “satellite lesions” are almost always present. Extracutaneous lesions also have been detected in several sites, including the meninges, lymph nodes, and placental villi. Often, these nevi have atypical histologic features as well. For children who develop malignant melanoma within a giant nevus, the prognosis is very poor. However, many of the lesions with an alarming appearance from birth do not exhibit malignant behavior or have widespread metastases, or cause death. In fact, congenital melanoma is very rare and is associated with congenital nevi in less than 50% of reported cases (Williams and Pennella, 1994).

The management of CMN remains controversial, with equal numbers of advocates for and against prophylactic excision. Newly published data question the rationale for routine excision. Nevertheless, case reports of melanoma arising in smaller CMN, as early as 6 months of age, continue to dramatize the issue (Ceballos et al, 1995; De Raeve et al, 1993; Ozturkcan et al, 1994). To date, the incidence of melanoma arising in small CMN remains unclear. A 3- to 21-fold increased relative risk for malignant transformation in both small and medium-sized lesions later in life has been reported, depending on the method of study (Richardson et al, 2002).

The least controversial recommendation has been for surgical excision of large or multiple CMN during

**FIGURE 100-6.** A, Newborn infant with large black nevus covering the “bathing trunk area.”  
B, The closer view permits visualization of the nodular surface typical of giant nevi.

infancy (Casson and Colen, 1993). However, surgical removal is never an easy option. Multiple procedures usually are required, with the attendant high risks of significant morbidity, sometimes yielding results that are more disfiguring than the birthmark (Figs. 100-7 and 100-8). Newer techniques performed in early childhood, such as tissue expansion (Vergnes et al, 1993) and partial-thickness resection (Sandsmark et al, 1993), may improve the aesthetic outcome. The efficacy of this approach in the prevention of malignancy has never been documented.

A Congenital Nevocytic Nevus Registry was established at the New York University Medical Center in 1978 to prospectively study the natural history of giant CMN (Gari et al, 1988; Kopf et al, 1979). To participate by mail, clinicians should contact the Skin and Cancer Unit, Department of Dermatology, New York University Medical Center, 550 First Ave., New York, NY 10016; telephone: (212) 340-5260.

Families with an affected child may benefit from information provided by the Nevus Network, a national support group founded by Dr. Bari Joan Bett, a physician with a giant congenital nevus. To receive the organization's newsletter, families should contact the Network, c/o Bari Joan Bett, MD, 1400 S. Joyce St. #C1201, Arlington, VA 22202; telephone: (703) 920-2349 or (405) 377-3403.

Neurocutaneous melanosis (NCM) is a congenital syndrome characterized by pigment cell tumors of the lep-

**FIGURE 100-7.** Cutis marmorata telangiectatica congenita. Note the striking network of dilated vessels, most distinct over the extremities. (From Humphries JM: *J Pediatr* 40:486, 1952.)

tomeninges in patients with large or multiple (at least three) CMN of the head, neck, or posterior midline (Kadonaga and Frieden, 1991). Symptomatic NCM manifests with signs or symptoms of increased intracranial pressure and carries a poor prognosis (Sandsmark et al, 1994;

**FIGURE 100-8.** Large café-au-lait spot on the trunk of a newborn infant.

Frieden et al, 1994). MRI can aid in the diagnosis of NCM (Barkovich et al, 1994). Although initial reports emphasized thickening of the leptomeninges, the most common MRI sign of NCM is actually spin-lattice (T1) nuclear magnetic relaxation time in the parenchyma of the cerebellum or anterior temporal lobes (sometimes accompanied by spin-spin [T2] relaxation time). Radiologic identification of malignant degeneration is difficult. Roughly half of asymptomatic infants and children with giant CMN have evidence of NCM on MRI (Frieden et al, 1994), a finding suggesting that numerous and extensive operations to remove the cutaneous lesion may not be justified in these patients.

Other issues have been raised that challenge the interpretation of signs that have been accepted as ominous. The risk of melanoma in early infancy may have been overestimated by misinterpretation of the histologic findings and extent of the lesions. Neither cellular atypia nor widespread involvement, including lymph nodes and placenta, proves malignancy (Carroll et al, 1994; Hara, 1993). Attempts to further define the risk of malignant degeneration in these lesions have not been insightful (Barnhill et al, 1994; Heimann et al, 1993).

### Lentiginos

Lentiginos are small tan-to-dark brown macules that most commonly appear sporadically in adulthood. They are distinguished from other pigmented lesions by histologic examination that reveals elongated rete ridges, an increased number of singly dispersed melanocytes along the basal layer, and increased melanization of the basal keratinocytes. Multiple or congenital lentiginos are features of several syndromes.

**Carney Syndrome (Including NAME and LAMB).** Carney syndrome and the related phenotypes designated NAME and LAMB share the features of atrial myxoma and pigmented skin lesions. NAME includes nevi and ephelides, while LAMB includes lentiginos and blue nevi. Pigmented lesions are present at birth.

**LEOPARD Syndrome.** This is an autosomal dominant disorder that includes multiple lentiginos, electrocardiographic defects, ocular hypertelorism, pulmonic stenosis, abnormal

genitalia, growth retardation/restriction, and sensorineural deafness. Skin lesions do not appear until after the first year of life.

**Peutz-Jeghers Syndrome.** This disorder of autosomal dominant inheritance includes mucocutaneous pigmented macules and intestinal polyposis. The pigmented lesions may be congenital and usually appear on the lips, buccal and gingival mucosae, and dorsa of the fingers and toes.

### Café-au-Lait Macules

Café-au-lait macules (CALMs) are light brown macules that vary in size, ranging from several millimeters to several centimeters in diameter. They cannot always be distinguished from nevocellular nevi on clinical grounds, but histologic examination is diagnostic, showing increased melanin within the basal keratinocytes, without melanocyte proliferation. CALMs are present in 2% of white infants and in up to 12% of African-American infants. Large or multiple CALMs in the neonatal period may be an isolated finding but should alert the physician to the possibility of an associated syndrome.

### Neurofibromatosis

Neurofibromatosis (NF) is a group of variable multisystem disorders that includes cutaneous neurofibromas and multiple CALMs. A classification that includes eight subtypes has been defined (Riccardi, 1983). The great majority of patients with NF have subtype 1 (NF-1), or von Recklinghausen disease. NF-1 is a relatively common autosomal dominant disorder with a high rate of new mutation, occurring in 1 in 3500 people. The diagnosis has traditionally been made by fulfilling a set of diagnostic criteria; the presence of six or more CALMs is the most common manifestation, occurring before age 6 years in 99% of affected persons (Zvulunov and Esterly, 1995). CALMs may be present at birth but often arise and grow during childhood. Other diagnostic cutaneous findings are axillary or inguinal freckling (Crowe sign) and cutaneous neurofibromas, which may be present at birth. Bony dysplasias (sphenoid wing dysplasia, pretibial pseudarthrosis) also can be detected at birth in a minority of patients. Symptomatic CNS involvement (developmental delay, learning disabilities, seizures) occurs in about one third of patients with NF-1. The most ominous complication of NF-1 is the development of malignant tumors (neurosarcoma, pheochromocytoma,

**TABLE 100-4**

#### Syndromes that Feature Café au Lait Macules

Neurofibromatosis (NF1, II)	Turner syndrome
Albright syndrome	Noonan syndrome
Watson syndrome	Ataxia-telangiectasis
Ruvalcaba-Myhre-Smith syndrome	Tuberous sclerosis
Bloom syndrome	Basal-cell nevus syndrome
Russell-Silver syndrome	Hunter syndrome
	Gaucher syndrome

and juvenile chronic myelogenous leukemia (Zvulunov and Esterly, 1995). The risk of leukemia is highest among children with both NF-1 and cutaneous juvenile xanthogranuloma (see later).

The genetic defects for NF-1 have been localized to chromosome 17q11;2. Most mutations occur on the paternally derived chromosome. "Sporadic" cases may be the result of paternal transmission from a mosaic mutation of a fraction of spermatozoa from a clinically normal father (Lazaro et al, 1994). A portion of the *NFI* gene has homology with mammalian genes that code for guanosine triphosphate-activating proteins (GAPs). GAPs function to regulate cell proliferation. Therefore, a functional mutation of the *NFI* gene would result in unsuppressed cellular proliferation (i.e., tumorigenesis). Prenatal diagnosis is now available for affected families by linkage analysis (Zvulunov and Esterly, 1995). Affected families should be advised to contact the National Neurofibromatosis Foundation, 141 Fifth Ave., Suite 7-S, New York, NY 10010; telephone: (800) 323-7938 or (212) 344-6633.

Type 2 neurofibromatosis (NF-2) is an autosomal dominant disorder with an incidence of about 1/40,000. It is characterized by bilateral acoustic neuromas. CALMs are not as prominent or numerous as in NF-1, occurring in less than 40% of affected persons. The gene defect has been localized to chromosome 22q11-q13 (Zvulunov and Esterly, 1995). The deduced gene product has homology with proteins at the plasma membrane and cytoskeleton interface, a previously unknown site of action of tumor suppressor genes in humans (Rouleau et al, 1993).

### McCune-Albright Syndrome

McCune-Albright syndrome (MAS) is a sporadic disease characterized by polyostotic fibrous dysplasia, sexual precocity and other hyper functional endocrinopathies, and large café-au-lait spots (Schwindinger et al, 1992; Shenker et al, 1993). In contrast with the café-au-lait spots seen in NF-1, those in this syndrome may be unilateral with irregular borders, in a distribution that suggests the lines of Blaschko and genetic mosaicism (Rieger et al, 1994). Affected tissues from patients with MAS have been found to harbor mutations of the gene that encodes the stimulatory G protein of adenylyl cyclase (Schwindinger et al, 1992; Shenker et al, 1993).

### Nevus Spilus

Nevus spilus (speckled lentiginous nevus) is a hyperpigmented lesion that consists of focal proliferation of melanocytes along the basal layer of the epidermis (the dark spots) within a café-au-lait spot. It may be disfiguring but has no other associated abnormalities.

### Blue-Gray Macule of Infancy

More than 90% of African-American infants, 81% of Asians, and 10% of whites (Pratt, 1953) are born with blue-gray macule of infancy, formerly called *mongolian spot*. These are brown, gray, or blue macules, most commonly

located on the lumbosacral area, but they can occur anywhere. Mongolian spots may be single or multiple and vary in size from a few millimeters to several centimeters in diameter. They often fade within the first few years of life. Extensive lesions have been mistakenly attributed to abuse. Histologically, blue-gray macule of infancy is a collection of spindle-shaped melanocytes located deep in the dermis. Malignant change has never been reported.

### Nevus of Ota/Ito

Nevus of Ota is a unilateral blue or gray discoloration involving the orbital and zygomatic areas, including the sclera and fundus. It is a sporadic condition, but it occurs with the highest frequency in Asians, affecting up to 1% of persons in Japan (Kopf and Weidman, 1962). The discoloration is detected at birth in 60% of cases. Glaucoma is a frequent complication. A similar lesion, located in the deltoid area, is called *nevus of Ito*. Histologically, these lesions cannot be distinguished from mongolian spots. However, spontaneous resolution is not common, and association with malignant melanoma has been reported. Successful treatment has been achieved with Q-switched ruby and Q-switched yttrium-aluminum-garnet (YAG) laser surgery.

## TUMORS OF EPITHELIAL ORIGIN

### Epidermal Nevus/Nevus Sebaceus

Epidermal nevus may manifest in the newborn period as a smooth hyperpigmented patch or rough, skin-colored plaque most often on the trunk or extremities, frequently oriented along the lines of Blaschko. With time, epidermal nevi may enlarge; most become verrucous. Nevus sebaceus has a yellow hue, occurs most often on the head, and may be nodular at birth and again after puberty, flattening during childhood. A variety of neoplasms, both benign and malignant, including basal cell carcinoma, develop in up to 15% of patients with sebaceous nevi. Development of neoplasms rarely occurs before puberty.

Like other mosaic disorders, epidermal and sebaceous nevi are believed to be localized manifestations of somatic genetic mutations that would be lethal if fully expressed. A subset of patients with epidermal nevi are genetic mosaics for an autosomal dominant form of ichthyosis, called *epidermolytic hyperkeratosis* (or bullous ichthyosiform erythroderma). These persons may be at risk for having offspring with total body involvement. The striking appearance of epidermal nevi has inspired descriptive nomenclature. *Nevus verrucosus* is a solitary plaque. *Nevus unius lateris* (Fig. 100-9) is an extensive linear lesion that is unilateral, following the lines of Blaschko. Both keratinocytic and sebaceous components may occur in the same patient, the former more commonly involving the trunk and extremities and the latter more often involving the head and neck. The term *ichthyosis hystrix* refers to extensive, bilateral involvement with epidermal nevus.

Skin biopsy will rule out other conditions, distinguish between epidermal nevus and nevus sebaceus, and detect

**FIGURE 100-9.** Linear hyperkeratotic epidermal nevus on the back and lateral aspect of the thorax.

the diagnostic histologic features of epidermolytic hyperkeratosis. Small epidermal nevi do not require treatment. Nevus sebaceous carries a risk of malignant degeneration and optimally is excised in adolescence using local anesthesia. Recent studies suggest that the risk of basal cell carcinoma, the most common malignancy to arise in nevus sebaceous, is closer to 1%, much lower than reported in the past (Cribier et al, 2000).

There is no optimal therapy for larger lesions or those that are disfiguring. Full-thickness excision, including the subcutaneous tissue, is recommended to decrease the risk of recurrence. Laser therapy holds promise for the future. Topically applied keratolytic agents may be palliative. Genetic counseling about the risk for offspring of fully expressed disease should be considered for persons with epidermal nevi that reveal the histologic features of epidermolytic hyperkeratosis.

### Epidermal (Linear Sebaceous) Nevus Syndrome

In less than 10% of affected people, epidermal nevi and sebaceous nevi (especially those involving the head) are associated with a variety of extracutaneous abnormalities, mainly ocular (in 33% of cases), neurologic (in 50%), and skeletal (in 70%), a condition referred to as *epidermal nevus syndrome*. Bone abnormalities include vertebral anomalies, kyphoscoliosis, limb shortening, and hemihypertrophy. CNS disorders include seizures, mental retardation, and hemiparesis; ocular abnormalities include eyelid/conjunctival nevus, coloboma, corneal opacity, and nystagmus. Malignancies also occur in this syndrome with a greater-than-expected frequency, including Wilms tumor, nephroblastoma, gastrointestinal carcinomas, and rhabdomyosarcoma (Marghoob et al, 1993).

## DERMAL TUMORS

### Juvenile Xanthogranuloma

Juvenile xanthogranuloma (JXG) is a benign, self-healing, non-Langerhans cell histiocytic tumor of infancy. JXG may be congenital; a majority of tumors manifest by 6 months of age (Nomland, 1959). Cutaneous lesions vary

in color from red-brown to yellow. They occur most often on the upper half of the body (Fig. 100-10), may be solitary or multiple, and vary from several millimeters to several centimeters in diameter (see Fig. 100-4). JXG also may be localized to the eye or mucous membranes (De Raeve et al, 1994).

Skin biopsy usually is diagnostic, revealing characteristic foamy histiocytes and Touton giant cells within the dermis.

The vast majority of infants with JXG are otherwise healthy. Giant JXG can have an alarming appearance and may be confused with other types of histiocytic tumors (Magana et al, 1994). The most clinically significant associations are ocular JXG with its complications and the triad of JXG, juvenile chronic granulocytic leukemia, and NF-1. Less than 0.5% of children with skin lesions have ocular involvement, but one half of children with ocular JXG have cutaneous lesions (Giacoaia and Berry, 1994). Ocular tumors may manifest as unilateral glaucoma, uveitis, heterochromia iridis, or proptosis; ocular JXG is the most common cause of hyphema in infancy (Gaynes and Cohen, 1967; Zimmerman, 1965). The iris is the most frequently affected ocular tissue (Hamdani et al, 2000). The triple association of JXG, juvenile chronic granulocytic leukemia, and NF-1 has been reported in 24 cases. The appearance of JXG usually preceded the diagnosis of leukemia; the NF, marked by multiple CALMs, was often missed (Sherer et al, 1993). Fewer than 20 patients with intracranial JXG without cutaneous manifestations have been described (Bostrom et al, 2000; Schultz et al, 1997).

The majority of cases of JXG are asymptomatic and self-limited. Giant lesions have a similar prognosis (Magana et al, 1994). Ophthalmologic evaluation is indicated for children who present in the first 2 years of life with multiple lesions. Parents should be provided with anticipatory guidance about the ocular complications (Giacoaia and Berry, 1994). JXG typically involutes within 3 to 6 years (Hansen, 1992). Recurrence has been documented following surgical excision; this form of therapy is indicated only

**FIGURE 100-10.** Solitary juvenile xanthogranuloma on the scalp, a typical site for these lesions.

for lesions that are frequently traumatized or are more disfiguring than the resultant scar would be.

## MASTOCYTOSIS

Mastocytosis comprises a group of disorders characterized by increased numbers of tissue mast cells. The skin is the most common site of involvement, but the lymphoreticular system, gastrointestinal tract, and bone marrow also may be affected. Symptoms result from the local or generalized effects following the release of histamine and other mast cell mediators. Pruritus, edema, blistering, and flushing are common. Abdominal pain, diarrhea, and vomiting are unusual. Hypotension is rare (Kettelhut and Metcalfe, 1991). If rubbed or traumatized, skin affected by mastocytosis will develop a diagnostic wheal (Darier sign). The site may blister or become hemorrhagic in a neonate.

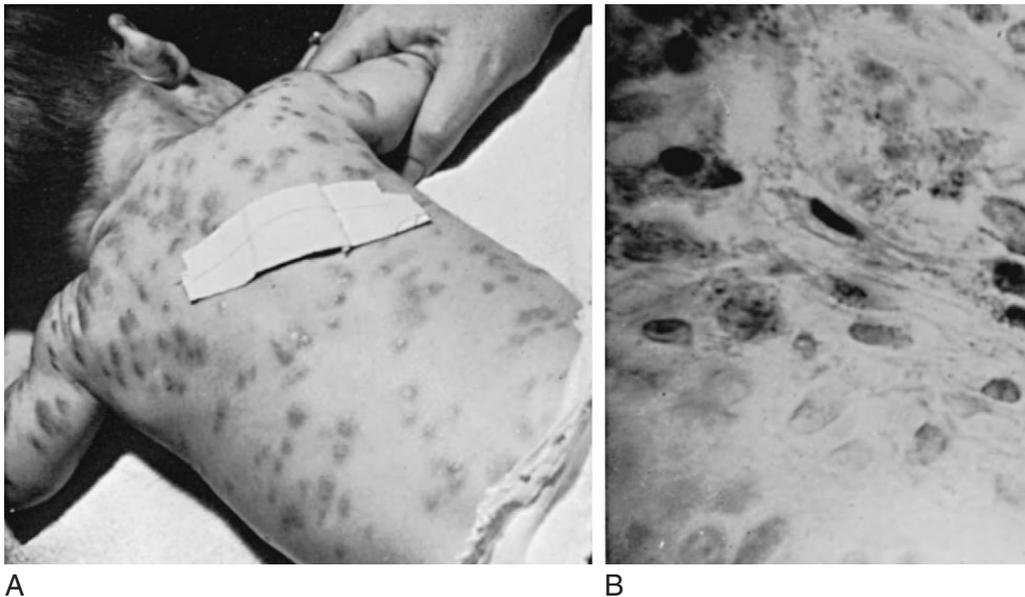

*Urticaria pigmentosa* is the name given to the most common form of mastocytosis in infants, featuring multiple, small (1 to 3 cm in diameter) papules usually located on the trunk (Fig. 100-11). The disease may be congenital but usually manifests within the first 6 months of life (Kettelhut and Metcalfe, 1991). A single, localized lesion is known as a solitary mastocytoma. These tumors can vary in size from a few to several centimeters. Diffuse cutaneous mastocytosis is an unusual condition that may manifest at birth with widespread blistering or diffuse thickening of the skin (Sagher and Evan-Paz, 1967; Solomon and Esterly, 1973). Systemic mastocytosis is more commonly seen in adults and is defined by multifocal lesions in the bone marrow or other extracutaneous organs, together with signs of systemic disease. It is further divided into indolent systemic mastocytosis, systemic mastocytosis with an associated clonal hematologic non-mast cell lineage

disease, aggressive systemic mastocytosis, and mast cell leukemia (Valent et al, 2001).

The diagnosis may be confirmed by a skin biopsy, which reveals mast cell hyperplasia within the dermis. Aminocaproate esterase is the most specific enzyme marker for identification of mast cells. Immunohistochemical stains for tryptase and *KIT* also are sensitive and specific markers for mast cells (Li, 2001). Mutations in *c-kit*, the gene encoding the receptor for stem cell factor, may play a significant role in the biology of mast cell malignancies (Gupta et al, 2002). Plasma histamine levels are elevated in a majority of children with mastocytosis, sometimes to remarkably high levels. Further workup for evidence of systemic involvement should be limited to pediatric patients with extracutaneous signs and symptoms, or those who require general anesthesia (Kettelhut and Metcalfe, 1991).

Caregivers should be educated to avoid exposing infants to factors that trigger mast cell degranulation, such as friction, pressure, temperature extremes, and substances that promote mast cell degranulation (aspirin, alcohol, narcotics, amphotericin B, or iodine-containing contrast media). If general anesthesia is required, perioperative administration of histamine receptor blockers is recommended (Lerno et al, 1990).

For patients with limited skin involvement, application of potent topical corticosteroids may hasten involution of lesions. Symptomatic patients may benefit from a classic histamine H<sub>1</sub> receptor blocker such as hydroxyzine or cyproheptadine. An H<sub>2</sub> blocker, such as ranitidine, or oral disodium cromoglycate may be added in the presence of gastrointestinal symptoms. Hypotension requires corticosteroids in addition to H<sub>1</sub> and H<sub>2</sub> antihistamines and intensive supportive care. Solitary mastocytomas usually involute by school age. Lesions of urticaria pigmentosa often resolve by puberty.

**FIGURE 100-11.** **A**, Deeply pigmented nodules and macules on the back of an infant with urticaria pigmentosa. A group of vesicles is visible just below the bandage that covers the biopsy site. **B**, Microscopic section from the biopsy specimen, stained with Giemsa stain. The mast cells can be identified as spindle-shaped cells containing granules that are located in the upper dermis.

## MIDLINE ANOMALIES

Congenital midline defects are a distinct group of diagnostically and therapeutically challenging conditions. These anomalies are located deep to the dermis, occurring at the cranial or caudal midline. Some of these lesions mark an underlying CNS problem or an intracranial connection. Considerations in the differential diagnosis include lesions that occasionally occur in the midline by serendipity; hemangiomas are the most common. Vascular malformations, hair tufts, dimples, and lipomas also may occur at the cranial or caudal midline and can mark a CNS or spinal malformation (Hayashi et al, 1984; Martinez-Lage et al, 1992). A midline mass in the nasal area may represent a dermoid cyst, encephalocele, or glioma (Paller et al, 1991). Occipital lesions include aplasia cutis congenita, encephalocele, and heterotopic brain tissue. The “hair collar sign” may mark ectopic neural tissue and CNS malformations (Commens et al, 1989; Drolet et al, 1995). Biopsy of a midline mass should not be performed unless an imaging study has been obtained to help clarify the nature of the lesion. If the possibility of an intracranial connection exists, referral to a neurosurgeon is indicated (Martinez-Lage et al, 1992).

## THE EYE

Editor: H. WILLIAM TAEUSCH

CHAPTER  
101

## Disorders of the Eye

Ashima Madan and William V. Good

**RETINOPATHY OF PREMATURITY**

Retinopathy of prematurity (ROP) is a neovascularizing disease that, in its most severe form, can lead to retinal detachment and subsequent blindness. It is the second most common cause of blindness among children in the United States (Steinkuller et al, 1999). Although the exact number of infants who are affected by the condition is unclear, current estimates suggest that each year, ROP will lead to blindness in approximately 500 infants in the United States alone, and to visual impairment from retinal scars in another 2300 (Hunter and Mukai, 1992; Phelps, 1997; Strodtbeck et al, 1998).

**Historical Overview**

ROP, or retrolental fibroplasia (RLP), was first reported in 1942 (Terry, 1942). Before the 1940s, which witnessed an epidemic of blindness, ROP was a relatively unrecognized condition. In spite of an intense search for a specific cause, it was not until 1951 that a pediatrician in Melbourne, Australia, provided the first link between the use of oxygen and ROP (Campbell, 1951). Several reports subsequently suggested that an inspired O<sub>2</sub> concentration of less than 40% was unlikely to lead to ROP (Guy et al, 1956; Lanman, 1954; Slobody and Wasserman, 1963). The decline in the use of greater than 40% supplemental O<sub>2</sub> for premature infants in the 1950s was followed by a decline in the incidence of ROP (Cross, 1973). However, decreased O<sub>2</sub> use resulted in cerebral hypoxic changes and an increase in brain damage and death among premature infants (Avery and Oppenheimer, 1960; McDonald, 1963). These findings led to a change in practice with more liberal use of O<sub>2</sub> in premature infants. The 1960s were associated with enormous advances in the field of newborn medicine. It was now possible to resuscitate and ventilate tiny premature infants. Increased survival of these small infants together with the liberal use of oxygen led to a resurgence of ROP (James and Lanman, 1976).

**Incidence**

ROP is predominantly a disease of low-birth-weight (LBW) and premature infants. The incidence of ROP increases with decreasing gestation and birth weight. Neonatal mortality in the 1990s has been considerably lower with the advent of artificial surfactant and improved ventilation strategies for the very LBW (VLBW) infant. The current survival rate for infants weighing between 750 and 1000 g is 70%, and that for infants weighing between 1000 and 1250 g is estimated to be 90% (Hack et al, 1996; Vohr and Msall, 1997). In view of the ongoing trend for resuscitation of smaller infants at lower gestational ages, along with the increased survival of extremely LBW (ELBW) infants, an increase in the incidence of ROP is to be expected. There are no good epidemiologic data on childhood blindness in the United States. The results from local registries and from clinical trials suggest an increase in the number of infants blinded by ROP (Steinkuller et al, 1999). There is also some evidence to suggest an increased prevalence of blindness from ROP in some geographic regions (Tompkins, 2001). However, some studies have reported a decreased incidence secondary to an improvement in neonatal care (Bullard et al, 1999; Hussain et al, 1999; Keith and Doyle, 1995).

**Development of the Retinal Vasculature**

The retina is one of the last organs to be vascularized in the fetus. Retinal vascularization occurs by a process of *vasculogenesis*, de novo formation of capillaries from endothelial cells that have differentiated from spindle cell precursors (Ashton, 1966; Kretzer and Hittner, 1988), and *angiogenesis*, formation of blood vessels from existing blood vessels (Ashton, 1970). The outer layers of the retina are supplied by the choroid plexus, which lies between the outermost layer of the retina and the retinal pigment epithelium (RPE), whereas the inner layers are supplied by a superficial plexus beneath the inner limiting membrane and a deep plexus in the inner nuclear layer. The choroid vasculature is mature by 21 weeks of gestation (Gariano et al, 1994). Vascularization of the inner retina begins by vasculogenesis from spindle cell precursors at approximately 16 weeks of gestation in the posterior region around the optic disc. With advancing gestation, blood vessels by a process of angiogenesis spread across the surface of the retina in the superficial and deep plexus, following the central peripheral gradient of retinal ganglion cell maturation toward the peripheral retina (Hughes et al, 2000). Formation of the outer capillary plexus in the human fetus begins between 25 and 26 weeks of gestation, concomitant with the peak period of eye opening, when the visual

evoked potential (VEP), an indication of visual function, is first detectable (Dreher and Robinson, 1988). It has been hypothesized that physiologic hypoxia, created by the increased metabolic demands of the fetal retina, is the major stimulus for the growth of the retinal blood vessels by angiogenesis in utero; retinal hypoxia leads to the release of vascular endothelial growth factor (VEGF) and subsequent growth of retinal blood vessels (Chan-Ling and Stone, 1993; Chan-Ling et al, 1990, 1995; Stone et al, 1995). However, vasculogenesis in the human retina is independent of metabolic demand and hypoxia-induced VEGF expression (Chan-Ling et al, 1995). The retinal vessels reach only 70% of the distance from the optic disc to the ora serrata at 27 weeks of gestation. Although there is considerable variation in the time course of retinal vascularization among infants, in most cases the retina is completely vascularized by 36 weeks of gestation on the nasal side and by 40 weeks on the temporal side (Palmer et al, 1991).

### Pathogenesis of Retinopathy of Prematurity

ROP is a disease of multifactorial etiology. Pathophysiology of ROP is a two-stage process: an initial phase of vasoattenuation following a second phase of abnormal proliferation. As in other ischemic retinopathies, such as sickle cell and vein occlusion retinopathy, the process probably is initiated by various environmental factors, such as hyperoxia, sepsis, or acidosis, that damage the vascular endothelium of the immature retinal blood vessels, thus leading to vaso-obliteration of existing blood vessels, as well to the arrest of new blood vessel growth. Prenatal events such as intrauterine hypoxia seen in the small-for-gestational-age (SGA) infant also may contribute to the injury. The increased susceptibility of premature infants of a lower gestational age, when compared with more mature infants, is due to the presence of a larger region of avascular retina. Given that the best maximal fetal  $PO_2$  is 35 mm Hg, compared with a  $PO_2$  of 60 to 80 mm Hg after birth, the process of normal retinal vascularization in the premature infant has to proceed in a relatively hyperoxic extrauterine environment.

Ashton and others have suggested that the susceptibility of the growing vessels in the retina to hyperoxia probably is related to the unique anatomic and developmental relationship between the retinal and choroidal circulations (Ashton, 1954; Dollery et al, 1969). The choroidal vasculature supplies the outer half of the retina by diffusion through the retinal pigment epithelium, while the retinal circulation supplies the inner half. The flow through the retinal circulation is far less than that through the choroidal circulation. Choroidal vessels form a honeycomb appearance, are much more permeable and have a high venous  $PaO_2$ . They also lack the ability to autoregulate in response to hyperoxia. Therefore, during hyperoxic conditions,  $PaO_2$  levels are raised across the thickness of the retina and the retinal vessels respond by constriction.

Two hypotheses have been suggested to explain the initial mechanism that leads to retinopathy in the premature infant. The first is that hyperoxia induces vasoconstriction of developing retinal blood vessels as a regulatory response (Ashton, 1954). The other theory implicates the effect of

reactive oxygen radicals in damaging cellular tight junctions in the precursor spindle cells, thereby leading to gap junction formation (Kretzer and Hittner, 1988).

Irrespective of the initial mechanism of injury, the retina then enters a quiescent phase for days or weeks, with the formation of a ridge-like structure separating the vascularized region from the peripheral avascular region. This structure, which is pathognomonic for ROP histologically, consists of mesenchymal cells and usually is seen between 33 and 36 weeks of gestation. Concomitant development of the photoreceptor retinal layer with advancing postnatal age results in increasing oxygen requirements, which cannot be met by the vaso-obliterated blood vessels, thus producing retinal hypoxia.

Some years ago, Michaelson (1948) and Ashton (1954) had suggested that retinal neovascularization occurs by release of one or more angiogenic factors from the ischemic retina. However, it was not until the 1980s that two groups of investigators identified VEGF, a glycoprotein molecule and endothelial cell-specific mitogen, as the key molecule responsible for angiogenesis (Keck et al, 1989; Senger et al, 1983). VEGF gene expression is hypoxia inducible (Forsythe et al, 1996; Levy et al, 1995). Several other lines of evidence also indicate that VEGF is the key molecule in retinal angiogenesis. VEGF levels have been shown to be increased in the vitreous and ocular fluid of patients with diabetes (Adamis et al, 1994; Aiello et al, 1994) and other neovascularizing diseases (Pe'er et al, 1995), as well as in animal models of ischemic retinopathy (Miller et al, 1994; Pierce et al, 1995). VEGF levels in the retina have been shown to be decreased in the initial phase of hyperoxic injury and increased in the hypoxic phase of retinopathy (Alon et al, 1995; Pierce et al, 1996). Inhibition of VEGF in animal models of retinopathy decreases neovascularization (Adamis et al, 1996; Aiello, 1995; Robinson et al, 1996). More recently, two separate receptors have been identified for VEGF. The one involved with new vessel growth and proliferation increases 60-fold during normal vascularization of the retina in mice. Specific activation of the other protects against vessel loss from hyperoxia without stimulating vascular proliferation and neovascularization in the mouse model, suggesting that therapies for the prevention of ROP can be targeted at this receptor (Shih et al, 2003).

Angiogenesis is a complex process that involves disruption of the basement membrane and extracellular matrix by proteolytic enzymes followed by cell proliferation and migration and subsequent formation and closure of nascent vascular tubes (Ausprunk and Folkman, 1977; Gross et al, 1982). Development of new blood vessels depends on the balance between angiogenic and angiostatic factors. Angiogenic factors implicated in retinal angiogenesis include several other growth factors besides VEGF: insulin-like growth factor (Smith et al, 1997), fibroblast growth factor (D'Amore, 1994), and platelet-derived growth factor (Andrews et al, 1999), along with interleukin 8 (IL-8), a chemotactic cytokine, and adhesion molecules VCAM-1 (vascular cell adhesion molecule-1), ICAM-1 (intercellular adhesion molecule-1), and E-selectin (Yoshida et al, 1999). Angiostatic factors include angiostatin, endostatin, and thrombospondin-1 (Folkman, 1995; O'Reilly et al, 1997). Identification of the genes involved in both normal and abnormal retinal

neovascularization is the focus of intense research at the present time. Several groups of investigators are using gene chip complementary DNA (cDNA) microarray analysis to study differential gene expression in the mouse model of retinopathy. Many genes involved in vascular remodeling, such as those encoding angiopoietin-2 (Hackett et al, 2000), different isoforms of nitric oxide synthase (Brooks et al, 2001; Hangai et al, 1999; Hardy et al, 2000), angiotensin II (Lonchamp et al, 2001; Moravski et al, 2000), neuropilin-1 (Ishida et al, 2000; Oh et al, 2002), presenilin-2 (Lukiw et al, 2001), and hypoxia-inducible factor-1 (Ozaki et al, 1999), have been identified as candidates in the process of angiogenesis in cell culture studies or animal models of ischemic retinopathy.

For reasons that are at present unclear, in over 80% to 90% of cases, the ridge-like structure pathognomonic for ROP gradually regresses and mesenchymal cells differentiate into normal capillary endothelium and vascularize the avascular retina. However, in other infants, there is an increased proliferation of abnormal blood vessels from the ridge-like structure followed by progressive disease leading to exudation, hemorrhages, fibrosis, and retinal detachment.

### Animal Models of Retinopathy

Much of our knowledge regarding development of the retinal vasculature has been obtained by meticulous studies conducted in animal models of retinopathy. The kitten model has been used by some investigators because of the similarity in extent of vascularization between the kitten retina and that of a premature infant born at 5 months of gestation (Chan-Ling et al, 1990). The rat model of retinopathy involves exposure of newborn rat pups to an alternative use of a hyperoxia/hypoxia paradigm every 24 hours for 2 weeks (Penn et al, 1994). The pattern of neovascularization produced is very similar to that seen in premature infants with ROP, with peripheral avascularity and neovascularization. With the advent of transgenic mice technology there has been a gradual increase in the use of the mouse model of retinopathy. This model involves exposure of mice on day 7 of life to 75% O<sub>2</sub> for 5 days followed by a return to room air or relative hypoxia on day 12. Retinal neovascularization is seen on day 17 (Smith et al, 1994). However, none of the currently available animal models except for the beagle puppy is associated with cicatricial scarring or retinal detachment.

### Etiology

ROP is a multifactorial disease, and analysis of the risk factors associated with ROP has been the subject of several studies (Biglan et al, 1984; Brown et al, 1998; Gallo et al, 1993; Hammer et al, 1986; Seiberth et al, 2000). Many risk factors have been implicated in the development of ROP.

### Prematurity

The most common causes of ROP are premature birth and low birth weight (Gunn et al, 1980; Hammer et al, 1986; Shohat et al, 1983). Incidence and severity of ROP increase with decreasing gestation. Results from the Cryotherapy for Retinopathy of Prematurity (CRYO-ROP) study (Cryotherapy for Retinopathy of Prematurity Coop-

erative Group, 1988) indicated that 90% of infants with a birth weight of less than 750 g and 47% of infants between 1000 and 1250 g will develop ROP. Approximately 80% of infants born at less than 28 weeks of gestation versus 30% of infants are at risk for developing ROP (Cryotherapy for Retinopathy of Prematurity Cooperative Group, 1988). In the CRYO-ROP trial, threshold ROP was noted in 10% of infants born at 27 weeks of gestation. Coats and colleagues (2000), in a retrospective study of infants born at less than 25 weeks of gestation, reported an incidence of threshold ROP of 40%.

### Race

Infants of European descent are more likely to develop severe ROP than are African-American infants (Cryotherapy for Retinopathy of Prematurity Cooperative Group, 1988; Saunders et al, 1997). Data on progression of disease in Hispanic and Asian infants are not available.

### Oxygen

The association between O<sub>2</sub> and ROP has been known for a long time and has been the subject of various studies (Kinsey et al, 1977; Lucey and Dangman, 1984; Patz et al, 1952). Bancalari and associates (1987) conducted a randomized prospective trial to determine whether the continuous use of transcutaneous O<sub>2</sub> (TCPO<sub>2</sub>) tension monitoring could reduce the incidence of ROP. They found no protective effect of continuous versus intermittent monitoring except in infants weighing between 1100 and 1300 g. In infants weighing less than 1000 g, the severity of ROP was increased in infants with a TCPO<sub>2</sub> greater than 80 mm of Hg in the first 1 to 2 weeks of life (Flynn et al, 1987). In a retrospective study comparing the incidence of ROP between centers with two different guidelines for maintenance of O<sub>2</sub> saturation, Tin and colleagues (2001) reported a decreased incidence of ROP in patients in whom O<sub>2</sub> saturation was maintained between 70% and 90%, versus 88% to 98%. However, there are no randomized, controlled trials to show the optimal range of O<sub>2</sub> saturation or PO<sub>2</sub> at which infants should be maintained to reduce the risk of ROP. A meta-analysis by Askie and Henderson-Smart (2000) of five randomized trials conducted in preterm infants in which ambient O<sub>2</sub> concentrations were targeted to achieve either a lower or higher blood O<sub>2</sub> range was unable to determine the optimal target range for maintaining blood PO<sub>2</sub> levels in preterm infants. However, unrestricted, unmonitored O<sub>2</sub> therapy has potential harm without clear benefits. Other, smaller studies that looked at the effect of late versus early weaning of O<sub>2</sub> and the effect of gradual versus abrupt weaning of O<sub>2</sub> on the incidence of ROP were unable to find any differences between the groups (Askie and Henderson-Smart, 2001).

Although much interest has been focused on the role of oxygen in ROP, retinopathy has been known to occur without oxygen supplementation in full-term infants (Brockhurst and Chisti, 1975; Kraushar et al, 1975; Stefani and Ehalt, 1974) and in cyanotic infants (Johns et al, 1991; Kalina et al, 1972).

Frequent fluctuations of transcutaneous oxygen measurements in the first 2 weeks of life have been reported to

be associated with a higher incidence of ROP (Cunningham et al, 2000). Studies in the neonatal rat model of retinopathy indicate that repeated episodes of alternating hyperoxia and hypoxia, more so than either alone, as well as the range of PaO<sub>2</sub> variation causes worse retinal vascular disease, probably as a result of increased secretion of VEGF (Penn et al, 1994, 1995).

### **Hypercapnia**

In animal studies, hypercapnia has been associated with increased retinal angiogenesis (Holmes et al, 1997). The mechanism of action appears to be either by inhibition of the normal vasoconstrictive response to hyperoxia, thus increasing retinal blood flow by vasodilation, or by decreasing the pH. A retrospective study by Bauer and Widmayer (1981) of infants weighing less than 1000 g noted that PaCO<sub>2</sub> was an important variable in predicting the development of ROP. However, other studies including a small randomized trial of permissive hypercapnea in premature infants showed no differences in the incidence of ROP between patients with PaCO<sub>2</sub> of 45 to 55 m Hg and infants with a lower PaCO<sub>2</sub> (Mariani et al, 1999).

### **Severity of Illness**

Increased severity of illness increases the odds that ROP will develop. It is a good predictor of the risk of ROP. The injury to retinal blood vessels by free radicals has been hypothesized to be the initiating insult in infants in whom development of ROP is related to severe illness (Rao and Wu, 1996; Sullivan, 1988). Sepsis (Gunn et al, 1980), particularly *Candida* sepsis, has been shown to be associated with increased severity of ROP and the need for laser surgery in premature infants (Mittal et al, 1998). It is not clear, however, if this is an independent risk factor for ROP.

### **Acidosis**

Metabolic acidosis generated by the administration of acetazolamide or ammonium chloride has been shown in studies in neonatal rats to cause preretinal neovascularization (Holmes et al, 1999). The molecular mechanism underlying the pathogenesis of this response is not known. In vitro studies in aortic endothelial cells suggest that acidosis may lead to increased VEGF expression and decreased apoptosis (D'Arcangelo et al, 2000).

### **Transfusions**

Several studies have shown that increases in the number and volume of blood transfusions are associated with an increased risk of developing of ROP (Aranda et al, 1975; Clark et al, 1981; Cooke et al, 1993; Hammer et al, 1986; Hesse et al, 1997; Inder et al, 1997; Sacks et al, 1981). However, it is not clear if the increased frequency of transfusions is indicative of the severity of illness or whether the increase directly contributes to the development of ROP. There are conflicting views on whether injury is caused by anemia or by oxidative stress from iron overload. Another hypothesis that has not been evaluated is whether transfusion of adult blood leads to an increase in retinal PO<sub>2</sub> by increased release of O<sub>2</sub> from adult hemoglobin. In contrast to the aforementioned studies,

Brooks and colleagues (1999) in a randomized, prospective, masked trial in 50 patients found no association between the hematocrit and incidence or severity of ROP.

### **Light**

Lighting in the intensive care nursery has been suggested by some investigators as a potential cause of ROP and has been the subject of much debate (Glass et al, 1985; Terry, 1943). The Light Reduction in Retinopathy of Prematurity (LIGHT-ROP) trial was the first multicenter, prospective randomized study that assessed the incidence of ROP in infants who weighed less than 1250 g and were exposed to either reduced light (399 lux) or normal lighting conditions (447 lux). The incidence rates of ROP in this study were similar in both groups (Reynolds et al, 1998). A meta-analysis of five randomized trials that studied the effect of reduction of light exposure in premature infants at less than 7 days of age concluded that there was no decrease in the incidence or severity of ROP in response to light reduction (Phelps and Watts, 2000).

Other factors such as magnesium, copper, and selenium deficiencies (Caddell, 1995; Papp et al, 1993); increased incidence of chronic lung disease (Biglan et al, 1984); intraventricular hemorrhage (Brown et al, 1987; Procianny et al, 1981); and twin gestation (Blumenfeld et al, 1998) have been implicated as risk factors for ROP. The use of antenatal steroids has been suggested as being beneficial in decreasing the incidence of ROP (Higgins et al, 1998). A meta-analysis of 15 trials that analyzed the effect of early postnatal corticosteroid use in preterm infants concluded that there was no difference in the incidence of severe ROP between treated and untreated patients (Halliday and Ehrenkranz, 2001). However, late use of steroids later than 3 weeks of age has been associated with an increase in severity of ROP (Halliday and Ehrenkranz, 2001). Similar studies in the mouse model of retinopathy have suggested that the timing of steroid use may be critical to the effect on the retinal vasculature (Yossuck et al, 2000).

### **Screening for ROP**

In order to maximize diagnosis of ROP without subjecting patients at low risk for ROP to an eye examination, the American Academy of Pediatrics, American Association for Pediatric Ophthalmology and Strabismus, and American Academy of Ophthalmology recommend screening all infants born either at a weight of less than 1500 g or at less than 28 weeks of gestation, as well as selected infants between 1500 and 2000 g with an unstable clinical course who are therefore at risk for ROP (Screening examination, 2001). Wright and colleagues (1998), in a study of 700 infants, found that limiting screening of infants to those with a gestational age of less than 28 weeks can potentially miss the diagnosis of severe ROP in several infants. Because ROP in all infants irrespective of their gestational age is rarely seen before 34 to 36 weeks of gestation, it is recommended that infants be screened when they are physiologically stable between 4 and 6 weeks of age or within 31 to 33 weeks of postconceptional age, whichever comes later. Subhani and associates (2001) have recommended screening infants born at less than 25 weeks of gestation at 4 to 6 weeks of chronologic age, because

infants of younger gestational ages can present with ROP on their first examination. Infants should undergo at least two examinations, unless the first examination shows complete retinal vascularization. A diagnosis of threshold ROP should be followed by treatment within 72 hours. A few centers are investigating the use of a new digital wide-field camera system (RetCam 120) for taking digitized images of the infant's retina and transferring the images by telemetry for reading by an experienced ophthalmologist (Roth et al, 2001; Schwartz et al, 2000; Yen et al, 2000). The examination, which involves the use of an indirect ophthalmoscope, a lid speculum, and dilating drops, is repeated every 2 weeks or weekly in the presence of prethreshold disease until discharge. The reader is encouraged to review the recent screening guidelines published by the American Academy of Pediatrics regarding timing of repeat examinations and the recommendations for ensuring timely diagnosis and treatment of ROP (Screening examination, 2001). Because the procedure could be stressful, the infant should be clinically stable at the time of examination. Parents should be informed about the diagnosis when it is first made and be given subsequent updates with following examinations.

### Staging and Classification

In 1981 ophthalmologists from eleven countries came together to adopt a uniform method of classifying ROP to enable assessment of efficacy of various modes of treatment. This led to the development of the International Classification of Retinopathy of Prematurity (ICROP) (International Classification, 1984). This classification is based on (1) staging of the disease, (2) extent of involvement along the junction of the avascular and vascular portions of the retina, (3) anterior or posterior location of the retinopathy, and (4) presence or absence of "plus disease."

Evidence of stage I disease (Table 101-1) is the earliest sign of ROP; stage I refers to a demarcation line between the vascular and avascular portions of the retina. Stage II disease is associated with the formation of a pink, ridge-like

structure between the two regions. In stage III ROP, fine vessels are seen growing from the ridge-like structure into the vitreous. Stage IV is subdivided into IVA, associated with partial detachment not involving the macula, and stage IVB, associated with partial detachment involving the macula. Total retinal detachment is seen in stage V disease. Plus disease, which can be seen at any stage, refers to the presence of dilated and tortuous retinal blood vessels in the posterior pole of the eye. It is a hallmark of rapidly progressive disease.

In order to define the anterior-posterior location of the retinopathy, the retina is divided into three concentric zones. Zone I refers to the posteriormost region around the optic disc and fovea, with a radius of twice the distance from the macula to the optic disc, and is the most critical region for development of visual acuity. Zone II extends from the periphery of zone I to the ora serrata on the nasal side and to approximately the equator on the temporal side. Zone III extends from the outer edge of zone II in a crescentic fashion to the ora serrata. Location of the disease and staging are helpful in predicting the outcome of ROP. The severity of disease is defined by the stage and location of the disease as well as the number of 30-degree sectors of the retina that are involved.

Prethreshold disease is defined as any ROP in zone I, or zone II with stage III, or zone II with plus disease less than threshold, or ROP in zone II, stage III without plus disease. Threshold disease is defined as 5 or more contiguous or 8 cumulative clock hours of ROP stage III in either zone I or zone II in the presence of plus disease.

### Prediction of Risk for ROP

Because ROP affects infants to different degrees of severity, a risk model to predict the risk of development of threshold ROP would be a useful tool for clinicians. Identification of such infants may lead to early eye examinations as well as more vigilance with respect to oxygen saturations in these infants. Risk models were developed by Hardy and colleagues (1997) from a 1986 to 1987 cohort of infants with birth weights of less than 1250 g enrolled in the CRYO-ROP trial. The model uses neonatal variables such as birth weight, gestation, gender, race, inborn/outborn status, and single/multiple birth, as well as ROP characteristics to determine the risk for progression to threshold disease for a specific eye.

### Prevention

It is difficult to prevent all cases of ROP without prevention of premature births. Close monitoring of O<sub>2</sub> saturations and prevention of repeated episodes of hyperoxia/hypoxia can possibly help decrease the incidence of severe ROP. Implementation of strict guidelines for monitoring O<sub>2</sub> saturation and prevention of repeated episodes of hypoxia that are treated with supplemental O<sub>2</sub> have been reported to reduce the incidence of ROP (Chow et al, 2001). Although bilirubin is presumed to be an antioxidant and free radical injury is hypothesized to cause ROP, there is no relationship between the incidence of ROP and hyperbilirubinemia (DeJonge et al, 1999).

Vitamin E is an antioxidant that was first reported in 1949 by Owens and Owens to have a promising effect

**TABLE 101-1**

### Staging of Retinopathy of Prematurity

Stage of Disease	Features
Stage I	Demarcation line between the vascular and avascular portions of the retina
Stage II	Ridge-like structure between avascular and vascular
Stage III	Fine vessels growing from the ridge into the vitreous
Stage IVA	Partial retinal detachment <i>not</i> involving the macula
Stage IVB	Partial retinal detachment involving the macula
Stage V	Total retinal detachment
Plus disease	Dilated and tortuous blood vessels in the posterior pole of the eye

against ROP in a group of premature infants (Owens and Owens, 1949). Lipid peroxidation has been hypothesized to be one of the mechanisms of injury that incites development of ROP. Preterm infants are relatively deficient in vitamin E (Haga et al, 1982). Of the several studies conducted to study the effect of vitamin E supplementation, only Hittner and associates (1981) demonstrated a statistically significant beneficial effect of therapy. Raju and colleagues (1997) conducted a meta-analysis of six randomized trials of vitamin E prophylaxis designed to reduce ROP. In all of these trials, vitamin E levels were above the physiologic range in the treated group and below the physiologic range in the control group. Although there was a 52% reduction in severe or stage III ROP in the treated group in comparison with the control group, there was no reduction in the incidence of ROP (Raju et al, 1997). Vitamin E use has been associated in at least two trials with an increase in incidence of necrotizing enterocolitis and sepsis (Finer et al, 1984; Johnson et al, 1985). The data indicate that the use of pharmacologic doses of vitamin E is not completely safe in newborns (Committee on Fetus and Newborn, 1985).

Gaynon and associates (1997), using a combined approach of administering supplemental O<sub>2</sub> to maintain O<sub>2</sub> saturations at 99% to 100% with exposure to ambient light in infants diagnosed with prethreshold ROP, have reported a reduction in conversion to threshold ROP and the subsequent need for laser surgery.

### Outcome

Much information about the natural history of ROP was obtained from follow-up studies of control infants who were enrolled in the multicenter CRYO-ROP trial (Cryotherapy for Retinopathy of Prematurity Cooperative Group, 1994; Schaffer et al, 1993). This randomized, blinded trial was conducted in 23 centers and included 4099 infants with birth weights of less than 1250 g who were born between January 1986 and November 1987. It was designed to evaluate the risks and benefits of transscleral cryotherapy and to describe the incidence and natural history of ROP. The “natural history” group was comprised of infants with all stages of ROP (65.8%) who did not get randomized to receive cryotherapy. The timing of appearance of ROP was at a later chronologic age but same postconceptional age (Cryotherapy for Retinopathy of Prematurity Cooperative Group, 1988) in infants of lower gestational age. ROP was found to regress in 80% of cases, with a gradual movement of the vascular shunt to the periphery (Cryotherapy for Retinopathy of Prematurity Cooperative Group, 1988). In a study of 766 infants in the “natural history” group with at least 1 clock hour of ROP between stages I and III, the mean age at regression was 38.6 weeks. ROP had involuted in 90% of infants before 44 weeks of postconceptional age (Repka et al, 2000).

Two hundred and forty-five (6%) infants developed threshold disease and were randomized to either receive cryotherapy or no treatment. Threshold ROP developed at a mean postconceptional age of 37.7 weeks, with a range of 31.9 to 50.4 weeks.

Eyes with no ROP and in which vascularization had progressed only into zone I before 35 weeks of gestation had a 1 in 3 chance of developing threshold ROP, in comparison with eyes in which vascularization had progressed

into zone II. An unfavorable structural outcome was seen in infants with plus disease, zone I ROP, increased severity of ROP, increased circumferential involvement, and rapid progression from prethreshold to threshold disease.

Premature infants as a group are more likely to develop motility problems such as myopia, amblyopia, strabismus, anisometropia, and nystagmus than are full-term infants (Laws, 1992; Phelps, 1997; Quinn et al, 1992, 1998; Robinson et al, 1993). All of these problems are even more likely in premature infants with any stage of ROP. Severity of refractive errors, motility problems, and poor vision increase with increased severity of ROP (Kushner, 1982; Repka et al, 1998). Other long-term complications of ROP include distortion of the retina from contraction and dragging by scar tissue as well as acute angle glaucoma in patients with stage V disease (Michael et al, 1991; Pollard, 1980). A history of ROP predisposes the patient to late-onset detachment or retinal tears in late childhood or early adulthood. Repka and colleagues (1998), in a follow-up study of infants enrolled in the CRYO-ROP trial, found that infants with ROP required a larger number of ophthalmic interventions (0.9 per child) when compared with infants with no ROP (0.4 per child). Although no guidelines exist regarding ophthalmology examinations after discharge in premature infants, it is recommended that given the increased incidence of visual problems in premature infants, all premature infants be seen by an ophthalmologist at 1 year of age (Holmstrom et al, 1999). Infants with a history of ROP should be seen earlier, depending on the degree of ROP, and then at least yearly during childhood. A longitudinal follow-up study of premature infants enrolled in the CRYO-ROP trial showed that the severity of ROP was predictive of a poorer neurodevelopmental outcome at 5.5 years of age (Msall et al, 2000). Thus, the long-term costs of ROP are not limited to ablative surgery but involve a societal loss related to possible blindness, as well as an increased burden on parents of these infants.

### Treatment

Treatment of threshold ROP is largely surgical, although there may be a role for supplemental O<sub>2</sub> in the treatment of infants with prethreshold ROP (Mills, 2000). Surgical treatment is recommended for infants with threshold disease, the stage at which the chance that the disease will regress spontaneously is 50%. Cryosurgery and laser photocoagulation, the latter becoming more universal, are the modalities of treatment. Both of these methods involve ablation of the peripheral avascular retina, with the goal of arresting the progression of the disease by decreasing release of VEGF and other angiogenic factors from the hypoxic retina; thus, central vision is preserved at the expense of peripheral vision.

Although surgical treatment had been used in several countries as early as the 1970s, it was difficult to compare results across centers because of the small size of patient populations, as well as the absence of screening criteria until the 1980s.

Cryosurgery involves cauterization of the hypoxic avascular retina by application of a very cold probe several times to the outer surface of the eye above the avascular retina. Results at the 3-month follow-up examination of patients enrolled in the CRYO-ROP trial showed a 39.5% reduction in unfavorable anatomic outcome in treated eyes, in comparison with control eyes ( $P < .00001$ ). Fifty-one

percent of the control eyes, versus 31.1% of the treated eyes, had an unfavorable outcome (Cryotherapy for Retinopathy of Prematurity Cooperative Group, 1988). At 1 year after treatment, anatomic results were unfavorable in 26% of eyes that received cryotherapy versus 47% of eyes that did not. Functional outcome at 1 year was better in 56% of treated eyes, compared with 35% of control eyes. There was also a reduction in the incidence of total retinal detachment from 43% in the untreated eye to 21% in the treated eye as well as in the occurrence of posterior retinal folds involving the macula (Cryotherapy for Retinopathy of Prematurity Cooperative Group, 1990).

Visual acuity testing performed at the 5.5-year follow-up examination showed a 47% versus 62% rate of unfavorable visual acuity and a 27% versus 45% rate of unfavorable anatomic outcome in the treated and control groups, respectively; of the treated eyes, 32% were blind, in comparison with 48% of the control eyes (Cryotherapy for Retinopathy of Prematurity Cooperative Group, 1996). The incidence of cataracts also was lower in treated eyes. At 5.5 years, however, fewer treated eyes had a visual acuity of 20/40 (13% versus 17%), and the treated eyes had a higher chance of developing more severe myopia.

Results of the follow-up visual acuity testing at 10 years were more reassuring, with a decrease in the incidence of blindness and detachment in treated eyes and no difference between the two groups with respect to attaining a visual acuity of 20/40 (Cryotherapy for Retinopathy of Prematurity Multicenter Trial, 2001). Although the results of cryosurgery demonstrate a beneficial effect, the results are far from perfect, especially for disease in zone I. Approximately 25.7% cases had an unfavorable outcome. Andersen and Phelps (2000) reviewed the results of all trials of peripheral ablation of the retina for threshold ROP in premature infants. Peripheral retinal ablation reduced the risk of early unfavorable retinal structure from 47.9% to 26.3% and the risk of unfavorable visual acuity in early childhood from 63% to 50.6%. Visual fields in sighted eyes were slightly smaller in the pretreated group than in the control group. Complications from cryotherapy included vitreous hemorrhage, swelling of eyelids and conjunctivae, and increased intraocular pressure. In addition, the long-term effects of cauterization of the peripheral retina in infants are not known.

Laser photocoagulation therapy using newer, indirect laser delivery systems is now becoming the standard of treatment for advanced ROP (Connolly et al, 1998; Iverson et al, 1991; McNamara et al, 1991). The laser beam in this method is applied directly to retinal tissue, and because it does not pass through the entire thickness of the eye, it produces less tissue destruction and inflammation than occurs with cryotherapy. It is less painful, thereby decreasing the need for narcotics or anesthesia. Although no study as large as the CRYO-ROP trial has been conducted to compare the effects of laser with those of cryosurgery, several smaller studies have been done. McNamara and colleagues (1991) reported regression of ROP in 15 of 16 infants who received laser treatment versus 9 of 12 infants who received cryosurgical treatment. The Laser ROP Study Group (1994) conducted a meta-analysis of four trials comparing the results of cryotherapy with those of laser therapy. The investigators concluded that laser therapy is at least as effective as cryotherapy in reducing vision loss from threshold ROP.

The Early Treatment of Retinopathy of Prematurity (ETROP) was a multicenter randomized trial that compared the safety and efficacy of earlier versus conventionally timed ablation of the peripheral retina for the management of severe ROP (Early Treatment for Retinopathy of Prematurity Cooperative Group, 2003). It is hypothesized that because most of the problems associated with ROP occur in association with development of stage III disease, early treatment in carefully selected cases of infants weighing less than 1250 g may result in improved visual acuity. Infants enrolled in the trial were randomized to early treatment if they had prethreshold ROP with a 15% or greater risk of an unfavorable problem as determined by a modification of the risk analysis program described by Hardy and associates (1997). The results of this trial showed that visual acuity and structural outcome at 9 months were significantly better in the early treatment group. Thus, peripheral retinal ablation should be considered for any eye with:

- Zone I, any stage ROP with plus disease
- Zone I, stage 3 ROP without plus disease
- Zone II, stage 2 or 3 ROP with plus disease

Scleral buckling, a procedure that involves placement of a silicone band around the eye in order to reduce tension exerted by the vitreous on the scar tissue, is done in cases in which cryosurgery or laser surgery is ineffective (Chuang et al, 2000). Vitrectomy is performed in other cases of complete retinal detachment due to scar tissue (Quinn et al, 1996; Repka et al, 1998). However, the effectiveness of these procedures in preserving vision is poor at this time (Quinn et al, 1996).

### Role of Supplemental Oxygen Therapy

The rationale for the Supplemental Therapeutic O<sub>2</sub> for Prevention of ROP (STOP-ROP) study was based on results from studies performed in kittens with ROP (STOP-ROP Multicenter Study Group, 2000). Use of supplemental O<sub>2</sub> in the recovery period after exposure to hyperoxia produced a less severe degree of neovascularization in these animals (Phelps, 1984; Phelps and Rosenbaum, 1988). In addition, a few clinical case reports from the 1950s indicated an improvement in severe ROP in infants who received supplemental O<sub>2</sub> (Bedrossian et al, 1955; Szewczyk, 1953). A clinical case series reported a benefit of supplemental O<sub>2</sub> in decreasing conversion to threshold ROP (Gaynon et al, 1997). The STOP-ROP trial tested the hypothesis that administration of supplemental O<sub>2</sub> to infants with prethreshold ROP to maintain their O<sub>2</sub> saturations at 96% to 99% versus 88% to 94% would lead to a decrease in the proportion of infants with at least one eye at prethreshold who converted to threshold ROP. Infants whose O<sub>2</sub> saturations were 88% to 94% in room air were excluded from the study. Although there was a trend toward a decrease in conversion in supplemented infants (48.5% versus 40.9%), the results did not show a statistically significant difference. A statistically significant improvement (46% versus 32%) was, however, noted in a small group of infants with no plus disease. One of the surprising findings of the study was that supplemented infants tended to have more episodes of exacerbation of chronic lung disease (8.5% versus 13.2%), although there were no ill effects on the eye.

The High O<sub>2</sub> Percent in ROP (HOPE-ROP) study was designed to determine the risk of progression of prethreshold to threshold disease in infants who were excluded from the STOP-ROP study because their O<sub>2</sub> saturations were greater than 94% (McLead et al, 2000). HOPE-ROP patients progressed to threshold ROP in at least one study eye 25% of the time, compared with 46% in STOP-ROP patients. This difference was less evident in cases with plus disease.

### Antiangiogenic Agents

Pharmacologic agents that inhibit angiogenesis without destroying retinal tissue could provide newer modes of treatment of retinopathy. Because angiogenesis is a complex process, with the involvement of various growth factors and extracellular molecules, interference with progression of the disease can be achieved in several ways. Although many agents are currently undergoing trials in adult patients with neovascularization, there have been no studies in infants. One of the problems with this approach is identifying an agent that selectively destroys abnormal blood vessels without affecting the process of normal vascularization of the immature retina. Thrombospondin-1, a tumor suppressor agent and an extracellular matrix glycoprotein, has been shown to have antiangiogenic activity in a rat model of retinopathy without affecting normal intraretinal blood vessel growth (Shafiee et al, 2000). Penn and colleagues (2001) have shown anecortave acetate, an angiostatic steroid, to be effective in inhibiting angiogenesis in a neonatal rat model of retinopathy without affecting the normal retinal vasculature. Lonchamp and associates (2001), in a mouse model of retinopathy, have shown a significant decrease in angiogenesis in animals treated with perindopril (angiotensin-converting enzyme inhibitor) or angiotensin AT<sub>2</sub> receptor inhibitor (losartan) during the hyperoxic phase. Recombinant angiostatin has been used to decrease neovascularization in the mouse model of retinopathy (Meneses et al, 2001). Antiangiogenic agents hold promise for a less invasive method of treating this debilitating disease in the future.

### Summary

ROP is a neovascularizing disease that affects premature and LBW newborns. It has a multifactorial etiology and is not completely preventable. There may be a role for supplemental O<sub>2</sub> in the treatment of milder forms of prethreshold disease and possibly a role for selective antiangiogenic drugs in the future. Cryosurgery or laser surgery is currently recommended for threshold disease, but the outcome is not perfect. Future trends in this area will involve changing the method and timing of treatment. An increased understanding of the molecular mechanisms underlying retinal vascular development is essential to developing better methods of prevention of ROP.

## EPIDEMIOLOGY OF VISION IMPAIRMENT IN CHILDREN

Vision impairment occurs with conditions that cause *bilateral* loss of vision. Because most of these cases occur in the perinatal period, it is appropriate to consider them in

this section. Very few studies have been performed to evaluate the incidence of vision impairment in the western world, and it is also difficult to know whether there are substantial changes in the spectrum of conditions that cause vision impairment. Nevertheless, some trends can be gleaned from studies that have monitored vision impairment in children (Steinkuller et al, 1999). The incidence of vision impairment in children varies from region to region, and is economics driven. In developed regions, the incidence may be as low as 0.1/10,000, but in underserved regions of the world, the number is higher, at 1.1/10,000 (Gilbert et al, 1999).

The most common cause of vision impairment in most studies is cortical visual impairment (CVI) (Steinkuller et al, 1999). Bilateral damage to the optic radiations (e.g., periventricular leukomalacia) (Jacobson et al, 1998) or bilateral damage to the visual cortex will cause CVI. The term probably should be reserved for children who cannot see clearly—that is, have lost visual acuity (Good et al, 2001). Causes include perinatal hypoxia-ischemia, infections, infarctions, metabolic disorders, and trauma (Good et al, 1994).

Retinopathy of prematurity remains an important and leading cause of vision impairment in children (see later). The exact incidence in a modern (i.e., the past 5 years) cohort is probably unknown, although baseline data from the LIGHT-ROP study suggest that the incidence and rate of blindness have not changed from the 1980s (Reynolds et al, 1998). The Early Treatment for Retinopathy of Prematurity study will include a natural history component, and it is hoped that useful incidence data will come from this study (Good and Hardy, 2001).

Optic nerve hypoplasia, a developmental disorder of optic nerve growth and function, ranks third, followed by retinal disease (e.g., albinism). Congenital cataract, formerly a leading cause of blindness in children, is less common, owing to advances in diagnosis and management.

### Visual Development

A considerable amount of visual development occurs postnatally, with some visual functions showing improvement even as late as 12 years of age. There is more to vision than simply Snellen acuity (the ability to see small letters or numbers projected on a screen or chart). Contrast sensitivity, stereopsis (high-grade depth perception), grating acuity (ability to see finely spaced lines), and Vernier acuity (ability to judge when lines are not perfectly positioned on top of each other) are examples of visual functions that develop independently and at different rates. Different cortical mechanisms could subserve these different types of vision.

Stereopsis and contrast sensitivity probably develop to near-maturity in the first several months of life. Grating acuity is mature to half that of an adult by approximately 1 year of age, and Snellen acuity develops up to the age of 4 or 5, at which time it is near adult normal levels. Therefore, a majority of children do not have normal Snellen acuity until the age of 5. Vernier acuity develops into adolescence, a fact that makes it interesting to study in various visual disorders (Skoczenski and Norcia, 1999).

Amblyopia is loss of vision in the absence of any underlying ocular disease. At least three types of amblyopia exist, although recent evidence suggests that many overlapping

varieties of amblyopia may be possible (Schor et al, 1997). Occlusion or form deprivation amblyopia, strabismic amblyopia, and anisometropic amblyopia (unequal refractive errors in the two eyes) affect visual acuity by allowing or causing lack of use of one of the visual pathways. In the neonate, occlusion amblyopia is a critical concern and must be diagnosed and treated as soon as possible. Prolonged visual development notwithstanding, diseases that involve blocking of the visual axis will permanently damage vision within 6 months of birth. Examples include corneal opacities, congenital cataracts, and complete ptosis. Prompt surgical management of these conditions is important when the visual axis is threatened. Delays in treatment affect acuity outcome such that even 20/400 visual acuity is usually impossible if treatment is rendered after 1 year of age (Birch and Stager, 1996; Birch et al, 1998).

### Physical Examination

The physical examination of the newborn should concentrate on one ophthalmologic feature: the red reflex. Ophthalmologists will perform dilated examinations when disease is suspected or in premature infants screened for retinopathy of prematurity. Conditions such as ptosis and nasolacrimal duct obstruction are easily identified. The use of the ophthalmoscope to determine that a clear visual axis is present is crucial.

Conditions that may cause leukocoria include cataracts, retinoblastoma, corneal opacity, Coats disease, detached retina due to ROP and other retinal diseases, and other, rare conditions. The neonatologist's and pediatrician's roles are to identify whether a possible problem exists and, if it does, to make a prompt referral.

Misalignment of the visual axes in the neonate, discussed next, usually is not a cause for concern in the several months following birth. Exceptions to this rule occur with suspected cranial nerve palsy (third or sixth cranial nerve). Third nerve palsy is suspected when ptosis occurs and is accompanied by deficient elevation, depression, and adduction of the eye. In many cases, the affected eye will be positioned lower (down) and abducted (out) compared with the fellow eye. Exceptions exist when third nerve palsies occur without ptosis, or without other features of motility dysfunction (Good et al, 1991).

## Congenital Disorders of Motility

### Nystagmus

Congenital nystagmus may be present at or shortly after birth, or the condition may not be noticed until 2 to 3 months of age. It is characterized by rhythmic movements of the eye or eyes occurring horizontally, vertically, or elliptically (Hertle and Dell'Osso, 1999).

Conditions that cause bilateral anterior visual pathway disease may lead to any sort of nystagmus in the first year of life. Vertical, horizontal, and elliptical nystagmic movements all have been reported. The fact that nystagmus in visually impaired children is seldom seen in cortical blindness (termed *cortical* or *cerebral visual impairment* in children) is a helpful distinguishing feature (Good and Hoyt, 1989). Conditions that cause nystagmus include bilateral

optic nerve hypoplasia, untreated congenital cataracts, and bilateral retinal detachments, occasionally seen in ROP.

Bilateral nystagmus will occasionally occur in monocular disease (Good et al, 1997), although this is not the rule. Monocular nystagmus, or dissociated nystagmus can result from monocular anterior visual pathway disease (Good et al, 1993). However, monocular or dissociated nystagmus occasionally heralds a lesion of the optic chiasm (glioma, cranio-pharyngioma) and should prompt a neuroimaging evaluation (Gittinger, 1988; Schulman et al, 1979). The exact incidence of glioma of the visual pathways as a cause of dissociated nystagmus is unknown, however, and some evidence suggests that gliomas may be uncommon in children with dissociated nystagmus (Arnoldi and Tychsen, 1995).

In some children with nystagmus, the anterior pathways are normal. In most of these, "motor" nystagmus is diagnosed. Genetics of this condition can be determined in some children (Kerrison et al, 1996, 1999). Again, nystagmus may be vertical, horizontal, or elliptical. Visual acuity in motor nystagmus ranges from 20/25 to 20/400 and remains stable throughout life.

Transient nystagmus can also occur in infants and may take on any waveform. Follow-up evaluation of children who had transient nystagmus shows no increased risk for central nervous system (CNS) abnormalities. There are no characteristics of transient nystagmus that identify it as such.

Periventricular leukomalacia will occasionally cause nystagmus, as will other significant diseases of the CNS (e.g., Pelizaeus-Merzbacher disease) (Jacobson and Dutton, 2000; Jacobson et al, 1998). When the etiology of nystagmus cannot otherwise be determined, a neurologic evaluation and neuroimaging investigation are warranted.

### Strabismus and Transient Motility Disorders

Newborn infants are likely to show a number of transient ocular motor signs that in older patients would indicate serious neurologic disease but that in infants are normal. Examples are skew deviations, tonic downward or upward deviation of the eyes (Ahn et al, 1989; Deonna et al, 1990; Ouvrier and Billson, 1988), and strabismus (Hoyt et al, 1980).

The significance of tonic upward deviation of the eyes, especially when it persists beyond a few months of age, has been reappraised, with some evidence that the sign may indicate more global neurologic dysfunction (Hayman et al, 1998).

Tonic downward eye deviation is not caused by serious neurologic disease, but clinicians should be careful to exclude the possibility that a child has hydrocephalus and paralysis of upgaze: the so-called setting sun sign (Chattha and Delong, 1975). With upgaze paralysis, the child exhibits the physical finding of eyes rotated down, with considerable sclera showing between the iris and upper eyelid. Periaqueductal disease probably is responsible for this important neuro-ophthalmologic finding.

Strabismus as a transient ocular motor finding also has been the subject of considerable interest and debate. Infantile esotropia and constant exotropia as abnormal findings become apparent after 2 to 4 months of age.

Before then, such strabismus-type findings are of no prognostic significance (Archer et al, 1989).

On the other hand, certain strabismus problems are characteristic and apparent at birth and persist. Cranial nerve palsies may be congenital and cause characteristic features of third, fourth, or sixth cranial nerve palsy. Fourth cranial nerve abnormalities may not become apparent until the infant gains head control, at which time a head tilt is used to adapt to the problem. Strabismus in these cases is noncomitant (i.e., changes with different directions of gaze). In the case of Möbius syndrome, a large-angle esotropia is accompanied by bilateral gaze palsies and facial paralysis.

Defects or diseases involving extraocular muscles also may cause persistent strabismus. Congenital fibrosis of the extraocular muscles will cause a large-angle hypotropia on the affected side, or esotropia that is noncomitant. As a general rule, neurologic evaluation is recommended in cases of congenital cranial nerve palsy, with the exception of isolated fourth nerve palsies.

### Nasolacrimal Duct Obstruction

Nasolacrimal duct obstruction has its onset between 2 and 6 weeks of age and is characterized by a nearly constant epiphora (tearing) and by thickened discharge from one or both eyes. The cause is an obstruction anywhere in the lacrimal system. In most children, obstruction occurs as an isolated event, although nasolacrimal duct obstruction is more common in Down syndrome (Markowitz et al, 1994), the ectodermal dysplasia–ectodactyly–clefing syndrome (EEC), and in any condition that may cause craniofacial defects (Fielding and Fryer, 1992).

In most cases the condition resolves by 6 months of age, and by 12 months of age more than 90% of cases have cleared (Paul and Shepherd, 1994). Conservative treatment with massage and topical antibiotics may help alleviate symptoms. After 8 months of age, or earlier if symptoms are severe, probing the obstructed nasolacrimal duct may be warranted.

Congenital dacryoceles (Fig. 101–1) occurs when an out-pouching of the lacrimal sac develops. Usually an underlying

**FIGURE 101-1.** (See also Color Plate 101–1.) One-week-old infant with dacryocoele. Note the bump in the area of the medial canthus.

nasolacrimal duct obstruction has played a role in preventing flow of amniotic fluid or tears (postnatally). Infection can occur, resulting in dacryocystitis. The differential diagnosis should rule out anterior encephalocele, usually easily distinguished by accompanying mild telecanthus and pulsations and its location medial to the lacrimal system.

Management includes vigorous massage, probing, and, in cases in which infection is superimposed, systemic antibiotics.

## Structural Defects of the Eye

### Congenital Cataracts

Cataracts in infants occur at a frequency of approximately 2.2 per 10,000 births, with most cases presenting in the first year of life (Wirth et al, 2002). Fewer than 20% of cases are associated with a known systemic abnormality (Wirth et al, 2002). Diagnosis is based on identification of an abnormal red reflex (Fig. 101–2).

Cataracts can be classified according to morphologic appearance. Transient cataracts are known to occur and are identified by their peripheral location in the lens (McCormick, 1968).

A very long list of genetic, metabolic, and hereditary problems that may cause cataracts have been identified, but identifiable systemic causes only occasionally account for congenital cataracts (Wirth et al, 2002). When an infant is identified with a cataracts, associated abnormalities are almost always obvious, so that a lengthy workup usually is not necessary. Causes include infectious diseases, particularly rubella, metabolic disorders (e.g., galactosemia), hereditary cataracts, and trauma. Trauma is a common cause of cataracts in children, especially boys, after the age of 5, but is a very uncommon cause in those younger than 1 year.

Congenital cataracts in children is associated with a high risk for glaucoma, although this risk may be tempered somewhat by the use of an artificial intraocular lens, positioned at the time of cataract removal (Asrani et al, 2000; Parks et al, 1993). The risk for glaucoma probably lasts for decades, with glaucoma developing many years after initial surgery in some children.

**FIGURE 101-2.** Infant with bilateral total cataracts. Note the leukocoria.

Treatment of congenital cataract usually involves surgical removal, with or without the use of an intraocular lens. Surprisingly, bilateral cases of cataract have a better prognosis than those associated with unilateral cases. In bilateral cases the prognosis for reasonable visual acuity development is good, unless diagnosis is late, or the child's eye has other ocular abnormalities (Gelbart et al, 1982). Following cataract removal, ongoing follow-up evaluation is required to treat amblyopia, strabismus, or other ocular problems that may develop (e.g., glaucoma).

### Retinoblastoma

One of the many causes of leukocoria in the newborn is retinoblastoma. This rare tumor affects 1 in 20,000 newborn children and occurs in two forms: hereditary and sporadic. Approximately 50% of cases are inherited and are due to a mutation in the *RB1* gene in the child's germ line. In most instances, inherited retinoblastoma is identified by the presence of multiple tumors, in either one or both eyes. Still, 15% of children with unilateral retinoblastoma have the inherited type, and there is a family history of retinoblastoma in only 25% (Jay et al, 1988). In unilateral cases a mutation occurs in both alleles of the *RB1* gene in a primitive somatic cell. The result is a unilateral, solitary tumor.

Retinoblastoma manifests as leukocoria in 56% of cases, followed by strabismus (20%), glaucoma (7%), and poor vision (5%). A screening examination will detect retinoblastoma in close relatives of children in whom the inherited version is present (Ellsworth, 1969). In retinoblastoma manifesting as strabismus, the affected eye is strabismic and sees poorly due to involvement of the macula.

Management includes investigation for metastases in cases in which the tumor is large. Bone marrow aspiration and lumbar puncture should be performed but may not be necessary in new cases, or with small tumors (Mohney and Robertson, 1994). After the initial evaluation, treatment may take any of several forms. Enucleation should be considered in cases of large tumors, particularly where no useful vision could be expected with local or systemic therapy. External beam irradiation is effective but can cause significant side effects, including cosmetic changes to the growing orbital bones around the eye, dry eye, cataracts, and secondary tumors in the radiation field, particularly in children with germline mutations. Chemotherapy with or without focal therapy (cryosurgery or laser applied directly to the tumor) also is used. The systemic chemotherapy often will shrink the tumor so that it is more amenable to local therapy (Gallie et al, 1992). The cure rate for retinoblastoma is 90%.

### Glaucoma

Congenital glaucoma has a nearly uniform presentation, no matter the etiology. Elevated intraocular pressure causes tearing, photophobia, enlargement of the eye (buphthalmos), and redness. Many of these signs are due to ruptures in Descemet's membrane of the cornea, as a result of elevated intraocular pressure. The cornea often appears cloudy as a result of penetration of the normally desiccated corneal stroma by intraocular fluid.

Considerations in the differential diagnosis of cloudy cornea at birth include congenital hereditary endothelial dystrophy, a rare disorder of corneal endothelial cells, and corneal infection. Neither of these conditions causes elevated intraocular pressure.

Etiologic associations include recessive inheritance and certain syndromes. The phakomatoses, Sturge-Weber syndrome and neurofibromatosis, are associated with glaucoma. Rubenstein-Taybi syndrome (Roy et al, 1968) also is commonly associated with glaucoma. Treatment is usually surgical and includes goniotomy, trabeculectomy, or other filtration surgery. Long-term follow-up evaluation is important, as in many children with glaucoma, amblyopia and refractive errors develop, even when intraocular pressure is controlled.

## Infections of the Eye

### Conjunctivitis of the Newborn

The term *conjunctivitis of the newborn* has replaced "ophthalmia neonatorum" to describe infections of the conjunctiva occurring in the first few weeks after birth (Chandler, 1989). The timing of onset may be helpful in establishing the infectious etiology, but clinical features are nonspecific. Discharge, which may be mucopurulent, and redness of the bulbar and palpebral conjunctiva are the prominent findings.

One possible exception to this rule, that physical findings are generic, occurs in gonococcal conjunctivitis, which may produce a marked purulent discharge. This type of conjunctivitis must always be carefully excluded with Gram stain and culture, because the organism has a tendency to cause keratitis and blindness from the ensuing corneal opacification. Treatment consists of a third-generation cephalosporin for 7 days, particularly in geographic areas where the organism is penicillin resistant.

Chlamydial infections occur in newborn children at a rate of 3/1000 (Schachter, 1978). Diagnosis is important, not only to prevent complications of the conjunctivitis but because the eye infection also may be accompanied by pneumonia. Pneumonia in children occurs in the first 6 weeks of life. Treatment for *Chlamydia* infection should be systemic, with erythromycin. Topical erythromycin or tetracycline also may be helpful, but neither does anything to prevent or treat concurrent pulmonary infections.

A variety of other pathogens also may cause conjunctivitis in infants, the most common of which is *Staphylococcus aureus* (Dannevig et al, 1992; Zannoni et al, 1992). Two percent silver nitrate was the mainstay of prophylaxis against neonatal conjunctivitis for more than a century, but topical erythromycin and tetracycline also are very effective, although perhaps less effective against *Chlamydia*.

### Coloboma of the Eye

A coloboma is a developmental gap that occurs as a result of failure of the fetal fissure or choroidal fissure to close. The defect is found in the inferonasal quadrant of the eye. Areas of the iris, lens, and choroid and retina may be affected, and the end result is a characteristic cleft, sometimes visible without instrumentation (Fig. 101-3).

**FIGURE 101-3.** Chorioretinal coloboma.

A number of neurologic conditions can cause or be associated with colobomata, particularly CHARGE (coloboma, heart disease, choanal atresia, retarded growth/development and/or CNS anomalies, genital hypoplasia, ear anomalies and/or deafness) syndrome, Meckel syndrome, and linear sebaceous nevus syndrome (Onwochei et al, 2000; Pagon, 1981). The list of genetic causes is lengthy and includes trisomies 13, 18, and 22, but not trisomy 21 (Onwochei et al, 2000). Many cases are sporadic, or the defect is inherited as an autosomal dominant condition without additional systemic or neurologic abnormalities.

Diagnosis of coloboma is based on characteristic findings (see Fig. 101-3), although a careful ophthalmoscopic examination may be required to identify presence or absence in the retina. Coloboma with cyst, wherein an orbital cyst extension of the coloboma occurs, is simply an extreme manifestation of coloboma. Microphthalmia commonly accompanies severe cases of coloboma.

No treatment exists for this coloboma, although an investigation for associated anomalies and genetic tendencies is always indicated. Colobomata may be asymptomatic but may also be large enough to involve the optic disc or macula. With such involvement, visual acuity will be diminished. With bilateral colobomata of the macula, nystagmus develops and may be accompanied by an adaptation by the infant termed *overlooking*. Children literally look above objects of visual interest in order to position uninvolved areas of retina on a visual target (Good et al, 1992).

## APPENDICES

Editor: CHRISTINE A. GLEASON

## Appendix 1

## Drugs

Robert M. Ward

## Pharmacopeia for the Newborn Period

Dosages and comments about these drugs are based on experience, consensus among neonatologists, and the limited evidence available from studies in neonates. Other styles of treatment are often acceptable and may be superior to those listed. Newer recommendations about extended interval dosing of gentamicin for premature newborns <35 weeks of gestation have not been included because of limited safety data to date.

<b>ADMINISTRATION ROUTES:</b>	<b>ET</b> —endotracheal <b>IM</b> —intramuscularly <b>IT</b> —intrathecally or intratracheally <b>IV</b> —intravenously	<b>PO</b> —by mouth <b>PR</b> —by rectum <b>SC</b> —subcutaneously <b>TOP</b> —topical
-------------------------------	--	---

Drug	Route and Dose	Adverse Effects and Cautions
Acetaminophen	Loading dose: PO: 24 mg/kg; PR: 30 mg/kg Maintenance: PO: 12 mg/kg; PR: 20 mg/kg; preterm: <32 wk: q12h; 32 wk: q8h; term: q6h	Divide suppositories lengthwise as drug may not be evenly distributed throughout the suppository; high doses, especially with glutathione deficiency from poor nutrition, may cause hepatic necrosis
Acetazolamide	IV, PO: 5 mg/kg/dose q6-8h; increase as needed to 25 mg/kg/dose ( <i>temporarily effective</i> ), max dose 55 mg/kg/day	Hyperchloremic metabolic acidosis, hypokalemia, drowsiness, paresthesias
Acyclovir	IV, PO: 15 mg/kg/dose q8h IV over 1 hr for neonatal skin, eye, or mouth infections 20 mg/kg/dose q8h IV over 1 hr for neonatal CNS or disseminated infection	Transient renal dysfunction; lengthen dose interval with renal failure
Adenosine	Initial: 50 µg/kg/dose IV as rapidly as possible (1-2 sec) followed by saline flush of the line Increase dose by 50 µg/kg/dose IV and repeat every 1-2 min if there is no response and no AV block	Contraindicated in heart transplant patients; higher dosages needed in patients receiving methylxanthines; antidote for severe bradycardia is aminophylline 5-6 mg/kg over 5 min
Albumin, 5%	IV: 0.5-1 g/kg slowly	Hypovolemia, heart failure; monitor blood pressure
Albuterol	Aerosol: 0.5-1 mg/dose q2-6h PO: 0.1-0.3 mg/kg/dose q6-8h	Tachycardia, arrhythmias, tremor, irritability
Amikacin	IM, IV: Postnatal age 0-4 wk, <1200 g: 7.5 mg/kg/dose q18-24h ≤1 week, 1200-2000 g: 7.5 mg/kg/dose q12-18h; and >2000 g 10 mg/kg/dose q12h >1 week, 1200-2000 g: 7.5 mg/kg/dose q8-12h; and >2000 g 10 mg/kg/dose q8h	Nephrotoxicity; ototoxicity; blood level monitoring recommended (desirable levels: peak, 10-25 µg/mL; trough, 3-5 µg/mL)
Aminophylline	See Theophylline Day 1: 0.5-1.0 mg/kg/dose infused over 4-6 hr	See Theophylline

Drug	Route and Dose	Adverse Effects and Cautions
Amiodarone	Loading dose: 5 mg/kg IV over 30-60 min, preferably by central venous catheter Maintenance: infusion: 5-15 µg/kg/min; PO: 5-10 mg/kg/dose q12h	Phlebitis, hypotension, bradycardia, liver enzyme elevations, increased and decreased thyroid function, photosensitivity, optic neuritis, pulmonary fibrosis in adults
Amoxicillin	PO: 15 mg/kg/dose q12h; <i>urinary tract prophylaxis</i> : often dosed at 5 mg/kg/dose q day	Diarrhea, nausea, vomiting
Amoxicillin-clavulanic acid	PO: 15 mg/kg/dose q12h based on amoxicillin component	Diarrhea, nausea, vomiting
Amphotericin	<i>Day 1</i> : 0.5-1.0 mg/kg/dose infused over 4-6 hr (may start at the maximum dose on day 1 if tolerated); <i>do not use filters with pore size &lt;1 µm</i> ; 1.5 mg/kg/dose q24h may be used with resistant infections; total dosage: 30-35 mg/kg over 6 wk	Decreased renal potassium reabsorption, anemia, thrombocytopenia, fever, chills, nausea, vomiting
Amphotericin B liposome	IV: 1-5 mg/kg/dose q24h over 2 hr; usually start with 1 mg/kg/day and increase to higher dose for more serious infections (e.g., osteomyelitis, meningitis)	Decreased renal potassium reabsorption, anemia, thrombocytopenia, fever, chills, nausea, vomiting
Ampicillin	IV: 50-100 mg/kg/dose; if <7 days and <2 kg: q12h; if ≥7 days or >2 kg: q8h Highest dose for meningitis Maintain q12h for 4 wk for <1200 g	Diarrhea, rash, urticaria are rare in infants; candida skin infections
Amrinone	Initial: 0.75 mg/kg over 2-3 min; maintenance: 3-5 µg/kg/min	Fluid balance, electrolytes, renal function
Ascorbic acid	See Vitamin C (ascorbic acid)	
Atropine	IV, IM, ET, SC: 0.01-0.03 mg/kg, repeat q4-6h prn; minimum dose of 0.1 mg	Hyperthermia, tachycardia, urinary retention
Bacitracin	TOP: as ointment (500 units/g), q4-8h	
Beractant	IT: <i>for prophylactic treatment</i> : Give 4 mL/kg as soon as possible; may repeat at 6-hr intervals to a maximum of 4 doses in 48 hr IT: <i>for rescue treatment</i> : Give 4 mL/kg as soon as respiratory distress syndrome is diagnosed; may repeat at 6-h intervals to a maximum of 4 doses in 48 hr	May give additional doses if infant still has respiratory distress and needs >30% FIO <sub>2</sub> to keep PAO <sub>2</sub> >50 mm Hg Administer each dose as 4 doses of 1 mL/kg each, giving each dose over 2-3 sec and turning newborn to a different position after each dose
Bethanechol	PO: 0.1-0.2 mg/kg/dose q6-8h or 3 mg/m <sup>2</sup> /dose q8h 20 min before feeding	Diarrhea, jitteriness, tremors, sleeplessness, bronchoconstriction, increased tracheobronchial secretions
Bumetanide	IV, PO: 0.02-0.2 mg/kg/dose q8-12h	Loop diuretic that also acts on proximal tubule; 40 times as potent as furosemide; less ototoxicity than furosemide; hypokalemia, hyponatremia, metabolic alkalosis
Caffeine	PO, IV: loading dose: 10 mg/kg; maintenance dose: 2.5 mg/kg/dose q24h ( <i>doses are for the nonsalt form of drug—caffeine base</i> )	Restlessness, emesis, tachycardia; therapeutic plasma concentration 5-20 µg/mL free base
Calcium chloride 10% (27 mg elemental Ca <sup>2+</sup> /mL)	IV: 0.2 mL (9 mg Ca <sup>2+</sup> )/kg/dose for acute hypocalcemia; repeat q10 min	Bradycardia if injected too quickly; necrosis from extravascular leakage
Calcium gluconate 6.47% (23 mg elemental Ca <sup>2+</sup> /mL)	PO: <i>treatment</i> : 500-1000 mg/kg/day q3-4h; <i>supplement</i> : 150 mg/kg/day q3-4h	High osmotic load of syrup may cause diarrhea
Calcium gluconate 10% (9.3 mg elemental Ca <sup>2+</sup> /mL)	IV: 1 mL (9 mg Ca <sup>2+</sup> )/kg/dose for acute hypocalcemia; repeat q10 min PO: 3-9 mL/kg/day in 2-4 divided doses (28-84 mg Ca <sup>2+</sup> /kg/day) for chronic use	Bradycardia if injected too quickly; necrosis from extravascular leakage
Calcium lactate 13% (130 mg elemental Ca <sup>2+</sup> /g powder)	PO: 0.5 g/kg/day in divided doses q6-8h	Same as for calcium gluconate; gastrointestinal irritation
Calfactant (Infasurf)	Initial: IT: 3 mL/kg divided into 2 aliquots repeated up to 3 times q12h	Do not shake or filter; ventilate for at least 30 seconds after dose until infant is stable

Drug	Route and Dose	Adverse Effects and Cautions
Captopril	PO: 0.01-0.05 mg/kg/dose q6-24h; increase dose up to 0.5 mg/kg/dose to control blood pressure	High initial doses may cause hypotension and renal insufficiency
Carnitine	IV: 10 mg/kg/day added to parenteral solution when not eating	Monitor serum carnitine concentrations
Cefotaxime	IV: 50 mg/kg/dose; <7 days: q12h; >7 days: q8h	Adjust dose for renal impairment
Ceftazidime	IV: 30 mg/kg/dose over 30 min; preterm <30 wk up to 4 wk age: q12h; >4 wk: q8h; 30-36 wk up to 2 wk age: q12h; >2 wk: q8h; 37-44 wk up to 1 wk age: q12h; >1 wk: q8h	Phlebitis. Cleared by glomerular filtration; increase dosing interval with renal dysfunction
Cefuroxime	IV, IM: 25-50 mg/kg/dose; <7 days: q12h; >7 days: q8h	Rare hypersensitivity reactions in infants; may cross-react with penicillins in older children causing rashes, eosinophilia, granulocytopenia
Cephalothin	IV, IM: 20 mg/kg/dose; preterm <7 days: q12h (until 4 wk for <1200 g); >7 days q8h; term: <7 days q8h; >7 days: q6h	Phlebitis, additive nephrotoxicity with gentamicin
Chloral hydrate	PO, PR: sedative: 10-30 mg/kg/day divided q6-8h; hypnotic: 50-100 mg/kg as single dose	Tolerance, physical dependence, and addiction may develop with seizures Irritant to skin and mucous membranes; gastritis Metabolism is slower in infants than in adults; metabolite half-life = 27.8 hr in term infants to 39 hr in preterm infants Repeated doses may accumulate metabolites, causing hypotension and renal failure
Chlorothiazide	PO: 5-15 mg/kg/dose q12-24h	Hypokalemia; hyponatremia decreases calcium excretion; hyperglycemia
Cimetidine	PO, IV: 2.5-5 mg/kg/dose q6h according to gastric pH $\geq 5$	Decreases drug clearance by hepatic cytochrome P450
Citric acid/sodium citrate	Dose according to degree of metabolic acidosis; each mL is equivalent to 1 mEq HCO <sub>3</sub> and contains 1 mEq sodium	Adds sodium and potassium and must be used carefully with renal dysfunction, hyperkalemia or hypernatremia
Clindamycin	PO, IV: 5 mg/kg/dose; preterm <1 wk: q12h; preterm >1 week or term <1 wk: q8h; term >1 wk: q6h; maintenance: q12h till 4 wk for <1200 g	Pseudomembranous colitis is rare in newborns; limited experience in newborns, hepatic metabolism
Colfosceril palmitate	IT: <i>for prophylactic treatment</i> : Give 5 mL/kg as soon as possible; may repeat second and third doses 12 and 24 hr later to those infants remaining on ventilators IT: <i>for rescue treatment</i> : Give 5 mL/kg as soon as respiratory distress syndrome diagnosed; may repeat second dose 12 hr later	Administer each dose as 2 doses of 2.5 mL/kg each, giving each dose over 1-2 min; and turning newborn 45 degrees for 30 seconds to the right after the first dose and then similarly to the left after the second dose
Corticotropin	IM, IV, SC: 3-5 units/kg/day in 4 divided doses, usual maximum of 30 units/day	Hypertension, immunosuppression, electrolyte imbalance, cataracts, growth retardation, gastrointestinal ulcers or dysfunction
Cosyntropin	40 $\mu$ g/kg/dose as stimulation test	Check serum cortisol 1-2 hr after dose
Cromolyn	Nebulization: 20 mg q6-8h; metered dose inhaler: 2 puffs q6-8h	Bronchoconstriction, nasal congestion; 8%-10% of dose is absorbed from the lung
Cyclopentolate 0.2% (may be combined with phenylephrine 1%)	1-2 drops each eye 10-30 min before examination	Hypertension with concentrations >0.5%; anticholinergic effects including fever, tachycardia, dry mouth, delayed gastric emptying, decreased gastrointestinal motility
Desoxycorticosterone acetate (DOCA) see Fludrocortisone		

Continued

Drug	Route and Dose	Adverse Effects and Cautions
Dexamethasone	IM, IV: <i>for bronchopulmonary dysplasia</i> : 0.25 mg/kg/dose q8-12h for 3-7 days; <i>for severe chronic lung</i> : 0.05-0.25 mg/kg/dose q12h IV or PO for 3-7 days	Delayed head growth and developmental delay associated with treatment for as little as 3 days; weigh risk and benefit
Diazepam	PO, IV, IM: sedative: 0.02-0.3 mg/kg/dose q6-8h; seizure: 0.1-0.2 mg/kg/dose slow IV push	Diluted injection may precipitate; IM absorption is poor; respiratory depression, hypotension
Diazoxide	PO: 2-5 mg/kg/dose q8h for inhibition of insulin secretion	Eliminated renally; sodium and fluid retention
Dicloxacillin	4-8 mg/kg/dose (PO) q6h	Diarrhea, abdominal pain, nausea, vomiting; rare pancreatitis; may decrease absorption of ketoconazole and ciprofloxacin; may increase absorption of trimethoprim-sulfamethoxazole and ganciclovir
Digoxin	IV: Acute digitalization* Prematures            Loading dose <1.5 kg            10-20 µg/kg 1.5-2.5 kg        20 µg/kg Term newborns        30 µg/kg Infants (1-12 mo)    35 µg/kg Maintenance dose: 1/8 loading dose q12h Begin 12 h after last digitalization dose	Risk of arrhythmias is increased during digitalization; IV formulation is twice as concentrated as oral; conduction defects, emesis, ventricular arrhythmias
Digoxin immune Fab	IV dose: mg digoxin immune Fab = total body digoxin load × 76 Total body digoxin load: mg digoxin elixir ingested × 0.8 or serum digoxin concentration (ng/mL) × 0.0056 × wt (kg)	Binds digoxin in circulation before renal excretion; serum digoxin levels within 6-10 hr of treatment will be falsely high
Diphenhydramine	PO: 5 mg/kg/day q6h	Somnolence
Diphenylhydantoin	See Phenytoin	
Diphtheria antitoxin	IM, IV: 20,000-50,000 units/day for 2-3 successive days	Hypersensitivity reaction
Dobutamine	IV: 2-20 µg/kg/min by continuous infusion and titrate to desired effect	Tachycardia, hypotension
Dopamine	IV: 2-20 µg/kg/min by continuous infusion and titrate to desired effect	Extravasation may lead to necrosis (phentolamine is an antidote); high dose may constrict renal arteries, but the dose for this effect is uncertain in neonates
Edrophonium	<i>Tensilon test for myasthenia gravis</i> : SC, IM: 0.2-0.5 mg/kg; IV: preliminary test dose: 0.04 mg slow push; test dose: 0.16 mg/kg (1 min later)	Cardiac arrhythmia, diarrhea, tracheal secretions may require atropine antagonism
Enalapril (PO), enalaprilat (IV)	IV enalaprilat: <i>for hypertension</i> : 5-10 µg/kg/dose q8-24h PO enalapril <i>for CHF</i> : 0.1 mg/kg/day q day to maximum of 0.5 mg/kg/day	Reduce dose with renal failure; severe hypotension may occur, especially with volume depletion from diuretic treatment
Epinephrine	<i>Resuscitation</i> : IV, ET—1:10,000: 0.05-0.1 mL/kg q 3-5 min <i>Hypotension</i> : 0.01-0.1 µg/kg/min by continuous infusion and titrate to desired effect	Tachycardia, arrhythmia
Ergocalciferol	See Vitamin D <sub>2</sub>	
Erythromycin	PO, IV: 10 mg/kg/dose; <7 days: q12h; >7 days: q8h Eye prophylaxis at birth: ophthalmic ointment 0.5% in each eye	IV administration is painful; may affect theophylline serum levels
Erythropoietin	200-300 units/kg/dose 3-5 times/wk SC: total weekly dose: 600-1400 units/kg/wk; treat 2-6 wk	Neutropenia; cotreat with iron
Famotidine	IV: 0.3-0.5 mg/kg/dose q8h PO: 1-2 mg/kg/day q8h	Monitor gastric pH for dosage adjustments

Drug	Route and Dose	Adverse Effects and Cautions
Fentanyl	IV, IM: 1-2 µg/kg/dose, q4-6h prn, increase as needed	50-100 times the potency of morphine; muscle rigidity (“stiff man syndrome”) may occur with rapid dose infusions; treat with muscle relaxants
Fibrinogen	IV: 50 mg/kg; repeated prn as determined by clotting time	
Fluconazole	IV or PO: loading dose: 12 mg/kg; maintenance: 6 mg/kg/dose <30 wk up to 2 wk age: q72h; >2 wk: q48h 30-36 wk up to 2 wk age: q48h; >2 wk: q24h 37-44 wk up to 1 wk age: q48h; >1 wk: q24h 45 wk: q24h	May reduce CYP3A4 metabolism of drugs, including caffeine, theophylline, midazolam; may interfere with metabolism of barbiturates, phenytoin
Flucytosine	PO: 20-40 mg/kg q6h	Monitor levels; effective antifungal concentration: 35-70 µg/mL; bone marrow dysfunction: >100 µg/mL; renal dysfunction decreases clearance
Fludrocortisone	PO: 0.025-0.2 mg/day	Mineralocorticoid replacement where 0.1 mg of fludrocortisone is equivalent to DOCA 1 mg
Folic acid	PO: 50 µg/day for preterm newborns after feeding is established for maintenance; 500 µg/day for therapy	Almost none in goat’s milk. Rash is very rare
Fosphenytoin	Fosphenytoin doses are expressed as phenytoin equivalents (PE), wherein fosphenytoin 1 mg PE = 1 mg phenytoin IV or IM: loading dose: 15-20 mg/kg given no faster than 0.5 mg/kg/min Maintenance: PO: 4-8 mg/kg/day divided q12h, although dosages as high as 15-20 mg/kg/day may be needed to reach therapeutic levels	Rapid IV infusions may cause bradycardia, hypotension, cardiovascular collapse, arrhythmias Therapeutic serum concentration range is 10-20 µg/mL, although lower levels of 6-14 µg/mL may be appropriate in premature newborns, due to reduced protein binding
Furosemide	IM, IV: 0.5-2 mg/kg/dose q12-24h PO: 1-2 mg/kg/dose q12-24h Bioavailability reduced by cor pulmonale; may require higher dosages	Hypokalemia, hyponatremia, hypochloremia; half-life prolonged in premature newborns
Gentamicin	IM, IV: postnatal age ≤7 days age: <1000 g and <28 wk 2.5 mg/kg/dose q24h; <1500 g and <34 wk 2.5 mg/kg/dose q18h; >1500 g and >34 wk 2.5 mg/kg/dose q12h >7-28 days age: <1200 g 2.5 mg/kg/dose q18-24h; >28 days <1200 g 2.5 mg/kg/dose q8h; <i>initial loading dose</i> : 4 mg/kg for neonates ≤32 wk EGA shortens the time to reach therapeutic concentrations	Blood level monitoring indicated for efficacy; toxicity is rare in newborn (desirable levels: trough, <2 µg/mL to avoid toxicity; peak, 5-10 µg/mL)
Gentian violet	TOP (skin): as 1%-2% aqueous solution, bid TOP (oral): as 1% aqueous solution, bid	Stains skin
Glucagon	IM, IV: 30-300 µg/kg; may be repeated after 20-30 min	Maximum dose 1 mg; higher doses possibly toxic
Granulocyte-stimulating factor	SC: bolus injection, IV infusion over 15-30 minutes, or continuous IV infusion: 5-10 µg/kg once daily for 3 to 17 days. Dilute in 5% dextrose with/without albumin. Do not dilute with saline	Monitor blood neutrophil count. Not considered useful for neutropenia from sepsis or NEC, unless it persists for more than 3 days with absolute neutrophil count <500/µL
Heparin	IV: initial dose: 50 units/kg; maintenance dose: 100 units/kg q4h or 20-25 units/kg/hr continuous infusion; titrate doses to 1½-2 times baseline whole blood clotting time or activated partial thromboplastin time	Intractable bleeding (reversible with protamine); heparin half-life: prematures < term < adults

Continued

Drug	Route and Dose	Adverse Effects and Cautions
Hepatitis B immune globulin	IM: 0.5 mL within 7 days of birth if mother is hepatitis B <sub>s</sub> antigen positive or status is unknown. May be given with hepatitis B vaccine	Local pain and tenderness, thrombocytopenia
Hydralazine	PO, IM, IV: 0.1-0.5 mg/kg every 6 hr; increase as needed in 0.1-mg/kg increments up to 4 mg/kg/day	Tachycardia, lupus-like reactions
Hydrochlorothiazide	PO: 2.0-4.0 mg/kg/day q12h	Hypercalcemia, hypokalemia, hyperglycemia
Hydrocortisone	Hypotension refractory to pressors: 1 mg/kg/dose IV; acute adrenal insufficiency: 0.25 mg/kg/dose q6h IV; physiologic replacement: 0.3 mg/kg/day IM	Treatment of more than 7-10 days requires gradual dosage reduction to avoid adrenal insufficiency; immunosuppression hyperglycemia, growth delay, leukocytosis, gastric irritation
Ibuprofen	PO: 4-10 mg/kg/dose q6-8h to a maximum of 40 mg/kg/day	Use cautiously in patients with active bleeding or renal or hepatic dysfunction. Avoid in patients with ductal dependent cardiac malformations
Imipenem-Cilastatin	IV: <1.2 kg during first 4 weeks: 20 mg/kg/dose q18-24h; 1.2-2 kg = 20 mg/kg/dose q12h; >2 kg first 7 days after birth: 20 mg/kg/dose q12h; >2 kg older than 7 days: 20 mg/kg/dose q8h	Lengthen dosing interval for reduced renal function. Early report of seizures has not been confirmed in later pediatric trials
Immunoglobulin intravenous, human	IV: 400-750 mg/kg/dose infused over 2-6 hr	Pyrogenic reactions, BP changes, tachycardia, necrotizing enterocolitis, volume overload
Indomethacin	PO, IV: 0.1-0.2 mg/kg/dose q12-24h 2-7 days; 0.25 mg/kg/dose, >7 days	Transient renal dysfunction, decreased platelet aggregation; infuse over a minimum of 30-60 min to minimize reduction in CNS and mesenteric perfusion. Avoid in patients with ductal dependent cardiac malformations
Insulin (Regular)	IV: hyperglycemia infusion dose, 0.01-0.1 unit/kg/h; SC; intermittent dose, 0.1-0.2 unit/kg q6-12h	Hypoglycemia
Iron	PO: 2-6 mg/kg/day elemental iron	Avoid with hemochromatosis
Isoniazid	PO: 10-15 mg/kg/day, single dose or divided q12h	Newborns do not require pyridoxine supplement; monitor liver function test
Isoproterenol	IV: 0.05-0.5 µg/kg/min by infusion	Arrhythmias, systemic vasodilation, tachycardia, hypotension, hypoglycemia
Kayexalate	See Sodium polystyrene sulfonate (Kayexalate)	
Levothyroxine	IV, PO: starting dose 10 µg/kg/day (round off to nearest 12.5, 25.0, or 37.5 µg to coincide with pill size); increase by 12.5-25 µg/24 hr every 2 weeks to desired effect; max 500 µg/day; IV dose = 50%-75% of oral dose after initiation of therapy	Adjust dosage on 3-6 wk schedule by clinical response and T <sub>4</sub> , optimal free T <sub>4</sub> , TSH
Lidocaine	IV: 1 mg/kg infused over 5-10 min; may be repeated q 10 min 5 times, prn; infusion dose 10-50 µg/kg/min or 1 mg/kg/hr	Monitoring of blood levels useful (therapeutic range 1-5 µg/mL plasma); dilute for ET administration
Lorazepam	IV: 0.05-0.1 mg/kg infused over 2-5 min	Limited data in newborns, preparations may contain benzyl alcohol; dilute
Magnesium sulfate	IM, IV: 25-50 mg/kg q4-6h for 3-4 doses prn; use 50% solution IM, 1% solution IV	Hypotension, central nervous system depression; monitor serum concentration; calcium gluconate should be available as an antidote
Medium-chain triglyceride (MCT)	PO: 1-8 mL/24 h divided in feedings (7.7 cal/mL)	Diarrhea; aspiration causes lipid pneumonia; may increase blood and CSF MCT levels causing coma with excess dose
Meropenem	IV: 20 mg/kg/dose q8-12h	Reduce dosage with reduced renal function. Not well studied in premature neonates, but may be needed for resistant infections

Drug	Route and Dose	Adverse Effects and Cautions
Methadone	PO, IV: 0.05-0.2 mg/kg/dose q12-24h; reduce dose 10%-20% per week according to signs of withdrawal	Ileus, respiratory depression, delayed gastric emptying. Difficult to taper due to long half-life
Methyldopa	IV, PO: 2-3 mg/kg q6-8h; increased as needed at 2-day intervals; maximum dosage 12-15 mg/kg/dose	Sedation, fever, false-positive Coombs test, hemolysis; sudden withdrawal of methyldopa may cause rebound hypertension
Methylene blue	IV: 1-1.5 mg/kg of 1% solution for methemoglobinemia, infused slowly	Do not use in patients with methemoglobinemia due to G6PD or cyanide poisoning. Do not give subcutaneously due to risk of tissue necrosis
Methylprednisolone	IV, IM: 0.1-0.4 mg/kg/dose, q6h	Hydrocortisone preferred for physiologic replacement
Metoclopramide	PO, IV: 0.1-0.2 mg/kg/dose q6-8h or prior to each feeding	Dystonic reactions, irritability, diarrhea, decreases glomerular filtration rate in adults. Efficacy for GERD shown at >6 mo
Metronidazole	IV or PO: loading dose: 15 mg/kg; maintenance: 7.5 mg/kg; infuse doses over 60 min <30 wk up to 4 wk age: q48h; >4 wk: q24h 30-36 wk up to 2 wk: q24h; >2 wk: q12h 37-44 wk up to 1 wk: q24h; >1 wk: q12h 45 wk: q8h	Carcinogenic in rodents, not reported in humans. Prolonged treatment in adults rarely associated with seizures and sensory polyneuropathy
Midazolam	IV, IM, intranasal: 0.07-0.20 mg/kg/dose q2-4h prn for sedation; infusion dosing: <33 wk; 30 µg/kg hr; >33 wk; 60 µg/kg hr	Limited experience in newborns; respiratory depression, apnea. Rapid infusion doses (<10 min) may cause tonic clonic movements
Morphine sulfate	IV, IM, SC: 0.05-0.1 mg/kg/dose q2-6h prn 0.1-0.2 mg/kg/dose PO q3-6h	Respiratory depression reversible with naloxone, local urticaria from histamine release
Nafcillin	IV, IM: 25 mg/kg/dose, newborns 0-7 days = q12h, infants >7 days = q6-8h; double dosage for meningitis; maintenance: q12h for 4 wk for <1200 g	Agranulocytosis; granulocytopenia; hepatic dysfunction; may require dosage adjustment
Naloxone	IV, IM, SC: 0.1 mg/kg/dose; may be repeated as necessary; delivery room minimum, 0.5 mg for term newborn	Onset of action may be delayed 15+ min after IM or SC administration; narcotic effects may outlast naloxone antagonism; dilute for ET administration
Neomycin	PO: 10-25 mg/kg/dose q6h Topical: 0.5% ointment, 3-4 times daily	Renal toxicity and ototoxicity if absorbed
Neostigmine	IV: <i>Test for myasthenia gravis:</i> 0.02 mg/kg; IM: <i>Test for myasthenia gravis:</i> 0.04 mg/kg PO: <i>Treatment for myasthenia gravis:</i> 0.33 mg/kg/day q3-6h	Cholinergic crisis. Atropine pretreatment is recommended
Nitroprusside	IV: begin in dose of 0.25 µg/kg/min and vary as needed up to 8 µg/kg/min to control blood pressure	Profound hypotension possible; requires arterial line to monitor blood pressure; thiocyanate toxicity with long-term use or renal insufficiency
Nystatin	PO: 100,000-200,000 units q6h TOP: as 2% ointment (in petrolatum 95% polyethylene 5%) 3-4 times daily	Poorly absorbed from GI tract; diarrhea
Omeprazole	PO: 0.5-1.5 mg/kg/dose q day	Hypergastrinemia, diarrhea, monitor gastric pH
Oxacillin	IV, IM: 25 mg/kg/dose Preterm <4 wk old <1200 g: q12h; 1200-2000 g q12h for <7 days old; 1200-2000 g q8h for 7 days old term 25-40 mg/kg/dose <7 days old: q12h; >7 days old: q6h	Sterile abscess formation after i.m. doses, nephrotoxicity; monitor liver enzymes and complete blood count; colitis

Continued

Drug	Route and Dose	Adverse Effects and Cautions
Pancreatin	PO: 2000 units of lipase with each feeding PR and into colostomy: 0.3-0.5 g in sufficient liquid (for meconium ileus)	Bowel stricture associated with excessive dosages
Pancuronium	IV: 0.03-0.1 mg/kg/dose q1-4h prn; titrate to age and effect desired	Ensure adequate oxygenation and ventilation; tachycardia, bradycardia, hypotension, hypertension; potentiated by acidosis, hypothermia, neuromuscular disease, aminoglycoside antibiotics
Paraldehyde	PR: 0.3 mL/kg q4-6h	Reserve for refractory status epilepticus; local irritation, pulmonary edema, hemorrhage; hepatic dysfunction decreases clearance; avoid IM if possible; do not give by arterial catheter; avoid plastic containers
Penicillin G	IV, IM: <i>sepsis</i> : 25,000-50,000 units/kg/dose; <i>meningitis</i> : 75,000-100,000 units/kg/dose q8-12h: <7 days and q6-8h >7 days; <i>use higher doses for group B streptococcal infections</i> . Maintain q12h for 4 wk for <1200 g	Use for susceptible organisms such as streptococci; syphilis
Pentobarbital	PO, IM, IV: 2-6 mg/kg prn	Blood level monitoring helpful (sedative level 0.5-3 µg/mL); higher doses may depress respirations and cardiac contractility; monitor blood pressure
Phenobarbital	IV, IM, PO: anticonvulsant loading dose: 15-20 mg/kg, may repeat 10 mg/kg/dose twice for status epilepticus; maintenance dose: 3-5 mg/kg/day q12-24h, begin 12-24 h after loading dose: Sedation: 2-3 mg/kg q8-12h prn	Blood level monitoring helpful (therapeutic range 15-40 µg/mL); half-life 40-200 hr in infants, prolonged by asphyxia
Phentolamine	SC: dilute to 0.5 mg/mL, inject 0.2 mL at 5 sites around alpha-adrenergic drug infiltration maximum 2.5 mg total dose	Marked hypotension, tachycardia, arrhythmia. Do not treat hypotension with epinephrine, because hypotension may worsen due to alpha-adrenergic blockade
Phenytoin	IV: loading dose: 15-20 mg/kg, infused <0.5 mg/kg/min PO, IV: maintenance: 4-8 mg/kg/dose q24h; higher doses q8h >7 days; flush IV tubing with saline before/after dose	Therapeutic blood level monitoring indicated (desirable level 10-20 µg/mL); infant clearance may be high
Phosphate, sodium, or potassium	PO: 1-3 mmol/kg/day in divided doses or supplement formula phosphorus intake to 75 mg/kg/day	Large amounts may cause catharsis; increase gradually to full supplementation; monitor electrolytes. Several formulations available
Piperacillin	IM, IV: 50-100 mg/kg/dose; ≤29 wk postmenstrual age at 0-4 wk age: q12h; ≤29 wk postmenstrual age >4 wk age: q8h; 30-36 wk postmenstrual age 0-2 wk age: q12h; 30-36 wk postmenstrual age >2 weeks age: q8h; 37-44 wk postmenstrual age 0-1 wk age: q12h; 37-44 wk postmenstrual age >1 wk age: q8h	Elimination is 60%-70% renal, and reduced renal function may require longer dosing intervals
Pitressin	See Vasopressin	
Plasma	IV: 5-10 mL/kg; repeated prn	Volume overload, viral infection risk
Poractant alfa (Curosurf)	IT: 2.5 mL/kg/dose divided into 2 aliquots, followed by 1.25 mL/kg/dose q12h up to twice if needed	Do not filter or shake; suction prior to administration; administer in 2-4 aliquots with positioning of infant to improve distribution within the lungs; ventilate for at least 30 seconds after dose until infant is stable
Prednisone	PO: 0.5-2 mg/kg/day, q6h	See Cortisone

Drug	Route and Dose	Adverse Effects and Cautions
Procainamide	IV: 1.5-2.5 mg/kg infused over 10-30 min; may be repeated in 30 min if needed; infusion: 20-60 µg/kg/min PO: 40-60 mg/kg/day q4-6h	Asystole, myocardial depression, anorexia, vomiting, nausea. Blood level monitoring helpful (therapeutic range: procainamide, 3-10 µg/mL; <i>N</i> -acetyl procainamide, 10-20 µg/mL)
Propranolol	IV: 0.01 mg/kg initial dose and 0.01-0.15 mg/kg infused over 10 min; may be repeated in 10 min and then q6-8h to maximum of 0.15 mg/kg/dose PO: 0.05-2 mg/kg q6h	Relatively contraindicated in low-output congestive heart failure and patients with bronchospasm
Propylthiouracil	PO: 2-4 mg/kg q8h; increase to maximum of 10 mg/kg/dose; onset of action may be delayed days to weeks	Dose is uncertain for newborns; monitor thyroid function
Prostaglandin E <sub>1</sub> , alprostadil	IV: 0.03-0.1 µg/kg/min; often, dose may be reduced by 1/2 after initial response; intra-arterial infusion offers no advantage	Apnea, seizures, fever, disseminated intravascular coagulation, diarrhea, cutaneous vasodilatation, decreased platelet aggregation, cortical bone proliferation during prolonged infusion
Protamine sulfate	IV: 1 mg for each 100 units of heparin in previous 30 min; 0.5-0.75 for 30-60 min; and 0.25-0.375 for heparin given >2 hr before	Excessive doses induce coagulopathy; hypotension, bradycardia, anaphylaxis
Pyridoxine	See Vitamin B <sub>6</sub> (pyridoxine)	
Quinidine gluconate	PO, IM: 2-10 mg/kg/dose q2-6h until desired effect or toxicity occurs IV route not recommended in neonates (Dose is specific for the salt form)	Check electrocardiogram before each dose; discontinue if QRS interval increases 50% or more Maintain level of 2-6 µg/mL; nausea, vomiting, diarrhea, fever, atrioventricular block
Ranitidine	PO, IV: 1-2 mg/kg q8-12h	Minimal inhibition of hepatic cytochrome P450 enzymes; monitor gastric pH
Ribavirin	6 g nebulized in hood with a solution of 20 mg/mL 12-18 hr/day for 3-7 days	May precipitate in endotracheal tube; avoid exposure of pregnant staff; possible teratogenic effects
Silver nitrate (1% solution)	Prophylaxis: 1 or 2 drops in each eye	Chemical conjunctivitis
Sodium bicarbonate (0.5 mEq/mL)	IV: 1-2 mEq/kg/dose infused slowly only if infant ventilated adequately	Intravascular hemolysis may be associated with rapid infusion
Sodium polystyrene sulfonate (Kayexalate)	PO, PR: 1 g/kg; approximately q6h	Usually administered as a solution with 20% sorbitol to prevent intestinal obstruction; 20% sorbitol solution may injure intestinal mucosa of very low-birth-weight newborns; may decrease serum calcium or magnesium
Spirolactone	PO: 1-3 mg/kg/day q8-12h	Contraindicated with hyperkalemia; onset of action delayed; drowsiness; nausea; vomiting; diarrhea; androgenic effects in females; gynecomastia in males
Streptomycin	IM: 20-30 mg/kg/day q24h	Nephrotoxicity, ototoxicity; use in newborns as part of triple therapy for tuberculosis
Sulfisoxazole	PO, IV: 25 mg/kg q6h; aggressive therapy is used only in full-term neonates >2 weeks old	In prematures or in presence of jaundice, may lead to kernicterus
Survanta	See Beractant	
Tetanus immune globulin	IM: 250-500 units/dose	Optimal dosage not established for newborns
Theophylline	PO, IV: loading dose: 5-6 mg/kg; maintenance dose: 1-2.5 mg/kg/dose q6-12h; aminophylline (IV) dose = theophylline (IV) dose × 1.25	Blood level monitoring indicated (therapeutic range: <i>apnea</i> : 7-12 µg/mL, <i>bronchospasm</i> : 10-20 µg/mL); tachycardia at 15-20 µg/mL, seizures at >40 µg/mL; avoid rectal dosing due to variable absorption, clearance decreased by asphyxia and prematurity; tachycardia

Continued

Drug	Route and Dose	Adverse Effects and Cautions
Thiamine	See Vitamin B <sub>1</sub> (thiamine)	
Ticarcillin	IM, IV: 75 mg/kg/dose; <7 days: q12h, >7 days: q8h; maintain q12h for 4 wk for <1200 g	Contains 5.2 mEq Na <sup>+</sup> /g; may inhibit platelet function
Tobramycin	See Gentamicin dosing guidelines	
Ursodeoxycholic acid	PO: 10-15 mg/kg/day q8-24h	Nausea, vomiting, abdominal pain, constipation, flatulence
Vancomycin	PO: 10 mg/kg, q6h IV: postnatal age ≤7 days: <1200 g: 15 mg/kg/day q24h; 1200-2000 g: 15 mg/kg/day q12-18h; >2000 g: 30 mg/kg/day q12h; >7 days: <1200 g 15 mg/kg/day q24h; 1200-2000 g 15 mg/kg/day q8-12h; >2000 g 45 mg/kg/day q8h Cerebrospinal fluid: 5-10 mg/day (cerebrospinal fluid trough, <20 μg/mL)	Ototoxicity (therapeutic levels: peak 25-40 μg/mL; trough, 5-10 μg/mL); rapid infusion may cause cutaneous vasodilatation and shock Higher concentrations are recommended for resistant organisms and toxicity appears to be low
Vasopressin	IM, SC: 2.5-10 U 2-4 times daily	20 units/mL aqueous injection
Vecuronium	IV: 0.08-0.1 mg/kg/dose, repeat prn at 0.03-0.15 mg/kg/dose q1-2h Dose to effect	Neuromuscular blockade potentiated by calcium channel blockers such as verapamil and aminoglycoside antibiotics
Verapamil	IV: 0.1-0.2 mg/kg infused over 2 min; if response is inadequate, repeat in 30 min PO: 2-5 mg/kg/day in 3 divided doses	Monitor electrocardiogram during infusion; bradycardia, atrioventricular block, asystole; contraindicated in patients with 2nd or 3rd degree atrioventricular block during treatment with beta blockers
Vitamin A (oleovitamin A)	PO: preventive, 600-1500 units/day IM: prevention of BPD: 5000 IU 3 × /week for 4 weeks	Pseudotumor cerebri; maintain plasma vitamin A concentration of 30 to 60 μg/mL
Vitamin B <sub>1</sub> (thiamine)	PO: preventive, 0.5-1 mg q day; PO: therapeutic, 5-10 mg q6-8h	Unstable in alkaline solution
Vitamin B <sub>6</sub> (pyridoxine)	PO: <i>preventive</i> : 100 μg/L of ingested formula; <i>therapeutic for deficiency</i> : 2-5 mg/day q6h; <i>test dose for pyridone dependency seizures</i> : 50-100 mg IV	May decrease serum levels of phenobarbital, phenytoin, or folic acid; hypersensitivity
Vitamin C (ascorbic acid)	IM, IV, PO: <i>preventive</i> : 25-50 mg/day (term infants); 100 mg/day (premature infants)	
Vitamin D <sub>2</sub> (ergocalciferol)	PO: <i>preventive</i> : 400-1000 IU/day (premature infants), 40-100 IU/day (term infants)	Hypercalcemia with excess dose
Vitamin E ( <i>d</i> -alpha tocopherol)	PO: <i>prevention of hemolysis</i> : 25-50 IU/day (1 IU = 1 mg)	Some preparations are hyperosmolar
Vitamin K <sub>1</sub> (phytonadione)	SC, IM: <i>preventive</i> : 0.5-1.0 mg, single dose; <i>therapeutic</i> : 1-2 mg/kg/dose q6-12h according to prothrombin time	With thrombocytopenia, slow IV infusion at same dose; anaphylaxis observed with rapid injection IV, more common with vitamin K <sub>3</sub>

**TRANSFER OF DRUGS AND CHEMICALS INTO HUMAN MILK**

A statement on the transfer of drugs and chemicals into human milk, by the Committee on Drugs of the American Academy of Pediatrics, was first published in 1983, with revisions in 1989, 1994 and 2001. The current statement addresses the use of psychotropic drugs and other drug therapies for the lactating woman, as well as the implications of smoking and the presence of silicone implants on breast-feeding. Information in the statement is updated to identify agents transferred into human milk and to describe their possible effects on the infant or on lactation, if known; current data are presented in Tables 1 through 7. If a pharmacologic or chemical agent does not appear in the tables, it does not mean that the agent is not transferred into human milk or that it

does not have an effect on the infant; omission of the agent indicates only that no reports have appeared in the literature. These tables are provided to assist the physician in counseling the nursing mother regarding breast-feeding when she has a condition for which a drug is medically indicated. The full text of this statement is available at <http://aapolicy.aapublications.org>.

American Academy of Pediatrics Committee on Drugs: The transfer of drugs and other chemicals into human milk. *Pediatrics* 108:776-789, 2001.

TABLE 1

**Cytotoxic Drugs that May Interfere with Cellular Metabolism in the Nursing Infant**

Drug	Reason for Concern, Reported Sign or Symptom in Infant, or Effect on Lactation
Cyclophosphamide	Possible immune suppression; unknown effect on growth or association with carcinogenesis; neutropenia
Cyclosporine	Possible immune suppression; unknown effect on growth or association with carcinogenesis
Doxorubicin <sup>o</sup>	Possible immune suppression; unknown effect on growth or association with carcinogenesis
Methotrexate	Possible immune suppression; unknown effect on growth or association with carcinogenesis; neutropenia

<sup>o</sup>Drug is concentrated in human milk.

TABLE 2

**Drugs of Abuse for Which Adverse Effects on the Infant During Breast-feeding Have Been Reported\***

Drug	Reported Effect or Reason for Concern
Amphetamine <sup>†</sup>	Irritability, poor sleeping pattern
Cocaine	Cocaine intoxication: irritability, vomiting, diarrhea, tremulousness, seizures
Heroin	Tremors, restlessness, vomiting, poor feeding
Marijuana	Only one report in literature; no effect mentioned; very long half-life for some components
Phencyclidine	Potent hallucinogen

\*The Committee on Drugs strongly believes that nursing mothers should not ingest drugs of abuse, because they are hazardous to the nursing infant and to the health of the mother.

<sup>†</sup>Drug is concentrated in human milk.

TABLE 3

**Radioactive Compounds Necessitating Temporary Cessation of Breast-feeding\***

Compound	Recommended Time for Cessation of Breast-feeding
Copper 64 ( <sup>64</sup> Cu)	Radioactivity in milk present at 50 hr
Gallium 67 ( <sup>67</sup> Ga)	Radioactivity in milk present for 2 wk
Indium 111 ( <sup>111</sup> In)	Very small amount present at 20 hr
Iodine 123 ( <sup>123</sup> I)	Radioactivity in milk present up to 36 hr
Iodine 125 ( <sup>125</sup> I)	Radioactivity in milk present for 12 days
Iodine 131 ( <sup>131</sup> I)	Radioactivity in milk present 2-14 days, depending on study
Iodine <sup>131</sup>	If used for treatment of thyroid cancer, high radioactivity may prolong exposure to infant
Radioactive sodium	Radioactivity in milk present 96 hr
Technetium 99 m ( <sup>99m</sup> Tc), <sup>99m</sup> Tc macroaggregates, <sup>99m</sup> Tc O <sub>4</sub>	Radioactivity in milk present 15 hr to 3 days

\*Consult nuclear medicine physician before performing diagnostic study so that radionuclide that has the shortest excretion time in breast milk can be used. Before the study, the mother should pump her breast and store enough milk in the freezer for feeding the infant; after the study, the mother should pump her breast to maintain milk production but discard all milk pumped for the required time that radioactivity is present in milk. Milk samples can be screened by radiology departments for radioactivity before resumption of nursing.

TABLE 4

**Drugs for Which the Effect on Nursing Infants is Unknown But May Be of Concern\***

Drug	Reported or Possible Effect
<b>Anxiolytics</b>	
Alprazolam	None
Diazepam	None
Lorazepam	None
Midazolam	—
Perphenazine	None

TABLE 4

**Drugs for Which the Effect on Nursing Infants is Unknown But May Be of Concern\*—Cont'd**

Drug	Reported or Possible Effect
Prazepam <sup>†</sup>	None
Quazepam	None
Temazepam	—
<b>Antidepressants</b>	
Amitriptyline	None
Amoxapine	None
Bupropion	None
Clomipramine	None
Desipramine	None
Dothiepin	None
Doxepin	None
Fluoxetine	Colic, irritability, feeding and sleep disorders, slow weight gain
Fluvoxamine	—
Imipramine	None
Nortriptyline	None
Paroxetine	None
Sertraline <sup>†</sup>	None
Trazodone	None
<b>Antipsychotics</b>	
Chlorpromazine	Galactorrhea in mother; drowsiness and lethargy in infant; decline in developmental scores
Chlorprothixene	None
Clozapine <sup>†</sup>	None
Haloperidol	Decline in developmental scores
Mesoridazine	None
Trifluoperazine	None
<b>Others</b>	
Amiodarone	Possible hypothyroidism
Chloramphenicol	Possible idiosyncratic bone marrow suppression
Clofazimine	Potential for transfer of high percentage of maternal dose; possible increase in skin pigmentation
Lamotrigine	Potential therapeutic serum concentrations in infant
Metoclopramide <sup>†</sup>	None described; dopaminergic blocking agent
Metronidazole	In vitro mutagen; may discontinue breast-feeding for 12-24 hr to allow excretion of dose when single-dose therapy is given to mother
Tinidazole	See Metronidazole

\*Psychotropic drugs, the compounds listed under the anxiolytic, antidepressant, and antipsychotic categories, are of special concern when given to nursing mothers for long periods. Although there are very few case reports of adverse effects in breast-feeding infants, these drugs do appear in human milk and thus could conceivably alter short-term and long-term central nervous system function. See discussion in the text on psychotropic drugs.

<sup>†</sup>Drug is concentrated in human milk relative to simultaneous maternal plasma concentrations.

TABLE 5

**Drugs That Have Been Associated with Significant Effects in Some Nursing Infants and Should Be Given to Nursing Mothers with Caution\***

Drug	Reported Effect
Acebutolol	Hypotension; bradycardia; tachypnea
5-Aminosalicylic acid	Diarrhea (one case)
Atenolol	Cyanosis; bradycardia
Bromocriptine	Suppresses lactation; may be hazardous to the mother
Aspirin (salicylates)	Metabolic acidosis (one case)
Clemastine	Drowsiness, irritability, refusal to feed, high-pitched cry, neck stiffness (one case)
Ergotamine	Vomiting, diarrhea, convulsions (doses used in migraine medications)
Lithium	One-third to one-half therapeutic blood concentration in infants
Phenindione	Anticoagulant: increased prothrombin and partial thromboplastin time in one infant; not used in the United States
Phenobarbital	Sedation; infantile spasms after weaning from milk containing phenobarbital, methemoglobinemia (one case)
Primidone	Sedation, feeding problems
Sulfasalazine (salicylazosulfapyridine)	Bloody diarrhea (one case)

\*Blood concentration in the infant may be of clinical importance.

TABLE 6

## Maternal Medications Usually Compatible with Breast-feeding\*

Drug	Reported Sign/Symptom in Infant or Effect on Lactation	Drug	Reported Sign/Symptom in Infant or Effect on Lactation
Acetaminophen	None	Dapsone	None; sulfonamide detected in infant's urine
Acetazolamide	None	Dexbrompheniramine maleate with <i>d</i> -isoephedrine	Crying, poor sleeping patterns, irritability
Acitretin	—	Diatrizoate	None
Acyclovir <sup>†</sup>	None	Digoxin	None
Alcohol (ethanol)	With large amounts, drowsiness, diaphoresis, deep sleep, weakness, decrease in linear growth, abnormal weight gain; maternal ingestion of 1 g/kg daily decreases milk ejection reflex	Diltiazem	None
Allopurinol	—	Dipyron	None
Amoxicillin	None	Disopyramide	None
Antimony	—	Domperidone	None
Atropine	None	Dyphylline <sup>†</sup>	None
Azapropazone (apazone)	—	Enalapril	—
Aztreonam	None	Erythromycin <sup>†</sup>	None
B vitamins		Estradiol	Withdrawal, vaginal bleeding
B <sub>1</sub> (thiamin)	None	Ethambutol	None
B <sub>6</sub> (pyridoxine)	None	Ethanol	See Alcohol
B <sub>12</sub>	None	Ethosuximide	None, drug appears in infant serum
Baclofen	None	Fentanyl	—
Barbiturate	See Table 5 (phenobarbital)	Fexofenadine	None
Bendroflumethiazide	Suppresses lactation	Flecainide	—
Bishydroxycoumarin (dicumarol)	None	Fleroxacin	One 400-mg dose given to nursing mothers; infants not given breast milk for 48 hr
Bromide	Rash, weakness, absence of cry with maternal intake of 5.4 g/day	Fluconazole	None
Butorphanol	None	Flufenamic acid	None
Caffeine	Irritability, poor sleeping pattern, excreted slowly; no effect with moderate intake of caffeinated beverages (2-3 cups per day)	Fluorescein	—
Captopril	None	Folic acid	None
Carbamazepine	None	Gadopentetic acid (gadolinium)	None
Carbetocin	None	Gentamicin	None
Carbimazole	Goiter	Gold salts	None
Cascara	None	Halothane	None
Cefadroxil	None	Hydralazine	None
Cefazolin	None	Hydrochlorothiazide	—
Cefotaxime	None	Hydroxychloroquine <sup>†</sup>	None
Cefoxitin	None	Ibuprofen	None
Cefprozil	—	Indomethacin	Seizure (one case)
Ceftazidime	None	Iodides	May affect thyroid activity; see Iodine
Ceftriaxone	None	Iodine	Goiter
Chloral hydrate	Sleepiness	Iodine (povidone-iodine; e.g., in a vaginal douche)	Elevated iodine levels in breast milk, odor of iodine on infant's skin
Chloroform	None	Iohexol	None
Chloroquine	None	Iopanoic acid	None
Chlorothiazide	None	Isoniazid	None; acetyl (hepatotoxic) metabolite secreted but no hepatotoxicity reported in infants
Chlorthalidone	Excreted slowly	Interferon- $\alpha$	—
Cimetidine <sup>†</sup>	None	Ivermectin	None
Ciprofloxacin	None	K <sub>1</sub> (vitamin)	None
Cisapride	None	Kanamycin	None
Cisplatin	Not found in milk	Ketoconazole	None
Clindamycin	None	Ketorolac	—
Clogestone	None	Labetalol	None
Codeine	None	Levonorgestrel	—
Colchicine	—	Levothyroxine	None
Contraceptive pill with estrogen/progesterone	Rare breast enlargement; decrease in milk production and protein content (not confirmed in several studies)	Lidocaine	None
Cycloserine	None	Loperamide	—
D (vitamin)	None; follow-up evaluation of infant's serum calcium level if mother receives pharmacologic doses	Loratadine	None
Danthron	Increased bowel activity	Magnesium sulfate	None
		Medroxyprogesterone	None
		Mefenamic acid	None
		Meperidine	None
		Methadone	None

TABLE 6

**Maternal Medication Usually Compatible with Breast-feeding\*—Cont'd**

Drug	Reported Sign/Symptom in Infant or Effect on Lactation	Drug	Reported Sign/Symptom in Infant or Effect on Lactation
Methimazole (active metabolite of carbimazole)	None	Pyrimethamine	None
Methohexital	None	Quinidine	None
Methyldopa	None	Quinine	None
Methypylon	Drowsiness	Riboflavin	None
Metoprolol <sup>†</sup>	None	Rifampin	None
Metrizamide	None	Scopolamine	—
Metrizoate	None	Secobarbital	None
Mexiletine	None	Senna	None
Minoxidil	None	Sotalol	—
Morphine	None; infant may have measurable blood concentration	Spironolactone	None
Moxalactam	None	Streptomycin	None
Nadolol <sup>†</sup>	None	Sulfactam	None
Nalidixic acid	Hemolysis in infant with glucose-6-phosphate dehydrogenase (G6PD) deficiency	Sulfapyridine	Caution in infant with jaundice or G6PD deficiency and ill, stressed, or premature infant; appears in mother's milk and infant's urine
Naproxen	—	Sulfisoxazole	Caution in infant with jaundice or G6PD deficiency and ill, stressed, or premature infant; appears in mother's milk and infant's urine
Nefopam	None	Sumatriptan	None
Nifedipine	—	Suprofen	None
Nitrofurantoin	Hemolysis in infant with G6PD deficiency	Terbutaline	None
Norethynodrel	None	Terfenadine	None
Norsteroids	None	Tetracycline	None; negligible absorption by infant
Noscapine	None	Theophylline	Irritability
Ofloxacin	None	Thiopental	None
Oxprenolol	None	Thiouracil	None mentioned; drug not used in the United States
Phenylbutazone	None	Ticarcillin	None
Phenytoin	Methemoglobinemia (one case)	Timolol	None
Piroxicam	None	Tolbutamide	Possible jaundice
Prednisolone	None	Tolmetin	None
Prednisone	None	Trimethoprim-sulfamethoxazole	None
Procainamide	None	Tripolidine	None
Progesterone	None	Valproic acid	None
Propoxyphene	None	Verapamil	None
Propranolol	None	Warfarin	None
Propylthiouracil	None	Zolpidem	None
Pseudoephedrine <sup>†</sup>	None		
Pyridostigmine	None		

\*Drugs listed have been reported in the literature as having the effects listed or no effect. "None" means that no observable change was seen in the nursing infant while the mother was ingesting the compound. Dashes indicate no mention of clinical effect on the infant. It is emphasized that many of the literature citations concern single case reports or small series of infants.

<sup>†</sup>Drug is concentrated in human milk.

TABLE 7

**Food and Environmental Agents: Effects on Breast-feeding**

Agent	Reported Sign/Symptom in Infant or Effect on Lactation
Aflatoxin	None
Aspartame	Caution if mother or infant has phenylketonuria
Bromide (photographic laboratory)	Potential absorption and bromide transfer into milk; see Table 6
Cadmium	None reported
Chlordane	None reported
Chocolate (theobromine)	Irritability or increased bowel activity if excess amounts ( $\geq 16$ oz/day) consumed by mother
DDT, benzene hexachlorides, dieldrin, aldrin, heptachlorepoxyde	None
Fava beans	Hemolysis in patient with glucose-6-phosphate dehydrogenase deficiency
Fluorides	None

Continued

TABLE 7

**Food and Environmental Agents: Effects on Breast-feeding—Cont'd**

Agent	Reported Sign/Symptom in Infant or Effect on Lactation
Hexachlorobenzene	Skin rash, diarrhea, vomiting, dark urine, neurotoxicity, death
Hexachlorophene	None; possible contamination of milk from nipple washing
Lead	Possible neurotoxicity
Mercury, methylmercury	May affect neurodevelopment
Methylmethacrylate	None
Monosodium glutamate	None
Polychlorinated biphenyls and polybrominated biphenyls	Lack of endurance; hypotonia; sullen, expressionless facies
Silicone	Esophageal dysmotility
Tetrachloroethylene cleaning fluid (perchloroethylene)	Obstructive jaundice, dark urine
Vegetarian diet	Signs of B <sub>12</sub> deficiency

IHDP Growth Percentiles: VLBW Premature Girls (cont'd)

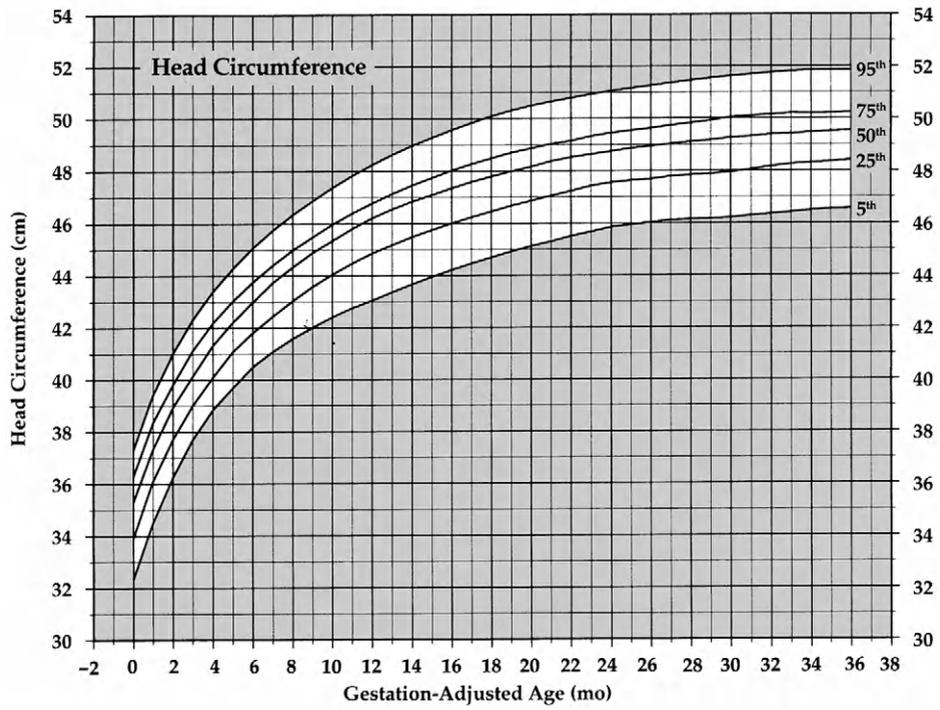

IHDP Growth Percentiles: LBW Premature Girls (cont'd)

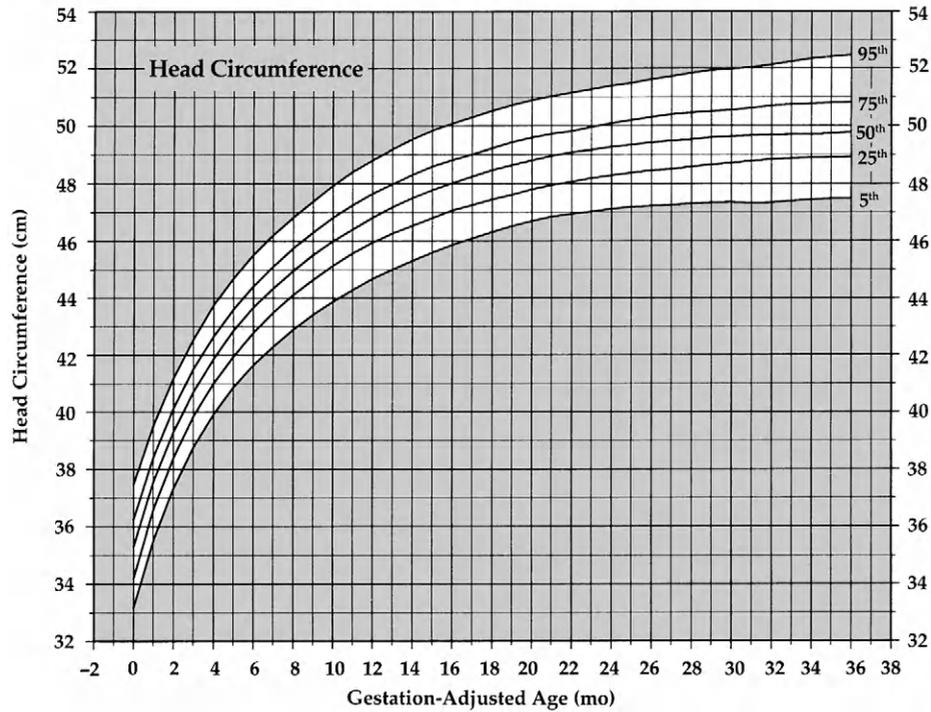

IHDP Growth Percentiles: VLBW Premature Boys (cont'd)

**IHDP Growth Percentiles: LBW Premature Boys (cont'd)**

The growth of very low-birth-weight (VLBW) ( $\leq 1500$  g) and low-birth-weight (LBW, 1501 to 2500 g) premature ( $\leq 37$  weeks, gestational age [GA]) infants differs from that of normal-birth-weight term infants during infancy and early childhood. Because these infants may not catch up to term infants in growth during the early years, their growth should be compared with that of premature infants of similar birth weight.

The growth percentiles presented here are based on a large sample of infants enrolled in the Infant Health and Development Program (IHDP).<sup>1,2</sup> Some infants most likely to experience growth problems from biologic or environmental causes, premature infants with birth weight greater than 2500 g, and small-for-gestational-age term infants were excluded.<sup>1</sup> Study infants, however, are probably typical of premature infants who receive modern neonatal intensive care.

**Instructions for Use**

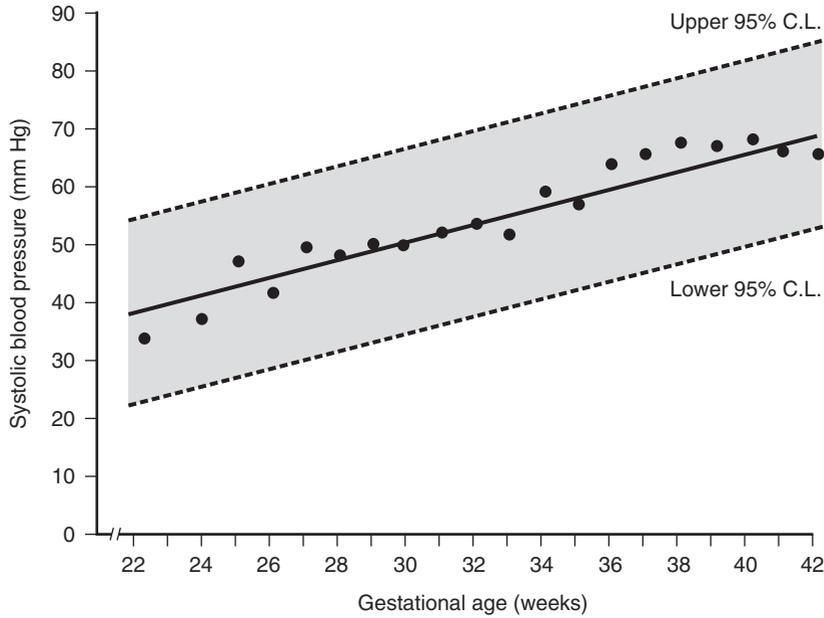

1. Measure and record weight, length, and head circumference.
2. Calculate gestation-adjusted age by subtracting Adjustment for Prematurity in weeks from postnatal age in weeks. Adjustment for Prematurity equals 40 weeks minus GA. For example, at 12 weeks of postnatal age, the gestation-adjusted age for an infant born at 30 weeks of GA would be 2 weeks (0.5 month).

Nomogram for estimating the body surface area of human fetuses and neonates. It is based on the equation  $S = 6.4954 \times W^{0.562} \times L^{0.320}$  where  $S$  is the surface area in  $\text{cm}^2$ ,  $W$  is the body weight in g, and  $L$  is the crown–heel length in cm. To use the nomogram, a ruler is aligned with the length and weight values on the outer axes. The point at which the central axis is intersected gives the value for body surface area. (Data from Mehan C: *The surface area and volume of the human fetus*. *J Anat* 137:271-278, 1983.)

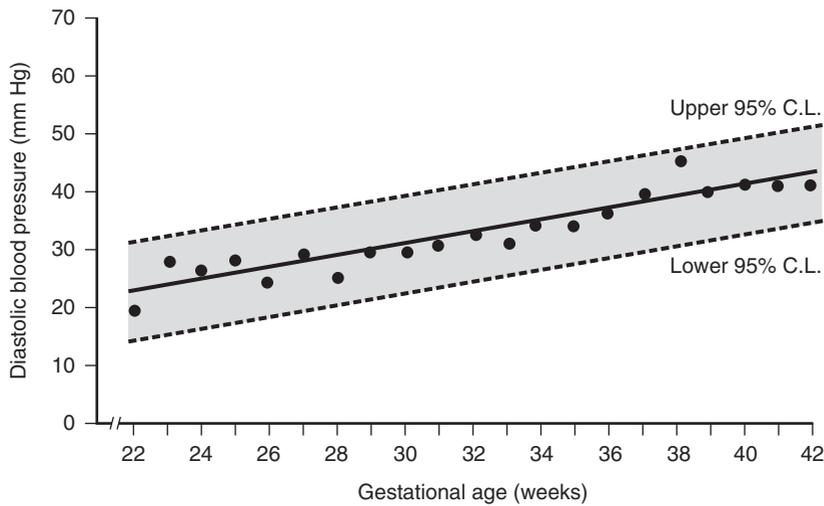

Linear regression of mean systolic (A) and diastolic (B) blood pressures (SBP and DBP) on birth weight in 329 infants admitted to NICU on day 1 of life is plotted. Equations are  $\text{SBP} = 8.52 \times \text{birth weight (kilograms)} + 39.36$  ( $r = 0.68$ ,  $P < 0.001$ ) and  $\text{DBP} = 5.21 \times \text{birth weight (kilograms)} + 23.38$  ( $r = 0.48$ ,  $P < 0.001$ ). Means of SBP and DBP for incremental birth weight groups are plotted about respective regression lines. The 95% confidence limits (C.L.; shaded area surrounded by dashed lines) is derived from standard error of regression estimate (SBP = 8.043 mm Hg, DBP = 8.370 mm Hg). This approximates mean  $\pm 2$  standard deviations. (Data from Zubrow AB, Hulman S, Kushner H, et al: *Determinants of blood pressure in infants admitted to neonatal intensive care units: A prospective multicenter study*. *J Perinatol* 15[6]:472, 1995.)

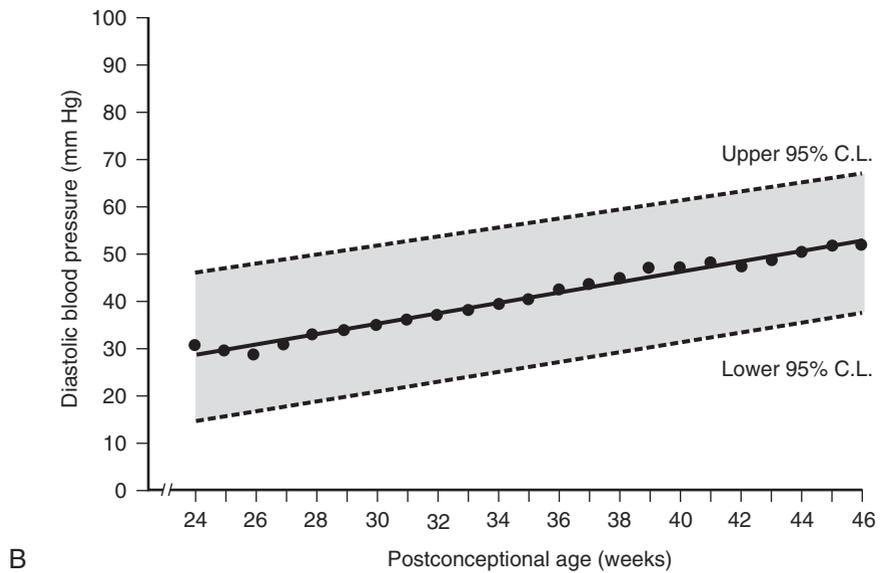

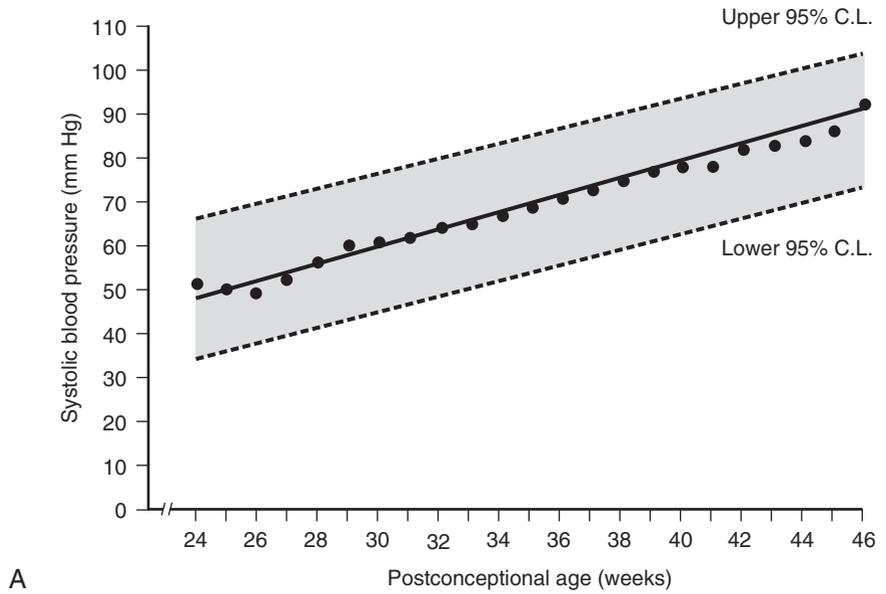

A

B

Linear regression of mean systolic (A) and diastolic (B) blood pressures (SBP and DBP) on gestational age in 329 infants admitted to the NICU on day 1 of life is plotted. Equations are  $SBP = 1.589 \times \text{gestational age (weeks)} + 3.778$  ( $r = 0.66, P < 0.0001$ ) and  $DBP = 0.997 \times \text{gestational age (weeks)} + 0.77$  ( $r = 0.47, P < 0.0001$ ). Computed mean values on day 1 of life are plotted for each week of gestational age at birth, from 22 to 42 weeks. The 95% confidence limits (C.L.; shaded area surrounded by dashed lines) is derived from standard error of regression estimate ( $SBP = 8.341 \text{ mm Hg}, DBP = 8.474 \text{ mm Hg}$ ). This approximates mean  $\pm 2$  standard deviations. (Data from Zubrow AB, Hulman S, Kushner H, et al: Determinants of blood pressure in infants admitted to neonatal intensive care units: A prospective multicenter study. *J Perinatol* 15[6]:473, 1995.)

Postconceptional age (gestational age in weeks + weeks after delivery) is computed daily for each infant (8566 daily records) and regressed against mean systolic (A) and diastolic (B) blood pressures (SBP and DBP) for that day. Regression lines and equations are  $SBP = (0.255 \times \text{postconceptional age in weeks} \times 7) + 6.34$ ,  $r = 0.61$ ,  $P < 0.0001$  and  $DBP = (0.151 \times \text{postconceptional age in weeks} \times 7) + 3.32$ ,  $r = 0.46$ ,  $P < 0.0001$ . Observed means of SBP and DBP for each postconceptional week are also plotted. C.L., confidence limit. (Data from Zubrow AB, Hulman S, Kushner H, et al: Determinants of blood pressure in infants admitted to neonatal intensive care units: A prospective multicenter study. *J Perinatol* 15[6]:474, 1995.)

<b>Colloid Osmotic Pressure (mm Hg) in Infants' Blood</b>	
Term, vaginal delivery	19.5 ± 2.1 (SD)
Term, cesarean section	16.1 ± 2.0
Term, vaginal (sick) (sepsis, asphyxia, heart failure, abdominal surgery)	19.5 ± 3.1
Preterm (700-1980 g) (hyaline membrane disease, asphyxia, necrotizing enterocolitis, etc.)	12.5 ± 2.5
Older infants, 1-11 months	25.1 ± 2.6

On day 3, all infants are included irrespective of antenatal steroids and transfusions up to day 3. Thereafter, infants who did not receive rhEPO were studied, irrespective of the use of antibiotics and steroids.

RBC, red blood cell; rhEPO, recombinant human erythropoietin; VLBW, very low-birth-weight.

Data from Obladen M, Diepold K, Maier RF, the European Multicenter rhEPO Study Group: Venous and arterial hematologic profiles of very low birth weight infants. *Pediatrics* 106:707, 2000.

NR, not recorded.

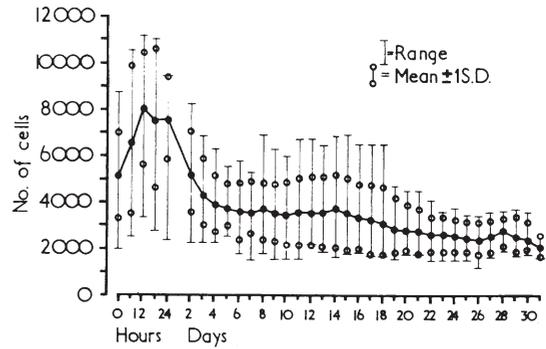

From Rodriguez AF, Kaplan SL, Mason EO: Cerebrospinal fluid values and the very LBW infant. *J Pediatr* 116:971, 1990.

TERM NEWBORN

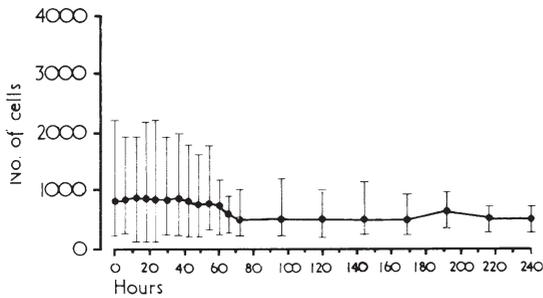

Means, ranges, and means  $\pm$  1 SD for neutrophil counts in 15 full-term healthy babies during the first 10 days of life. (Data from Xanthou M: Arch Dis Child 45:242, 1970.)

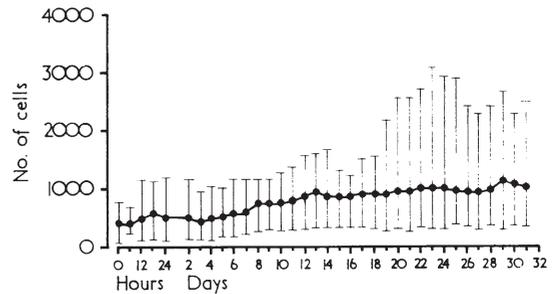

PREMATURES

Means, ranges, and means  $\pm$  1 SD for neutrophil counts in 14 healthy babies during the first month of life (13 premature + 1 small for dates). (Data from Xanthou M: Arch Dis Child 45:242, 1970.)

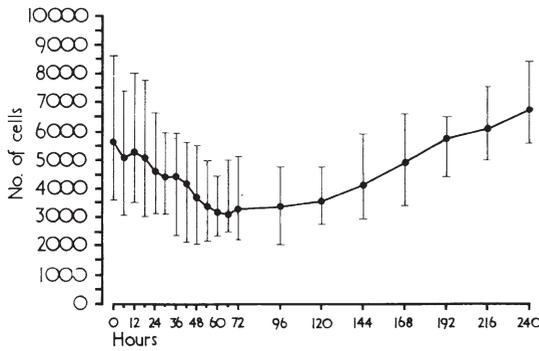

Means and ranges for eosinophil counts in full-term babies during the first 10 days of life. (Data from Xanthou M: Arch Dis Child 45:242, 1970.)

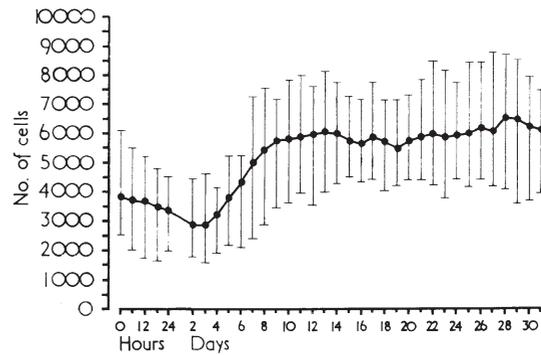

Means and ranges for eosinophil counts in low-birth-weight babies during the first month of life. (Data from Xanthou M: Arch Dis Child 45:242, 1970.)

TERM NEWBORN

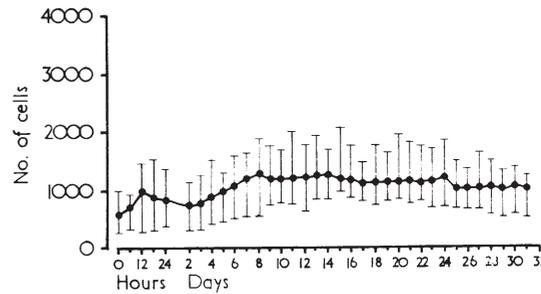

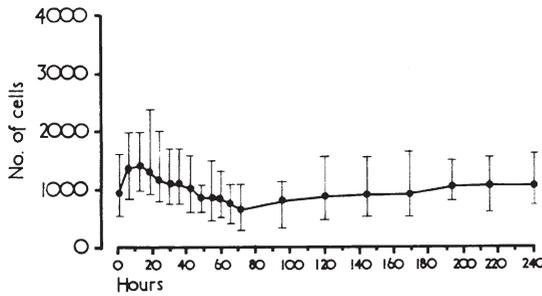

PREMATURES

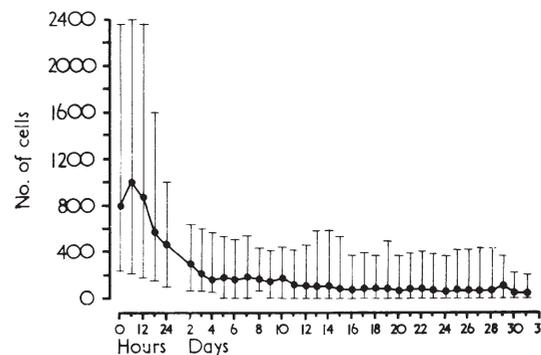

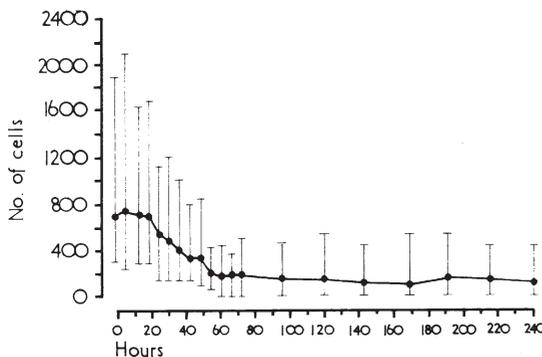

Means and ranges for lymphocyte counts in full-term babies during the first 10 days of life. (Data from Xanthou M: Arch Dis Child 45:242, 1970.)

Means and ranges for lymphocyte counts in low-birth-weight babies during the first month of life. (Data from Xanthou M: Arch Dis Child 45:242, 1970.)

Means and ranges for monocyte counts in healthy full-term babies during the first 10 days of life. (Data from Xanthou M: Arch Dis Child 45:242, 1970.)

Means and ranges for monocyte counts in low-birth-weight babies during the first month of life. (Data from Xanthou M: Arch Dis Child 45:242, 1970.)

Means and ranges for metamyelocyte counts in full-term babies during the first 10 days of life. (Data from Xanthou M: Arch Dis Child 45:242, 1970.)

Means and ranges for metamyelocyte counts in 14 healthy babies during the first month of life. (Data from Xanthou M: Arch Dis Child 45:242, 1970.)

**Nucleated Red Blood Cells in Normal Infants and Infants of Diabetic Mothers**

Variables	Control Infants (n = 102)	Infants of Diabetic Mothers	
		No Perinatal Asphyxia (n = 54)	Perinatal Asphyxia (n = 25)
Gestational age (weeks)	39.5 ± 1.5	38.0 ± 1.0°	37.9 ± 1.2°
Birth weight (kg)	3.3 ± 0.3	3.5 ± 0.6°	3.6 ± 0.6°
Leukocyte count†	27.3 ± 9.2	17.1 ± 5.1°	16.8 ± 6.1°
NRBCs (absolute count)	0.4 ± 1.3	1.4 ± 3.1°	1.8 ± 2.3°
NRBCs/100 leukocytes	1.7 ± 6.2	8.3 ± 17.8°	13.0 ± 18.9°

°Significantly different from control infant values (*P* at least < .05).

†Data are expressed as ×10<sup>9</sup>/L.

NRBC, nucleated red blood cell.

 blood pressure standards and, 1327-1328, 1328f,  
 1329t

- Hypertension (*Continued*)  
 clinical signs of, 1328  
 definition and incidence of, 1327  
 etiology of, 1328, 1330t  
 evaluation of, 1328-1329  
 prognosis of, 1330-1331  
 treatment of, 1329-1330, 1331t  
 persistent, in preterm infant, 401f, 401-402  
 pregnancy-induced, thrombocytopenia due to, neonatal, 1169  
 renal and urinary tract disorders and, 1270  
 severe, definition of, 99  
 with extracorporeal membrane oxygenation, 718  
 Hypertensive emergency(ies), neonatal, 1330, 1331t  
 Hyperthermia, neonatal, 332  
 Hyperthyroidism  
 maternal, in pregnancy, 83-84  
 diagnosis of, 83  
 maternal management for, 83-84  
 neonatal effects of, 84, 84f  
 pathogenesis of, 83  
 primary, transient, in premature infants, 1406  
 Hyperthyrotropinemia, transient, in premature infants, 1406-1407  
 Hyperthyroxinemia, dysalbuminemic, familial, 1407-1408  
 Hypertrophic cardiomyopathy, neonatal, in infants of diabetic mothers, 77  
 Hypertyrosinemia, 237  
 Hyperventilation  
 alveolar ventilation and, 639  
 for congenital diaphragmatic hernia, 766  
 Hyperviscosity  
 cerebral blood flow and, 904  
 neonatal, in infants of diabetic mothers, 77  
 Hypocalcemia, seizures and, 1015  
 Hypocalcemic crisis(es), treatment of, 1355  
 Hypocapnia, with mechanical ventilation, 655  
 Hypocarbica, intraventricular hemorrhage and, 968  
 Hypogastric omphalocele, 1114  
 Hypoglycemia, 218, 218t, 1410-1419, 1411f, 1411t  
 cerebral effects of, 905  
 fasting system development and, 1411-1413, 1412t, 1413t  
 hyperinsulinemic, persistent, of infancy, 1109  
 in inborn errors of metabolism, 222t  
 neonatal  
 clinical presentation of, 1418, 1418t  
 diagnosis of, 1417-1418  
 during postnatal fasting  
 in normal neonates, 1413f, 1413-1414  
 in preterm or small for gestational age infants, 1414  
 etiology of, 1411, 1412t  
 in infants of diabetic mothers, 77  
 in intrauterine growth restriction, 37  
 neuroimaging in, 932, 932f  
 persistent hyperinsulinism causing, 1415-1417  
 self-limited disorders causing, 1413f, 1413-1414  
 transient excessive glucose utilization causing, 1414  
 transient hyperinsulinism causing, 1414-1415  
 treatment of, 1418  
 underlying disorder in, diagnosis of, 1418-1419, 1419f  
 seizures and, 1015  
 Hypogonadotropic hypogonadism and anosmia, 1275  
 Hypokalemia, in metabolic acidosis, 393  
 Hypokalemic renal tubular disorder(s), inherited, 1310  
 Hypomagnesemia, neonatal, 1360  
 neonatal hypocalcemia associated with, 1354  
 Hypomelanosis of Ito, 1528  
 Hyponatremia  
 hypertonic, neonatal, 380  
 hypotonic, neonatal, 380, 381f  
 in renal failure, 1303  
 neonatal, 380  
 treatment of, 380, 381f, 388  
 seizures and, 1015  
 Hypoparathyroidism  
 maternal, neonatal hypocalcemia associated with, 1353  
 neonatal, with hypocalcemia, 1264, 1352-1353  
 Hypophosphatasia, perinatal, 287-288  
 etiology of, 288  
 inheritance of, 288  
 treatment of, 288  
 Hypophosphatemia  
 hypercalcemia associated with, 1359  
 X-linked, dominant, 1363  
 Hypopigmented lesions, 1527-1528  
 definition of, 1527, 1527f, 1528f  
 Hypoplastic anemia, 1202-1203  
 Hypoplastic kidney(s), 1278  
 Hypoplastic left heart syndrome (HLHS), neonatal, 841, 846-853  
 ethical decision making for, 19-20  
 heart transplantation for, 851-853, 852f  
 "high" oxygen saturation in, indications for treatment of, 847-848  
 hypotension and, 849  
 in low-birth-weight infants, 889  
 in shock, presentation of, 848  
 inspired gases and, 848-849  
 oxygen therapy for, 847  
 restrictive atrial septum and, 849  
 staged surgical reconstruction for, 849-851, 850f, 851f, 852-853  
 Hypoproteinemia, hydrops fetalis associated with, 66  
 Hypospadias, 1293, 1394  
 examination of, 1382, 1382f

 Kallmann syndrome, 1275, 1488  
 Kanamycin, for tuberculosis, congenital, 545  
 Kangaroo care, 323  
   for temperature regulation of premature infants, 368-369
- Kartagener syndrome, 792  
 Karyotype, 204-205, 205f  
 Karyotyping  
   spectral, 175, 175t  
   using Giemsa-banded chromosomes, 175
- Kasabach-Merritt syndrome, 1521, 1524  
 thrombocytopenia due to, neonatal, 1169
- Kaufman Assessment Battery for Children (K-ABC), 1037t
- Kayexalate, route, dose, adverse effects, and cautions regarding, 1562, 1565
- Keratitis-ichthyosis-deafness syndrome, 1488  
 Kernicterus, 1236-1241  
   clinical manifestations of, 1237-1238  
   historical background of, 1236-1237  
   neonatal, 334  
   neuroimaging in, 932  
   pathophysiology of, 1238t, 1238-1241
- Ketamine  
   as anesthetic induction agent, obstetric, 167  
   for obstetric analgesia, 162
- Ketogenesis, hepatic, 1410, 1411t  
 Ketone metabolism, defects in, 247  
 Ketosis, in inborn errors of metabolism, 221t  
 17-Ketosteroid reductase deficiency, 1390  
 Ketotic hyperglycemia, 241-242  
 Ketotic hyperglycemia syndromes, 238
- Kidney(s). *See also* Renal entries.  
   dysgenetic, 1278-1279  
   ectopic, 1272  
   glomerulocystic, 1278, 1278f  
   glomerulonephropathies of, 1307-1308  
   horseshoe, 1272  
   hypoplastic, 1278  
   in overgrowth syndromes, 1279  
   morphogenesis of, 1257-1258  
   multicystic, 1272, 1274f  
   polycystic, 1275-1277  
     in autosomal dominant polycystic kidney disease, 1276-1277, 1277f  
     in autosomal recessive polycystic kidney disease, 1275-1276, 1276f  
     in tuberous sclerosis, 1277  
     with autosomal recessive inheritance, 1277-1278  
   rhabdoid tumor of, 1458-1459
- Kinetic dosing, 433-434  
 Kinky hair, in inborn errors of metabolism, 220t  
 Kleihauer-Betke preparation, 1186  
 Kliefelter syndrome, tumors associated with, 1440t  
 Klippel-Feil syndrome, 1426-1427  
 Klippel-Trénaunay syndrome, 1526  
 Klumpke paralysis, 1431  
   perinatal trauma and, 983  
 Kniest syndrome, 283t  
 Kocher-Debré-Sémélaigne syndrome, 999  
 Kostmann syndrome, 1217  
 Krabbe disease, 262t, 266-267  
   clinical features of, 266-267  
   diagnosis of, 270  
   etiology of, 266  
   management of, 270
- Kugelberg-Welander disease, 999-1000  
 Kyphosis, thoracolumbar, in achondroplasia, 290
- ## L
- Labetalol  
   during pregnancy, 100  
   for hypertension, 1331t
- Labioscrotal fold(s), examination of, 1381, 1381t
- Labor  
   analgesia for. *See* Analgesia, obstetric.  
   changes in body composition and fluid compartments during, 372-373  
   events of, in maternal history, 305  
   HIV/AIDS prophylaxis during, 489, 490t  
   normal, 146, 147f  
   onset of, in maternal history, 305  
   pain of, 159, 160f  
   preterm  
     definition of, 141  
     spontaneous, 139  
     tocolysis to stop, 141-142  
   stages of, 146
- Laboratory tests. *See also specific tests.*  
   false-positive results on, 341, 343t, 347  
   in neonatal examination, 319-320  
   predictive accuracy of, 557-558  
   receiver operating characteristic curve and, 557, 558f  
   sensitivity of, 557-558  
   specificity of, 557-558
- β-Lactalbumin, in bovine milk, 1045  
 α-Lactalbumin, in human milk, 1045  
 Lactase, small intestinal activity of, 1074, 1075f  
 Lactate, normal values in term infants, 1589
- Lactic acid  
   circulatory compromise and, 403  
   normal values in term infants, 1589
- Lactic acidosis  
   in inborn errors of metabolism, 221t-222t  
   lethal, early, 252-253  
   primary, 247-248
- Lactobacillus*, gastrointestinal host defenses and, 1082
- Lacunae, 23, 24f  
 Lamaze method, 161  
 LAMB syndrome, 945, 946t, 1531  
 "Lambda" sing, 57  
 Lamellar ichthyosis, 1485t, 1486-1487, 1487f  
 Lamivudine, teratogenicity of, 483t  
 Language assessments, 1036t, 1036-1037  
 Larsen-like syndrome, lethal type, pulmonary malformations in, 603t
- Laryngeal atresia, congenital, 739  
 Laryngeal chemoreflex hypothesis of SIDS, 626-627
- Laryngeal cleft, congenital, 739-740  
 Laryngeal deformities, 738-740. *See also specific disorders.*  
 Laryngeal stenosis, congenital, 739  
 Laryngeal stridor, congenital, 738  
 Laryngoesophageal cleft, neonatal, 1091, 1091f  
 Laryngomalacia, 738  
 Laryngoscopy, in gastroesophageal reflux, 1106  
 Laryngotracheoesophageal cleft, 739-740
- Laser therapy, for capillary malformations, 1527  
 LeBoyer technique, 161
- Lecithin-sphingomyelin (L/S) ratio, in respiratory distress syndrome, 691, 693  
 Left-to-right shunt lesions, in low-birth-weight infants, 889
- Legal issues, Human Genomic Project and, 183-184  
 Leigh disease, 249, 251-252  
 Length, of neonate, assessment of, 308-309  
 Lens dislocation, in inborn errors of metabolism, 220t
- Lentiginosities, 1531  
 LEOPARD syndrome, 945, 946t, 1531  
 Leprechaunism, infant, 52t
- Lethal congenital contracture syndrome, pulmonary malformations in, 603t  
 Lethargy, neonatal, differential diagnosis of, 571t
- Leucine, normal range for, in newborn period, 236  
 Leucovorin, for toxoplasmosis, congenital, 533t
- Leukemia  
   congenital, 1449-1453  
     cellular morphology and immunophenotype of, 1451  
     clinical manifestations of, 1449-1450, 1450f  
     differential diagnosis of, 1450-1451  
     epidemiology of, 1449  
     genetics and prognosis of, 1451-1452  
     in Down syndrome, 1452, 1453  
     laboratory manifestations of, 1450, 1450f  
     treatment of, 1452  
   lymphoblastic, acute, 1437  
   maternal, transplacental transmission of, 1441  
   "mixed lineage," 1437  
   myeloid, acute, congenital, teratogens causing, 1442  
   twin-to-twin transmission of, 1441
- Leukemia inhibitory factor (LIF), fetal loss and, 450  
 Leukocoria, 1547  
 Leukocyte count, in bacterial sepsis, 559-560  
 Leukocyte indices, in bacterial sepsis, 560, 560t, 561t
- Leukomalacia, periventricular, with high-frequency ventilation, 659
- Leukopenia, in inborn errors of metabolism, 222t
- Leukotrienes, fetal development and, 51t, 54  
 Levobupivacaine, for obstetric analgesia, 163  
 Levocardia, 780
- Levothyroxine, route, dose, adverse effects, and cautions regarding, 1562
- Leydig cell hypoplasia, 1391
- Lidocaine  
   for arterial puncture, 443  
   for obstetric analgesia, 163  
   for supraventricular tachycardia  
     fetal, 878t  
     neonatal, 883t  
   for ventricular tachycardia, neonatal, 885  
   route, dose, adverse effects, and cautions regarding, 1562
- Life expectancy, 1  
 Life-sustaining medical treatment (LSMT), withdrawal of, 17
- Li-Fraumeni syndrome, tumors associated with, 1440t
- Light  
   retinopathy of prematurity and, 1542  
   to reduce serum bilirubin production, 1248-1250
- Likelihood ratio, 558
- Limb malformation(s)  
   in inborn errors of metabolism, 220t  
   pulmonary malformations in, 604t  
   risk of, with chorionic villus sampling, 190
- Limb-girdle muscular dystrophy, neonatal, 996  
 Lindane, percutaneous toxicity of, 1474t
- Line infection(s)  
   *Candida*, in neonatal intensive care unit, 597-598  
   lipophilic organisms causing, in neonatal intensive care unit, 598-599
- Linear and whorled nevoid melanosis, 1528  
 Linear sebaceous syndrome, 1533  
 Linkage, dysequilibrium, 175  
 Linkage analysis, 173-174  
 Lipemia, in inborn errors of metabolism, 222t
- Lipid(s)  
   digestion of, 1075-1076  
   in parenteral nutrition, 1064t, 1064-1065

- Lipid emulsions, intravenous, nosocomial infections associated with, 581
- Lipogranulomatosis, Farber, 263t  
clinical features of, 267  
diagnosis of, 270  
etiology of, 267  
management of, 270
- Lipoid adrenal hyperplasia, congenital, 1370
- Lipolysis, adipose tissue, 1410, 1411t
- Lipopolysaccharide (LPS), 462
- Liquid ventilation, 659, 660, 718  
for congenital diaphragmatic hernia, 767
- Lissencephaly  
cobblestone, 958  
pachygyria and, 956f, 956-957, 957f  
with cerebellar hypoplasia, 957
- Listeria monocytogenes* infection  
meningitis due to, 569, 571t  
sepsis due to, 556-557, 564
- Lithium, maternal, 97
- Liver. *See also* Hepatic entries.  
as primary site of erythropoiesis, 1137  
development of, 1073, 1074f
- Liver disease  
coagulopathies of, 1158  
in inborn errors of metabolism, 224, 224t
- Lobar emphysema, congenital, 750
- Lobectomy  
for bronchopulmonary sequestration, 750  
for congenital cystic adenomatoid malformation of lung, 748

**NOTICE**

Neonatology is an ever-changing field. Standard safety precautions must be followed, but as new research and clinical experience broaden our knowledge, changes in treatment and drug therapy may become necessary or appropriate. Readers are advised to check the most current product information provided by the manufacturer of each drug to be administered to verify the recommended dose, the method and duration of administration, and contraindications. It is the responsibility of the treating physician, relying on experience and knowledge of the patient, to determine dosages and the best treatment for each individual patient. Neither the Publisher nor the editor assumes any liability for any injury and/or damage to persons or property arising from this publication.
