Cross-sectional analyses in postmenopausal women without cancer suggest both low physical activity and high caloric intake are related to higher fasting insulin levels (37). A number of interventional studies in at-risk and breast cancer populations also demonstrate that modification of lifestyle factors can lead to favorable changes in fasting insulin levels. The Nutrition and Exercise for Women (NEW) trial evaluated the impact of weight loss and increased physical activity on levels of insulin and other biomarkers in 439 overweight postmenopausal women and demonstrated that weight loss induced a 26% decrease in levels of fasting insulin, whereas exercise without weight loss induced a much more modest change in insulin levels (38). In contrast, two small studies in overweight, inactive breast cancer survivors demonstrated a 20% to 30% decrease in insulin levels with exercise alone (39,40).

TABLE 50-3

Select Studies of Insulin (and Related Factors) and Breast Cancer Prognosis

	Study	*N*	*Factor Measured*	*Results*
Insulin	Goodwin (31)	512	Fasting insulin	Highest vs. lowest quartile: **Recurrence:** HR 2.0 (95% CI 1.2–3.3) **Death from Any Cause:** HR 3.1 (95% CI 1.7–5.7)
	HEAL (33)	527	Insulin resistance (Homeostatic Model Assessment [HOMA])	Higher HOMA scores vs. lower **Breast Cancer Death**: HR 1.12 (95% CI 1.05–1.20) **Death from Any Cause:** HR 1.09 (95% CI 1.02–1.51)
C-peptide	Pritchard (43)	667	Nonfasting c-peptide	Higher c-peptide levels associated with worse event free survival in adjusted analyses (p <.05)
	HEAL (32)	689	Fasting c-peptide	1 ng/mL increase in c-peptide: **Breast Cancer Death**: HR 1.35 (95% CI 1.02–1.87) **Death from Any Cause**: HR 1.31 (95% CI 1.06–1.63)
Metabolic/Insulin Resistance Syndrome	Emaus (34)	1,364	Components: • BMI • Cholesterol • BP	Risk of mortality for: **BMI ≥ 30 kg/m^2 vs. <30 kg/m^2** 1.47 (95% CI 1.08–1.99) **High vs. low cholesterol** 1.29 (95% CI 1.01–1.64) **High vs. low BP** 1.41 (95% CI 1.09–1.83)
	Pasanisi (44)	110	Metabolic Syndrome: • Hyperglycemia • Hypertension • Visceral adiposity • High triglycerides	In patients with vs. without metabolic syndrome: **Recurrence**: HR 3.0 (95% CI 1.2–7.1)

The evidence linking insulin to breast cancer outcomes has led to significant interest in the drug metformin, an oral biguanide used in the treatment of type 2 diabetes. Unlike most agents used for this purpose, metformin decreases systemic insulin levels by inhibiting hepatic gluconoegensis and thus suppressing insulin levels. A number of observational studies have shown an association between metformin use and decreased cancer incidence and mortality (41), and a report from MD Anderson demonstrated a higher pathological complete response rate to neoadjuvant therapy for locally advanced breast cancer in diabetic patients treated with metformin compared with diabetics treated with other agents (42). This work has led to the MA-32 trial (41), which will test the impact of adjuvant metformin on rates of invasive disease free survival in early breast cancer. The study randomized 3,582 individuals with stage Ic to III breast cancer to 5 years of metformin (850 mg bid) or placebo. Embedded correlatives will further elucidate the role of insulin and other metabolic mediators in breast cancer prognosis. Enrollment was completed in January 2012 and follow-up is ongoing.

CONCLUSIONS

As the evidence linking lifestyle factors and breast cancer outcomes mounts, there is a growing desire on the part of many patients to make lifestyle changes after breast cancer diagnosis. However, given the relative paucity of available randomized data, and that most medical oncologists lack expertise in this area, many breast cancer patients do not receive any guidance to help make these changes.

Observational evidence suggests that women who are overweight or obese at the time of breast cancer diagnosis, and possibly those who gain weight during and after cancer treatment, appear to have a worse prognosis as compared with leaner women. Similar evidence suggests that women who are inactive after breast cancer diagnosis also have a poor prognosis compared with women who engage in modest amounts of physical activity. Randomized data suggest that lowering fat intake, or modest weight loss, is associated with a modest decrease in breast cancer recurrence, whereas increasing fruit, vegetable, and fiber intake does not appear to have an impact on breast cancer outcomes. Randomized trials are needed to further explore the impact of lifestyle change after diagnosis on breast cancer outcomes, and to determine the most important lifestyle factors and target populations for intervention.

MANAGEMENT SUMMARY

- Advocating weight maintenance for women with a BMI less than 25, and moderate weight loss for overweight and obese women, are reasonable goals for most breast cancer patients.

- Specific recommendations for individual patients will depend on the goals of the treatment plan (weight maintenance vs. weight loss), as well as the presence of comorbid conditions that could influence diet or activity level.
- A diet emphasizing complex carbohydrates and limiting refined sugars and fats, combined with moderate-intensity physical activity, could be considered for most breast cancer patients.
- The U.S. surgeon general recommends 30 minutes of moderate exercise five times per week as a general health measure, and this level of physical activity may be associated with improved survival in breast cancer patients.
- Ongoing studies will evaluate the role of insulin-lowering strategies to improve prognosis in breast cancer patients.

CHAPTER 51

Management of Menopausal Symptoms in Breast Cancer Survivors

Daniela Stan, Dawn Hershman, and Charles L. Loprinzi

CHAPTER CONTENTS

INTRODUCTION

In the United States today, approximately 2.7 million women live as breast cancer survivors, a number that is increasing. This increase is particularly attributable to women diagnosed with early stage breast cancer, who have a life expectancy similar to age-matched controls. The issues facing cancer survivors are multiple and unique as the long-term side effects of cancer treatment and of aging play an increasingly prominent role in the routine care of these patients. Of special concern are the short and long-term effects of sex hormone deprivation such as vasomotor instability, osteoporosis, sexual dysfunction, arthralgias, and weight gain; currently there are several trials investigating ways to counteract these effects.

The average age of onset of natural menopause is 51 years. However, breast cancer therapy often leads to both an earlier onset of menopause and the exacerbation of existing menopausal symptoms. Hormone replacement therapy (HRT) is frequently used to treat these problems in the general population, but concerns about its potential to increase the risk of recurrence in breast cancer survivors have forced physicians to utilize alternative treatments.

While long-term HRT has beneficial effects on women's bones and menopausal symptoms, this is more than offset by an increased risk of venous thromboembolic disease, breast cancer, stroke, cognitive decline, and coronary heart disease. In addition, the routine use of HRT in women does not appear to increase quality of life. These results support that long-term combination therapy with estrogen and progesterone cannot be recommended to most women at this time.

This chapter reviews current issues surrounding the acute and late effects associated with hormone deprivation in breast cancer survivors, and summarizes the scientific and therapeutic discoveries to date to identify optimal non-estrogenic treatments for individual patients.

VASOMOTOR INSTABILITY

Pathophysiology and Epidemiology

Hot flashes affect about three-fourths of all postmenopausal women, being the most commonly described health problem among this age group. Vasomotor instability usually begins 1 to 2 years prior to menopause and often persists for 6 months to 5 years after menopause. It is characterized by the sudden onset of a sensation of intense warmth that typically begins in the chest and progresses to the neck and face, often accompanied by anxiety, palpitations, profuse sweating, and red blotching of the skin. Hot flash symptoms can affect a woman's ability to work, her social life, her sleep pattern, and her general perception of health and quality of life.

Changes in circulating estrogen levels can induce abnormalities of the central thermoregulatory centers, resulting in hot flashes. Perspiration and vasodilation, classic mechanisms of heat loss controlled by the hypothalamus, are activated during a hot flash. In normal homeostasis, these mechanisms are activated to maintain core body temperature in a regulated range termed the "thermoregulatory zone." Complex neuroendocrine pathways that involve norepinephrine, estrogen, testosterone, and endorphins appear to govern regulation in the thermoregulatory nucleus and are possible sites where dysfunction may occur. In women undergoing natural menopause there is an association of hot flash symptoms with maternal history of hot flashes and with cigarette smoking.

Hot flashes are the most common reason women seek estrogen replacement therapy and, while estrogen effectively relieves symptoms for 80% to 90% of women who initiate treatment, women with a history of breast, ovarian, or uterine cancer, venous thromboembolism, coronary artery disease, or a family history of breast cancer comprise large populations for whom estrogen therapy may be contraindicated. Results from the Women's Health Initiative (WHI) and the Million Women Study, in combination with other reports, suggest that long-term combined estrogen and progesterone therapy results in an increased risk of breast cancer, coronary heart disease, venous thromboembolism, and stroke. Although HRT with estrogen alone did not appear to increase the risk of breast cancer in the WHI study (1), the controversy surrounding its effects has been very influential in clinical practice and has led to a significant decrease in the use of HRT in the last decade (2). For these reasons, many women assume that hot flashes are an inevitable symptom of being a breast cancer survivor.

In breast cancer patients, vasomotor symptoms negatively impact sleep, quality of life, energy, as well as compliance with therapy and satisfaction with treatment decisions. The cause of vasomotor symptoms in breast cancer patients can be the result of abrupt estrogen loss due to surgery or chemotherapy, the use of adjuvant hormonal therapy, discontinuation of hormone replacement therapy, or from natural menopause. Tamoxifen, the most commonly prescribed pharmacologic treatment for breast cancer over the past decade, is associated with hot flashes in more than 50% of users (3,4). Tamoxifen-associated hot flashes increase over the first several months of treatment and then gradually resolve (3). Postmenopausal women with a history of significant hot flashes prior to tamoxifen and a history of prior estrogen therapy use are likely to experience more severe hot flashes with tamoxifen therapy (3,5). Compared to tamoxifen, adjuvant therapy with aromatase inhibitors (AIs) results in a lower incidence of hot flashes.

In premenopausal women with breast cancer, adjuvant chemotherapy is frequently associated with temporary or permanent amenorrhea, due to toxicity to the ovary. The incidence of chemotherapy-induced ovarian failure depends on the regimen used, the cumulative drug doses, and the age of the patient. The rapid changes in hormone concentrations associated with chemotherapy can lead to more severe symptoms than those of natural menopause.

Hormonal Therapies

Studies investigating the use of HRT for menopausal symptoms in breast cancer survivors have led to varying results. Although a few small pilot studies found the use of HRT after breast cancer safe, more recently, two randomized placebo-controlled studies of HRT—The HABITS study (6) and the LIBERATE study (7)—were closed early due to evidence of an increased breast cancer recurrence in the HRT group. The HABITS study of estrogen alone or in combination with progesterone versus placebo included 434 participants and closed at 2 years due to safety concerns, after a 3.5 relative hazard ratio for recurrence was seen in the HRT versus placebo group. In the LIBERATE study, 3,148 participants were randomized to tibolone (a synthetic compound with weak estrogenic, progestogenic, and androgenic actions) versus placebo; similar findings of increased breast cancer recurrence in the tibolone group were seen after a median follow-up of 3 years. In contrast to these findings, the Stockholm trial of 378 participants given estrogen with or without progestin versus placebo did not show a difference in recurrence after 4 years of follow-up (8). In this study the use of progesterone was minimized, which could explain the different results.

Some reports suggest that low-dose transdermal estrogen might be safer to use in this population and is very effective for symptom relief in the general population. In breast cancer survivors this therapy was not studied.

Current guidelines recommend that providers avoid the use of HRT for treatment of hot flashes in this population (9). If such therapy is used, it should be done over the shortest time period and with the lowest effective dose.

Progesterone alone, via oral megestrol acetate (20 mg/day) or the long-acting intramuscular depomedroxyprogesterone acetate (DMPA), was also demonstrated to be highly effective in the management of hot flashes in breast cancer survivors, with a 75% to 80% reduction in their severity and frequency (10,11). Although minimal side effects are described during the treatment period, some women experienced withdrawal bleeding 1 to 4 weeks after discontinuation of treatment with megestrol acetate; the effects of the progesterone on hot flash reductions appear to be long-lasting. In a randomized trial comparing a single intramuscular dose of medroxyprogesterone acetate to venlafaxine, medroxyprogesterone acetate was more effective and appeared to have fewer short-term toxicities (12). It should be noted, however, that there are no long-term prospective data to establish the safety of progesterone analogs agents for women with hormone-sensitive breast cancer.

Nonhormonal Therapies

Newer Antidepressants

It is difficult to evaluate the efficacy of pharmacologic therapy for hot flashes with anecdotal reports alone, because of placebo effects. Multiple placebo-controlled trials demonstrate a 20% to 35% reduction in hot flashes with 4 weeks of placebo treatment. The most studied and effective nonhormonal pharmacological agents in the treatment of hot flashes are the newer antidepressants (selective serotonin reuptake inhibitors [SSRIs] and selective norepinephrine reuptake inhibitors [SNRIs]), as well as the anticonvulsants gabapentin and pregabalin.

Venlafaxine is thought to inhibit serotonin reuptake at lower doses and to induce a more profound inhibition of norepinephrine reuptake at higher doses. A double-blind, placebo-controlled trial with 191 breast cancer survivors randomized subjects to placebo or to one of three target venlafaxine doses (37.5 mg, 75 mg, or 150 mg daily) (13). After 4 weeks of treatment, the placebo groups had a 27% reduction in symptoms, versus 40%, 61%, and 61% reductions in the three venlafaxine groups, respectively. The side effects observed with venlafaxine include dry mouth, decreased appetite, nausea, and constipation (the latter only at doses of 150 mg/day).

A comparison study between venlafaxine and DMPA injections (12) showed a decrease in hot flashes by 55% with venlafaxine and by 79% with DMPA. In a crossover study comparing target dose venlafaxine ER 75 mg daily with gabapentin at a target dose of 300 mg three times daily, both treatments were equally effective (reduction in hot flashes scores by 66%), but venlafaxine was preferred by the patients (14). From these studies, it appears that venlafaxine adequately balances the symptom relief with the side effects. When venlafaxine is started, it should be started at 37.5 mg/day. When the drug is to be stopped, it should be slowly weaned down.

Another SNRI, desvenlafaxine, was found to be more effective than placebo, in two RCTs of women without cancer, at a target dose of 100 mg daily, with a starting dose of 50 mg daily for 3 days (15,16).

SSRIs are also effective for the treatment of hot flashes. A double-blind, randomized, placebo-controlled, crossover clinical trial demonstrated that fluoxetine reduces the incidence of hot flashes, although the reduction does not appear to be as great as that observed with venlafaxine (13,17). No significant toxicity was observed. Two placebo-controlled, double-blinded randomized trials found that paroxetine decreased hot flashes significantly more than did a placebo (18–20). However, both paroxetine and fluoxetine are potent inhibitors of P450 (CYP) 2D6, an enzyme involved in the metabolism of tamoxifen to its active metabolite, endoxifen, thus raising concerns about the coadministration of these drugs with tamoxifen, as they may lower the mean endoxifen level. Endoxifen seems to also be the active metabolite in hot flashes, from studies showing that decreased CYP 2D6 activity leads to less prominent hot flashes after starting tamoxifen (and also worse breast cancer prognosis) and that patients without hot flashes on tamoxifen have an increase in breast cancer recurrence compared to those with hot flashes. Early studies supported that venlafaxine did not appear to inhibit CYP 2D6 to any appreciable degree; however, this remains a topic of investigation. Further information regarding tamoxifen metabolism can be found in Chapter 55.

Three randomized, placebo-controlled trials evaluating sertraline (50–100 mg/day) for the management of hot flashes failed to reveal any substantial benefit from this drug. Citalopram, a potent and specific SSRI, however, was shown to be effective against hot flashes in an RCT of 254 patients randomized to placebo, 10 mg, 20 mg, or 30 mg of citalopram daily (21). Hot flashes were reduced by 20%, 46%, 43%, and 50% respectively. Side effects were minimal. The recommended dose of citalopram is 10 to 20 mg daily. Escitalopram, a stereo-isomer of citalopram, was studied in 205 postmenopausal women and found to be more effective than placebo (47% vs. 33%) in decreasing the frequency of hot flashes (22). The dose used in this study was 10 mg/day. Increasing the does to 20 mg/day after 4 weeks was recommended in nonresponders.

Two randomized, placebo-controlled clinical trials of some of these newer antidepressants (23,24) have been interpreted to be negative studies (25). Nonetheless, neither of these trials had hot flash diary data from a baseline period prior to the initiation of the study agents, making it impossible to determine how much hot flash reduction occurred. An individual patient pooled analysis of all the randomized trials looking at newer antidepressants that had baseline data available (26) demonstrates that they significantly decrease hot flashes ($p < .0001$).

Anticonvulsants and Other Centrally Acting Agents

Four placebo-controlled trials and a pooled analysis have confirmed the ability of gabapentin, a gamma aminobutyric acid (GABA) analogue, to decrease hot flashes (27–31). Although one study suggested that gabapentin was as effective as estrogen therapy (29), this does not appear to be the case, as all data are considered together. The recommended starting gabapentin dose is 300 mg/day, titrating up to 900 mg/day. Side effects include lightheadedness and sleepiness early on, which generally resolve with continued treatment. Pregabalin also appears to be helpful for hot flash management, per a RCT of 75 mg twice a day versus 150 mg twice daily versus placebo (32). It is recommended at a starting dose is 50 mg/day, with a target dose of 75 mg twice a day.

Clonidine decreases hot flashes to a moderate degree but is associated with side effects that limit its utility. Methyldopa and belladonna alkaloids do not appear to be very useful for hot flashes due to modest efficacy and unpleasant side effects.

Complementary and Alternative Agents

Despite anecdotal reports, the benefits of herbal therapies in clinical trials have been disappointing to date. Herbal treatments, such as black cohosh (*Cimicifuga racemosa*), ginseng (*Panax Ginseng*), evening primrose oil (*Oenothera biennis*), wild yam (*Dioscorea villosa*), and a standardized blend of 12 Chinese herbs have been prospectively evaluated, with minimal activity observed.

A randomized, placebo-controlled, crossover trial in 120 women found that vitamin E therapy decreased the average hot flash frequency by one episode per day (33), whereas more significant improvements in the vitamin E group were seen in a crossover trial (34). The low cost and minimal side effects of vitamin E make a trial of this agent (800 IU qd) one approach for individuals with mild symptoms that do not interfere with sleep or daily function. Therapy with vitamin E may increase the risk of heart failure in patients with vascular disease and diabetes mellitus but does not appear to affect the risk of cancers.

Studies of phytoestrogens in the treatment of hot flashes are also inconclusive. The isoflavone group (soy, red clover) was found to be no better than placebo in a meta-analysis of 17 placebo-controlled trials (25). Similarly, the lignants (found in flaxseed, whole grains, miller, fruits, and vegetables) did not help in hot flash treatment more than placebo in a randomized trial of flaxseed versus placebo bars (35). Furthermore, the long-term safety of pharmacologic doses of soy (90–400 mg/day) in patients with a history of breast or uterine cancer is not established.

The effect of nonestrogenic agents on hot flashes is similar in women with or without a history of breast cancer, irrespective of their use of tamoxifen (36).

Nonpharmacologic Interventions

Mind–body interventions, such as acupuncture, relaxation-training/paced respiration, mindfulness-based stress reduction, cognitive behavioral therapy (CBT), and yoga all appear to be beneficial in small uncontrolled studies, but systematic reviews of some of these interventions have been inconclusive, given the small size of the studies and methodological flaws (37). Hypnosis has been suggested to be helpful via pilot trials and a small randomized trial of breast cancer survivors, published recently.

Although acupuncture appeared to be effective in alleviating hot flashes in uncontrolled studies, when compared to sham acupuncture, there was no significant reduction in symptoms. These findings were confirmed by a recent meta-analysis of 11 randomized trials (38), although some trials do still report positive results. There may be a form of acupuncture that does help hot flashes, but one has not been clearly identified, to date.

Another promising intervention in alleviating hot flashes in small studies is a stellate ganglion block; larger studies are underway to further investigate its effect. A review of RCTs on exercise for hot flashes was not able to demonstrate a benefit for this approach. For mild hot flashes, interventions such as using a fan, lowing room temperature, wearing loose-fitting clothing, consuming cold drinks, and avoiding alcohol and spices can be suggested.

Other comprehensive reviews of the pathogenesis and treatment of hot flashes in breast cancer survivors are available (39–41). Table 51-1 provides a summary of the most active available therapies for hot flashes.

TABLE 51-1

Hot Flash Treatment Options

Treatment Option	*Efficacy (%)*[a]	*Comment*
Estrogen	85%	Breast cancer concern
Progesterone[b]	85%	Breast cancer concern
Antidepressants (e.g., venlafaxine, paroxetine, desvenlafaxine, citalopram, and escitalopram)	50%–60%	Do not use paroxetine or fluoxetine with tamoxifen
Gabapentin	50%–60%	

[a]Percentage of reduction from baseline after about 4 weeks, noting that a placebo decreases them about 20% to 30%.
[b]Megestrol acetate 20 to 40 mg/d orally or medroxyprogesterone acetate 400 mg intramuscularly once.

OSTEOPOROSIS

Definition and Pathophysiology

Osteoporosis is a metabolic bone disease characterized by low bone mass and microarchitectural deterioration of bone tissue, leading to enhanced bone fragility and a consequent increase in fracture risk. Decreased body mass index (BMI) is an important known risk factor for low bone mineral density (BMD) and osteoporotic fractures. A BMD that is 2.5 standard deviations below the young adult female mean value is used to diagnose osteoporosis. At menopause, women enter a 10-year period of accelerated bone loss, responsible for a 20% to 30% loss of cancellous bone and a 5% to 10% loss of cortical bone. Estrogen and testosterone play important roles in the regulation of BMD and bone health. In postmenopausal women, the conversion of adrenal androgens to estrogen by the enzyme, aromatase, leads to continued low levels of circulating estrogen, which may play an important role in calcium homeostasis through its effects on renal and GI absorption of calcium. Osteoporotic fractures are an important health hazard; women have an estimated 1-year mortality risk of 21% after a hip fracture.

Characteristics in Breast Cancer Survivors

Women with premenopausal breast cancer have higher than average rates of bone loss and fracture, with nonmetastatic breast cancer patients having a risk of vertebral fractures nearly five times that of the general population. Premature ovarian failure due to chemotherapy, estrogen blocking therapies, or ovarian ablation therapy, as well as direct effects of chemotherapy on bone, inactivity, use of corticosteroids, and inadequate intake of calcium and vitamin D can all contribute to the increased osteoporosis risk in breast cancer survivors.

The effects of tamoxifen, a selective estrogen receptor modulator with both agonist and antagonist activity widely used as adjuvant endocrine therapy in hormone-receptor-positive breast cancer, on BMD differ depending on the menopausal status of the patient at the time of treatment. The first study to look at the bone effects of tamoxifen versus placebo was conducted by Love et al. in 1992, on 140 postmenopausal breast cancer survivors, over 2 years (42). The mean BMD at the lumbar spine increased by 0.61% per year in the tamoxifen group and decreased by 1% per year in the placebo group. Other studies in postmenopausal women have confirmed this observation (43,44) whereas in premenopausal women tamoxifen therapy is associated with varying levels of bone loss. In a chemoprevention study of tamoxifen versus placebo in 179 women at high risk for breast cancer, premenopausal women treated with tamoxifen experienced a 1.4% decrease in BMD per year over the 3-year study, while the BMD increased 1.2% per year in postmenopausal women in the tamoxifen group (42,45). In a population-based case-control study of women older than 50 who suffered a first osteoporotic fracture, the use of tamoxifen was associated with a lower risk of fractures compared to controls (46). Treatment with tamoxifen also reduces markers of bone turnover in postmenopausal women.

Aromatase inhibitors (AIs) play a central role in the management of postmenopausal breast cancer, being superior to tamoxifen for disease-free survival and time to recurrence. They almost completely eliminate endogenous estrogen production, affecting bone metabolism in breast cancer patients. This abrupt decline in serum estradiol and estrogen in both postmenopausal healthy women and postmenopausal patients with breast cancer may dramatically affect bone turnover and loss.

The effect of AIs on bone mineral densities (BMDs) and bone turnover was measured in studies of adjuvant AIs in breast cancer survivors. In the ATAC (Anastrozole, Tamoxifen, Alone or in Combination) trial, a subgroup of 197 postmenopausal women receiving anastrozole or tamoxifen and 46 control patients with breast cancer who did not receive hormone therapy, were included in a bone substudy (47). At five years, therapy with anastrozole was associated with bone loss at the lumbar spine (–6.08%) and total hip (–7.24%) whereas the tamoxifen-treated group experienced an increase in the BMD (+2.77% at the lumbar spine and +0.74 at the total hip). Most of the bone loss at the lumbar spine was seen in the first 2 years of therapy with anastrozole, whereas it continued uniformly at the hip. The control group showed an increase in the BMD at the lumbar spine (+1.35%) and a slight decrease at the hip (–2.81%). The 10-year safety data from the ATAC trial (48) reported more fractures in the anastrozole vs. tamoxifen group (14.5% vs. 11.3%, OR=1.33, CI 1.15–1.55) only during active treatment (difference was accounted for by fractures of the spine, not the hip), after which the number of fractures was similar in the two groups. The bone remodeling markers mirrored the changes in BMD, with AIs causing a significant increase in bone remodeling compared to the tamoxifen and control groups. Similar findings were reported in bone subgroup studies of exemestane (49) and letrozole (50) in the adjuvant breast cancer setting. It is unclear to what degree the decrease in BMD seen with AIs represents the effect on bones of this class of medication versus a reflection of the beneficial effect of tamoxifen. When tamoxifen is taken out of the picture, such as in the MAP-3 trial of exemestane versus placebo for breast cancer prevention (51), the incidence of fractures at 3 years was similar between the groups, although a significant decrease in BMD was noted in the exemestane group in the bone substudy (52). These findings might be a reflection of exemestane's weak androgenic activity, which was postulated to have favorable bone effects (53). However, a pharmacodynamics trial of biochemical bone markers and parathyroid hormone levels did not show a significant difference between the three AIs (anastrazole, exemestane, and letrozole) (54).

Importantly, in all of the adjuvant and chemoprevention AI trials, none of the participants with normal BMD at baseline had osteoporosis at follow-up, leading the investigators to conclude that, although treatment with AIs is associated with accelerated bone loss over the treatment period, patients with normal BMD at baseline do not appear to require bone density monitoring beyond that of healthy women. Patients with osteopenia at baseline should have BMD monitoring and bone-protection strategies, but the effect on bone loss need not influence the use of AIs for breast cancer treatment (47).

Screening

The American Society of Clinical Oncology recommends BMD screening for breast cancer survivors at high risk for osteoporosis (advanced age, estrogen deficiency, treatment with AIs, history of fracture, family history of osteoporosis, low BMI, inadequate physical activity, cigarette smoking, excessive alcohol consumption) and treatment with bisphosphonates for those diagnosed with osteoporosis (55). A recent cost-effectiveness analysis of different osteoporosis screening schedules and treatment strategies in breast cancer patients receiving AIs has supported this recommendation as being the most cost-effective for society, with a cost of less than $100, 000 per quality-adjusted life year gained (56). Given the fact that 80% of the fractures in the general population occur in women with normal BMD or osteopenia, the World Health Organization has developed a tool to assess the 10-year risk of a fracture based on clinical risk factors for fracture (http://www.sheffield.ac.uk/FRAX/). Based on this tool, therapy for osteoporosis is recommended for women with osteopenia and a 10-year risk of hip fracture 3% or higher or of major osteoporotic fracture greater than 20% (57).

Treatment

In the general population, estrogen administration reduces bone turnover and the rate of bone loss, and thereby increases bone mineral density substantially in postmenopausal women. It is associated with a reduced risk of vertebral and possibly hip fractures. However, as soon as estrogen therapy is discontinued, BMD begins to decline at a rate similar to that observed before initiation of estrogen therapy. For women with a history of breast cancer, the use of estrogen to prevent bone loss has classically been considered contraindicated.

Similar to what was noted above regarding tamoxifen's effect on bones, another selective estrogen receptor modulator, raloxifene, also reduces the risk of osteoporotic fractures in postmenopausal women (58). The effects of this agent in premenopausal women are currently unknown. The advantages and/or disadvantages of using raloxifene in patients who had previously been treated with tamoxifen have not been clarified. When it was previously thought that there was a potential disadvantage for using tamoxifen for longer than 5 years (no longer a viable thought), physicians had raised concerns regarding raloxifene use in this situation.

Four bisphosphonates (alendronate, risedronate, ibandronate, and zolendronate) are approved for both the treatment and prevention of osteoporosis. Bisphosphonates are pyrophosphate analogues that are avidly adsorbed to bone surfaces. They reduce bone turnover by specifically inhibiting osteoclastic bone reabsorption and have demonstrated therapeutic efficacy in the treatment of hypercalcemia of malignancy, lytic bone disease associated with multiple myeloma, and mixed lytic and blastic bone metastases associated with breast cancer.

Alendronate and risedronate, the most extensively studied bisphosphonates, reduce vertebral and hip fractures by 50% in women with osteoporosis, and prevent bone loss in perimenopausal and postmenopausal women without osteoporosis at baseline. Clinical trials suggest that these drugs prevent bone loss as effectively as the recommended dose of estrogen in standard hormone replacement therapy regimens. In addition, unlike estrogen, these drugs can be discontinued without causing rapidly accelerated bone loss. However, they can trigger erosive esophagitis. Newer, more potent bisphosphonates include zoledronate and ibandronate. The preclinical safety (toxicology) profile of zoledronate is, in general, similar to that of other bisphosphonates, but this compound appears to produce fewer and/or less severe adverse events. In addition, these intravenous second- and third-generation bisphosphonates can be given every 6 to 12 months to achieve appropriate effects on bone loss.

The ability of intravenous bisphosphonates to restore bone in patients with osteolytic lesions associated with breast cancer or multiple myeloma is established. An 11% increase in lumbar spine bone mineral density was noted in patients receiving zoledronic acid at 2 mg or 4 mg; with the 4 mg/month dose being more effective (59).

Oral clodronate has been evaluated in two British studies of early stage breast cancer (60,61). Among these patients, most of whom also received chemotherapy and/or hormonal therapy, oral clodronate taken for 2 years was efficacious in preventing bone loss. By 1 year, BMD had fallen by 2.2% in the placebo group and had risen by 0.2% in the clodronate group. In a second trial in premenopausal women receiving chemotherapy with CMF, the clodronate and placebo groups differed in lumbar spine BMD by 3% at 1 year and by 3.7% at 2 years ($p < .01$). Among patients who developed ovarian failure, the lumbar spine bone loss in the clodronate group was 5.9%, versus 9.5% in the placebo group ($p < .001$). In both groups, the treatment was well tolerated with no differences in adverse events.

The use of bisphosphonates for primary osteoporosis prevention has recently undergone evaluation in premenopausal women, as they initiate adjuvant systemic breast cancer treatment. Delmas et al. evaluated an unconventional cyclic regimen of risedronate in women who had entered early menopause secondary to chemotherapy and who had completed chemotherapy an average of 15 months before randomization (62). Greenspan et al. evaluated weekly oral risedronate in patients who had completed chemotherapy an average of 3 years before randomization, and who were receiving other medications known to affect bone metabolism, such as tamoxifen and aromatase inhibitors (63). In both studies, BMD remained stable or increased in the risedronate-treated groups. Similarly, risedronate given at the time of initiation of AIs therapy resulted in a reduction of bone loss over time compared to placebo (64).

In addition, premenopausal women were randomized before initiation of chemotherapy in several studies. Saarto et al. randomized women to 1,600 mg of clodronate or placebo. At 1 year, the women in the placebo group sustained 4% bone loss at the lumbar spine, while BMD declined by only 1% in the clodronate treated women (65). Clodronate, however, is not available in the United States and is associated with gastrointestinal side effects. A second study randomized 40 premenopausal Lebanese women to pamidronate, 60 mg every 3 months, or placebo prior to initiating chemotherapy (66). In the placebo arm, lumbar spine BMD declined by approximately 3.2% by 12 months, and by 4% in the group that became amenorrheic. This loss was

prevented with pamidronate. Similar results have also been reported with the use of zoledronate at a dose of 4 mg every 3 months (67). However, initiating bisphosphonate therapy in young women who are at low risk of fractures with the goal of preventing short-term bone loss that may result in future fractures may not be necessary, beneficial or cost-effective, and from this perspective, it remains unclear when to intervene.

The timing of treatment initiation with bisphosphonates has been evaluated in postmenopausal women initiating AIs therapy. Although some studies have shown that up-front use of bisphosphonates in patients treated with adjuvant AIs preserves the BMD and improves disease recurrence (68), recent meta-analyses did not confirm a decreased risk of fractures (69) nor did they show improvement in survival, recurrence or bone metastases in this population (70). As a result, the optimal timing for the initiation of bisphosphonate therapy in postmenopausal women on aromatase inhibitor therapy also remains unclear (71).

The duration of the treatment with bisphosphonates also remains controversial. In the general population, given the small but important potential risks of therapy with bisphosphonates (atypical femoral fractures, jaw osteonecrosis, and esophageal cancer) and the evidence that extension of bisphosphonate therapy beyond 3 to 5 years does not further decrease fracture risk, the FDA has added an "Important Limitation of Use" statement to the labeling of bisphosphonates. The statement indicates that the benefits and risks of this therapy should be reassessed periodically and therapy be discontinued, unless the patient remains at an increased risk for fractures.

Another osteoclast inhibitor, denosumab, was recently approved by the FDA for treating postmenopausal osteoporosis, osteopenia in women treated with AIs, and breast cancer with bone metastasis. Denosumab is a monoclonal antibody that inhibits the receptor activator of nuclear factor kappa-B ligand (RANKL), thus inhibiting the formation, function and survival of osteoclasts, resulting in its bone-protective effects.

In postmenopausal women, denosumab, at a dose of 60 mg SQ every 6 months, improves BMD by 9.2% at the lumbar spine and by 4% at the hip (vs. 0% and –2%, respectively, for a placebo), as shown in the FREEDOM trial of 7,868 women with osteoporosis (72). In addition, this study found that denosumab statistically significantly reduces the risk of new radiographic vertebral fracture, hip fracture, and non-vertebral fracture, compared to placebo. When compared with alendronate, denosumab was slightly, but statistically significantly, superior in improving the BMD in 1,189 postmenopausal women with a baseline BMD of –2.0 or less (73).

Denosumab has also been studied for patients receiving AIs for nonmetastatic breast cancer; 252 breast cancer survivors with osteopenia and treated with AIs were randomized to placebo versus denosumab (60 mg SQ every 6 months). Lumbar spine BMD increased by 5.5% at 12 months and 7.6% at 24 months for denosumab, compared to a placebo, regardless of the duration of AIs therapy (74).

Bisphosphonates and denosumab are also approved for use in decreasing bone-related events in patients with breast cancer metastatic to the bone.

Other pharmacologic agents used to prevent and treat bone loss include calcium and vitamin D supplements. This includes calcium (total daily dose 1,000–1,500 mg, including dietary intake) and vitamin D (800 IU or more daily), which have been shown to reduce hip and vertebral fractures by 43% and 32%, respectively. Salmon calcitonin is approved for the treatment of osteoporosis, but is less efficacious than the bisphosphonates with respect to improvement of BMD and the reduction of fracture rates.

TABLE 51-2

Management Options for Prevention and Treatment of Osteoporosis

Lifestyle recommendations	Weight-bearing exercise Maintenance of ideal body weight No smoking Moderation of alcohol
Dietary nutrients	Calcium (1,200–1,500 mg/d, including dietary intake) Vitamin D (800–1,000 IU/d)
Bone-modifying agents	Bisphosphonates: zolendronate, alendronate, risedronate, or clodronate RANKL-inhibitor: denosumab
Selective estrogen receptor modifiers (SERMs)	Raloxifene or tamoxifen
Thyroid-derived hormone	Calcitonin

Smoking cessation and weight-bearing physical activity should also be strongly recommended to all women for osteoporosis prevention.

Table 51-2 reviews common therapeutic options for preventing and/or treating osteoporosis.

SEXUAL DYSFUNCTION

Sexual dysfunction occurs in up to 60% of breast cancer survivors and may be due to the effects of surgery, radiation therapy, or chemotherapy. Many women are hesitant to discuss sexual dysfunction with their health care providers; however, when questioned, 96% of women report at least one problem (75,76). In one study of breast cancer survivors, 64% of women reported decreased libido, 38% reported dyspareunia, 44% anorgasmy, and 42% lubrication problems. Sexual dysfunction tends to worsen over the first several years of treatment, but improves with longer follow-up.

While breast-conserving surgery has shown benefits over mastectomy with regard to body image, most studies find no difference between lumpectomy and mastectomy in regard to sexual functioning. A prospective evaluation of women during the first year after mastectomy or lumpectomy and studies of survivors evaluated 4 to 8 years after treatment failed to show a difference in sexual function or quality of life between groups (77). Age may be a significant factor in a patient's self-image and thus lumpectomy may have a different effect than mastectomy on quality of life for younger women. In these studies, however, the relationship of self-image to sexual function is not entirely clear.

Women who have been treated with adjuvant chemotherapy are 5.7 times more likely to report vaginal dryness, 5.5 times more likely to report dyspareunia, 3 times more likely to report decreased libido, and 7.1 times more likely to

report difficulty achieving orgasm. Younger women appear to be at increased risk of sexual dysfunction after receiving chemotherapy and the chemotherapy-induced sexual dysfunction appears to diminish over time such that, at more than 10 years out from treatment, sexual functioning is similar, regardless of whether they had received prior chemotherapy.

Hormonal therapy with tamoxifen does not appear to cause sexual dysfunction, despite tamoxifen being associated with vaginal discharge. Ganz et al. surveyed 1,098 breast cancer survivors 1 to 5 years after primary breast cancer treatment (75). The women who had been treated with tamoxifen (n = 305), after controlling for adjuvant chemotherapy, did not report more sexual function troubles. Comparing women on tamoxifen to a group of noncancer controls, Mortimer et al. likewise found no differences in sexual desire, sexual arousal, or the ability to achieve orgasm (75,78). Treatment of breast cancer using the GnRH agonist zoladex in combination with tamoxifen was associated with increased sexual dysfunction, in comparison to patients treated with zoladex alone; the reason for this is not clear. Interestingly, in this same study, tamoxifen as a single agent did not produce sexual dysfunction.

Therapy with AIs contributes significantly to sexual dysfunction in breast cancer survivors. In a QOL analysis of the ATAC trial anastrozole caused more vaginal dryness (16.3% vs. 8.4%), dyspareunia (17.8% vs. 7.5%) and decreased libido (15.8% vs. 8.5%) compared to tamoxifen (79), although tamoxifen caused more vaginal discharge and vaginal bleeding (80). Similar findings were reported on the TEAM (Tamoxifen Exemestane Adjuvant Multicenter) trial. Compared to nonusers, women on current therapy with AIs have more decreased libido, vaginal dryness, and unsatisfactory sex drive. Although all these factors are important causes of sexual dysfunction, the most consistent predictor of sexual satisfaction in women with breast cancer is the quality of their relationships (81).

Treatment of sexual dysfunction requires comprehensive assessment and intervention. Ganz et al. found a significant decrease in sexual dysfunction in women randomized to undergo a comprehensive assessment of menopausal symptoms by a nurse practitioner who screened for symptoms of vaginal dryness. If symptoms of sexual dysfunction were identified, recommendations for vaginal lubricants were provided along with individualized counseling and referral as indicated (82). Other data also suggest that vaginal dryness may play a significant, if not central, role in sexual dysfunction after chemotherapy. Vaginal lubricants (Astroglide) and vaginal moisturizers (KY Jelly, Replens) can be used to treat symptoms of dryness or for lubrication, and may indirectly improve other sexual problems as well. A prospective study in breast cancer survivors reported that women using Replens had decreased vaginal dryness equal to that of women using a water-soluble lubricating placebo; however, a decrease in dyspareunia was significantly better with Replens than with the placebo lubricant (83).

Topical estrogen preparations appear to alleviate vaginal dryness more effectively than do nonestrogenic vaginal preparations. At least three formulations exist: Estring is an estrogen-impregnated ring that is inserted into the vagina, where it releases small amounts of estrogen over a 12-week period. Another is a vaginal estrogen tablet called Vagifem. Last, a small dose of Premarin vaginal cream can be helpful. Nonetheless, there is evidence of some absorption of virtually all vaginal estrogen products and newer data, showing that decreasing postmenopausal estrogen levels by AIs leads to improved breast cancer outcomes, makes clinicians concerned about the use of any vaginal estrogen products. The use of estrogenic vaginal preparations in women taking AIs doesn't make much sense, as the goal of AI therapy is to induce low estradiol levels. Given these concerns, nonhormonal vaginal preparations should be used as first line of therapy in breast cancer survivors, while the use of the hormonal agents should be short term and limited to women who are not receiving an AI and who have severe refractory symptoms.

Testosterone improves sexual desire and the frequency of sexual activity in women after surgical menopause or with sexual arousal disorders. A phase III randomized, placebo-controlled crossover clinical trial studied sexual desire in postmenopausal women with a history of cancer, who had no current evidence of disease, had reported a decrease in sexual desire, and had a sexual partner. Eligible women were randomly assigned to receive 2% testosterone in Vanicream, for a testosterone dose of 10 mg daily, or placebo Vanicream for 4 weeks and were then crossed over to the opposite treatment for an additional 4 weeks. Women who were on active testosterone cream had higher serum levels of bioavailable testosterone than women on placebo. However, the mean intrapatient libido change from baseline to weeks 4 and 8 was similar on both arms (84). The reason that this study was negative, while other similar studies have been positive, may be because all of the other positive studies involved women who were premenopausal or were receiving ongoing estrogen therapy, while the current study did not include women receiving concurrent estrogen therapy. Thus, it appears that testosterone, when used without concurrent estrogen, does not improve libido.

ARTHRALGIAS

Musculoskeletal symptoms commonly occur in postmenopausal women and are a frequent side effect of therapy with AIs, a standard of care for postmenopausal women with both early and late stage hormone-sensitive breast tumors. In large adjuvant trials involving AIs, the incidence of musculoskeletal disorders was 20% to 40%, and nearly 5% of patients discontinued therapy in the AI group because of toxic effects.

Recent studies have shown that AI arthralgias are more prevalent than originally reported from clinical trials. In a cross-sectional survey of 200 consecutive postmenopausal women receiving adjuvant AI therapy for early-stage hormone-sensitive breast cancer, 94 (47%) reported having AI-related joint pain and 88 (44%) reported AI-related joint stiffness. Being overweight (body mass index of 25–30 kg/m^2) and prior tamoxifen therapies were inversely associated with AI-related joint symptoms. Patients who received taxane chemotherapy were over four times more likely than other patients to have AI-related joint pain and stiffness (85). Not all studies, however, have noted an association with taxanes therapy. In clinical practice, 10% to 20% of women treated with AIs decide to discontinue this therapy due to arthralgias. AIs-associated arthralgias seem to improve within 6 months of therapy and some studies support that breast cancer survivors who experience arthralgias have a better prognosis. Women who reached menopause within 5 years of the start of AIs are more likely to experience AI-related musculoskeletal symptoms than whose menopause started more than 10 years from AI therapy (86).

The exact mechanism of AI-related arthralgia is unclear, but is thought to likely be related to estrogen deprivation.

It is postulated that estrogen has nociceptive protective effects and thus, a significant drop in the estrogen levels contributes to a decreased pain threshold. In addition, fluid buildup within the joints and tendons might contribute to the arthralgias seen with AI therapy and account for the increased incidence of carpal tunnel syndrome seen in these women.

No large prospective studies have defined an optimal treatment or prevention of AIs-related arthralgias. Nonsteroidal anti-inflammatories, acetaminophen, and opioids may have some efficacy for this condition in retrospective reports from the ATAC trial (87) and in small uncontrolled studies. A prospective, randomized, placebo-controlled study of vitamin D for AI-related arthralgias was reported in abstract form, with positive results (88). A large placebo-controlled study on vitamin D in arthralgias associated with AIs in underway (NCT00263185).

A prospective, randomized, placebo-controlled trial supported that testosterone could effectively treat AIs-associated arthralgias (89) which has led to the development of an Alliance cooperative group placebo-controlled trial. In addition, a Southwest Oncology Group placebo-controlled trial has been developed to look at an omega-3-fatty acid preparation for alleviating this problem.

In a randomized, sham-controlled, double-blind study of acupuncture in women with AI-associated arthralgias, the true acupuncture group had significant improvements in joint pain and stiffness, which was not seen in the sham-acupuncture group (90). Other strategies that might help alleviate the musculoskeletal side effects of the AIs include switching to another AI, taking a drug holiday or switching to tamoxifen, if clinically safe. The effects of switching between classes of AIs (steroidal vs. nonsteroidal group) has not been well studied.

WEIGHT GAIN

Weight gain is a common side effect for women who receive adjuvant chemotherapy. Gains in weight are typically around 2.5 to 6.2 kg, but can be up to 25 kg and may be influenced by menopausal status; nodal status; and the type, duration, and intensity of treatment. Although there is some variability in the literature, in one study, the mean change in weight of 100 women treated with chemotherapy was +3.68 kg ($p < .001$); 64% of patients gained more than 2 kg in weight, approximately one-third of patients gained more than 5 kg, and 6 patients gained more than 10 kg. The majority of these patients (85%) received steroids as antiemetics, but no effect of steroid dose was seen on the level of weight change (91). Weight gain appears to be greater among premenopausal women; those who are node-positive; those receiving higher dose, longer duration, multiagent regimens; and those who enter into menopause. Psychosocial research suggests that weight gain has a profoundly negative impact on the quality of life for patients with breast cancer.

Weight gain also leads to an increased risk of comorbid conditions such as cardiovascular disease, gallbladder disease, diabetes, and orthopedic complications and is associated with an increased mortality. In a prospective cohort of 4,000 breast cancer survivors, every 5 kg of weight gain after treatment was associated with a 12% increase in all-cause mortality, 13% increase in breast cancer–specific mortality, and a 19% increase in cardiovascular disease mortality (92) findings confirmed in other trials. However, other large studies did not show a correlation between posttreatment weigh gain and mortality (93).

Limited research conducted in this area does not support overeating as a major cause of weight gain among breast cancer patients. Mean body weight increases significantly during chemotherapy, primarily due to an increase in mean total body and mean fat mass and a decrease in fat free mass and leg lean body mass. Both chemotherapy and radiation were associated with development of sarcopenic obesity (gain of fat mass without gain of lean tissue mass). Adjuvant treatment with tamoxifen or AIs was not associated with weight gain (94). Weight gain in the presence of lean tissue loss or the absence of lean tissue gain supports the need for interventions focused on exercise, especially resistance training in the lower body, to prevent undesirable weight gain (95).

Premenopausal women starting adjuvant chemotherapy for breast cancer were randomized to a control group, or to receive monthly counseling by a dietitian aimed at weight maintenance. The median weight gains at 6 months after the start of chemotherapy were 2.0 kg in the dietitian counseling group versus 3.5 kg in the control group (statistically insignificant differences). The median changes in average caloric consumption were reductions of 120 versus 46 cal/day on weekdays and 196 versus 20 cal/day on weekends for the counseling and control groups, respectively. Routine prospective dietitian counseling aimed at weight maintenance thus appeared to produce small but statistically insignificant reductions in both caloric consumption and weight gain in this group of patients (96).

Caloric restriction, either alone or in conjunction with other interventions such as exercise and psychological support or counseling through Weight Watchers, has led to successful weight loss in this population. A recent study of home-based diet and exercise intervention in older overweight or obese, breast, prostate, and colorectal cancer survivors showed decreased weight and increased functional capacity (97). Similarly, a home-based exercise intervention during the first 4 cycles of chemotherapy in 78 women with breast cancer demonstrated that women who adhered to the exercise program maintained their body weight, while nonexercisers steadily gained weight ($p < .05$) (98). Finally, in a small randomized crossover study of a commercial-based exercise program (Curves), 6 months of the intervention resulted in moderate weight loss, but weight loss was not maintained postintervention (99).

However, it is not clear whether promoting weight loss impacts the disease outcomes (100). A large, multicenter trial (the ENERGY trial) of weight loss (through diet, physical exercise, behavioral strategies, cognitive restructuring social support, self-nurturing) in 2,500 breast cancer survivors is underway to further investigate this issue. Until more scientific evidence becomes available, women who are diagnosed with breast cancer should be advised to follow the general exercise recommendations of 30 minutes or more on most of the days of the week and follow a healthy diet, high in low-calorie density foods such as vegetable and fruits and low in fats and refined sugars and to maintain a healthy weight (100,101).

CONCLUSION

As the population of breast cancer survivors grows, it has become increasingly important to develop strategies to prevent and treat both short-term and long-term complications from breast cancer treatment. Advances in this area may improve the quality of life of the almost 3 million breast cancer survivors in the United States alone.

MANAGEMENT SUMMARY

- Nonhormonal means of treating hot flashes are available, including the use of antidepressants (e.g., venlafaxine, desvenlafaxine, citalopram, escitalopram, and paroxetine) and gabapentin.
- Paroxetine and fluoxetine should not be used in patients taking tamoxifen.
- Osteoporosis is a common problem in women with a history of breast cancer, primarily related to estrogen deprivation.
- Standard measures for preventing and treating osteoporosis should include adequate calcium and vitamin D intake and weight-bearing exercise.
- Bone-modifying agents should be used in patients with substantial osteopenia and osteoporosis.
- While bone-modifying agents can attenuate bone loss from chemotherapy-induced ovarian suppression or aromatase inhibitors, routine use of these in clinical practice for osteoporosis prevention is not yet recommended. Although some clinicians use these medications in selected patients, most would recommend routine surveillance with bone mineral density testing.
- While sexual dysfunction is common in women with breast cancer, testosterone, in the absence of estrogen, does not alleviate this problem.
- Vaginal dryness can be treated with nonestrogenic vaginal lubricants or local estrogen therapy, although there are some safety concerns regarding the latter except for patients on tamoxifen which remains effective even with the high estrogen levels in premenopausal women.
- Aromatase inhibitor-induced arthralgias are common, but there is no good established therapy for this problem.
- Weight gain is common after a diagnosis of breast cancer treatment and is managed by counseling the patient before the start of therapy, by decreasing caloric intake, and by increasing caloric output (i.e., exercise).

CHAPTER 52

Long-Term and Late Effects of Primary Curative Intent Therapy: Neurocognitive, Cardiac, and Secondary Malignancies

Rena D. Callahan and Patricia A. Ganz

CHAPTER CONTENTS

The number of women living in the United States with a history of breast cancer has been rising and is estimated to be over 2.8 million (1). Every year, new treatments and refinements of existing treatments are incorporated into the armamentarium against breast cancer. Advances in therapy have led to decreases in breast cancer mortality, and are partly responsible for the large number of survivors. While efficacious, many treatments are associated with persistent difficulties that are especially impactful for those who are long-term disease-free survivors (2,3). Among the most feared and disabling are cognitive and cardiac dysfunction. Rarely, breast cancer treatment results in a new, second cancer. The ability to better characterize these treatment-related consequences, specifically the incidence, etiology, pathogenesis, and risk factors for development, will facilitate the design of effective preventive strategies and/or therapeutic interventions in the future. To this end, we review what is known about these long-term and late effects of breast cancer treatments, and where appropriate, discuss strategies for prevention and treatment.

NEUROCOGNITIVE EFFECTS OF BREAST CANCER TREATMENT

Etiology and Setting of Cognitive Dysfunction

Cognitive complaints are extremely common during adjuvant chemotherapy, and may be caused by anxiety, depression, supportive care medications (e.g., anxiolytics, steroids, and sedatives), or by the acute effects of cancer therapy such as fatigue. However, for the majority of women, these acute changes resolve in the months following the end of treatment (4). What is more concerning is the persistence of difficulties in cognitive functioning that affect work, self-management, and caring for others that have been identified for 20 years, as something called *chemobrain* (5). Chemobrain may be a misnomer, since the manifestations that include memory impairment and difficulty with attention and concentration are also seen in breast cancer patients who have not received chemotherapy. A more inclusive term to describe these manifestations is *cancer- or cancer-therapy-associated cognitive change* (6).

Across clinical studies of treatment associated cognitive dysfunction, the incidence varies greatly, ranging between 15% to 61% (7,8) and can be seen in association with chemotherapy and with endocrine therapy alone. Additionally, subtle cognitive impairment is present in many patients prior to treatment (9–11) and could reflect postsurgical systemic changes or psychological effects on the brain associated with the cancer diagnosis. In one study, 22% of patients with stages I to III invasive breast cancer scored "lower than expected" on cognitive testing prior to chemotherapy compared with the absence of such findings in patients with stage 0 breast cancer (12).

It has been difficult to accurately assess the scope of the problem due to heterogeneity in study design, including patient population and measurement instruments (13). Early studies were cross-sectional in design, and although comparison groups were available, it was difficult to assess causal attribution (14–16). Subsequent studies were designed to clarify the epidemiology of chemobrain, with assessments of neurocognitive function before and after treatment, at several timepoints, and using a concurrent control or comparison group. A recent meta-analysis of multiple posttreatment studies of breast cancer patients concluded that there were small, but significant differences in verbal abilities and visuospatial functioning in these survivors who had been treated with standard dose adjuvant chemotherapy (17).

The mechanism by which cancer treatment leads to cognitive dysfunction is not well understood. Additionally, there may be interplay of various mechanisms that collectively impair cognitive functioning. There are excellent reviews of this topic that the reader should consider that are beyond the scope of this chapter (18–20). However, in the text that follows, we highlight some of the findings from various studies that relate to cancer-associated cognitive dysfunction.

Risk Factors for Cognitive Dysfunction

There are a number of potential risk factors that interact with each other or work independently influencing cerebral function in the setting of early breast cancer treatment. Ganz and colleagues (21) have recently proposed a breast cancer specific model as part of their Mind Body Study (see Fig. 52-1). Below, we discuss how these factors may be influencing cognitive dysfunction in posttreatment breast cancer survivors.

Psychosocial Factors: Both the diagnosis and treatment of breast cancer result in psychological distress. The association of depression and deterioration in cognitive performance has been well described, and when severe is termed, *pseudodementia* (22). For the breast cancer patient, emotional factors can contribute to, but alone cannot explain the treatment-associated cognitive decline. In a prospective study of 41 women with breast cancer and without depression at baseline, who were followed prior to and during chemotherapy treatment, the objective cognitive decline seen was independent of emotional factors (7). However, the development of depression and anxiety did correlate with a self-reported decline in cognitive functioning, even when objective performance remained stable (7). In a report of the Cognitive Impairment in Therapy of Breast Cancer (COGITO) study (23), a validated battery of 12 cognitive tests, self-reports on cognition and emotional state, were assessed prior to and up to 1 year postchemotherapy treatment. In this study, depression and the personality trait negative affectivity predicted for self-reported cognitive impairment. However, there was no statistically significant association between self-reports and objective measures of cognitive changes (23). While asynchrony between self-report and formal neurocognitive testing has been observed in some studies, a recent report by Deprez et al. identified concordance between self-report, neurocognitive testing, and white matter tract changes in a prospective, observational study of women initiating chemotherapy (24). Similarly, in a long-term cross-sectional study comparing controls and breast cancer survivors who had been treated with chemotherapy (25), executive function self-report difficulties corresponded to decreased frontal activation on MRI as well as poorer performance on neurocognitive tests. These imaging studies, with examination of domain-specific cognitive complaints and relevant NP tests, suggest that it is possible to identify neurophysiological correlates of these subjective complaints (25,26).

Genetic Susceptibility: There has been considerable interest in establishing potential genetic vulnerability to the development of cognitive dysfunction after breast cancer treatments. Initial interest has focused on risk factors common for dementia in older adults. In a cross-sectional evaluation of long-term survivors of breast cancer and

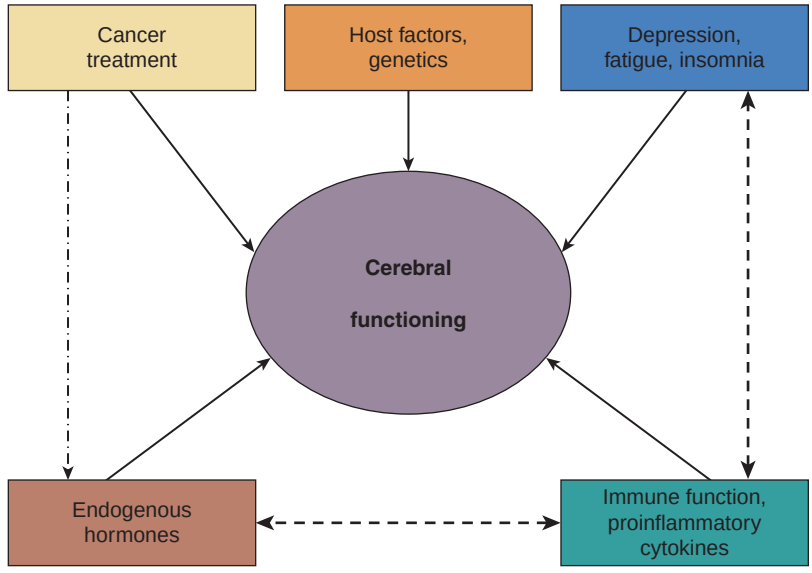

FIGURE 52-1 Risk factors for treatment-associated cognitive dysfunction.

lymphoma, Ahles et al. (27) found an association between poorer neuropsychological performance and the presence of the apolipoprotein (APOE) E4 allele. This was significant for visual memory and spatial domains, with a trend toward lower scores in the psychomotor domain, when E4 carriers were compared to noncarriers among the survivors.

In another study of breast cancer survivors, Small et al. (28) examined single-nucleotide polymorphisms (SNPs) in the catechol-*o*-methyl transferase (COMT) gene, which is involved in the metabolism of catecholamines through the methylation of dopamine, an important neurotransmitter. The valine version (val allele) of the gene is more active than the methionine (met allele), and individuals who are homozygous for the val allele are thought to metabolize dopamine more rapidly and thus have lower levels available than those with the met allele, potentially modulating the dopaminergic tone in the frontal cortex. In their study (28), breast cancer patients who had the *COMT*-val allele who received chemotherapy were found to have poorer neuropsychological performance on attention, verbal fluency, and motor speed in comparison to breast cancer patients who were *COMT*-met homozygotes.

In our work examining SNPs in the promoter region of several proinflammatory genes, we have found an association between cognitive complaints and the TNFα 308 G > A polymorphism (p = .055), and for a genetic risk index among polymorphisms in the *IL-1β* –511 C>T (rs16944), *IL6* -174 G>C (rs1800795), and *TNF* –308 G>A (rs1800629), p = .016) (28a). An additive genetic risk score was computed by summing the number of high expression alleles (0/1/2) across all three polymorphisms, reflecting the potential for interaction among multiple SNPs in leading the risk for a persistent elevation in proinflammatory cytokines as a result of cancer treatment. While this has been most extensively studied in the setting of post-treatment fatigue (29), uncontrolled systemic inflammation may also be affecting neurocognitive processes (see below).

Inflammatory Processes: A potential etiologic factor in cognitive decline is systemic inflammation. Proinflammatory cytokines have been found to be associated with cancer symptoms as well as age-related cognitive decline (30,31). Tumor necrosis factor alpha (TNFα), a cytokine involved in the inflammatory response, was elevated in a study of patient with Alzheimer's dementia (32). In addition to its role in inflammation, TNFα may play a regulatory role in mediating synaptic function in the brain (33). Thus, elevated circulating levels of TNFα from systemic inflammatory processes are implicated in the pathogenesis of Alzheimer's dementia and possibly other forms of cognitive dysfunction. In mice treated with doxorubicin, increased levels of TNFα in serum and brain tissue have been reported (34). Analysis of the first 93 patients of a prospective, longitudinal study of breast cancer patients who had been treated with surgery, radiation, and chemotherapy revealed increases in TNFα among those who reported cognitive dysfunction (21). In this study, patients were enrolled after chemotherapy, surgery, and radiation and monitored with neuropsychological tests and bloodwork including markers of inflammation. Of the inflammatory cytokines tested (IL-1ra, sTNF-RII, CRP, and IL-6), only sTNF-RII was elevated at baseline in those with memory complaints. Additionally, there was a statistically significant correlation between decrease in memory complaints and decline in levels of sTNF-RII (21). Another recent study in long-term breast cancer survivors (35) found an association between increased IL-6 and TNFα and decreased hippocampal volume, increased cognitive complaints, and poorer verbal memory test performance compared to a healthy control group. These emerging data suggest a potential inflammatory etiology for cognitive dysfunction in breast cancer patients and survivors.

Hormonal Effects and the Brain: Endocrine therapy has been implicated in therapy-associated cognitive decline among breast cancer patients. Additionally, endocrine effects of chemotherapy may play a role in cognitive impairment after treatment. In a prospective, longitudinal study of women with early-stage breast cancer, the ability to perform various neuropsychological "tasks" was assessed before and after treatment (36). Women who experienced chemotherapy-induced amenorrhea were more likely to show a decline from baseline in multiple tasks (36). Endogenous estrogen appears to play an important role in cognitive function, especially with respect to verbal memory. It has been shown that estrogen receptors are concentrated in the hippocampus, which is involved in cholinergic neurotransmission to areas of the brain involved with memory and learning. A second potential mechanism by which estrogen is neuroprotective lies in its ability to relieve oxidative stress by scavenging oxygen free radicals and reducing the formation of reactive oxygen species (37). A third mechanism by which estrogen affects cognition is via effects on telomeres. Telomeres are DNA protein structures that form caps on the ends of chromosomes, which results in genomic stability. During the process of aging, telomere length shortens. This increase in genomic instability may contribute to various age-related phenomena, including decline in cognitive ability (38). One study of 53 postmenopausal women on 1 year of hormone replacement therapy found that duration of endogenous estrogen exposure (length of reproductive years) was correlated with longer telomere length and decreased telomerase activity. Interestingly, duration of exogenous estrogen exposure did not show the same effects (39). However, in another study of 393 community-dwelling women aged 55 to 89 years who were not using replacement estrogen, there was no relationship of endogenous estrogen levels to higher performance tests of cognitive function, including the mini mental status examination (MMSE) (40).

The role of medications that alter estrogen levels in the body in cognition is unclear. The Women's Health Initiative Memory Study (WHIMS) assessed annual MMSE scores in 4,532 postmenopausal women enrolled in the larger WHI study who were over age 65 years and free of probable dementia at baseline (41,42). After a mean follow-up of 4.2 years, no significant improvement in global cognitive function was seen with combined estrogen–progestin therapy compared with placebo (41). In addition, more women in the combined hormone therapy group had clinically significant declines in MMSE scores compared with placebo (6.7% vs. 4.8%, respectively). A similar decline in cognitive ability was shown in women taking estrogen without progestin (43). This analysis was not able to assess the relationship of timing of estrogen replacement to cognitive decline, which is important in interpreting the significance of these data. Estrogen exposure may have differential effects depending on timing in relation to menopause. The critical window hypothesis posits that estrogen serves a neuroprotective role in perimenopause, but has neutral, and even detrimental effects later in the menopausal transition (44). One mechanistic explanation is that "healthy cells," such as those neurons in the younger female brain, derive benefit from estrogenic effects, whereas the age-damaged neurons of older women do not (45).

Evidence for Brain Abnormalities after Cancer Treatment

Neuroimaging has been utilized to define structural and functional correlates of cognitive function. Treatment-induced memory loss may be attributable to damage to the frontal lobes involved in executive function and the hippocampus, important for memory. Alterations in cerebral blood flow during neuropsychological testing have been observed in patients 5 to 10 years after adjuvant chemotherapy treatment (46). In this cross-sectional comparison study, the alteration was most marked in the inferior frontal gyrus, an area of the brain involved in memory processing, and was most marked in patients who had received both chemotherapy and tamoxifen. In a recent prospective, pretreatment study using MRI in patients with breast cancer treated with chemotherapy compared to breast cancer patients without chemotherapy and healthy controls, McDonald and colleagues (47) observed decreased gray matter density in the bilateral frontal, temporal, and cerebellar regions and right thalamus in both cancer groups that was most prominent after chemotherapy. These changes partially recovered, at 1 year posttreatment. Another prospective study demonstrated changes in white matter detected by magnetic resonance diffusion tensor imaging after chemotherapy treatment (24). White matter abnormalities were not seen at baseline in any group or in patients with breast cancer who did not receive chemotherapy. And in a more recent prospective pretreatment longitudinal study using functional MRI, with similar comparison groups, the investigators observed baseline frontal lobe hyperactivation during working memory tasks in cancer patients versus healthy controls (48). The cancer patients also exhibited a decline in frontal activation 1 month after completion of chemotherapy or at a similar interval for those patients who did not receive chemotherapy. One report of identical twins, one with breast cancer who received chemotherapy and the other without breast cancer, revealed marked differences in structural and functional MRI (49). The twin with breast cancer exhibited greater white matter volume, which is also seen in patients with Alzheimer's dementia. On functional MRI, she showed a greater spatial extent of brain activation than her untreated twin, a feature seen as a compensatory mechanism in patients with underlying brain dysfunction (49–51). Taken together, all of these studies provide increasing support for both structural and functional brain changes that are associated with chemotherapy treatment, along with evidence of both subjective and objective measures of impaired cognitive function in the patients who have been studied (26).

Strategies for Prevention and Treatment

Because the specific causal factors for cancer-related cognitive dysfunction are not well defined, preventive strategies have been difficult to develop. In addition, breast cancer adjuvant therapy has been shown to provide substantial survival benefit, and thus avoidance of therapy to prevent this side effect does not seem warranted at this time. Further, identification of at-risk populations has been difficult, although the earliest studies of chemotherapy-related cognitive problems were associated with the historic cytoxan, methotrexate, and 5-fluorouracil (CMF) regimen, which appears to have had long-lasting effects on cognitive function and brain structure (52–54). This regimen might be avoided given these problems, while uncertainty remains about the specificity of harms from regimens that are currently in common use in the adjuvant setting.

Thus, the few treatment approaches that have been developed focus on management of symptoms. Cognitive behavioral therapy has shown promise in smaller trials and is now being explored in larger-scale trials. In a pilot study of a brief cognitive behavioral intervention, improvements in cognitive function, quality of life, and standard neuropsychological test performance were observed (55). This intervention was further developed and evaluated in 40 patients with early-stage breast cancer. The study was randomized with a waitlist-control group. Postintervention, there were significant improvements in verbal memory and quality of life but not for cognitive complaints (56). A recent study examined a group-based cognitive intervention in 23 cancer survivors, compared to 9 waitlist-control cancer survivors and to 23 adults without a history of cancer. In comparison to the control groups, the intervention group demonstrated improvements in cognitive functioning, memory, and visuospatial function that were maintained over 3 months (57). Finally, a randomized waitlist-control trial, which included a computerized task, evaluated two different cognitive training interventions: speed of processing and memory training (58). Both interventions improved objective and perceived cognitive function, symptom distress, and quality of life. Interestingly, the speed of processing training resulted in transferred benefits on memory tests.

It is unclear whether medications have a role in the treatment of cognitive dysfunction. A randomized study was conducted to evaluate modafinil for the treatment of fatigue in patients posttreatment for breast cancer. Secondary analysis of the study to assess for modafinil effect on cognitive function was performed. Improvements in memory and attention skills were seen in the group treated with modafinil. These findings must be viewed with caution given that this study was designed to evaluate treatment of fatigue (59). While the aforementioned cognitive interventions hold promise, larger trials inclusive of a wider cancer population are necessary to establish effective treatment and prevention protocols for therapy-associated cognitive dysfunction.

Summary

As with many late effects of cancer treatment, it is sometimes difficult to assess how much of what is seen in long-term survivors is a direct effect of the cancer treatment or is a manifestation of normal age-related changes. This is certainly the case for cognitive dysfunction, which is common in the aging population. However, when one observes a midlife woman who was previously engaged in high-level intellectual activities who can no longer perform those tasks in the same way, and has great difficulty managing everyday activities, one must acknowledge the likely connection between treatment exposures and the outcomes. The perplexing problem for the clinician is the fact that this problem is apparent only in a handful of patients who receive the very same treatment regimens. Elucidating the mechanisms by which some women are susceptible to this complication of cancer treatment and others are not is now our main challenge. As with all aspects of cancer treatment, the patient or host meets the disease with a variety of personal risk factors and protective factors that will interact with the cancer treatment. Factors such as cognitive reserve may be critical in determining who will experience this problem. Research advances of the past decade and studies currently underway should provide greater precision in identifying vulnerability as well as developing preventive interventions. In the meantime, we should avoid exposing patients to treatments that are not evidence based or medically indicated, given the potential risk for this long-term effect of treatment.

CARDIAC EFFECTS OF BREAST CANCER TREATMENT

The cardiotoxicity of breast cancer therapy has a major impact given the large number of women treated with adjuvant therapy who have excellent long-term survival. This includes older women who may have preexisting subclinical cardiac disease at the time of treatment, as well as younger women who can expect long-term survival and could have accelerated or premature cardiac disease as they age.

Cardiotoxicity Associated with Specific Agents Used to Treat Breast Cancer

Anthracycline-Associated Cardiotoxicity

Mechanism: Cardiotoxicity is a known side effect of anthracycline chemotherapy, which is widely used in the treatment of breast cancer. The mechanisms of cardiac damage are multifactorial and include oxygen free radical production that preferentially damages cardiac myocyte mitochondria. In addition, anthracyclines intercalate into DNA, which affects intracellular signaling and may cause cell death and the disruption of sarcomere maintenance (60). Exposure to anthracyclines may also reduce the numbers of cardiac progenitor cells available to help repair damaged myocardium (61).

Risk Factors: It is well known that anthracycline-induced cardiotoxicity is partially related to dose. The toxicity is cumulative and more common when doses approach 450 mg/m^2 of doxorubicin. Von Hoff et al. reported the incidence of congestive heart failure (CHF) was 7% and 18% at doses of 550 mg/m^2 and 700 mg/m^2, respectively (62). However, a more recent analysis of patients enrolled in three studies of doxorubicin containing chemotherapy for breast or small cell lung carcinoma suggests that the incidence of CHF is actually higher than previously thought (63). This study estimated that doxorubicin-induced cardiotoxicity occurred in 5% of patients at a cumulative dose of 400 mg/m^2, 26% of patients at 550 mg/m^2, and 48% of patients at 700 mg/m^2 (63). Epirubicin is also commonly used in the treatment of breast cancer. In a retrospective analysis of over 1,000 anthracycline-naïve, metastatic breast cancer patients treated with epirubicin, the maximum dose of epirubicin associated with a 5% risk of congestive heart failure was calculated. Based on the patients' cardiac risk factors, including age, the maximum cumulative dose ranged from 300 mg/m^2 to 900 mg/m^2, underscoring the importance of taking individual patient characteristics into account when using cardiotoxic chemotherapy (64). In addition to cumulative dose, other risk factors for the development of anthracycline-induced cardiomyopathy include age, cardiovascular risk factors, prior radiation dose, and coexisting drug therapy.

Genetic polymorphisms may also play a role in susceptibility to anthracycline-induced cardiotoxicity. These genetic variants may affect the expression of proteins associated with the transport, metabolism, and mechanism of action of doxorubicin. Single-nucleotide polymorphisms (SNPs) in the carbonyl reductase (*CRB1* and *CRB3*) genes that encode drug-metabolizing enzymes that reduce doxorubicin to cardiotoxic alcohols may increase the risk of doxorubicin-induced cardiomyopathy. A recently reported case-control study examined the relationship between single-nucleotide polymorphisms in *CBR1 (CBR1* 1096G>A) and/or *CBR3* (*CBR3* V244M) and the dose-dependent risk of anthracycline-related cardiomyopathy in childhood cancer survivors. One hundred sixty-five cases of childhood cancer survivors were compared with 323 control subjects with no documented cardiomyopathy. The patients were prospectively genotyped at study entry. Homozygosity for the G allele in *CBR3* gene conferred an increase in risk for cardiomyopathy associated with low- to moderate-dose anthracyclines (65). This finding, however, was not replicated in candidate gene study of 2,977 single- nucleotide polymorphisms (SNPs) in 220 key drug biotransformation genes in a cohort of 156 children treated with anthracycline. There were 9 SNPs that were significantly associated with cardiac toxicity. *CBR3* polymorphisms were not among those 9 (66).

In addition to identifying susceptibility genes, there is an ongoing search for biomarkers that predict cardiomyopathy risk. In a small prospective study of patients treated with adjuvant chemotherapy and trastuzumab, cardiac biomarkers (Troponin and BNP), TVI (tissue velocity imaging), strain imaging, and cardiac magnetic resonance imaging were evaluated for ability to detect preclinical changes in LV systolic function before conventional changes in left ventricular ejection fraction (LVEF) appeared. Troponin I and BNP did not show an association with LVEF decline. TVI and strain imaging, however, were able to show preclinical cardiac function changes (67).

Time Course: Acute toxicities of anthracyclines are seen uncommonly and include cardiac arrhythmias, heart block, pericarditis, myocarditis, and left ventricular dysfunction. These toxicities are generally reversible and the relationship with the future development of chronic cardiotoxicity is unclear.

Chronic cardiotoxicity is a feared complication of anthracycline treatment especially when given in the adjuvant, curative setting. Typically patients present with heart failure symptoms from nonischemic dilated cardiomyopathy within 1 year after chemotherapy, but as late as 10 years after completion of chemotherapy. Very long-term cardiotoxicity has been difficult to assess and may be underreported in breast cancer survivors. It is particularly difficult to assess in a case-control study due to survival bias (i.e., those patients with the most severe cardiotoxicity may have already died as a result). In a prospective study of breast cancer patients treated as part of a SWOG (Southwest Oncology Group) protocol with adjuvant chemotherapy, both with and without an anthracycline, LVEF was measured at 5 to 8 and again at 10 to 13 years posttreatment. There was a significant difference in LVEF at 5 to 8 years in patients treated with an anthracycline (64.8% with anthracycline vs. 61.4% no anthracycline; p = .01) but not at 10 to 13 years posttreatment (68). Additional long-term prospective studies are needed with newer dose-dense regimens.

Because of the potential for anthracyclines to cause long-term, irreversible cardiomyopathy, there has been a search for effective adjuvant treatment regimens that maintain efficacy without the use of an anthracycline. Jones et al. showed that four cycles of TC (docetaxel plus cyclophosphamide) achieved superior disease-free and overall survival compared to four cycles of AC (adriamycin and cyclophosphamide) in 1,016 patients with early-stage breast cancer (69). There is an ongoing trial to evaluate whether the addition of an anthracycline- to a taxane-based regimen results in greater efficacy versus the taxane-based regime alone (ClinicalTrials.gov Identifier: NCT00493870).

Trastuzumab-Associated Cardiotoxicity

Mechanism: The incorporation of trastuzumab into the adjuvant treatment of HER2 positive breast cancer has had a dramatic impact on survival. However, trastuzumab-associated cardiac dysfunction is an important, but not well understood, adverse effect. It appears to be a result

TABLE 52-1

Cardiotoxicity of Doxorubicin versus Trastuzumab

Agent	*Type of Cardiac Dysfunction*
Doxorubicin	
• Cumulative dose dependent	CHF
• Irreversible>reversible	
• Acute	Arrhythmia, heart block, pericarditis, myocarditis (uncommon)
Trastuzumab	
• Not dose dependent	CHF
• Reversible>irreversible	
• Increased risk with anthracyclines	

of impaired HER2 signaling in the heart. The HER2 gene is involved in cardiac development during embryogeneses and after birth, with the growth, survival, and inhibition of apoptosis of cardiac myocytes (70). The cardiac effects of trastuzumab in many patients is reversible and amenable to rechallenge, which distinguishes it from the cardiomyopathy attributed to anthracycline use. Additionally, it does not appear to be dose related (see Table 52-1).

Risk Factors of Coadministration with Anthracyclines: In the BCIRG001 study that led to the widespread use of trastuzumab in the metastatic breast cancer setting, New York Heart Association class III or IV heart failure occurred in 16% of the group given an anthracycline, cyclophosphamide, and trastuzumab; 3% of the group given an anthracycline and cyclophosphamide alone; 2% of the group given paclitaxel and trastuzumab; and 1% of the group given paclitaxel alone. Most cases ultimately resolved. Of the 5 patients with persistent cardiac dysfunction, 3 were in the anthracycline, cyclophosphamide, and trastuzumab group (71). This finding describes the well observed phenomenon of synergistic cardiotoxicity with the use of anthracyclines and trastuzumab together.

Seven-year follow-up of cardiac safety in the NSABP B-31 trial has recently been published. In this study, 1,831 women with early-stage HER2-positive breast cancer were randomized to receive four cycles of adriamycin and cyclophosphamide, followed by paclitaxel with or with or without trastuzumab. At 7-year follow-up, 4.0% patients who received trastuzumab experienced a cardiac event (CE) versus 1.3% of patients who did not. A CE was defined as cardiac death or congestive heart failure manifested by dyspnea with normal activity or at rest and associated with an absolute decrease in LVEF of greater than 10 percentage points from baseline to a value less than 55% or a decrease of more than 5% to a value below the lower limit of normal. Risk factors for a CE included marginal left ventricular ejection fraction prior to trastuzumab (50% to 54%), baseline use of antihypertensive agents, and age 50 or older (72). In the Breast Cancer International Research Group (BCIRG) trial 006 comparing three different chemotherapy regimens—AC plus docetaxel (AC-T); AC plus docetaxel and trastuzumab (AC-TH); and docetaxel, carboplatin, and trastuzumab (TCH)—at a follow-up of 65 months, TCH had comparable efficacy to AC-TH (overall survival of 91% vs. 92%, respectively). Both TCH and ACTH had statistically significant improvements in DFS and OS, over the non-trastuzumab-treated group. However, the risk of grade 3 or 4 CHF was significantly lower among patients receiving TCH (0.4%) than among those receiving AC-TH (2%) (73).

The NCCTG N9831 Intergroup trial was a phase III study in which almost 2,000 patients with operable HER2 positive breast cancer treated with AC were randomized to receive (i) paclitaxel alone, (ii) paclitaxel followed by trastuzumab, or (iii) paclitaxel with concurrent trastuzumab. The 3-year cumulative incidence rates of cardiac events (symptomatic CHF or cardiac death) were 0.3%, 2.8%, and 3.3% in these three treatment arms, respectively. Of note, in this trial 5% of patients developed LVEF decreases precluding randomization to treatment after AC (74).

Multiple large, randomized trials of chemotherapy with trastuzumab show low rates of cardiac events that are easily overshadowed by improvements in patient survival. In a meta-analysis of over 11,000 patients in 8 randomized controlled trials of trastuzumab and chemotherapy, trastuzumab significantly increased the risk of congestive heart failure (relative risk [RR] 5.11, 90% confidence interval [CI] 3.00–8.72, $p < .00001$); and left ventricular ejection fraction decline (RR 1.83, 90% CI 1.36–2.47, $p = .0008$). However, the trastuzumab-containing regimens improved overall survival (HR for death 0.66, 95% CI 0.57–0.77, $p < .00001$), and disease-free survival (HR for relapse 0.60, 95% CI 0.50–0.71, $p < .00001$) (75). However, these trials have had stringent criteria for entry with regard to baseline cardiac function as well as criteria for monitoring and continuation of therapy. In an observational, community-based insurance database analysis, the risk of heart failure was higher in patients treated with anthracycline alone (hazard ratio [HR] 1.40, 95% CI 1.11–1.76), any chemotherapy (HR 1.49, 95% CI 1.25–1.77), versus no chemotherapy. This risk was increased in patients treated with trastuzumab alone (HR 4.12, 95% CI 2.30–7.42) and anthracycline plus trastuzumab (HR 7.19, 95% CI 5.00–10.35). One strength of this analysis was inclusion of real-world patients. However, increased reports of cardiotoxicity in the anthracycline- and trastuzumab-treated groups may partly be due to detection bias, as a result of more frequent monitoring and misclassification due to overcoding "heart failure" in these patients (76).

Monitoring for Treatment-Associated Cardiotoxicity

Ideally, close surveillance of cardiac function will reduce the incidence of irreversible heart failure. The most widely used surveillance method today is echocardiography. Left ventricular ejection fraction is measured to represent left ventricular systolic function. Echocardiography is widely available, but there is significant interoperator variability. Echocardiogram may also miss very small, subtle changes in cardiac function that may forewarn of later cardiotoxicity. Multiple gated acquisition (MUGA) scanning is comparable to echocardiography in terms of LVEF monitoring. It is a nuclear medicine scan, and assessments of LVEF may be more objective than echocardiography. However, MUGA does expose the patient to radiation. The Herceptin prescribing information recommends either echocardiogram or MUGA scan, prior to initiation, every 3 months during treatment, upon completion of treatment, and then every 6 months for 2 years postcompletion of therapy. If Herceptin is withheld due to cardiac dysfunction, repeat echocardiogram at 4 weeks is recommended (77).

There is no global agreement on the definition of cardiac dysfunction. The Cardiac Review and Evaluation Committee has sought to standardize the definition for cardiac

dysfunction in trastuzumab trials, diagnosed by echocardiography. The following criteria were proposed: (i) cardiomyopathy established by a decrease in LVEF that is global or more severe in the septum; (ii) symptoms of CHF; (iii) signs of CHF, including but not limited to third heart sound, tachycardia, or both; and (iv) a decline in LVEF of 5% or more to less than 55% with accompanying signs and symptoms of CHF or a decline in LVEF of 10% or more to less than 55% without signs or symptoms of HF (78). The doxorubicin hydrochloride prescribing information suggests that a 10% decline in LVEF to below the lower limit of normal or an absolute LVEF of 45%, or a 20% decline in LVEF at any level is indicative of deterioration in cardiac function (79). Both of these definitions do not capture subclinical cardiovascular damage occurring early in the course of treatment. There is an ongoing trial to evaluate long-term cardiac effects of doxorubicin and cyclophosphamide followed by paclitaxel with or without trastuzumab in patients treated as part of the NSABP B-31 trial, using MUGA, medication review, and quality of life 5 to 7 years postdiagnosis (ClinicalTrials.gov Identifier: NCT00004067).

Cardiotoxicity Associated with Newer HER2-Targeted Agents

When used in the adjuvant setting, trastuzumab is very effective in reducing breast cancer recurrence rates. However, patients who experience breast cancer recurrence eventually manifest resistance to trastuzumab over time. Therefore, several new agents targeting HER2 have been developed over the past several years and incorporated into clinical practice. Table 52-2 summarizes cardiotoxicity of adjuvant and neoadjuvant HER2-directed therapies.

Lapatinib: An oral, small molecule tyrosine kinase inhibitor that inhibits HER1 (EGFR) and HER2 is used in the treatment of metastatic HER2-positive breast cancer. The effect of lapatinib on cardiac function has been scrutinized, but to date it does not appear to be causally associated with cardiomyopathy. In a phase III study comparing paclitaxel with or without lapatinib as first-line treatment for metastatic breast cancer, six patients (2%) in each treatment group had a decrease in LVEF. None of these events was symptomatic and none required dose adjustment or resulted in treatment withdrawal or death. Forty-four percent of patients had prior exposure to anthracyclines in the adjuvant setting (80). The combination of lapatinib and trastuzumab versus trastuzumab was evaluated in heavily pretreated metastatic HER2-positive breast cancer; 3.4% of patients treated with the lapatinib with trastuzumab and 1.4% of patients treated with lapatinib alone experienced asymptomatic transient decreases in LVEF. Of patients with a decline in LVEF, for 5 of the 8 patients receiving combination therapy, and all 3 patients receiving monotherapy, the decline was reversible (81). In a pooled analysis of 3,689 patients treated with lapatinib across 44 prospective trials, there was a low incidence of cardiotoxicity. Only 60 patients experienced a cardiac event, of which most (83%) were asymptomatic. There were no cardiac deaths and development of cardiotoxicity did not correlate with anthracycline or trastuzumab pretreatment. Eighty-eight percent of the declines in LVEF were at least partly reversible regardless of continuation or discontinuation of lapatinib (82).

Since lapatinib is not associated with cardiomyopathy, like trastuzumab, large-scale trials have been undertaken to evaluate whether lapatinib can substitute for trastuzumab

TABLE 52-2

Cardiac Events in Adjuvant and Neoadjuvant Trials of HER2-Directed Therapies

STUDY	*Type of Cardiac Dysfunction*	*Incidence (%)*
BCIRG-006 (73)	Symptomatic HF	
AC + docetaxel		0.7
AC + docetaxel + trastuzumab		2
Trastuzumab + carboplatin + docetaxel		0.4
NSABP B-31 (72)	Symptomatic HF or cardiac death	
AC/paclitaxel		1.3
AC/paclitaxel plus trastuzumab		4.0
NCCTG9831 (112)	Symptomatic HF or cardiac death	
AC/paclitaxel		0.3
AC/paclitaxel + trastuzumab (concurrent)		3.3
AC/paclitaxel + trastuzumab (concurrent)		2.8
NEOALLTO (113)	LVEF decline, CHF, or "myocardial ischaemia"	
Lapatinib		0.6
Trastuzumab		1.3
Lapatinib + trastuzumab		2.6
NEOSPHERE (114)	LVEF decline over 10%	
Trastuzumab + docetaxel		0.9
Pertuzumab + trastuzumab + docetaxel		2.8
Pertuzumab + trastuzumab		0.9
Pertuzumab + docetaxel		1

in terms of efficacy. The COMPLETE (COMParison of Lapatinib Efficacy vs. Trastuzumab, each with a taxane, in first-line metastatic breast cancer) was one such study. It was closed early after an interim analysis in April 2012 revealed inferior progression free survival with lapatinib when compared with trastuzumab. PFS in the patients with centrally confirmed HER-positive cancer had HR 1.48 (95% CI 1.15–1.92, $p = .003$) (lapatinib + taxane to trastuzumab + taxane) (83). The ALTTO trial (Adjuvant Lapatinib And/Or Trastuzumab Treatment Optimisation; ClinicalTrials.gov identifier: NCT00490139) is an ongoing, randomized, open label, multicenter, phase III study comparing the activity of lapatinib alone versus trastuzumab alone versus trastuzumab followed by lapatinib versus lapatinib concomitantly with trastuzumab in the adjuvant treatment of patients with HER2-positive breast cancer. In August 2011, the independent data monitoring committee review found that the lapatinib alone arm was unlikely to meet the prespecified criteria to demonstrate noninferiority to trastuzumab alone with respect to disease-free survival (DFS). Therefore, that study arm has been subsequently discontinued.

Pertuzumab: A monoclonal antibody that binds to the extracellular domain of HER2, similar to trastuzumab. However, it binds to a different epitope than trastuzumab. Pertuzumab prevents receptor homodimerization and heterodimerization within the HER-family and with IGF-1R. Pertuzumab inhibits HER family signaling and may also overcome trastuzumab resistance. In the CLEOPATRA study, 808 patients with metastatic HER2-positive breast cancer were randomized to receive trastuzumab plus docetaxel with or without pertuzumab. At a median follow-up of 19.3 months, patients who received pertuzumab demonstrated significantly improved PFS (12.4 months for control arm vs. 18.5 months pertuzumab arm, HR 0.62, 95% CI 0.51–0.75, $p < .001$). In this study, assessments of LVEF were performed at baseline, every 9 weeks during treatment, at treatment discontinuation, every 6 months in the first year after discontinuation, and annually thereafter for up to 3 years. Left ventricular systolic dysfunction was reported more frequently in the control group than in the pertuzumab group (8.3% vs. 4.4%). Grade 3 or higher left ventricular systolic dysfunction was also reported more frequently in the control group versus the pertuzumab group (2.8% vs. 1.2%). Of note, 89% of patients had not previously received trastuzumab (84). Therefore, more information on the cardiac safety of pertuzumab in trastuzumab pretreated patients will be available in the future.

Cardiotoxicity of Endocrine Therapies

Aromatase inhibitors (AIs) have emerged as an alternative to tamoxifen for use in adjuvant endocrine treatment. Among postmenopausal women with hormone-receptor-positive early-stage breast cancer, benefits in DFS have been demonstrated with AIs compared with tamoxifen without a corresponding clear benefit in overall survival. A possible explanation for this discrepancy may relate to the toxicity profile of AIs versus tamoxifen. In a meta-analysis of seven adjuvant endocrine therapy breast cancer trials, longer duration of aromatase inhibitor use was associated with a statistically significant increase in the odds of developing cardiovascular disease compared with tamoxifen alone or shorter duration of aromatase inhibitor use (OR 1.26, 95% CI 1.10–1.43, $p < .001$) (85,86). In the ATAC (anastrazole, tamoxifen alone or in combination) study among women with preexisting heart disease, the incidence of cardiovascular events was 17% with the AI, anastrazole, and 10% with tamoxifen (86). These data caution clinicians to consider individual cardiovascular risk in determining the best adjuvant endocrine treatment for early-stage breast cancer. One mechanism to potentially explain the decreased coronary risk seen in this study with tamoxifen may be its effects on lowering lipids. Tamoxifen decreases total cholesterol and low-density lipoprotein (LDL), without an effect on high-density lipoprotein (HDL). Triglycerides may increase while on tamoxifen. Women on AIs do not experience similar decreases in LDL. However, the changes in lipid profiles have no proven effect on cardiac outcomes. In the P-1 study, which randomized 13,387 women at higher than average risk of developing breast cancer to 5 years of tamoxifen or placebo, women treated with tamoxifen were no more or less likely to have an ischemic cardiovascular event (87).

Radiation-Associated Cardiotoxicity

Several studies have demonstrated an increase in coronary artery disease and/or nonfatal myocardial infarction associated with left-sided radiotherapy compared with right-sided radiotherapy or no radiotherapy. The incidence of heart disease was analyzed in 4,414 10-year survivors of breast cancer who were treated between 1970 and 1986. Those patients treated before 1980 had a greater incidence of heart disease than those treated after 1980 (88). This finding corroborates the notion that advanced radiation techniques have improved cardiovascular outcomes after breast irradiation. Also seen in this study was an increase in cardiovascular risk when chemotherapy was added to radiation. Smoking also conferred a more than additive risk of developing a second cancer when combined with radiation (88).

Strategies for Prevention of Treatment-Associated Cardiotoxicity

Cardioprotective Agents

Dexrazoxane: Several strategies to prevent and treat anthracycline-induced heart failure have been developed. Dexrazoxane is a cardioprotective agent that may have a role in preventing anthracycline-induced cardiomyopathy in high-risk patients. It is a cyclic derivative of EDTA that penetrates the cell membrane and is then converted intracellularly to a chelating agent that can interfere with the iron-mediated free radical generation which contributes to cardiomyopathy. In a meta-analysis of 10 randomized controlled trials enrolling over 1,600 patients, the use of dexrazoxane in addition to anthracycline containing chemotherapy, there was a significant decrease in the incidence of congestive heart failure with the use of dexrazoxane (RR 0.29, 95% CI 0.20–0.41, $p < .00001$). Additionally, no statistically significant difference in response rate between the dexrazoxane and control group was found (RR 0.89, 95% CI 0.78–1.02, $p = .08$) as had been suggested in earlier analyses (89,90). There was also no difference in progression free or overall survival in patients treated with or without dexrazoxane. In this meta-analysis, no definitive conclusions could be made regarding adverse effects of dexrazoxane (90). In the 2008 American Society of Clinical oncology guidelines issued on the use of cardioprotectants, the expert panel suggested that clinicians consider use of dexrazoxane for patients with metastatic breast cancer and other malignancies in patients who have received more than 300 mg/m^2 doxorubicin who may benefit from continued doxorubicin-containing therapy (91).

ACE Inhibitors and Beta Blockers: Both ACE inhibitors and beta blockers are important therapeutic agents for treating heart failure. These agents thus serve as ideal candidates for

treating anthracycline-induced cardiomyopathy. One study of 201 consecutive patients with anthracycline-induced cardiomyopathy and left ventricular ejection fraction 45% or less evaluated treatment with enalapril and carvedilol. Patients were more likely to respond to treatment and fully recover EF if cardiac therapy started earlier (i.e., closer to the end of chemotherapy) (92). In a single-institution study of patients receiving high-dose chemotherapy, those who developed increases in serum Troponin T were randomized to ACE inhibitor therapy or placebo. Patients who received ACE inhibitors were less likely to experience declines in ejection fraction (43% vs. 0%; $p < .001$). There were many patients who had not received anthracyclines as part of their chemotherapy regimen, so the broader applicability of this study to patients with anthracycline-induced cardiomyopathy is yet to be determined (93). Additionally, it is not known whether the use of these therapies as cardioprotective agents has any influence on breast cancer outcomes.

Exercise to Prevent Cardiotoxicity

Aerobic exercise forms an integral part of the cardiac rehabilitation programs used to treat patients with heart failure. Therefore, the use of exercise therapy for patients treated with doxorubicin has been evaluated. In several animal studies, exercise improved LVEF and diastolic function when instituted prior to and during doxorubicin treatment (94,95). However, studies in humans are necessary to assess whether these findings from animal studies are relevant to humans and, if so, whether exercise affects both acute and chronic cardiomyopathy.

Summary

The cardiac effects of breast cancer therapy have a major impact on quality of life and longevity of a subgroup of patients. Over the past several years we have identified patients at greatest risk of cardiotoxicity, based on baseline cardiac function. However, in the future the identification of genetic characteristics and biomarkers that indicate increased susceptibility to treatment-related cardiotoxicity will play a greater role in risk stratification of the individual patient. Currently, we are developing therapies that maintain efficacy while reducing risk of cardiac dysfunction.

SECONDARY MALIGNANCIES CAUSED BY BREAST CANCER TREATMENT

Breast cancer mortality has been declining over the past two to three decades, in part due to the advances in treatment. Now, with improved survival, the development of a second nonbreast malignancy, as a result of treatment, remains a major concern. While secondary malignancies are uncommon, they can be life threatening in an otherwise "cured" breast cancer survivor. In addition, there are concerns raised regarding the development of contralateral breast cancers.

Radiation-Associated Secondary Malignancies

Mechanism and Incidence: Radiation therapy can induce a secondary cancer via damage to DNA, which alters cellular programming to favor abnormal cell proliferation. Usually, there is a long latency period, from 5 to 20 years. In the first study to assess and quantify the long-term risk of all solid cancers after breast cancer radiotherapy in the United States using the Surveillance Epidemiology and End Results (SEER) databases, it was estimated that about 5% (95% CI 2.0–7.0) of contralateral breast cancers and 6% (3.0–8.0) of other solid cancers could be related to radiotherapy. For contralateral breast cancer, there was an estimated excess absolute risk of 2 cases per 10,000 person-years and for solid tumors 4 cases per 10,000 person-years. Of the solid tumors, most were located in areas receiving a higher dose of radiation such as the lung and esophagus (96).

These findings were substantiated in a second retrospective analysis of 647,672 patients across 15 primary solid cancer types who were analyzed for the development of a second cancer. Patients who were treated with and without radiation therapy were included in the analysis. Patients were excluded from the analysis if they did not survive to 5 years, given the latency period of secondary cancers. Among all patients, 60,271 (9%) developed a second solid cancer, of which 3,266 were estimated to be related to radiotherapy, corresponding to a risk of five excess cancers per 1,000 patients treated with radiotherapy by 15 years after diagnosis. In the specific subset of patients with breast cancer, there was a 5% increased risk in secondary cancer attributable to radiotherapy. Of note, the risk attributable to radiation decreased with patient age. The risk decreased with later year of treatment, suggesting that newer radiation techniques may be safer (97). These two analyses, while confirming that there is an increased risk of secondary cancer in breast cancer patients receiving radiation, also confirm that the absolute risk is low. In the breast cancer population, 10% of patients developed a second cancer of which only 0.5% were attributable to radiation. This indicates that other factors, both patient and treatment related, are involved.

Risk Factors for Radiation-Induced Secondary Malignancies

Genetic: A patient's genotype may confer an increased risk of developing radiogenic cancers. For example, *BRCA1, BRCA2*, and *ATM* are known to mediate cellular response to ionizing radiation, but it is unclear whether pathogenic mutations in these genes increase the risk of developing a radiogenic cancer. To date, a single susceptibility locus, in which allelic variants display a high-penetrance for radiogenic cancer, has not yet been identified. More likely, the development of a radiogenic cancer results from the coinheritance of multiple polymorphisms that increase risk in an additive fashion. Similar genetic factors that render a patient more susceptible to developing breast cancer in the first place may also contribute to developing a radiogenic cancer.

Age: Patient age was again identified as a risk for radiogenic cancers in the Women's Environmental, Cancer, and Radiation Epidemiology (WECARE) case-control study. Women with a second, asynchronous, contralateral breast cancer (cases) were compared with women with unilateral breast cancer (controls) matched by radiation treatment. Those women under the age of 40, who received higher doses of radiation, had an elevated risk of developing a second primary breast cancer (98).

Radiation-associated sarcomas (RAS) are rare secondary malignancies that deserve mention. The median latency period is approximately 10 years, ranging from 2 to 50 years. While there is some disagreement, one definition of RAS includes a "sarcoma within the path or adjacent to a radiation field, occurring at least 3 years post radiation" (99). The prognosis may be worse for RAS as opposed to sporadic soft-tissue sarcomas, adjusting for histologic type, size, age, margin status, and site (100).

Secondary Malignancies Associated with Specific Systemic Agents

Anthracycline-Induced Secondary Malignancies

Chemotherapy used in the adjuvant setting for early-stage breast cancer has improved overall survival. But, therapy-related myeloid neoplasms, such as treatment-related acute myelogenous leukemia (t-AML), are well described and deadly. Therapy-related AML constitutes 10% to 20% of all AML cases. Poor-risk cytogenetics and treatment resistance is often seen. Alkylating agents, such as cyclophosphamide, increase t-AML at approximately 5 years posttreatment. These leukemias are distinguished by certain morphologic and cytogenetic features. They are most often FAB subtype, M1 or M2, with abnormalities in chromosomes 5 and 7. In contrast, t-AML related to topoisomerase II inhibitors, such as doxorubicin and mitoxantrone, develops on average at 2 years posttreatment and is frequently associated with the 11q23 cytogenetic abnormality (101). Long-term survival after t-AML is worse compared with de novo AML (102). Common risk factors for both the development of breast cancer and t-AML may include genetic polymorphisms affecting DNA repair processes. Genetic factors influencing drug metabolism may also increase individual susceptibility to t-AML from chemotherapeutic agents. Additionally, older age, which in itself is linked with decreased DNA repair ability, is associated with t-AML. Using the SEER-Medicare database, 10,130 breast cancer patients who received adjuvant chemotherapy were compared with 54,585 who did not and observed for development of AML. All women in this study were older than 65 (median age 75.6). The absolute risk of developing AML at 10 years after any adjuvant chemotherapy for breast cancer was 1.8% versus 1.2% for women who had not received chemotherapy. These numbers may represent an underestimation of risk, since myelodysplastic syndrome (MDS) is not captured by claims in the database (103).

In a case-control study of women treated for breast cancer in France, there was a greater risk of AML/MDS with topoisomerase-II inhibitor–based chemotherapy than with other drug regimens (104). In this study, mitoxantrone treatment conferred a greater risk of MDS/AML than anthracycline treatment. Dose intensity may affect leukemia risk in patients treated with anthracyclines. An observational study of 9,796 patients treated with adjuvant chemotherapy regimens containing epirubicin demonstrated an 8-year cumulative probability of developing AML/MDS of 0.37% (95% CI 0.13–0.61) using standard doses (i.e., 720 mg/m^2 or less epirubicin and 6,300 mg/m^2 or less cyclophosphamide) compared with 4.97% (95% CI 2.06–7.87) for patients given higher doses of epirubicin and cyclophosphamide (105). In the randomized, prospective study comparing TC with AC, there were two cases of leukemia (myelofibrosis and myelodysplasia) in the 510 patients in the adriamycin group and none in docetaxel group. These numbers are small, but thought provoking (106).

Alkylating Agent–Induced Secondary Malignancies

In an analysis of six NSABP trials examining different schedules of adriamycin and cyclophophamide, the incidence of AML/MDS from 8,563 patients (representing 61,810 PYs of follow-up) was 0.50%. The cumulative incidence of AML/MDS at 5 years rose sharply according to the dose of cyclophosphamide given. For patients receiving the more intense regimens, the incidence was 1.01% (95% CI 0.63–1.62), compared with 0.21% (95% CI 0.11–0.41) for patients treated with standard AC (60 mg/m^2/600 mg/m^2 × 4). All of the protocols used standard dose adriamycin (60 mg/m^2), therefore dose intensity of adriamycin as a risk factor for AML/MDS could not be evaluated (107).

Granulocyte colony-stimulating factor (G-CSF) is commonly used with myelosuppressive chemotherapy to prevent neutropenia, specifically febrile neutropenia. While the NCCN guidelines recommend using G-CSF when the incidence of febrile neutropenia is 20% or greater, in clinical practice it is used more broadly. G-CSF activates signaling molecules, such as those in the Jak/STAT pathway, which are associated with hematologic malignancy. Therefore, there is a potential connection between t-AML and G-CSF. An evaluation of the incidence of secondary AML in breast cancer patients receiving chemotherapy with and without G-CSF was undertaken using the SEER-Medicare database. Of the 906 patients who were treated with G-CSF, 16 (1.77%) developed AML/MDS versus 48 (1.04%) of the 4,604 patients not treated with G-CSF, which corresponded to a HR of 2.14 (95% CI 1.12–4.08) (108). Dose and dose intensity was not available in the dataset, therefore the use of G-CSF may be a marker for increased dose. The population was over age 65 and may also represent a differential effect of either chemotherapy dose or G-CSF use in the elderly patient population. It is also important to note that in two large trials, one of dose-dense chemotherapy and the other using a SEER-Medicare database, there was no increase in t-AML observed with G-CSF use (103).

Radiation and chemotherapy together confer a greater risk of second cancers than either alone. A group of 5,790 patients with stages 0 to III breast cancer, treated with surgery and/or chemotherapy and/or radiation between 1990 and 2005, were analyzed for secondary malignancies using a community-based cancer center registry. There were 17 cases of MDS/AML, over an average 7.2 years' follow-up. Median survival of MDS/AML patients postdiagnosis was 9 months. No difference in MDS/AML was observed in the anthracycline compared to the nonanthracycline adjuvant chemotherapy treatment group. No cases of MDS/AML were observed in the surgery-only group. A threefold increase in risk was observed among patients treated with radiation alone and a sixfold increase in risk among patients treated with radiation and chemotherapy indicating a possible synergistic effect of radiation and chemotherapy. Ultimately, the authors concluded there was an elevated rate of MDS and AML was observed among breast cancer patients under 65, those treated with radiation, and those treated with radiation and chemotherapy compared to available population incidence data (109).

Endocrine Therapy–Induced Secondary Malignancies

The use of adjuvant endocrine therapy in women with early-stage breast cancer has improved overall survival in the 75% of patients with hormone-receptor- (ER- and/or PR-) positive disease. Tamoxifen, a selective estrogen receptor modulator, has been used for adjuvant treatment since the 1970s and remains the first-line adjuvant endocrine therapy in premenopausal women. Tamoxifen has also been shown to effectively prevent breast cancer in women at higher risk. It has agonist activity in several tissues of the body, including the endometrium. As a result, tamoxifen use is associated with an increased risk of endometrial cancer. The risks are small when compared with the benefits. But, the ability to identify risk factors will help tailor discussions of risk versus benefits to the individual patient.

In the P-1 trial, 13,387 women at higher than average risk of developing breast cancer were randomized to 5 years of tamoxifen or placebo. In this trial, tamoxifen reduced the risk of invasive breast cancer by 49% ($p < .0001$). However, the RR for endometrial carcinoma was increased among tamoxifen

users relative to nonusers (RR 2.53, 95% CI 1.35–4.97), primarily among women aged 50 or older. The absolute numbers were low—15 cases of uterine cancer with placebo versus 36 cases with tamoxifen. It is noteworthy that all 36 invasive endometrial cancers that occurred in the group receiving tamoxifen were FIGO stage I. There was no statistically significant increase in the incidence of endometrial cancer among women 49 and under (87). However, a case-control study using United Kingdom cancer registries demonstrated that tamoxifen use increased the risk of endometrial cancer in cases versus controls. Regardless of menopausal status, the elevated risk was present and continued for at least 5 years posttamoxifen discontinuation (110). Uterine sarcoma, a rare malignancy, is included in these reports of endometrial cancer. Across several NSABP trials (B-09, B-14, B-21, B-23, B-24, and P-1), uterine sarcomas comprised about 10% of uterine malignancies. The pooled results of these trials do suggest a slight increase in uterine sarcoma in tamoxifen-treated patients (111). See Chapter 43 for additional information.

CONCLUSIONS

For most women with breast cancer, the benefits of treatment outweigh the short- and long-term risks. However, an important minority suffer devastating consequences that affect longevity and/or quality of life. Researching the side effects of treatment, especially long-term side effects, must keep pace with the rapid development of new therapies. Observational data should serve as the foundation for prospective, longitudinal analysis of important treatment-related sequelae. With more information on these consequences, we can refine our risk–benefit assessments and target them to the individual patient.

CHAPTER 53

Adjuvant Systemic Therapy Treatment Guidelines

C. Kent Osborne

CHAPTER CONTENTS

Adjuvant therapy decisions have become more complicated as breast cancers are further subdivided into groups that mandate different treatment approaches. Division of breast cancers into three groups, ER-positive, HER2-positive, and triple negative, while providing a general basis for treatment decisions, is insufficient to provide optimal therapy for a given patient. Multi-gene assays of the primary tumor in addition to other prognostic and predictive factors are often used to determine the molecular fingerprint of the tumor and, thus, to help guide patient therapy.

Because the rational for adjuvant systemic therapy is to eradicate distant micro-metastases that are present at diagnosis in many patients, the first step in decision-making requires an assessment of the likelihood that a given patient harbors occult distant metastases, which then translates into the risk for recurrence and death, using various validated prognostic factors. The second and equally important step is to estimate the benefit of treatment for that patient using validated predictive factors. It should be emphasized that the factors associated with risk for recurrence do not necessarily predict treatment benefit. For example, positive lymph nodes is a powerful prognostic factor and is associated with a higher risk for recurrence, but this does not necessarily mean that such tumors are responsive to chemotherapy. Considering the risk for recurrence and the estimated reduction in that risk, the third step is for the physician to have an honest discussion with the patient outlining the potential benefits relative to the side effects, toxicity, and cost of treatment, in the context of the patient's general health and preferences, to make a final decision.

Established prognostic markers include nodal status, pathological tumor size, histologic grade, markers of proliferation, ER status, and HER2 expression. Multi-gene assays such as the 21-gene recurrence score (Oncotype DX) and Mammaprint are widely used as prognostic factors in patients with ER-positive tumors based on results of retrospective studies. Prospective studies are underway to more fully evaluate their prognostic and predictive capabilities for response to chemotherapy. Retrospective studies suggest that the 21-gene recurrence score is predictive for chemotherapy benefit in both node-negative and node-positive, ER-positive patients with high scores predicting benefit of several chemotherapy regimens. Ki-67 (MIB1) is a proliferation marker used by some as both a prognostic and predictive marker although its widespread use is limited by the lack of standardization of the assay and its interpretation. An international consortium is working to standardize this potentially very valuable marker. Molecular classification of tumors into Lumina A and B, HER2-positive, basal-like, and claudin-low is still a research tool, but additional studies to evaluate its prognostic/predictive value are underway. For the most part, these assays all differentiate between the same tumor phenotypes. Well-differentiated, hormone receptor strongly positive, HER2-negative, slowly proliferating tumors respond well to endocrine therapy but less well, if at all, to chemotherapy, whereas more poorly differentiated tumors with low or absent ER, low or absent PR, rapid proliferation, and that are HER2-positive benefit from chemotherapy but respond less well, if at all (ER-negative), to endocrine therapy. In fact, studies suggest that immunohistochemical (IHC) assays for just four gene products, ER, PR, HER2, and Ki67, may be adequate to identify these phenotypes if they are done in a very standardized manner (1). This observation needs confirmation but is potentially important in reducing the cost of care and in extending this helpful test to patients in countries with fewer resources. Data are now emerging from DNA sequencing and other genomic, epigenomic, transcriptomic, proteomic, and metabolomic studies, suggesting that in the future breast cancer may be further broken down to even more subtypes with different prognoses and responses to therapy. At present, however, these studies are at the stage of cataloguing and characterizing these alterations, and none are clinically useful for adjuvant decision-making.

ADJUVANT ENDOCRINE THERAPY

Nearly all women with ER-positive invasive breast cancer should be considered for adjuvant endocrine therapy because of its favorable effects in reducing local and distant recurrence, mortality, and contralateral breast cancer, with relatively little toxicity. Even patients with tumors expressing low levels of ER (1% or more cells staining positive for ER) are candidates for endocrine therapy. This cutoff is similar

to that of the old ligand-binding assay where a cutoff of 4 or more fmoles per mg protein (lower limit of detection of the assay) predicted benefit from endocrine therapy. ER-negative but PR-positive tumors are rare with IHC, but patients with such tumors should probably receive endocrine therapy as the ER assay is likely to be falsely negative given that PR needs ER for its synthesis. ER- and PR-negative tumors do not benefit from adjuvant endocrine therapy, and it should not be given. For unclear reasons, the incidence of contralateral breast cancer is not reduced in these patients either.

All endocrine therapies block the effects of estrogen but in somewhat different ways. Tamoxifen binds to ER and prevents the binding of estrogen. Aromatase inhibitors (AIs) lower the level of estrogen available to bind ER in postmenopausal patients. They are ineffective in premenopausal patients with functioning ovaries. LHRH agonists block ovarian production of estrogen in premenopausal patients. Tamoxifen remains the treatment of choice for premenopausal women with ER-positive tumors and for many postmenopausal patients as well. Tamoxifen plus ovarian ablation or ovarian ablation alone is another option for premenopausal patients. Ovarian ablation plus an AI should not be used at the present time due to inferior results reported in one trial (2). The optimal duration of adjuvant endocrine therapy is in transition. Two large recent studies suggest that extending tamoxifen treatment to 10 years is superior to stopping at 5 (3,4). Five years may still be adequate for patients with very low-risk tumors because the anticipated additional benefit is very small and may be balanced by the additional toxicity. For many other patients, especially those remaining premenopausal, extending tamoxifen to 10 years is the new standard. Five years is still standard for breast cancer prevention and for ductal carcinoma in situ. Postmenopausal patients finishing 5 years of tamoxifen have the optional strategy of switching to an AI for 5 years rather than extending tamoxifen.

Aromatase inhibitors offer a slight advantage over tamoxifen in reducing recurrence and should be considered as part of the adjuvant endocrine therapy for many postmenopausal women. Randomized trials suggest that 5 years of an AI or the sequence of tamoxifen before or after an AI are acceptable strategies. Some studies suggest that 5 years of treatment with an AI, without a switch, should be considered in women at risk for early recurrence with higher-risk tumors characterized by high grade, lower ER and/or PR, HER2-positive, or higher rates of proliferation. Whether to extend initial AI therapy from 5 to 10 years is the subject of ongoing trials.

Because the recurrence benefits of an AI are not dramatically superior to tamoxifen and there is no definitive survival advantage for an AI, other factors should also be considered when making a treatment decision. Obesity is an adverse prognostic factor for outcome and some studies also suggest that obesity reduces the benefit from an AI. A history of venous thrombosis makes tamoxifen a poor choice for adjuvant endocrine therapy though it might be favored in women with a history of coronary artery disease or osteoporosis. Blood lipids and bone mineral density should be monitored in patients on an AI. Patients on tamoxifen should not be routinely monitored for endometrial cancer with ultrasound or endometrial biopsy in the absence vaginal bleeding or spotting. There are no clinical data to suggest the superiority of any of the three approved AIs: anastrozole, letrozole, or exemestane. Patients suffering joint/bone symptoms on anastrozole or letrozole sometimes have reduced symptoms upon switching to exemestane.

ADJUVANT CHEMOTHERAPY

Adjuvant chemotherapy is generally considered for healthy women with moderate to high-risk cancers. Chemotherapy is still the only option for patients with triple negative breast cancer. The use of chemotherapy has declined in the past 5 to 10 years with the recognition that many patients with ER-positive tumors, such as those with low grade, high ER and PR, negative HER2, and low proliferation, fail to benefit. Although several chemotherapy combinations provide options for patients, most include cyclophosphamide, an anthracycline, and a taxane together or in sequence. The dose-dense every 2-week regimen of doxorubicin plus cyclophosphamide for 4 treatments followed by paclitaxel for 4 treatments has been shown to be superior to the every 3-week regimen. The addition of paclitaxel provides the greatest benefit in patients with ER-negative tumors although some patients with ER-positive tumors with higher-risk features also benefit. Not all studies of dose-dense chemotherapy show positive results, but, because of the benefit of every 2-week AC followed by paclitaxel and its acceptable toxicity, this regimen has become standard for higher risk patients, particularly if they are ER-negative. Other regimens incorporating anthracyclines, cyclophosphamide, and a taxane are also acceptable and are used frequently. The docetaxel plus cyclophosphamide every 3-week for four treatments regimen, which was superior to doxorubicin plus cyclophosphamide in a large trial, is also used frequently in ER-positive patients who seem to benefit less from more intensive regimens. However, there are relatively little data comparing various regimens to demonstrate the clear superiority of one regimen over another. Older regimens using cyclophosphamide, methotrexate, and 5-flourouarcil are still used for some patients although they may be slightly inferior to newer regimens. The chemotherapy benefit in younger patients with ER-positive tumors is in part related to the ovarian ablation activity of the chemotherapy, which produces an endocrine therapy effect in addition to the cytotoxic effects.

CHEMO ENDOCRINE THERAPY

For women with ER-positive breast cancer, the addition of chemotherapy to endocrine therapy is an option. For Luminal A tumors with high ER and PR, negative HER2, grade 1, low rates of proliferation, and low 21-gene recurrence scores, the addition of chemotherapy provides little or no benefit. Although there are less data, while larger tumor size and lymph node positivity confer a higher risk for recurrence, still these tumors might not benefit from chemotherapy if they demonstrate the features noted above. Additional data on the predictive ability of the 21-gene recurrence score and Mammaprint will come from the TAILORx, RxPONDER, and MINDACT clinical trials that have or are nearing completion of the accrual phase.

In patients with ER-positive tumors who are considered candidates to also receive chemotherapy, endocrine therapy should be delayed until after the completion of chemotherapy. This recommendation is only based on studies of tamoxifen given concomitantly or sequentially with chemotherapy. Studies using an AI as the endocrine therapy together with chemotherapy are warranted because the effects of tamoxifen and estrogen deprivation on the biology of the cell are different.

ADJUVANT THERAPY FOR HER2-POSITIVE BREAST CANCER

Treatment of patients with HER2-positive tumors is also undergoing a transition. Neoadjuvant trials testing the hypothesis that multiple drugs targeting HER2 signaling are better than trastuzumab alone because they more completely block the HER2 pathway are strikingly positive (5,6).

Combinations of trastuzumab plus lapatinib or trastuzumab plus pertuzumab show a doubling of the pathologic complete response rate, suggesting that they will also be superior in the adjuvant setting for long-term DFS and OS. Adjuvant trials investigating this hypothesis are ongoing. Until completed, trastuzumab alone for one year remains the HER2-targeting agent to consider along with chemotherapy in patients with HER2-amplified tumors. The chemotherapy regimens to consider include combinations of cyclophosphamide, an anthracycline, and a taxane, or carboplatin plus docetaxel (TCH). Because of cardiac toxicity, trastuzumab should not be given together with doxorubicin but should be given concomitantly with a taxane. TCH is associated with slightly less cardiac toxicity than AC/paclitaxel plus trastuzumab. Patients on trastuzumab need to have serial monitoring of cardiac ejection fraction. For ER-positive, HER2-positive tumors, endocrine therapy should also be given after completion of chemotherapy and along with trastuzumab. There are no studies of trastuzumab plus endocrine therapy alone without chemotherapy. Furthermore, there are no large randomized trials of trastuzumab combined with a less intensive chemotherapy regimen such as paclitaxel alone. Patients with node-negative small tumors less than 1 cm were not included in the large randomized trials, but they do have higher than expected risks of recurrence, and treatment of such patients can be considered depending on other factors. Finally, small neoadjuvant studies of HER2-targeted therapy alone without chemotherapy suggest that there may be a subset of patients that does not need chemotherapy. However, this approach requires additional study and it should not be used outside of a clinical trial.

SUMMARY

Adjuvant systemic therapy has markedly improved the outcome of patients with early breast cancer and has contributed to the reduction in mortality rates observed in Western countries since 1990. Adjuvant therapy decision-making is complex and requires knowledge of the biology of breast cancer, the myriad breast cancer subtypes, prognostic and predictive factors, various treatment options, and patient characteristics and preferences. Several groups have provided evidence-based or expert opinion-derived guidelines to help in the decision-making process. Given the rapid changes occurring in this area, these guidelines may not always be up to date, but they can be very helpful to the clinician in determining optimal care for patients. Among them, the recommendations from the 2013 St. Gallen Consensus Conference and the National Comprehensive Cancer Network (NCCN) may be useful to clinicians (7,8). These recommendations should be viewed as guidelines and not mandates for management of individual patients. Although adjuvant therapy has improved patient outcomes, still many thousands of patients die each year from breast cancer. Participation in clinical trials provides optimal management for the patient while at the same time helping to further reduce mortality for patients in the future.

SECTION VIII

Preoperative Systemic Therapy

CHAPTER 54

Preoperative Chemotherapy for Operable Breast Cancer

Aditya Bardia and José Baselga

CHAPTER CONTENTS

INTRODUCTION

Preoperative chemotherapy, also referred to as neoadjuvant chemotherapy or primary systemic therapy, today constitutes one of the standards of care in patients with newly diagnosed early stage breast cancer. This approach was initially introduced in the 1970s for the treatment of patients with locally advanced breast cancer (LABC) where it was found to result in high response rates, allow surgery for these initially unresectable tumors, and improve survival when compared to historical controls (1,2).

The success of preoperative chemotherapy for locally advanced disease together with emerging data on the benefits of adjuvant chemotherapy has led to the conduct of a number of studies in patients with operable breast cancer. These studies, some of which will be discussed in this chapter, have provided a number of important clinical insights regarding preoperative chemotherapy that are applicable to the management of patients with breast cancer. First, the majority of patients achieve a clinical response to induction chemotherapy, and the progression of disease during therapy, a legitimate concern, is rare. Second, preoperative chemotherapy results in surgical downstaging of tumors and allows breast conservation in women who, otherwise, would have needed a mastectomy. Furthermore, preoperative chemotherapy does not limit or interfere with posterior surgery and radiation therapy. Third, disease-free control and overall survival are similar between preoperative and postoperative (adjuvant) therapy. Fourth, the same chemotherapy agents and sequence of administration used in the adjuvant setting is also used in the preoperative space. As such, there are not preoperative or adjuvant-restricted chemotherapy regimens. Fifth, emerging data suggests that a good response to therapy resulting in absence of tumor at the time of surgery (pathological complete remission [pCR]) may be a surrogate marker of improved disease-free survival and overall survival. Finally, investigational agents are being increasingly studied in the preoperative setting even before the launch of large adjuvant studies as the number of patients required is smaller than in the adjuvant settings and follow up is shorter as a result of using the pCR rate, an early readout as a surrogate marker of improved disease-free survival and overall survival.

While preoperative chemotherapy is not for every patient and a large number of those patients with newly diagnosed breast cancer for whom chemotherapy is recommended will continue to be treated in the adjuvant setting, preoperative chemotherapy is a treatment approach to be considered and is likely to become a space for the rapid approval of active compounds in the early disease setting.

THE EVOLUTION OF PREOPERATIVE CHEMOTHERAPY

The first prospective preoperative study was launched in 1973 by investigators from the Milan Cancer Institute. The primary objective was to downstage the tumor and facilitate surgical resection. Women with stage III breast cancer received combination chemotherapy with adriamycin and vincristine for three cycles, followed by radiation therapy followed by additional chemotherapy. This preoperative approach was not only effective in downstaging the tumors

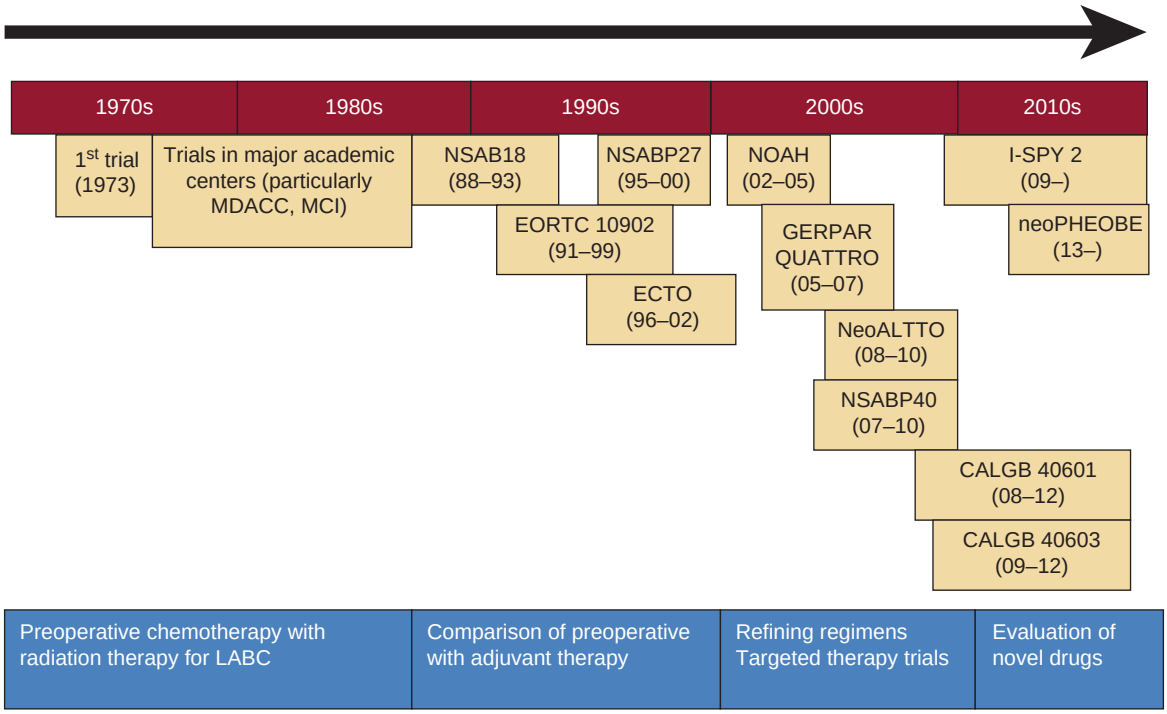

FIGURE 54-1 Evolution of preoperative chemotherapy over the past 30 years. MDACC, MD Anderson Cancer Center, USA; MCI, Milan Cancer Institute, Italy; LABC, locally advanced breast cancer.

but also improved survival (3,4). In the late 1970s and the 1980s, several preoperative trials assessed the benefit of chemotherapy in women with LABC, and, in addition to improving the rates of operability, most suggested a survival benefit as well (5,6). Based on these results and the lack of effective alternative strategies, the administration of preoperative chemotherapy with or without radiation therapy prior to surgery thus became the standard for initially inoperable, nonmetastatic breast cancer.

The success of preoperative chemotherapy in downstaging tumors and improving survival prompted further evaluation in operable tumors as well. Furthermore, there was a suggestion from preclinical models that chemotherapy before tumor removal may result in better outcomes than administration after surgery due to early eradication of micrometastasis (7,8). Consequently, in the late 1980s and the 1990s, a new series of clinical trials were launched in the United States and Europe that compared preoperative and adjuvant therapies. The National Surgical Adjuvant Breast and Bowel Project (NSABP) conducted a large phase III study (NSABP B-18), in which 1,523 women with operable breast cancer were randomly assigned to pre- or postoperative doxorubicin and cyclophosphamide (adriamycin cyclophosphamide [AC]; 60/600 mg/mg^2 for four cycles) (9). Preoperative chemotherapy was associated with a higher rate of breast conservation surgery (68% vs. 60%; p = .001) as compared to adjuvant therapy. However, there was no difference in the Disease Free Survival (DFS, 55% vs. 58%) or Overall Survival (OS, 72% vs. 72%) observed between the preoperative and adjuvant groups. Among those patients who received preoperative therapy, achieving pCR was associated with significant improvement in DFS (HR = 0.47; p <.0001) and OS (HR = 0.32; p <.0001) compared with those who had residual tumor at the time of surgery. Similar results were observed in other randomized trials comparing preoperative and adjuvant regimens (10–12).

Although any of these trials showed superiority in DFS or OS, the demonstration of equivalence between preoperative and adjuvant chemotherapy set the stage for the development in the preoperative setting of a number of treatment regimens that were developed in parallel with new adjuvant approaches. Today, similar guiding principles apply for the choice of agents, sequencing, and duration of therapy between the preoperative and adjuvant setting. In addition, new targeted agents are today being tested preoperatively. Figure 54-1 outlines the evolution of preoperative chemotherapy over the past 30 years.

CURRENT PREOPERATIVE REGIMENS AND PRACTICE

A number of conditions have to be met in order to consider the administration of preoperative therapy. First, appropriate tumor tissue in the diagnostic specimen should be available for histological diagnosis, including assessment of hormone receptor (HR) and Human epidermal receptor-2 (HER2) status. Ideally, enough tumor tissue for additional studies, such as gene-signature profile, should also be available. Second, it is helpful to place clips to mark the tumor location as it aids the radiologist, surgeon, and pathologist in providing post-treatment assessment. Third, biopsy of clinically palpable axillary lymph nodes, and sentinel lymph node biopsy in the absence of palpable lymph nodes, may be considered before initiating preoperative therapy. The management of sentinel lymph node (SLN) is detailed in Chapter 56. The determination of pathological involvement of axillary lymph nodes has prognostic significance and could influence the radiation therapy decision after surgery. Finally, preoperative chemotherapy requires a fully integrated, strong multidisciplinary team.

The commonly used preoperative regimens are summarized in Table 54-1. The salient features are reviewed below.

TABLE 54-1

Commonly Used Neoadjuvant Chemotherapy Therapy Regimens

Regimen	*Dose and Frequency*
AC-T[a]	Adriamycin/doxorubicin 60 mg/m^2 Cyclophosphamide 600 mg/m^2 every 3 weeks for four cycles, followed by Paclitaxel 80 mg/m^2[b]
ddAC-T[a]	Adriamycin/doxorubicin 60 mg/m^2 Cyclophosphamide 600 mg/m^2 every 2 weeks for four cycles with pegfilgrastim, followed by Paclitaxel 80 mg/m^2[b]
TC[a]	Docetaxel 75 mg/m^2 Cyclophosphamide 600 mg/m^2 every 3 weeks for six cycles
TAC	Docetaxel 75 mg/m^2 Doxorubicin 50 mg/m^2 Cyclophosphamide 500 mg/m^2 every 3 weeks for six cycles with pegfilgrastim
FAC	5-Fluorouracil 500 mg/m^2 (days 1, 8 or days 1, 4) Doxorubicin 50 mg/m^2 Cyclophosphamide 500 mg/m^2 every 3 weeks for six cycles
FEC-D	5-Fluorouracil 500 mg/m^2 Epirubicin 100 mg/m^2 Cyclophosphamide 500 mg/m^2 every 3 weeks for three cycles, followed by Docetaxel 100 mg/m^2 day 1 every 3 weeks for three cycles
CMF	Cyclophosphamide 100 mg/m^2 PO (days 1–14) Methotrexate 40 mg/m^2 IV (days 1, 8) 5-Fluorouracil 600 mg/m^2 IV (days 1, 8) every 4 weeks for six cycles

[a]Preferred regimen.
[b]Can also be given as paclitaxel 175 mg/m^2 every 2 weeks with pegfilgrastim or every 3 weeks.

Choice of Drugs

A standard preoperative chemotherapy regimen should ideally include an anthracycline such as doxorubicin or epirubicin. Doxorubicin is usually given as 50 to 60 mg/m^2 every 2 to 3 weeks, and epirubicin as 90 to 100 mg/m^2 every 3 weeks. A baseline evaluation of heart function (ejection fraction) should be obtained before initiating anthracyclines.

The addition of taxanes to anthracycline-containing regimens should also be strongly considered as it improves efficacy and clinical outcomes. This was well demonstrated in the NSABP-27 trial, wherein 2,400 patients were randomly assigned to receive either (a) preoperative AC alone (every 3 weeks for four cycles) followed by surgery or (b) preoperative AC followed by docetaxel (100 mg/m^2 every 3 weeks for four cycles) followed by surgery or (c) preoperative AC followed by surgery followed by adjuvant docetaxel (13). Preoperative AC-docetaxel significantly improved pCR rate as compared to AC alone (26.1% vs. 13.7%; p <.001). Like the NSABP B-18, the pCR was a significant predictor of DFS (HR = 0.49; p <.0001) and OS (HR = 0.36; p <.0001) regardless of treatment. Multiple other preoperative trials have demonstrated the advantage of adding docetaxel (14–16), and paclitaxel (17,18) in the preoperative setting.

If there is a contraindication to use of anthracyclines, a non-anthracycline regimen preferably with a taxane, such as TC, should be considered based on extrapolation from the adjuvant studies (19). The TC regimen involves the administration of docetaxel 75 mg/m^2 with cyclophosphamide 600 mg/m^2 every 3 weeks for a total of four cycles. This should be given in conjunction with appropriate antiemetic prophylaxis and growth factor support.

Schedule

Weekly paclitaxel seems to be superior to every-3-week paclitaxel, similar to that observed in the adjuvant setting. For example, in a preoperative trial led by investigators at MDACC, 258 patients were randomly assigned to receive a) weekly paclitaxel (either 80 mg/m^2 for 12 weeks to those with clinically node-positive disease or 150 mg/m^2 3 weeks on and 1 week off for 12 weeks to those with clinically node-positive disease) or b) every-3-week paclitaxel (225 mg/m^2 every 3 weeks for four cycles). Both the pCR rates (28.2% vs. 15.7%; p = .02) and breast conservation rate (47% vs. 38%; p = .05) were higher in those who received weekly paclitaxel than those who received every-3-week paclitaxel (20).

Conceptually, the same regimen and schedule used for adjuvant therapy could be used for preoperative therapy. Thus, as in the adjuvant setting, the administration of chemotherapy cycles every 2 weeks instead of every 3 weeks, an approach that is being referred to as *dose-dense chemotherapy,* might be superior to a conventional dose regimen, though strong data from randomized clinical trials is lacking. Trials comparing dose-dense regimens to conventional regimens have had differences in the dose and regimen between the groups, making it difficult to draw clear conclusions. For example, in the AGO-1 trial (21), eligible patients (n = 668) were randomly assigned to receive either a) dose-dense epirubin (150 mg/m^2 every 2 weeks for three cycles) followed by paclitaxel (225 mg/m^2 every 2 weeks for three cycles) or b) a conventional dose of epirubicin (90 mg/m^2 every 3 weeks for four cycles) and paclitaxel (175 mg/m^2 every 3 weeks for four cycles); the dose-dense sequential schedule was associated with higher pCR (18% vs. 10%; p = .008) as well as improvement in DFS (HR = 0.71; p = .011), and OS (HR = 0.83; p = .041) as compared to the conventional combination schedule. However, it is unclear whether the superiority of the dose-dense regimen was due to the dose-dense schedule or the addition of taxanes.

Nevertheless, in the U.S., dose-dense AC (followed by paclitaxel) is commonly used in clinical practice. This involves the administration of Adriamycin 60 mg/m^2 every 2 weeks along with cyclophosphamide 600 mg/m^2 every 2 weeks for a total of four cycles. This should be given in conjunction with appropriate antiemetic prophylaxis and growth factor support.

Sequence

The sequential administration of taxane following anthracyclines appears to be better than combination therapy. In the German Preoperative Adriamycin Docetaxel Trial (GeparDUO) trial, women (n = 913) were randomized to either a) a combination of doxorubicin and docetaxel (AD; 50/75 mg/m^2 every 2 weeks for four cycles) or b) AC (60/600 mg/m^2 every 3 weeks for four cycles) followed by docetaxel (100 mg/m^2 every 3 weeks for four cycles) (16). As compared to the AD

group, the AC-D group had better clinical responses (75.2% vs. 85%; p <.001), radiographic responses (68.6% vs. 78.6%; p <.001), breast conservation surgery rate (58.1% vs. 63.4%; p = .05), and pCR rate (7% vs. 14.3%; p <.001). The Hoosier Oncology Group trial also demonstrated the superiority of the sequential adriamycin-docetaxel regimen over the combination regimen (22).

Duration

There is a consensus of opinion based on currently available data that preoperative chemotherapy should be administered for at least six cycles, as in the adjuvant setting (2). The continuation of the same regimen beyond the standard number of cycles is not recommended, and sequential use of cross-resistant therapy is preferred over a longer duration of the same regimen (14,15). A German meta-analysis has suggested that duration of chemotherapy might be more important for HR+ tumors, and dose intensity more important for triple-negative breast cancers (TNBCs) (23), but this approach has not been validated in prospective studies.

In general, it is recommended that the full preoperative regimen should be administered before surgery, particularly if breast conservation surgery is desired. Sometimes preoperative therapy is used as a "bridge" until the mastectomy and reconstruction can be scheduled, and, in such settings, a sandwich technique (i.e., delivering part of chemotherapy before surgery and the remainder after surgery) can be used. The survival outcomes are similar as demonstrated by the NSABP-27 trial (13).

After preoperative chemotherapy, definitive breast surgery should be performed. The American Joint Committee on Cancer Staging manual uses "y" to indicate pathologic staging after preoperative therapy. After surgery, radiation and/or biologic therapy as appropriate (i.e., trastuzumab in HER2-positive disease, hormonal therapy for HR+ disease) should be pursued. The presence of residual disease after completion of preoperative therapy can be a therapeutic challenge, particularly for TNBCs. While the presence of residual disease is associated with worse outcomes as compared to pCR, there is no data that demonstrates additional postoperative chemotherapy improves outcomes. This is an area of active research and several clinical trials are investigating the role of additional therapies in this setting (NCT01401959, NCT0087750, NCT00925652, NCT01772472).

ADDITIONAL CHEMOTHERAPY AGENTS

In addition to the standard anthracyclines and taxanes discussed above, other chemotherapeutic agents have been studied in the preoperative setting. While they have shown clinical activity, they are not considered to be standard of care at this time.

Platinum

Gene-expression profiling of breast cancer has demonstrated that triple-negative breast cancer shares molecular features with basal-like BRCA-1 tumors, which are very sensitive to DNA cross-linking agents such as cisplatin (24). This has led to a renewed interest in the role of platinum agents in breast cancer.

Various small preoperative trials have investigated the role of platinums in TNBC. In a small phase II trial, women with triple-negative breast cancer (n = 28) were treated with preoperative cisplatin (75 mg/m^2 every 3 weeks for four cycles), and a pCR rate of 22% was observed (25). Other authors have reported a higher pCR rate (as high as 67%) with platinum and taxane combinations (26,27), albeit still lower than the >80% pCR rate reported for BRCA tumors (28). Randomized trials comparing platinum-containing chemotherapy to nonplatinum-based chemotherapy, such as CALGB 40603, are ongoing and will help identify predictive biomarkers of platinum response.

Capecitabine

While capecitabine can improve response rates and survival among women with locally advanced or metastatic disease, in the preoperative setting the addition of capecitabine to an anthracycline and taxane-based regimen has not been associated with any significant benefit and leads to higher toxicity. For example, in the NSABP trial B40, 1,206 women with primary operable HER2-negative breast cancer were randomly assigned to receive preoperative therapy consisting of either (a) docetaxel (100 mg/m^2), (b) docetaxel (75 mg/m^2) with capecitabine (825 mg/m^2 days 1 to 14), or (c) docetaxel (75 mg/m^2 plus gemcitabine 1000 mg/m^2), every 21 days for four cycles, with each regimen followed by AC for four cycles (29). The addition of capecitabine or gemcitabine to docetaxel therapy, as compared with docetaxel therapy alone, did not significantly increase the rate of pathological complete response (29.7% and 31.8%, respectively, vs. 32.7%; p = .69), but both capecitabine or gemcitabine-containing regimens were associated with increased adverse effects, particularly hand-foot syndrome, mucositis, and neutropenia. Similar results were observed in the German GeparQuattro preoperative trial in which women with large or locally advanced tumors (n = 1,509) were randomized to receive four cycles of 5-fluorouracil, epirubicin, and cyclophosphamide (FEC), followed by either (a) docetaxel (100 mg/m^2), (b) docetaxel (75 mg/m^2) plus capecitabine (1,800 mg/m^2), or (c) docetaxel (75 mg/m^2) followed by capecitabine (1,800 mg/m^2), every 21 days for four cycles. There was no significant difference in pCR rates (22.3%, 19.5%, and 22.3%, respectively; p = .298), or breast conservation rates (70.1%, 68.4%, and 65.3%, respectively; p = .781) between the groups, but increases in adverse effects were noted (30). Thus, addition of capecitabine to an anthracycline and taxane-based preoperative regimen is not routinely recommended.

Ixabepilone

Ixabepilone has demonstrated efficacy in metastatic breast cancer including taxane-resistant tumors. In the preoperative setting, the single agent ixabepilone has been reported to have a pCR rate close to 20%, comparable to taxanes, and is particularly associated with a higher pCR rate among ER-negative tumors. In a phase II preoperative study designed to evaluate genomic predictors of ixabepilone response, ER, microtubule-associated protein *tau*, and a 10-gene penalized logistic regression (PLR) model were reported to be predictive of ixabepilone sensitivity (31). If confirmed in additional randomized trials, ixabepilone might serve as an alternative to taxanes for certain breast cancers.

Eribulin

Eribulin, a mitotic inhibitor similar to the taxanes, has significant activity among women with heavily pretreated metastatic breast cancer and was FDA approved for this purpose in 2010. While eribulin is not approved for use in the preoperative setting, clinical trials are ongoing. These include comparison of eribulin versus weekly paclitaxel after AC (NSABP FB-9, NCT01705691) or FEC (NCT01593020) and eribulin in combination with cyclophosphamide as a potential alternate to TC (NCT01527487). Similar to ixabepilone, eribulin might serve as an alternative to taxanes for certain breast cancers.

INCORPORATION OF BIOLOGICAL AGENTS IN PREOPERATIVE CHEMOTHERAPY

Anti-HER2 Agents

The study of new anticancer agents, mostly chemotherapy, in the preoperative setting has usually lagged behind their development in the adjuvant setting. However, with the demonstration of similar outcomes in both the preoperative and adjuvant setting and the early readout of clinical benefit provided by clinical and pathological responses, there has been a progressive shift in studying new agents earlier in the preoperative setting. This trend is well exemplified in the case of anti-HER2 therapies. After the pivotal study with the anti-HER monoclonal antibody trastuzumab showed improved outcomes in the metastatic setting, a number of studies both in the adjuvant and preoperative setting were launched almost simultaneously. These early studies with anti-HER2 agents in the preoperative setting were exploratory, hypothesis testing, and mostly supportive of the large registration phase III adjuvant studies. These studies were found to have comparable outcomes to those of the larger adjuvant studies, and, as a result, second-generation anti-HER2 studies with newer anti-HER2 therapies and combinations have been initiated and already reported ahead of their adjuvant counterparts. If the results of these second-generation anti-HER2 studies are confirmed in the adjuvant studies, it is conceivable that some of these newer agents could be approved for use based on the outcomes of preoperative studies.

The first generation of anti-HER2 therapies in the preoperative setting were based on the addition of trastuzumab to anthracycline and taxane-based chemotherapy (32–36). In summary, all these studies observed a higher pCR when therapy with trastuzumab was added to a number of chemotherapy regimens when compared to chemotherapy alone (Table 54-2). Among them, the NOAH study was a phase III study that showed that in patients with HER2-positive locally advanced or inflammatory breast cancer, addition of 1 year of trastuzumab (starting as preoperative and continuing as adjuvant therapy) to preoperative chemotherapy improved overall response rates, almost doubled rates of pathological complete response, and reduced risk of relapse, progression, or death compared to patients who did not receive trastuzumab. The benefit of trastuzumab was observed in all subgroups tested, including women with inflammatory disease (27% of HER2-positive patients) who benefitted substantially from trastuzumab. The important point to consider about NOAH is that it showed a good correlation between a higher rate of pCR and improved survival, suggesting that in HER2-positive tumors, pCR may be a correlate of survival. In addition, this study led to approval of preoperative trastuzumab in a number of countries, including those of the European Union. In support of the findings that pCR is correlated with improved overall outcomes, in the TECHNO trial that studied preoperative trastuzumab in combination with anthracyclines and taxanes (33) followed by up to 1 year of trastuzumab, the 3-year disease-free survival (DFS) was 88% in patients with pCR compared to 73% in patients without pCR ($p = .01$).

The next generation of preoperative studies in patients with HER2-positive breast cancer has explored the combination of two anti-HER2 agents given together. This approach was based on preclinical studies (36–37), as well as emerging clinical data in patients with advanced disease. In clinical trials of patients with metastatic disease that had progressed on trastuzumab, the combination of trastuzumab and the tyrosine kinase inhibitor lapatinib was superior to lapatinib alone (38). Likewise, the addition of pertuzumab (an antibody that prevents dimerization of HER2 with the closely related HER3 receptor) to trastuzumab was found to be superior to trastuzumab alone (39). In the case of pertuzumab, a phase III study in the first-line metastatic setting in patients with HER2-positive breast cancer has demonstrated that the combination of trastuzumab and pertuzumab with chemotherapy is superior to trastuzumab alone with chemotherapy and has resulted in its recent approval for therapy (40).

A number of studies have shown the superiority of the combination of trastuzumab and lapatinib when compared to either trastuzumab or lapatinib alone. In the NeoALTTO study, patients with HER2-positive primary breast cancer with tumors greater than 2 cm in diameter were randomly assigned to lapatinib, trastuzumab, or lapatinib plus trastuzumab therapies (41). Anti-HER2 therapy alone was given for the first 6 weeks; weekly paclitaxel was then added to the regimen for a further 12 weeks, before definitive surgery was undertaken. After surgery, patients received adjuvant chemotherapy followed by the same targeted therapy as in the preoperative phase for 52 weeks. The pCR rate was significantly higher in the group given lapatinib and trastuzumab (78 of 152 patients [51.3%; 95% CI, 43.1–59.5]) than in the group given trastuzumab alone (44 of 149 patients [29.5%; 95% CI, 22.4–37.5]; difference 21.1%; 95% CI, 9.1–34.2; $p = .0001$). No significant differences in pCR existed between the lapatinib (38 of 154 patients [24.7%; 95% CI, 18.1–32.3]) and the trastuzumab (difference –4.8%; 95% CI, –17.6 to 8.2; $p = .34$) groups. The recently reported NSABP-B41 study compared lapatinib versus trastuzumab in combination with weekly paclitaxel following AC, as well as combining weekly lapatinib and trastuzumab with weekly paclitaxel following AC on pathologic complete response (pCR) rates (42). Unlike the NeoALTTO study, following surgery, all patients received trastuzumab to complete 52 weeks of HER2-targeted therapy. At the time of initial presentation, pCR assessments were available for 519 patients. The pCR percentages in the HR-positive subset were 46.7%, 48% ($p = .85$), and 55.6% ($p = .18$), respectively, and were 65.5%, 60.6% ($p = .57$), and 73% ($p = .37$) in the HR-negative cohort. The corresponding pCR breast and nodes percentages were 49.1%, 47.4% ($p = .74$), and 60.4% ($p = .04$). Finally, the smaller CHER-LOB study also showed the superiority of dual HER2 blockade with trastuzumab and lapatinib (43).

The combination of trastuzumab and pertuzumab has also been shown to be superior to trastuzumab alone. In the Neosphere study, a randomized phase II study, a total of 417 treatment-naive women with HER2-positive breast cancer were randomized to receive 4 preoperative cycles of trastuzumab plus docetaxel or pertuzumab and trastuzumab plus docetaxel or pertuzumab and trastuzumab or pertuzumab plus docetaxel (44). The primary endpoint was, like in NeoALTTO, pCR in the breast. Patients given pertuzumab and trastuzumab plus docetaxel had a significantly improved pCR rate (49 of 107 patients; 45.8% [95% CI, 36.1–55.7]) compared to those given trastuzumab plus docetaxel (31 of 107; 29.0% [95% CI, 20.6–38.5]; $p = .0141$). And 23 of 96 (24.0% [95% CI, 15.8–33.7]) women given pertuzumab plus docetaxel had a pCR. In this study, the one group that received pertuzumab and trastuzumab without chemotherapy also had a substantial pCR rate (18 of 107 (16.8% [95% CI, 10.3–25.3]), raising the hope that a subgroup of patients with early HER2-positive breast cancer may not need chemotherapy. The molecular features of these tumors that are sensitive to anti-HER2 therapy without chemotherapy are yet to be identified, and it is anticipated that this will be an area of intense research over the next few years.

TABLE 54-2

Neoadjuvant Clinical Trials Evaluating Combinations of Dual Anti-HER2 Therapies

Study	*Regimen*	*Sample Size*	*Results*
NeoALLTO	A) Trastuzumab with paclitaxel weekly*12 B) Lapatinib with paclitaxel weekly*12 C) Trastuzumab and lapatinib with paclitaxel weekly*12	455	pCR 29.5% in Group A vs. 24.7% in Group B vs. 51.3 in Group C p = .32 B vs. A p = .0001 C vs. A
NSABP-41 (NCT00486668)	A) Doxorubicin plus cyclophosphamide (AC)*4 followed by weekly paclitaxel with trastuzumab B) Doxorubicin plus cyclophosphamide (AC)*4 followed by weekly paclitaxel with lapatinib C) Doxorubicin plus cyclophosphamide (AC)*4 followed by weekly paclitaxel with trastuzumab and lapatinib	522 (reported on 519)	pCR (breast and nodes) 49.1% in Group A vs. 47.4% in Group B vs. 60.4% in Group C p = .74 B vs. A p = .04 C vs. A
TBCRC 006	Trastuzumab and lapatinib*12 (ER+ patients also received letrozole)		pCR Overall: 28% ER+ = 21% ER– = 42%
CHERLOB (81)	A) Paclitaxel weekly*12, followed by 5-fluorouracil, epirubicin, cyclophosphamide (FEC) q3weeks*4 with trastuzumab B) Paclitaxel weekly*12, followed by 5-fluorouracil, epirubicin, cyclophosphamide (FEC) q3weeks*4 with lapatinib C) Paclitaxel weekly*12, followed by 5-fluorouracil, epirubicin, cyclophosphamide (FEC) q3weeks*4 with trastuzumab and lapatinib	121	pCR 28% in Group A vs. 32% in Group B vs. 48% in Group C p <.05 for C vs. A p <.05 C vs. B
Neosphere (97)	A) Trastuzumab with docetaxel q3weeks*4 B) Pertuzumab with docetaxel q3weeks*4 C) Trastuzumab and pertuzumab with docetaxel q3weeks*4 D) Trastuzumab and pertuzumab q3weeks*4	417	pCR 29% in Group A vs. 24% in Group B vs. 45.8% in Group C vs. 16.8% in Group D p = .01 C vs. A p = .03 C vs. B p = .01 D vs. A
TRYPHEANA (98)	A) Pertuzumab and trastuzumab*6 with FEC*3 and then docetaxel*3 B) Pertuzumab and trastuzumab*3 with FEC*3 C) Pertuzumab, trastuzumab, docetaxel, and carboplatin*6	225	pCR rates ranging from 45% to 66% with no significant difference between the groups
CALGB 40601 (NCT00770809)	A) Paclitaxel weekly with trastuzumab*4 B) Paclitaxel weekly with trastuzumab and lapatinib*4	400 (planned)	Clinical trial ongoing

pCR, pathological complete remission; ER, estrogen receptor.

These second-generation anti-HER2 preoperative studies were initiated concurrently or prior to their companion registration adjuvant trials, and, at this time, the results of the much larger adjuvant studies of lapatinib plus trastuzumab (ALTTO; NCT00490139) and pertuzumab plus trastuzumab (Aphinity; NCT01358877) have not yet been reported. If these adjuvant studies are positive and confirm the findings from the preoperative studies mentioned here, it would strongly support that pCR in the preoperative setting is a surrogate marker of disease-free survival and overall survival in HER2-positive breast cancer.

Finally, the role of endocrine therapy in combination with anti-HER2 therapy needs to be addressed in patients with HER2-positive and HR-positive tumors for a number of reasons. First, as mentioned above, the pCR rate in patients with HR-positive tumors is lower than in patients with HR-negative tumors. For example, the pCR rates of the chemotherapy- and endocrine-free trastuzumab and pertuzumab group of the NeoSphere trial were 5.9% and 27.3% in patients with HR-positive and HR-negative tumors, respectively. This data clearly indicates that the different responses according to HR status is an intrinsic characteristic of tumors and not just due to the known differential effect of chemotherapy in HR-positive and HR-negative disease. Second, a recently reported pilot study known as TBCRC006 suggests that combined endocrine and HER2 therapy is highly effective in the preoperative setting (45). In this study, 66 patients with primary HER2-positive breast cancer were treated with trastuzumab and lapatinib without chemotherapy for 12 weeks in the neoadjuvant setting. Patients with estrogen receptor (ER)-positive disease also received endocrine therapy. Of note, the study population had particularly poor prognostic features with 52% of patients aged 50 or below at diagnosis, and 62% of patients with stage III disease (i.e., >5.0 cm). The study reported an overall pCR rate of 27% without chemotherapy (HR+ = 21%; HR– = 36%). The high pCR rate in patients with HR-positive disease treated with dual HER2 blockade in combination with endocrine therapy in the TBCRC006 trial was 3.5-fold higher than the pCR rate in the NeoSphere chemotherapy- and endocrine-free group (21.0% vs. 5.9%) and more similar to the pCR rates of HR-negative tumors treated with trastuzumab/pertuzumab alone (36.0% in TBCRC006 and 27.3% in NeoSphere) or the pCR rates of HR-positive tumors treated with trastuzumab/pertuzumab and docetaxel (26.0%). Because pCR after endocrine therapy alone or dual HER2 blockade alone is an infrequent event in HER2-positive/HR-positive disease, the 21.0% pCR rate after dual HER2 blockade and endocrine therapy should be interpreted as a confirmation of the cross-talk between HER2 and the estrogen receptor as was elegantly shown by the same authors and others in preclinical models.

Anti-Angiogenic Agents

The role of the antivascular endothelial growth factor antibody bevacizumab has been studied in two large preoperative trials. The GeparQuinto study randomized 1,948 patients to conventional preoperative chemotherapy with epirubicin and cyclophosphamide with or without concomitant bevacizumab (46). Overall, the improvement of pCR was modest with a pCR rate of 14.9% with epirubicin and cyclophosphamide followed by docetaxel and 18.4% with epirubicin and cyclophosphamide followed by docetaxel plus bevacizumab (odds ratio with addition of bevacizumab, 1.29; 95% CI, 1.02–1.65; p = .04); however, the corresponding rates of pathological complete response were 27.9% and 39.3% among 663 patients with triple-negative tumors (p = .003) while patients with hormone-receptor–positive tumors benefitted less. Another large study, NSABP B40, randomized 1,206 patients to receive a series of anthracycline and taxane-based chemotherapy combinations with and without bevacizumab (29). The addition of bevacizumab significantly increased the rate of pathological complete response in the breast, from 28.2% to 34.5% (p = .02). When the rate of pathological complete response was examined according to hormone-receptor status, the effect of bevacizumab was more pronounced in the hormone-receptor–positive subset (15.1% without bevacizumab vs. 23.2% with bevacizumab; p = .007), with a weaker effect in the hormone-receptor–negative subset (47.1% without bevacizumab vs. 51.5% with bevacizumab; p = .34). There was an increase in the rate of pathological complete response in the breast and nodes with bevacizumab therapy, but the difference in the overall cohort was not significant (23.0% without bevacizumab vs. 27.6% with bevacizumab; p = .08).

The results of these two studies have to be analyzed in the context of the recently reported bevacizumab adjuvant phase III study BEATRICE that failed to show that bevacizumab improved disease-free survival in the postoperative setting (47). BEATRICE randomized 2,500 patients with TNBC to receive ≥4 cycles of chemotherapy alone or with the addition of bevacizumab for 1 year. The 3-year disease-free survival rate was 82.7% in the control group and 83.7% in the bevacizumab group (HR = 0.87; 95% CI, 0.72–1.07; p = .18).

Taken together, there are two positive preoperative studies and a large adjuvant negative study with the same anti-angiogenic agent. From the patient care viewpoint, the results of the adjuvant study prevail, and the use of bevacizumab in this setting should not be considered outside clinical trials. However, it is important to try to interpret the underlying reasons for the discrepancy. One potential explanation is that with bevacizumab, as with other anti-angiogenic agents, there is an initial response followed by the rapid development of resistance due to the activation of additional angiogenic pathways. This rapid development of acquired resistance has been well documented in experimental models (48) and may also explain the increased response rate observed in the trials in the metastatic setting that does not correlate with improved disease-free survival. The implication of this hypothesis is that several anti-angiogenic pathways would need to be inhibited at the same time in order to achieve a durable clinical benefit. The other potential explanation is that the results from the preoperative studies were not robust enough in addition to the lack of consistency between the two studies of the subgroups of patients that derived clinical benefit. For example, in GeparQuinto, the benefit was seen in the TNBC tumors, whereas in the NASBP study, the benefit was almost restricted to the HR-positive subgroup. Furthermore, as will be discussed in the next section, we do not know yet what magnitude in the improvement of pCR correlates with true clinical benefit.

SIGNIFICANCE OF PATHOLOGICAL COMPLETE REMISSION

One of the limitations of adjuvant chemotherapy clinical trials is that it does take a long time to be able to document the presence of clinical benefit. In contrast, preoperative trials may allow for an earlier readout of clinical benefit by documenting responses to therapy in the tumors. While monitoring clinical response has been proven to be challenging for a variety of reasons (49), the documentation of the absence of invasive tumor at the time of surgery, also known as pathological complete remission (pCR), is a powerful indicator of the benefit of preoperative chemotherapy and

is associated with improved clinical outcomes. A potential concern, however, is that the definition of pCR has not been consistent among the clinical trials. For example, some trials have considered pCR to be the absence of both invasive and DCIS (ductal carcinoma in situ), while others have considered pCR as the absence of invasive cancer in the surgical specimen. Because the presence of residual ductal carcinoma in situ (DCIS) after preoperative therapy does not impact DFS or OS, pCR may not require the absence of DCIS. Also, some trials have considered pCR to be the absence of cancer in both the breast and lymph nodes, while others have considered pCR as the absence of cancer in the breast only. Because the presence of residual tumors in lymph nodes after preoperative therapy could impact DFS or OS, absence of cancer in both the breast and lymph nodes should be required for pCR. In March 2013, the FDA released a regulatory guideline defining pCR as "the absence of any residual invasive cancer on hematoxylin and eosin evaluation of the resected breast specimen and all sampled ipsilateral lymph nodes following completion of preoperative systemic therapy (i.e., ypT0ypN0 in the current AJCC staging system)."

Overall, pCR has been shown to be a strong predictor of improved disease-free and overall survival. We recently conducted a systematic review of published preoperative chemotherapy studies and found that pCR after preoperative chemotherapy was associated with significantly improved survival across the various breast cancer subtypes (50). While HR-positive tumors were less likely to achieve pCR compared to triple-negative tumors, when present, pCR was associated with significantly improved outcomes. Another large meta-analysis based on the pooling of individual patient data (n = 12,993) from 12 preoperative randomized controlled trials recently reported similar results (51). The authors of the working group of investigators, collectively known as the Collaborative Trials in Neoadjuvant Breast Cancer (CTNeoBC), reported that pCR was a strong predictor of improved DFS (HR = 0.48; p = <0.001) and OS (HR = 0.36; p = <0.001). The positive association between pCR and outcomes was seen for all the three breast cancer subtypes: HR-positive (HR = 0.49; p <.001), HER2-positive (HR = 0.39; p <.001), and TNBC (HR = 0.24; p <.001). For HR-positive tumors, the association was stronger for grade 3 tumors (HR = 0.27; p <.001) than grade 1 or 2 tumors (HR = 0.63; p = .07). In the meta-analyses, the magnitude of pCR improvement that predicts long-term clinical benefit could not be established.

ROLE IN IDENTIFICATION OF PREDICTIVE BIOMARKERS

Besides quick and efficient assessment of therapeutic efficacy using pCR as an endpoint, the preoperative setting also provides an ideal opportunity to identify predictive biomarkers of response and assess pharmacodynamic effects of individual agents.

A randomized two-group study design, similar to the NeoALLTO study design (41), could be used to achieve these objectives and is outlined in Figure 54-2. In such a preoperative trial, eligible women with biopsy-proven invasive breast cancer (T2 or higher) are randomized to receive the novel targeted therapy (experimental group) or standard targeted therapy such as trastuzumab (control group). A short lead-in phase with mandatory biopsy is built in to facilitate pharmacodynamic evaluation of the targeted therapy. After this "biological window," patients continue on the same targeted therapy plus standard chemotherapy, such as weekly paclitaxel for 12 weeks, up to definitive surgery. The primary endpoint of the trial is a difference in the rate of pCR. Such a study design has the potential to answer multiple questions rather quickly. For example, midtreatment research biopsies could be built in to identify early prediction of drug efficacy similar to those used for early response to preoperative endocrine therapies (52). Noninvasive functional imaging modalities such as PET (positron emission tomography)

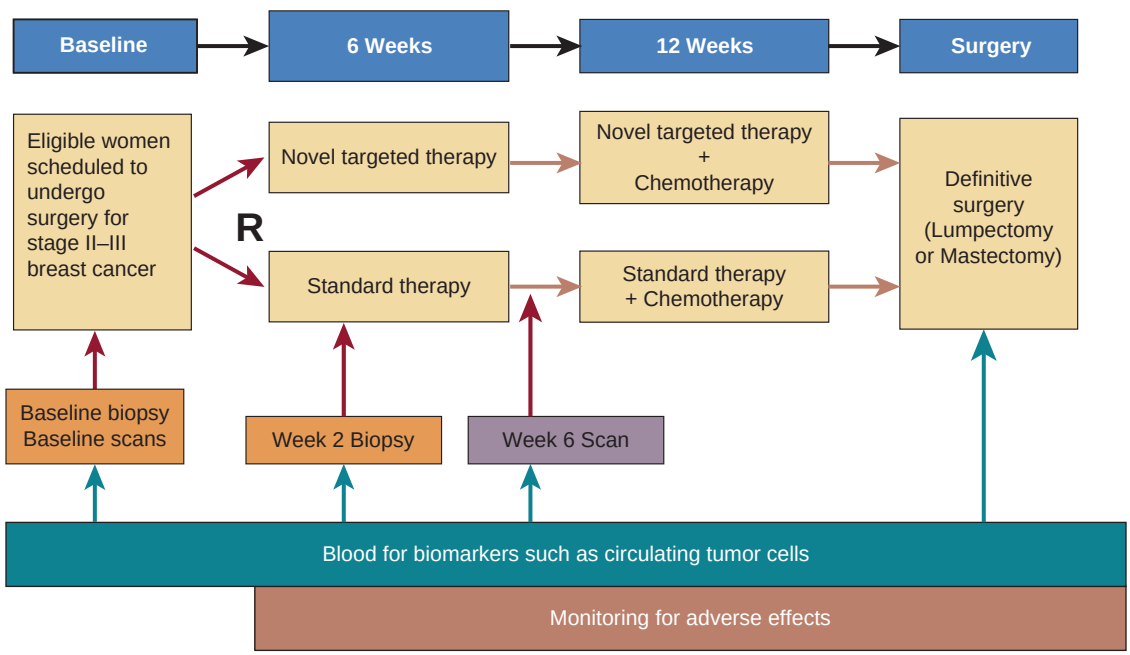

FIGURE 54-2 Schema of a clinical trial evaluating a novel preoperative therapy. MDACC, MD Anderson Cancer Center, USA; MCI, Milan Cancer Institute, Italy; LABC, locally advanced breast cancer.

scans could be incorporated to identify potential pharmacodynamic effects and early prediction of response. Similarly, blood can be collected to check for serum biomarkers such as circulating tumor cells. Besides estimating pCR, the surgical specimen could be analyzed for changes in various biomarkers such as downstream effectors and activators of compensatory pathways. Thus, such a preoperative study design provides an ideal setting for biomarker identification and evaluation of efficacy.

ROLE IN ACCELERATED APPROVAL OF NOVEL DRUGS

The traditional drug model of taking drugs from phase I to phase II to phase III studies is slow, inefficient, and expensive. It takes an average of 10 years from phase I to FDA approval (53). The unselected patient population requires large-scale trials to see any treatment benefit. Furthermore, the early testing of new agents is usually done in heavily pretreated patients with metastatic cancer. This is not optimal as these tumors may have already evolved into high-resistance clones. Testing in the adjuvant setting takes a long time to document the presence of clinical benefits and is an inefficient model for drug development.

Preoperative trials could be potentially used for drug approval purposes. In this regard, in 2012, the FDA stated that they would be willing to consider randomized trials of preoperative breast-cancer treatment for an accelerated-approval submission (54). A randomized trial in this setting, if adequately powered, could both support accelerated approval of a drug on the basis of substantial improvement in the pathological complete response rate and, with further follow-up, provide data on potential improvements in disease-free and overall survival to establish clinical benefit. Demonstration, with mature data, of a clinically and statistically significant improvement in disease-free or overall survival would still be needed to fulfill the requirements for regular approval. The advantages in the setting of preoperative studies would be many. First of all, preoperative studies are faster, require far fewer patients, and are less costly than large adjuvant studies. The current data available with chemotherapy in TNBC and with anti-HER2 agents in HER2-positive disease strongly support that pCR is a good correlate of disease-free and overall survival. However, an important aspect of this approach would be the amount of safety data required because, unlike in the advanced disease setting, these are patients with curable disease, and there is concern about potential long-term toxicities.

SUMMARY AND FUTURE DIRECTIONS

Preoperative chemotherapy requires careful patient selection and a multidisciplinary care set up. Clear indicators for preoperative chemotherapy are locally advanced and inflammatory breast cancer (Table 54-3). This treatment modality also needs to be considered in the case of large operable tumors that would require a mastectomy. In the case of smaller tumors, outside of a clinical trial, this option has no clear benefit to adjuvant chemotherapy and both approaches may be used interchangeably for tumors small enough to be candidates for breast conserving surgery upfront. On the other hand, clear indicators not to pursue preoperative chemotherapy are multicentric tumors that would require a mastectomy regardless of the benefit of chemotherapy and those small tumors with limited tissue for full anatomic and molecular characterization.

TABLE 54-3

Recommendations for Neoadjuvant Chemotherapy for Breast Cancer

Recommendation	*Indication*
Absolute recommendation	1. Locally advanced breast cancer 2. Inflammatory breast cancer
Relative recommendation	1. T2–T3 tumors with goal of breast conservation therapy 2. Alternative to adjuvant therapy
Not recommended	1. Small (T1N0), HR+/HER-2 negative, grade 1–2 tumor 2. Multicentric tumor

Preoperative chemotherapy requires a fully integrated multidisciplinary team that includes an oncologist, a breast surgeon, a radiation oncologist, a pathologist, and a radiologist who should coordinate care, monitor therapy, and coordinate the different sequential therapies. Only in a setting with a seasoned multidisciplinary team should this approach be contemplated. A standard preoperative chemotherapy regimen should ideally include an anthracycline and taxane. The continuation of the same regimen beyond the standard number of cycles is not recommended, and sequential use of cross-resistant therapy is preferred over a longer duration of the same regimen. Anti-HER2–based therapy should be strongly considered for patients with HER2-positive breast cancer.

In the future, preoperative trials testing targeted therapy combinations with or without chemotherapy could change the landscape of localized breast cancer management. A number of preoperative trials investigating novel drugs such as PI3K inhibitors (NeoPHOEBE, NCT01816594), PARP inhibitors (NeoPARP, NCT01204125), multikinase inhibitors such as sunitinib, pazopanib (NCT00849472, NCT00887575), and IAP (Inhibitor of Apoptosis Protein) antagonists such as LCL161 (NCT01617668) are ongoing. The results of these trials will help establish the role of targeted therapy regimen combinations with less chemotherapy or no chemotherapy, representing a paradigm shift in the management of breast cancer.

MANAGEMENT SUMMARY

- Preoperative chemotherapy, also referred to as neoadjuvant chemotherapy or primary systemic therapy, is the administration of chemotherapy before surgery.
- Preoperative chemotherapy is the preferred therapeutic modality for locally advanced (T3 or T4) and inflammatory breast cancer. Preoperative chemotherapy can be used to downstage tumors and facilitate breast conservation in women who would have otherwise needed a mastectomy.
- A standard preoperative chemotherapy regimen should include a taxane. In addition, anthracyclines should be considered. For HER2-positive tumors, incorporation of anti-HER2–directed therapy, such as trastuzumab, is strongly recommended.

- Patients receiving preoperative chemotherapy should be followed at regular intervals for monitoring response. Even among patients who have a complete clinical response to preoperative chemotherapy, definitive breast surgery after chemotherapy is recommended as there could be microscopic residual disease. The absence of any residual invasive tumor in the surgical specimen is referred to as pathological complete remission (pCR) and is associated with good prognosis.
- Preoperative clinical trials are increasingly being used to evaluate novel therapies. In the coming years, preoperative targeted therapy combinations with or without chemotherapy will be preferentially used to manage localized breast cancer.

CHAPTER 55

Preoperative Endocrine Therapy for Operable Breast Cancer

Ian E. Smith

CHAPTER CONTENTS

INTRODUCTION

Preoperative estrogen therapy was first described more than 50 years ago for postmenopausal women with large and sometimes locally advanced breast cancers (1). In the modern era of breast cancer management, its use has been overshadowed until recently by preoperative chemotherapy. Today, however, the potential of neoadjuvant endocrine therapy is being increasingly exploited, not simply to downstage large cancers to allow less extensive surgery but also as a scientific tool, using molecular markers to predict outcomes both in adjuvant trials and for the individual patient. This chapter will address both the clinical and research potential of the preoperative endocrine approach to operable breast cancer.

PREOPERATIVE TAMOXIFEN

From the 1980s onward, tamoxifen was evaluated before, or as an alternative to, surgery in a series of small studies usually involving elderly women. Most of these studies reported response rates of over 50% (2–4). In one of the larger trials, carried out by the Cancer Research Campaign in the UK, tamoxifen alone was compared with surgery and tamoxifen in 381 women aged 70 or over. In the initial analysis after 34 months follow-up, there were no significant differences in survival or quality of life between the two approaches (5). A significantly higher local regional relapse rate was, however, seen in the tamoxifen alone group (23% vs. 8%), and, in a subsequent later analysis, both overall mortality and breast cancer mortality were worse with tamoxifen alone (hazard ratio of 1.29 and 1.68, respectively) although these differences took over 3 years to emerge (6).

In contrast, a similarly designed Italian multicenter trial involving 474 patients over 70 years of age did not show any difference in overall survival or breast cancer survival with a median follow-up of 18 months, but there was a significantly higher incidence of locoregional recurrences in the tamoxifen alone group (p = .0001) (7).

These pioneering trials in elderly patients urged caution in using preoperative endocrine therapy instead of surgery but nevertheless showed the approach to be a reasonable one for patients unfit for surgery.

THE MODERN ERA: PREOPERATIVE AROMATASE INHIBITORS VERSUS TAMOXIFEN

Over the last decade, the aromatase inhibitors (AIs) anastrozole, letrozole, and exemestane have established themselves as having modestly superior long-term outcomes to

tamoxifen as adjuvant therapy for early breast cancer in a series of adjuvant trials described elsewhere in this book.

These results have been largely mirrored by smaller neoadjuvant trials with short-term clinical and biological endpoints. The first of these, a very small trial comparing vorazole (a now discontinued nonsteroidal third-generation inhibitor) with tamoxifen, unsurprisingly showed no significant difference in outcome (8), but it was one the first to compare the effects of treatment on molecular markers within the tumor (see below).

Letrozole versus Tamoxifen

There has been one multinational double-blind randomized trial (PO24) comparing preoperative letrozole 2.5 mg with tamoxifen for 4 months prior to surgery (9). This involved 337 postmenopausal women with estrogen receptor (ER) or progesterone receptor (PgR)-positive cancers, defined by at least 10% nuclear staining. All patients would have otherwise required mastectomy at entry to the trial or were considered inoperable (14%). The overall clinical response rate, the primary endpoint, was significantly higher for letrozole than for tamoxifen (55% vs. 36%; $p = .001$). The median time to response was 66 days for letrozole and 70 days for tamoxifen. Progressive disease during treatment was seen with 12% of patients treated with letrozole and 17% with tamoxifen. Letrozole was also more effective than tamoxifen when the response rate was determined by ultrasound (35% vs. 25%; $p = .0042$) and by mammography (34% vs. 16%; $p = .001$).

The main secondary endpoint of the trial was breast conservation, and significantly more breast-conserving surgery was achieved with letrozole than with tamoxifen (45% vs. 35%; $p = .022$). Pathological complete remission (pCR) in the primary breast lesion was seen in only 2 patients treated with letrozole and 3 with tamoxifen. Only 2 of these 5 patients with pCRs had no involved nodes at surgery.

In a further analysis of the same study, ER and PgR expression were re-assessed in a central laboratory, and 12% of patients were found to have tumors that were both ER and PgR-negative (10). In patients whose tumors were confirmed ER or PgR-positive, the response rate to letrozole was 60% compared with 41% for tamoxifen ($p = .004$), and 48% versus 36%, respectively, underwent successful breast-conserving surgery ($p = .036$).

In this analysis ER and PgR were quantified using the Allred scoring system in which an intensity score (range, 1–3) is added to a frequency score (range, 1–5) (11). Letrozole response rates were numerically superior to tamoxifen for all ER Allred scores from 3 to 8; furthermore, responses to letrozole were seen in all Allred scores between 3 and 8, whereas responses were only seen in tamoxifen for scores between 6 and 8. Based on this, the authors suggested that letrozole might be more effective than tamoxifen in patients whose tumors show relatively low ER expression, but it is important to note that the numbers were small in each of these Allred groupings and no definite conclusions should be drawn.

Anastrozole versus Tamoxifen

There have been 2 multinational double-blind trials comparing preoperative anastrozole 1 mg daily with tamoxifen 20 mg daily for 12 weeks prior to surgery in postmenopausal women with ER-positive breast cancer.

The IMPACT (IMmediate Preoperative Anastrozole, tamoxifen or Combined with Tamoxifen) trial compared anastrozole with tamoxifen or with both in combination given for only 12 weeks (in contrast to 16 weeks for PO24 above) (12); the trial was designed to be the preoperative equivalent of the adjuvant ATAC trial described elsewhere. The main clinical aim was to compare the efficacies of these treatments in terms of response and in downstaging to avoid mastectomy. An important further aim, however, was to determine whether short-term surrogate endpoints of response could be identified to predict for long-term outcome in the adjuvant ATAC trial; these included clinical changes after 12 weeks or biological changes in proliferation assessed by the proliferation marker Ki-67 after 2 and 12 weeks. For this reason, postmenopausal patients with smaller breast cancers not necessarily requiring mastectomy were also included, in contrast to the preoperative letrozole trial described above. This trial involved 330 patients with confirmed invasive histology and ER positivity on core needle biopsy. Median age was 73 years, median tumor size was 4 cm for each of the three groups, and tumors were confirmed in a central reference laboratory as ER-positive in 98% of cases. Objective clinical response rates by caliper measurement for anastrozole, tamoxifen, and the combination were 37%, 36%, and 39%, respectively, on an intent-to-treat basis, and none of these differences was significant. Ultrasound response rates were 24%, 20%, and 28%, respectively; again, none of these differences was significant. Progressive disease during treatment occurred in only 9%, 5%, and 5% of patients respectively.

A subgroup of 124 patients was assessed by the surgeon as requiring mastectomy at baseline. In these, 46%, 22%, and 26% were deemed to have achieved tumor regression sufficient to allow breast-conserving surgery after treatment with anastrozole, tamoxifen, and combination therapy, respectively. The improvement with anastrozole compared with tamoxifen was statistically significant with an odds ratio (OR) of 2.94 ($p = .03$).

There was no significant difference between the tamoxifen and combination groups.

An important secondary endpoint in the IMPACT trial was the reduction in proliferation as measured by Ki-67 staining after preoperative treatment. This was significantly reduced by all three treatments after 2 and 12 weeks, anastrozole by 76% and 82%, tamoxifen by 60% and 64%, and the combination by 65% and 64% (13). Change after 2 weeks correlated with the change after 12 weeks. The decrease with anastrozole was significantly greater than that with tamoxifen, as assessed by geometric mean ratios of the changes in Ki-67 after 2 weeks' treatment ($p = .04$) and again after 12 weeks' ($p = .001$), but there were no significant differences between tamoxifen and the combination. The changes in Ki-67 after only 2 weeks of treatment therefore predicted for long-term differences in relapse-free survival in the adjuvant ATAC trial, suggesting that change in proliferation as measured by Ki-67 might be a short-term surrogate for predicting differences in long-term outcome between different endocrine therapies in adjuvant trials.

This possibility is reinforced in an earlier and much smaller preoperative trial comparing vorozole with tamoxifen, which found a similar but nonsignificant trend in favor of an aromatase inhibitor, with mean drops in Ki-67 of 58% and 43% for vorozole and tamoxifen, respectively, after 2 weeks' treatment (20).

A statistically significant correlation was found between Ki-67 reduction after 2 weeks and response in the IMPACT trial, but this was not seen with Ki-67 reduction at 12 weeks: A weakly significant relationship was seen between the percentage of tumor shrinkage and change in Ki-67 (13).

In the second preoperative anastrozole trial, PROACT (PReOperative Anastrozole Compared with Tamoxifen), also multicenter and double-blind, 451 postmenopausal women with operable or locally advanced but potentially operable

(T2-4b) hormone receptor–positive breast cancers were randomized to anastrozole 1 mg or tamoxifen 20 mg for 12 weeks prior to surgery (14). As in the IMPACT trial, patients with small breast cancers appropriate for breast-conserving surgery were eligible for entry. In contrast to other trials, concomitant chemotherapy was also allowed and was given to 29% of patients on anastrozole and 32% on tamoxifen. Mean age was 67 in both groups, and mean ultrasound tumor diameter was 3.6 cm. Overall ultrasound response, the primary endpoint, was 40% for anastrozole and 35% for tamoxifen (p = .29). Clinical response by caliper measurement was 50% and 46%, respectively (p = .37). Chemotherapy was clearly confounding here, and in the 314 patients treated with endocrine therapy alone without chemotherapy, ultrasound and clinical response rates for anastrozole and tamoxifen, respectively, were 36% versus 27% (p = .07) and 50% versus 40% (p = .08).

In the 262 patients treated with endocrine therapy alone without chemotherapy who would have required mastectomy or had locally advanced disease at baseline, surgical improvement (inoperable to mastectomy or mastectomy to breast-conserving surgery) was deemed feasible in 47% after anastrozole compared with 38% after tamoxifen (p = .15) and actually occurred in 43% versus 31% (p = .04).

Combined IMPACT and PROACT Results

A common population of 535 patients treated with anastrozole or tamoxifen alone was derived from the combined results of the IMPACT and PROACT trials, with respective caliper-measured response rates of 45% for anastrozole and 36% for tamoxifen (p = .052) (15). Of these, 344 were deemed to require mastectomy or had inoperable cancer at baseline, representing a comparable group to the PO24 letrozole trial (21), and in this subgroup the clinical response rate was significantly higher for anastrozole than for tamoxifen (47% vs. 35%; OR 1.65; p = .026). In this group, improvement in feasible surgery was 47% and 35% (OR 1.67; p = .021) and in actual surgery 43% and 31% (OR 1.70; p = .019), respectively.

Exemestane versus Tamoxifen

Preoperative exemestane has also been shown to be active in achieving clinical responses and downstaging to avoid mastectomy (16), but so far only one small randomized trial, comparing preoperative exemestane with tamoxifen, has been reported. Seventy-three postmenopausal women with hormone receptor–positive status were randomized to receive exemestane 25 mg or tamoxifen 20 mg daily for 3 months before surgery (17). Clinical objective response rates were reported as 89% for exemestane compared with 57% for tamoxifen (p = .05), including complete clinical remission rates of 14% and 11%, respectively (ns). Ultrasound response rates were 70% and 41% (ns), and breast conservation rates 39% versus 11%, respectively (p = .05). Two pathological complete remissions were found with exemestane and one with tamoxifen.

The authors reported without details that responses were more likely with higher levels of estrogen-receptor expression.

AIs versus Tamoxifen in HER2-Positive Breast Cancers

In the PO24 trial, preoperative letrozole was markedly superior to tamoxifen in the small subgroup of 36 patients with HER2-positive cancers (88% vs. 21%; p = .004) (10), and a similar marked numerical difference was seen for anastrozole over tamoxifen for the 34 patients with centrally confirmed HER2-positive cancer in the IMPACT trial (58% vs. 22%; p = .09) (10,12). These differences were not, however, supported by subsequent results from the equivalent large adjuvant trials BIG 1-98 and ATAC (see Chapter 43), neither of which showed an increased benefit for AIs over tamoxifen compared with cancers not overexpressing HER2. These results therefore emphasize the potential pitfalls of extrapolating clinical preoperative data as a surrogate marker for long-term outcomes. A possible explanation for this discrepancy emerged with molecular marker studies from the IMPACT trial, described later in this chapter.

Response to Preoperative AIs and Body Mass Index (BMI)

There are some data suggesting that a high body mass index (BMI) may be associated with inferior outcome after adjuvant anastozole. In a recent Japanese study involving 109 patients treated with preoperative exemestane, a low BMI was paradoxically associated with a lower objective response rate (ORRs were 21.7% in low BMI, 56.0% in intermediate BMI, and 60.6% in high BMI, respectively; p = .01) (18). In a multivariate analysis, a low BMI was an independent negative predictor of clinical response. The authors do not postulate an explanation for these paradoxical results.

Conclusions from Neoadjuvant Trials Comparing AIs with Tamoxifen

Although these trials were relatively small compared with large adjuvant trials, the balance of evidence from them shows that the AIs are more effective clinically than tamoxifen in achieving objective responses and in downstaging to avoid mastectomy or to convert inoperable to operable cancers. AIs should therefore be considered the first-line preoperative endocrine therapy of choice for postmenopausal patients with ER-positive breast cancers.

AROMATASE INHIBITORS VERSUS OTHER ENDOCRINE AGENTS

Anastrozole versus Fulvestrant

A French trial, UNICANCER CARMINA 02, randomized 116 postmenopausal women with T2–T4, N0–N3, ER-positive, HER2-negative breast cancers to preoperative anastrozole 1 mg daily or fulvestrant 500 mg on Day 1, 15, and 29 and then 4 weekly, for 4 to 6 months. Clinical response rates at 4 months were 54% for anastrozole and 44% for fulvestrant and at 6 months 53% and 35% (a smaller number were treated to 6 months), respectively. These differences were not significant (19).

IS THERE A BEST PREOPERATIVE AROMATASE INHIBITOR?

The preoperative efficacy of the 3 currently used aromatase inhibitors have been compared in the Z1031 trial, a randomized phase 2 study in which 377 postmenopausal women with stage 2–3 ER-rich (Allred score 6–8) breast cancer were randomized to receive preoperative exemestane, letrozole, or anastrozole, with the aim of choosing which should go ahead for further investigation. Clinical response, the primary endpoint, was achieved in 63% (n = 78) patients on exemestane, 75% on letrozole (n = 95), and 69% (n = 85) on anastrozole (20). Letrozole and anastrozole went forward for further biomarker study on the basis of achieving the

highest scores. This analysis included comparison of the change in Ki-67 after treatment compared with baseline, but no significant differences emerged between the three treatments: The geometric mean percentage change in Ki-67 for anastrozole was 78% (standard error of the mean [SEM], 4%), for exemestane, 81.2% (SEM, 3.5%), and for letrozole, 87.1%. The authors concluded that large adjuvant trials comparing these agents were therefore unlikely to find significant differences in outcome (see below). Surgical outcomes were markedly improved in all 3 groups with overall 83% of those initially marginal for breast conservation and 51% of those initially deemed candidates for mastectomy only achieving breast conservation after preoperative treatment. No significant differences in surgical outcome were detected between the 3 aromatase inhibitors. Clinical response and surgical outcomes were similar for Luminal A and Luminal B tumors.

AROMATASE INHIBITORS IN COMBINATION WITH OTHER AGENTS

Letrozole and the mTOR Inhibitor Everolimus

There are good experimental data to show that cross-talk between the ER and the phosphoinositide-3-kinase (PI3K)/Akt/mammalian target of rapamycin (mTOR) pathways is a mechanism of resistance to endocrine therapy. Preclinical models have shown that blockade of both pathways can enhance antitumor activity (21). A phase 2 randomized trial of 4 months of letrozole in combination with everolimus (RAD001), an oral mTOR inhibitor, in a dose of 10 mg/day, versus letrozole alone was carried out in 270 postmenopausal women with operable ER-positive breast cancer. Response rate by clinical palpation, the primary endpoint, was significantly higher at the preplanned, one-sided 0.1 level in the everolimus group than with letrozole alone (68.1% vs. 59.1%; $p = .062$). An antiproliferative response, as defined by a reduction in Ki-67 expression to natural logarithm of percentage positive Ki-67 of less than 1 at day 15, occurred in 52 (57%) of 91 patients in the everolimus group compared with 25 (30%) of 82 patients in the placebo group ($p = .01$) (22). Marked downregulation of phospho-S6, a downstream intermediary of mTOR, occurred only in the everolimus group.

These positive results, particularly with respect to differences in Ki-67 suppression, prompted a subsequent phase 3 trial (BOLERO 1), which confirmed the clinical superiority of the everolimus combination; this trial is described in detail elsewhere in this book.

Anastrozole and Gefitinib

Preclinical evidence suggests that concurrent blockade of both estrogen-receptor and EGFR-signaling pathways might enhance response to endocrine therapy (23). Gefitinib is an orally active EGF tyrosine kinase inhibitor shown to suppress the growth of MCF7 cells otherwise resistant to estrogen withdrawal (24). This hypothesis was tested in a preoperative endocrine therapy trial in which 206 postmenopausal women with hormone receptor–positive early breast cancer received anastrozole daily for 16 weeks and were randomized in a 2:5:5 ratio to receive in addition gefitinib 250 mg daily orally for 16 weeks versus placebo orally for 2 weeks and then gefitinib for 14 weeks versus placebo for 16 weeks (25). The trial was designed to see whether tumors that did not show significant Ki-67 suppression after 2 weeks (and by implication were relatively resistant to endocrine therapy) could have this resistance reversed by the addition of gefitinib. There was no significant difference in the mean change in Ki-67 with anastrozole and gefitinib versus anastrozole alone between baseline and 16 weeks, baseline and 2 weeks, or between 2 and 16 weeks. Forty-eight percent achieved clinical response with anastrozole and gefitinib versus 61% on anastrozole alone, and this nonsignificant trend in favor of anastrozole alone was reflected in the Ki-67 change at 16 weeks with reductions of 77.4% and 83.6%, respectively. In the PgR-positive subgroup, there was a significant difference in favor of anastrozole alone versus the combination (72% vs. 48%; $p = .03$), and this was consistent with the Ki-67 changes in this subgroup. This trial, using biological as well as clinical endpoints, therefore failed to demonstrate a benefit from the addition of gefitinib to anastrozole and, indeed, suggested the possibility of an adverse interaction. It demonstrates, however, the potential of preoperative studies to investigate therapies that might overcome endocrine resistance using Ki-67 as an endpoint.

Letrozole and Zoledronic Acid

In a German trial (FEMZONE), 168 postmenopausal patients with ER-positive early breast cancer were randomized to 6 months' treatment with neoadjuvant letrozole alone or in combination with zoledronate 4 mg every 4 weeks. Clinical overall response rates at 6 months were 54.5% compared with 69.2% (externally assessed). This numerical trend in favor of letrozole with zoledronic acid was, however, not statistically significant. Overall there was no difference in the number of patients requiring mastectomy after neoadjuvant treatment (15.6 vs. 15.2%, respectively) (26).

PREOPERATIVE ENDOCRINE THERAPY IN PREMENOPAUSAL WOMEN

In contrast to postmenopausal women, data are very limited on preoperative endocrine therapy in premenopausal women.

Recently, however, a Japanese group has reported on the primary analysis of the STAGE (Study of Tamoxifen or Arimidex combined with Goserelin Acetate to Compare Efficacy and Safety) trial to compare the efficacy of anastrozole with goserelin versus tamoxifen with goserelin for 24 weeks preoperatively in 197 premenopausal women with ER-positive and HER2-negative early breast cancer. The clinical complete or partial response rate in the anastrozole group (70.4%) was significantly higher than in the tamoxifen group (50.5%) ($p = .04$) (27). Overall response was also higher for the anastrozole group when response was measured by ultrasound, MRI, or CT. Tumor responses increased gradually throughout the 24-week treatment period for both treatment groups.

The mean Ki-67 index at baseline and again at week 24 was 21.9% and 2.9% for the anastrozole group compared with 21.6% and 8% for the tamoxifen group. The difference in Ki-67 at 24 weeks was significantly greater in favor of anastrozole (estimated ratio of reduction 0.35 $p < .0001$).

This significantly improved clinical response rate for anastrozole and goserelin versus tamoxifen and goserelin reflects results in postmenopausal patients with preoperative letrozole versus tamoxifen (9) but not anastrozole in the IMPACT study (12), as described above. The significantly greater Ki-67 suppression with anastrozole reflects similar findings in the postmenopausal preoperative IMPACT trial described above (13).

These results are encouraging and indeed are better in terms of response rate than for the postmenopausal preoperative endocrine therapy trials. They do not, however, reflect my own albeit limited experience with preoperative endocrine therapy in premenopausal women,

where objective clinical responses have been uncommon. Likewise, the significantly improved short-term benefit with anastrozole and goserelin in terms of both response and Ki-67 suppression is not so far reflected in the ABCSG-12 adjuvant trial, which has so far failed to show any significant difference in long-term outcomes between anastrozole and goserelin versus tamoxifen and goserelin (28). Nevertheless, these data should serve as a stimulus for further preoperative endocrine therapy trials in premenopausal women in downstaging to avoid mastectomy where chemotherapy is contraindicated for whatever reason and in the planning of subsequent adjuvant trials (see below).

Current dogma based on the SWOG INT-0100 study is that premenopausal women should not be given adjuvant tamoxifen concurrently with chemotherapy (29). A retrospective preoperative endocrine therapy analysis challenges this belief, however. A group of 119 premenopausal women with locally advanced breast cancer treated with preoperative letrozole plus GnRH analogue (GnRH-a) administered concurrently with preoperative chemotherapy was compared with a matched group of 95 controls given only preoperative chemotherapy (and adjuvant endocrine therapy); the pCR rate was 5.0% in those given GnRH-a compared with only 1.1% in the control group. Likewise, significantly greater Ki-67 suppression was observed in patients receiving combined chemo endocrine therapy compared with controls ($p = .003$). Five-year disease-free survival (DFS) was 78 versus 41% in the study and in the control group, respectively (adjusted HR 0.46; 95% CI, 0.27–0.79; $p = .0047$) (30). These data argue for further clinical studies in this field to challenge current dogma.

PREOPERATIVE ENDOCRINE THERAPY VERSUS NONE

Many years ago, it was shown that noncurative surgery in a murine model was associated with serum growth factor stimulation of residual metastases that could be blocked by tamoxifen (and by chemotherapy) (31). More recently, it has also been shown that short-term preoperative endocrine therapy in the clinic for 2 weeks prior to surgery significantly reduces tumor cell proliferation in women with estrogen receptor–positive early breast cancer (32). There is therefore some experimental background to argue that preoperative endocrine therapy might improve long-term outlooks.

Curiously, only one clinical trial appears to have reported so far on this important issue. An Indian group randomized 976 eligible pre- and postmenopausal women with operable breast cancer to receive or not receive a single intramuscular injection of depot-hydroxyprogesterone 500 mg 5 to 14 days before surgery. There was no overall difference in the primary endpoint, disease free survival (73.9 vs. 70.2%) or overall survival (80.2 vs. 78.4%), but, in a pre-planned analysis of 471 women with node-positive disease, the progesterone-treated group had a significant improvement in 5 year DFS (65.3% vs. 54.7%; HR 0.72; $p = .02$) and OS (75.7% vs. 66.8%; HR 0.70; $p = .4$). In a post-hoc analysis, the effects of preoperative progesterone did not differ significantly according to menopausal status or estrogen receptor status. The authors considered their finding to be hypothesis-generating (33).

There are important caveats to this trial including why a benefit would also be seen in women with ER-negative tumors, and an uncertainty about the underlying mechanism of action of progesterone. Nevertheless, further trials are now clearly indicated in this important area, given the potential for improved long-term outcome with no increase in resources.

The question is being addressed in the much larger UK POETIC trial (Perioperative Endocrine Therapy-Individualizing Care) in which 4,000 postmenopausal women with ER-positive breast cancer have been randomized to 2 weeks preoperative and a further 2 weeks perioperative aromatase inhibitor therapy or not (Fig. 55-1). Accrual completes early in 2013. The primary endpoint is relapse-free survival (RFS), but the POETIC trial is also assessing whether Ki-67 and other molecular markers 2 weeks after the start of treatment will provide more accurate prognostic information than pre-treatment values (see below).

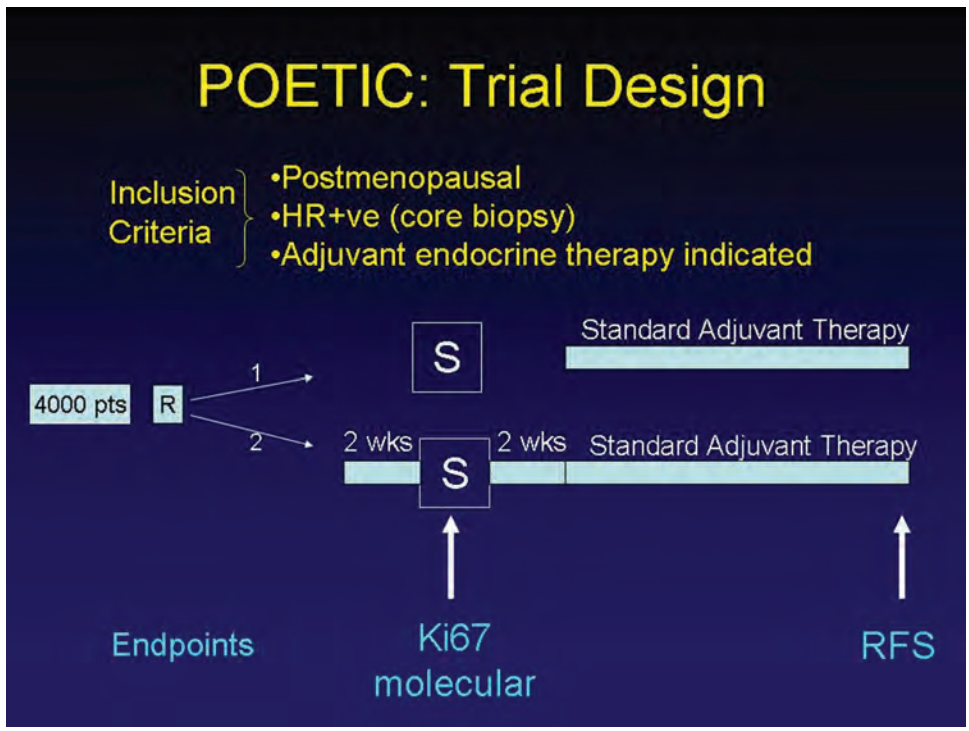

FIGURE 55-1 Schema for POETIC trial.

THE OPTIMAL DURATION OF PREOPERATIVE ENDOCRINE THERAPY

The main preoperative endocrine therapy trials described above have used treatment for 3 to 4 months prior to surgery. Yet the clinical response rate to anastrozole given for 12 weeks in our IMPACT trial was 37% (12,25) but was 61% in a subsequent trial by the same investigators where treatment was extended to 16 weeks (25), raising the possibility that longer duration might be more effective.

In a series of 182 consecutive postmenopausal patients with ER-rich breast cancers treated in Edinburgh with preoperative letrozole for 3 months or longer (63 of these continued letrozole beyond 3 months), the median reduction in clinical volume in the first 3 months was 52%, but similar reductions in median clinical volume were seen between 3 and 6 months (50%), 6 to 12 months (37%), and even between 12 and 24 months (33%) (34). The overall clinical response rate at 3 months was 69.8% of the original 182 patients, increasing to 83.5% with prolonged letrozole treatment. At 3 months, the number of women originally requiring mastectomy who became suitable for breast-conserving surgery was 60%, but this rose to 72% with more prolonged therapy. In this study, the median time to treatment failure had not been reached by 3 years.

A multicenter, prospective, longitudinal phase IV study involving 139 eligible postmenopausal patients with early breast cancer requiring mastectomy tried to establish the optimal duration of preoperative letrozole that would allow breast-conservation surgery (BCS). At study closure, 69% of patients were eligible for BCS. The median time to achieve a tumor response sufficient to allow BCS with neoadjuvant letrozole was 7.5 months (95% CI, 6.3–8.5 months) (35).

In the Japanese preoperative endocrine therapy study involving premenopausal patients described above, clinical responses for both the anastrozole plus goserelin and the tamoxifen plus goserelin groups continued to rise from 62.2% and 47.5%, respectively, at week 16 to 75.5% and 56.6%, respectively, at week 24 (27). In a small German study, 16 of 29 postmenopausal women with ER-positive breast cancer and clinical stage T2 or greater achieved a complete or partial response to preoperative letrozole after 4 months (55%), and 3 more subsequently achieved a partial or complete response between 4 and 8 months (final total 72%). Although all patients were initially candidates for mastectomy, 22 of 29 (76%) eventually managed conservative surgery (36).

In a phase 2 multicenter, open-label study addressing the same question, 70 postmenopausal patients over 65 years of age with a median age of 79 were given preoperative letrozole. In this study, 43 of 56 evaluable patients (77%) achieved an objective response with a median time to maximum response of 4.2 months (95% CI, 4.0–4.5), although 20 (37.1%) patients took 6 to 12 months to achieve a maximal response (37).

Finally, in a recent Italian study, so far presented only in abstract, 120 postmenopausal women were given neoadjuvant letrozole for 4, 8, or 12 months with overall clinical response rates of 50%, 85%, and 95%, respectively. These results are surprisingly high, as were the pathCR rates of 2.5%, 5%, and 17.5%, respectively (38), but they reinforce the point that longer treatment beyond 4 months is often more effective.

The optimal duration of preoperative endocrine therapy very likely varies for individual patients, but relapses within less than 12 months appear rare (34), and a pragmatic policy is to continue preoperative endocrine therapy in responding patients initially requiring mastectomy until downstaging is sufficient to allow conservative surgery.

PREOPERATIVE ENDOCRINE THERAPY VERSUS CHEMOTHERAPY

A Russian trial directly compared preoperative chemotherapy (doxorubicin 60 mg/m^2 and paclitaxel 200 mg/m^2 every 3 weeks in four courses) against AI endocrine therapy (exemestane or anastrozole for 3 months) in 239 postmenopausal women with hormone receptor–positive cancer (39). The primary endpoint, overall clinical response rate, was similar for each treatment (63% for chemotherapy, 67% for exemestane, and 62% for anastrozole). Rates of breast-conserving surgery were higher in the endocrine therapy group (33% vs. 24%; p = .058). The authors concluded that neoadjuvant endocrine therapy, with its low toxicity, was a reasonable alternative to chemotherapy in this elderly population.

In a more recent GEICAM Group trial, preoperative endocrine therapy with exemestane 25 mg daily for 24 weeks (combined with goserelin in premenopausal patients) was compared with chemotherapy (epirubicin 90 mg/m^2 plus cyclophosphamide 600 mg/m^2 for 4 cycles [cy] followed by docetaxel 100 mg/m^2 for 4 cy [EC-T]) in 95 postmenopausal patients defined as having immunophenotypical Luminal B breast cancer (ER+/PR+/HER2-/cytokeratin 8/18+ assessed in a central laboratory), operable stage T2 or 3. Adjuvant treatment was individualized. Clinical response rate, the primary endpoint, was 66% for chemotherapy and 48% for endocrine therapy (p = .07). Three patients on chemotherapy and none on endocrine therapy achieved a pCR (p = ns). Mastectomy rates were similar in both groups, at 49% and 35%, respectively (p = .18). An unplanned analysis based on Ki-67 levels showed similar clinical response rates in both groups in patients with low Ki-67 (<10%) (63% and 58%, respectively; p = .7), but patients with higher Ki-67 had a better response to chemotherapy (67% vs. 42%; p = .07). The authors concluded that a luminal immunophenotype was insufficient to identify patients who would not benefit from neoadjuvant chemotherapy (40).

These trials make the important point that for many postmenopausal patients preoperative endocrine therapy may have as high a chance of achieving a response as chemotherapy, but in the current era, when increasing emphasis is being placed on molecular markers including gene expression assays to select appropriate adjuvant therapies, the value of further direct comparative "one size fits all" trials of this type is doubtful.

HISTOLOGICAL EFFECTS OF PREOPERATIVE ENDOCRINE THERAPY

Pathological complete remissions (pCR) are increasingly used as an endpoint to predict long-term outcome following preoperative chemotherapy, but these are rare with preoperative endocrine therapy (9,12,17,41) and, as such, are of no prognostic or predictive value. Interestingly, and in contrast to chemotherapy, preoperative aromatase inhibitors have been reported as producing the histological feature of central scarring with a statistically significant correlation between central scarring and clinical tumor volume reduction (p = .034) (42). This observation requires validation; if confirmed, central scarring could be explored as a predictive endpoint for long-term outcomes.

PREOPERATIVE ENDOCRINE THERAPY TRIALS TO PREDICT LONG-TERM OUTCOMES IN ADJUVANT ENDOCRINE THERAPY TRIALS

Preoperative trials involve much smaller patient numbers than large adjuvant trials and have short-term primary endpoints (e.g., response rate versus disease-free survival). They therefore produce results much faster and at a fraction of the cost. It is attractive therefore to question whether they might predict for long-term outcomes in adjuvant trials, and, if so, they could therefore act as substitutes for such trials.

Some preoperative endocrine therapy trials have shown an excellent correlation between clinical response and subsequent long-term outcome in an adjuvant trial; examples described above include the PO24 trial, in which a superior response rate to letrozole correctly predicted long-term benefit for adjuvant letrozole over tamoxifen in the BIG 1-98 trial, and the preoperative everolimus trial, in which the marginally superior response rate of combined letrozole and everolimus over letrozole alone correctly predicted the improved results for the combination in the treatment of advanced disease shown in the BOLERO 2 (Breast Cancer Trials of Oral Everolimus-2) trial described elsewhere in this book. Others did not, however: The comparative clinical response rates in the IMPACT trial failed to predict the long-term gain for adjuvant anastrozole over tamoxifen or the combination shown in the equivalent ATAC trial, and, as already described, the very marked gain for a preoperative AI over tamoxifen in patients with ER-positive, HER2-positive cancers shown in both PO24 and IMPACT was not reflected in subsequent adjuvant trials.

In contrast, the proliferation biomarker Ki-67 seems a more secure endpoint for extrapolating results from preoperative to subsequent adjuvant trials. In the IMPACT trial, Ki-67 after 2 weeks and 12 weeks of treatment, in contrast to clinical response rate, correctly predicted for the superiority of anastrozole over tamoxifen or the combination found in the 9,000-patient adjuvant ATAC trial. Likewise, differences in Ki-67 after preoperative letrozole versus tamoxifen treatment in the PO24 trial correctly predicted the outcome of the equivalent 8,000-patient adjuvant BIG 1-98 trial, and, in the preoperative combination letrozole/everolimus trial, Ki-67 after treatment was a more powerful discriminator of benefit for the combination than clinical response, in predicting subsequent benefit for the combination in advanced disease. In the Z1031 trial described above comparing preoperative anastrozole, letrozole, and exemestane, the absence of a significant difference in the *change* in Ki-67 after treatment between the 3 groups led the authors to predict a similar difference in treatment outcomes in currently running comparative adjuvant trials. Time will tell.

Quality assurance is an important issue here, and guidelines for standardization of Ki-67 measurement have recently been proposed (43).

Serial Ki-67 Measurements

Ki-67 measurements after treatment may also help to explain the major lack of correlation between preoperative clinical response rates and long-term outcomes in ER-positive, HER2-positive cancers described above. In the IMPACT trial, Ki-67 levels 2 weeks after therapy were very similar to those after 12 weeks, except in around 15% of patients, where Ki-67 levels rose significantly, suggesting the rapid emergence of acquired resistance (44). HER2-positive cancers predominated in this group, supporting experimental evidence that the emergence of cross-talk between overexpressed HER2 and ER may be an important mechanism of acquired resistance to endocrine therapy.

It is possible that a similar approach using serial posttreatment Ki-67 levels could determine the emergence of acquired resistance in individual cancers that could be amenable to other combination therapies, including topical everolimus. Indeed, this approach has already been used in a trial described above aimed at determining whether gefitinib might overcome resistance to preoperative endocrine therapy (25).

PREOPERATIVE ENDOCRINE THERAPY TO PREDICT LONG-TERM OUTCOME IN THE INDIVIDUAL PATIENT

One of the most important challenges in the treatment of early ER-positive breast cancer is to determine which patients will do well with endocrine therapy alone without the need for additional chemotherapy. A similar issue is emerging in selecting those patients who might benefit from the m-TOR inhibitor everolimus in addition to endocrine therapy.

It is well established that the proliferation biomarker Ki-67 in the cancer at baseline is of prognostic significance in ER-positive breast cancer, but its predictive role for treatment outcome is less certain (45). Preoperative endocrine therapy has the potential to predict long-term benefit in the individual patient by measuring posttreatment levels of Ki-67 and other molecular markers, by incorporating both the innate biology of the tumor (prognostic) and the treatment sensitivity (predictive) (Fig. 55-2).

Many studies have shown that endocrine therapy can have a profound effect on proliferation in ER-positive cancers, and a few have suggested that early changes in Ki-67 following endocrine therapy correlate positively with clinical response (46–49). Long-term follow-up in the IMPACT trial described above showed that tumor Ki-67 2 weeks after starting preoperative endocrine therapy significantly predicted relapse-free survival (p = .004), the highest tertile of Ki-67 expression carrying an excellent prognosis

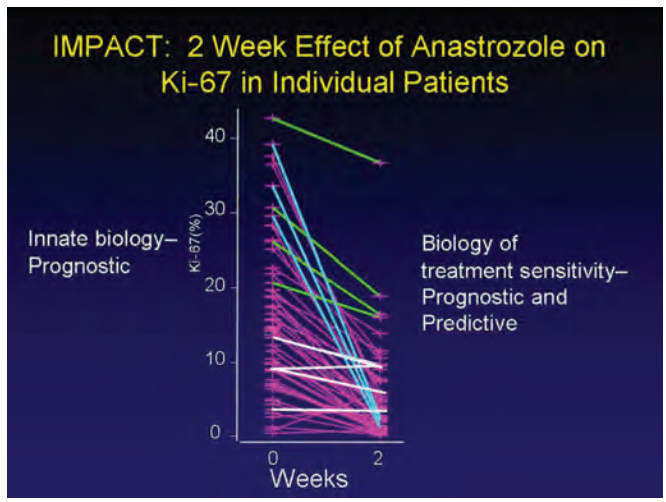

FIGURE 55-2 Change in tumor percentage of Ki-67 in individual patients after 2 weeks' treatment with anastrazole. Data from IMPACT trial (see text for details).

and the lowest tertile a poor one (32). The predictive significance of 2-week Ki-67 was sustained in a multivariate analysis. In contrast, baseline Ki-67 was only just significant in univariate analysis and dropped out in multivariate analysis, confirming the greater predictive significance of posttreatment levels (Fig. 55-3).

These findings, if validated, could provide the basis for predicting which patients might require additional chemotherapy (or indeed an m-TOR inhibitor) following 2 weeks' preoperative treatment with an aromatase inhibitor. This is now being investigated further in the 4,000-patient UK POETIC trial described above. In addition to the primary aim of determining whether short-term preoperative endocrine therapy might improve long-term outcomes, an additional and equally important aim is to determine the accuracy with which posttreatment Ki-67 in the individual tumor 2 weeks after starting an aromatase inhibitor predicts for long-term RFS compared with pretreatment Ki-67. This will establish whether preoperative endocrine therapy can indeed be used as standard practice to predict outcome and determine which patients will have a very good outcome with endocrine therapy and will not require additional adjuvant therapies, including chemotherapy. A key feature of the POETIC trial is that all patients with a measurable breast cancer 1.5 cm or larger on ultrasound were eligible (the majority of breast cancer patients), not just the minority patients with large breast cancers as in the traditional neoadjuvant model.

A similar approach has been developed using a preoperative endocrine prognostic index (PEPI) to determine which postmenopausal patients with ER-positive breast cancers have an extremely low risk of relapse and are therefore unlikely to benefit from adjuvant chemotherapy (50). Tumors from 158 women with confirmed ER+ stage 2 and 3 breast cancers in the P024 neoadjuvant endocrine therapy trial (comparing 4 months preoperative letrozole with tamoxifen) were analyzed for posttreatment ER status, Ki-67 proliferation, histological grade, pathological tumor size, node status, and treatment response. A PEPI for RFS was developed from these data with a median follow-up of 61 months. Patients with confirmed baseline ER-positive clinical stage 2 and 3 tumors that were downstaged to stage 1 or 0 at surgery had 100% RFS (compared with higher stages, $p < .001$). Multivariable testing of posttreatment tumor characteristics revealed that pathological tumor size, node status, Ki-67 level, and ER status were independently associated with both RFS and breast cancer–specific survival (BCSS). These results were validated in an independent study of 203 postmenopausal women in the IMPACT trial described above where the PEPI model again predicted RFS ($p = .002$).

The disadvantage of the original PEPI approach is that it requires around 4 months' treatment and surgical excision of the primary tumor, greatly limiting its potential for early prediction of treatment outcomes. The same group have therefore carried out a phase 2 trial in which 245 postmenopausal patients with stage 2 or 3 ER+ve (Allred score 6–8) cancers are treated with short duration (2–4 weeks) preoperative aromatase inhibitor followed by rebiopsy, similar to the POETIC trial described above. Patients whose tumors had a persisting Ki-67 of >10% were triaged to neoadjuvant chemotherapy or immediate surgery, while those with Ki-67 less than or equal to 10% continued on the aromatase inhibitor for 16 to 18 weeks and then had surgery. In this latter group, the PEPI was then calculated to determine whether adjuvant chemotherapy should be offered or not (50). Only 2 out of 35 patients triaged to neoadjuvant chemotherapy have so far had tumors achieving a pCR (6%). Pathological CR rates are low anyway in patients with ER-positive, HER2-negative tumors treated with chemotherapy, but these results nevertheless suggest that for some cancers neither endocrine therapy nor chemotherapy might be adequate and that new therapies up front may be required in this group. Whatever the interpretation, this approach further emphasizes the potential of preoperative endocrine therapy with short-term posttreatment molecular markers to determine optimal long-term adjuvant treatment in the individual patient.

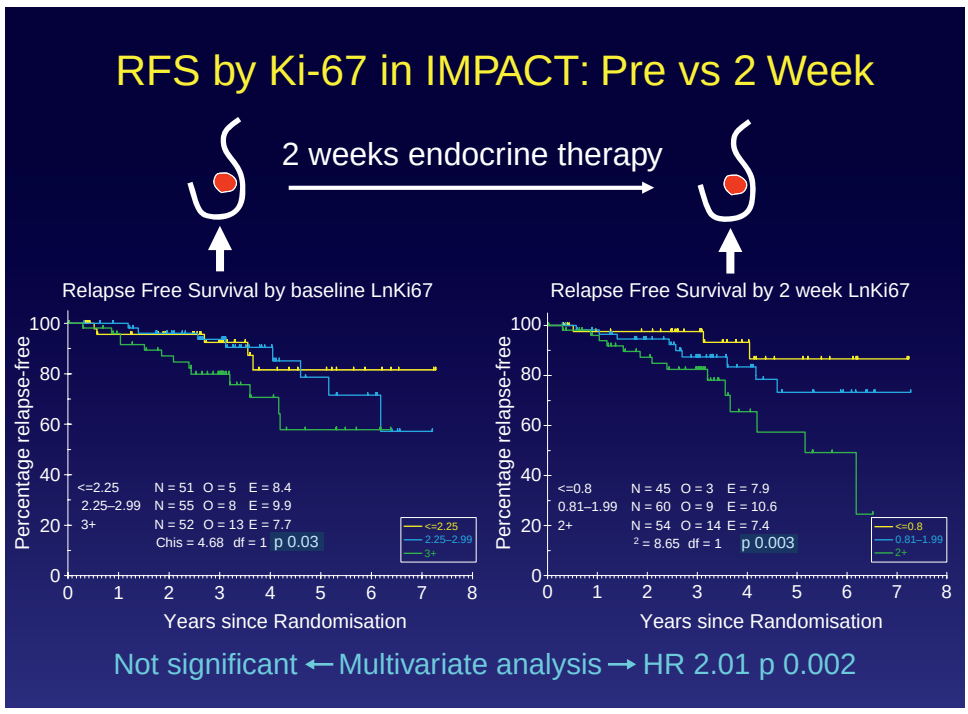

FIGURE 55-3 Relapse-free survival by log Ki-67 tertiles. **(A)** Before treatment, left panel. **(B)** After 2 weeks of anastrazole, right panel. (From Dowsett M, Smith IE, Ebbs SR, et al.; IMPACT Trialists Group. Prognostic value of Ki67 expression after short-term presurgical endocrine therapy for primary breast cancer. *J Natl Cancer Inst* 2007;99(2):167–170.)

MANAGEMENT SUMMARY

- Preoperative tamoxifen instead of surgery is a reasonable short-term approach in patients unfit for surgery, but it is associated with a higher risk of local relapse and perhaps impaired long-term overall survival.
- Preoperative aromatase inhibitors are more effective than tamoxifen at downstaging large ER-positive breast cancers in postmenopausal women and allow conservative surgery in up to 50% of patients.
- No individual preoperative aromatase inhibitor has been shown to be clinically superior to the others.
- The optimal duration of preoperative endocrine therapy to achieve conservative surgery varies considerably between patients but can be more than 6 months. A pragmatic policy is to continue treatment in responding patients until downstaging is sufficient to avoid mastectomy.
- Preoperative endocrine therapy cannot yet be considered standard in premenopausal women but is an important area for further study.

CHAPTER 56

Pathologic Assessment of Treatment Response after Neoadjuvant Therapy

Sunati Sahoo and Susan Carole Lester

CHAPTER CONTENTS

INTRODUCTION

Neoadjuvant therapy (NAT) reveals the response of cancers to therapy *in vivo* and, thus, generates a wealth of information for individual patients as well as for clinical trials. Pathologic downstaging after treatment is a strong predictor of disease-free and overall survival. In addition, pre- and post-therapy tumor samples are an essential resource underpinning research to understand the biologic mechanisms of how and why tumors respond. Clinical and radiologic examinations are helpful to evaluate changes in tumors during treatment, but these modalities frequently overestimate or underestimate the amount of residual carcinoma present. For example, extensive but paucicellular carcinomas may not be palpable or detectable by imaging. In contrast, densely fibrotic tumor beds often mimic residual carcinoma. Only careful pathologic examination can determine the type and extent of residual tumor and provide detailed information about treatment-related changes. However, without coordination and communication this information can be lost. In a recent review of a NAT trial for which there were no consensus guidelines for processing and reporting the specimens, only 45% of pathology reports for patients without a pathologic complete response (pCR) included an evaluation of treatment-related changes in the breast and fewer than 10% utilized a specific method to classify the degree of response (1). In addition, less than one-third of reports commented on nodal-related treatment changes. Thus, careful presurgical planning and close communication among surgeons, radiologists, medical oncologists, and pathologists are necessary to maximize the amount of pathologic information obtained from specimens after NAT.

PATHOLOGIC EVALUATION PRIOR TO TREATMENT

Breast Core Needle Biopsy

For patients who achieve a pCR, the diagnostic core needle biopsy may be the only sample of their carcinoma. Therefore, a definitive diagnosis of invasive carcinoma must be established and it is essential that all marker studies (in general, estrogen receptor [ER], progesterone receptor [PgR], and HER2) be completed before treatment. If very limited tumor is available for evaluation (e.g., < 0.5 cm) and marker studies are negative, repeat biopsies may be considered to obtain a more representative sample.

The type of breast cancer most likely to respond to chemotherapy is negative for hormone receptors, is poorly differentiated, and has a high proliferative rate. Typical pCR rates range from 30% to 40% (2). If the carcinoma also overexpresses HER2, HER2 targeted therapy often results in even higher rates of pCR. The type of breast cancer least likely to respond to therapy is well differentiated, expresses hormone receptors, and has a low proliferative rate. Lobular

carcinomas are frequently of this type. Fewer than 10% of these cancers undergo a pCR after chemotherapy (2). For these cancers, pCR is not a good predictor of prognosis, as many patients with extensive residual cancer experience long-term survival with endocrine therapy.

Additional predictors of a pCR are extensive tumor necrosis and a dense lymphocytic infiltrate (3,4). Immunohistochemical markers for identification of carcinomas more likely to be of basal type as defined by gene expression profiling (basal cytokeratins or epidermal growth factor receptor) have not been shown to predict response (5).

It is essential that a clip or clips be placed at the time of core needle biopsy to mark the site of the carcinoma prior to treatment, as this may be the only method to identify the tumor bed in many cases after treatment. If the tumor bed cannot be identified with certainty, a pCR cannot be confirmed.

Lymph Node Evaluation

The method of evaluating lymph nodes prior to treatment will impact the ability to identify node-negative and node-positive patient groups, to evaluate response in the lymph nodes, and to utilize some of the systems for classifying response to NAT.

Clinical Evaluation

Determination of nodal status by palpation alone is not accurate in many cases. In one study, 85% of patients with locally advanced breast cancer determined to be clinically node negative were found to be node positive after sentinel lymph node biopsy (6). Therefore, pretreatment nodal staging based on clinical examination alone will preclude accurate classification after treatment of cancers that never metastasized from cancers with metastases that have completely responded to treatment. This could confound efforts into investigating the biologic basis of tumor response to therapy.

Fine-Needle Aspiration (FNA) or Core Needle Biopsy of Nodes

Palpable nodes can be sampled using either FNA or core needle biopsy. If no nodes are palpable, ultrasound is a useful method to identify and biopsy suspicious nodes. Needle biopsy can confirm node positivity and also allows the evaluation of response to therapy, thus maximizing the amount of information gained from NAT.

Sentinel Lymph Node Biopsy (SLNB)

If the results of FNA or core needle biopsy do not reveal metastatic carcinoma, SLNB may be used to document node negativity before treatment. A negative SLNB prior to treatment may be more predictive of the status of the remaining nodes than SLNB after treatment due to the observation that metastases may not all respond to treatment to the same extent.

Excising a positive lymph node prior to treatment precludes the ability to evaluate response in the metastasis and also precludes documentation of a pCR in the nodes. Therefore, needle biopsies that do not completely remove the metastasis are advantageous when NAT is planned.

PATHOLOGIC EVALUATION AFTER TREATMENT

Gross Evaluation of the Breast Specimen (Partial or Total Mastectomy)

If a clinically palpable tumor mass is present after treatment (usually associated with a minimal to moderate response), the pathologist should be able to identify the mass by gross examination. However, carcinomas typically become softer and more compressible after treatment, and thus are more difficult to palpate. The reasons for the change in palpability most likely relate to loss of cellularity and the composition of the desmoplastic stroma. In addition, a decrease in blood flow is frequently detected by MRI and could contribute to a change in the firmness of the carcinoma. If the carcinoma is no longer palpable or visible on follow-up imaging studies after treatment, then the prior tumor area (tumor bed) will likely be difficult to identify. In those cases, it is preferable to have the specimen radiographed before slicing to identify a clip, calcifications, or any other radiologic finding that would localize the prior tumor site. Clips can be dislodged or lost if the specimen is sliced first. If no radiologic findings mark the tumor bed, the surgeon should place a suture at the pretreatment site of the carcinoma. If the specimen is a mastectomy, it is helpful to also provide a clock location and the distance from the nipple.

The gross appearance of a tumor bed after a marked response to NAT can be quite subtle and may consist of only an ill-defined area of fibrotic tissue (Fig. 56-1). Residual cancer may not be visible (due to low cellularity) or may consist of multiple small tan foci scattered throughout the fibrotic tumor bed.

The pathologist requires information about the number, size, and location of carcinomas prior to treatment in order to determine the best method to sample the specimen. At least one section per centimeter of the pretreatment carcinoma size of the tumor bed is suggested (7). If this sampling does not reveal residual invasive carcinoma, additional sampling may be considered to confirm a pCR.

FIGURE 56-1 All that remains of this invasive carcinoma after chemotherapy is an ill-defined area of white fibrous tissue (outlined). A clip placed prior to treatment would be necessary to recognize this area as the prior tumor site. Extensive sampling and microscopic evaluation of this area did not reveal residual carcinoma and a pathologic complete response was confirmed.

Involvement of chest wall (skeletal muscle) or skin prior to treatment should be evaluated by sampling the areas of prior tumor involvement. These areas should be marked by the surgeon. Patients with inflammatory carcinoma should have additional areas of skin sampled. However, clinically evident skin changes often resolve during treatment and dermal lymphovascular invasion is frequently no longer seen.

Failure to find and adequately sample the tumor bed can result in an erroneous conclusion that there has been a pCR. Inaccurate information about tumor response may adversely affect patient care, evaluation of clinical trials, and interpretation of research results. If no residual cancer is present, the pathology report should clearly document the gross and microscopic identification of the tumor bed.

Gross Evaluation of the Lymph Node Specimen

The examination of lymph node specimens after treatment is the same as for specimens in the absence of treatment. All lymph nodes are identified grossly and separately evaluated by placing in designated cassettes and/or by inking nodes in different colors. Some studies report slightly fewer nodes after NAT, although other studies report similar numbers. Nodes may be more difficult to identify after NAT due to atrophy and fibrosis as a result of toxic effects of chemotherapy on normal lymphocytes. This effect could vary for different types of chemotherapy.

The nodes are thinly sliced (0.2 to 0.3 cm) and all slices are processed for microscopic examination. The use of additional levels through the paraffin blocks or immunohistochemical studies have not been shown to add useful prognostic information if the nodes appear negative on the initial H&E section. However, if scattered atypical cells are present, immunohistochemical stains for cytokeratin may be useful to identify the cells as residual carcinoma.

MICROSCOPIC EVALUATION OF BREAST CANCERS

All pathologic prognostic factors significant for untreated carcinomas are also important for carcinomas that have undergone treatment prior to surgery. However, many of these factors are more difficult to assess after neoadjuvant therapy (7,8). In addition, the changes induced by the treatment also have prognostic importance. Although NAT protocols use a wide variety of chemotherapeutic regimes, typical changes are seen in the majority of cancers with any type of treatment. In future NAT studies with new therapeutic agents, pathologists should report any new or unusual types of tumor response.

Tumor Bed

The tumor bed consists of dense hyalinized stroma with fibroelastosis, often infiltrated by foamy histiocytes, lymphocytes, and hemosiderin-laden macrophages. It does not have the appearance of normal fibrotic breast tissue. The size of the tumor bed is generally about the size of the pretreatment cancer, although moderate increase or decrease in size are reported. The tumor bed never completely disappears but could be significantly small and subtle in rare occasion, and must be identified in order to document a pCR.

Ductal Carcinoma *In Situ* (DCIS)

For unknown reasons, in some patients the invasive carcinoma responds to treatment, but the associated DCIS does not. Residual DCIS can mimic invasive carcinoma on MRI, as it may continue to be associated with increased enhancement.

Many definitions of pCR allow residual DCIS (9,10). Thus, it is very important to distinguish residual invasive from *in situ* carcinoma. DCIS after treatment may show marked nuclear atypia and may be intermingled with normal ductal cells and histiocytes. In difficult-to-interpret lesions, immunohistochemical studies to demonstrate myoepithelial cells associated with DCIS are helpful. Pathologists always must be provided with information about prior therapy in order to avoid misinterpreting residual *in situ* carcinoma in a sclerotic tumor bed as invasion. In addition, it may be difficult to distinguish atypical hyperplasia with nuclear atypia due to treatment effect from residual DCIS at margins.

Size of the Invasive Carcinoma

In cases of a minor response to therapy in which the gross carcinoma remains identifiable by palpation, a narrow rim of fibrosis may be present around the edge of the tumor. These carcinomas typically remain highly cellular. With marked response, multiple small foci of invasive carcinoma, or scattered cells, are present throughout the tumor bed (Fig. 56-2). In the absence of a pCR, the entire tumor bed would need to be excised to ensure complete removal of all foci of carcinoma.

Providing a measurement of tumor size is often difficult. The size of the entire tumor bed without notation of cellularity may overestimate residual carcinoma when there has been a marked response. Alternatively, reporting only the size of the largest single focus when multiple foci are present may underestimate tumor burden. Judgment must be used in individual cases to choose the best size for AJCC T classification (11–13). It may also be useful for the pathologist to report the number of foci and/or the number of blocks with residual carcinoma. Because size is difficult to quantify, cellularity is also a useful parameter to assess response.

Cellularity of the Invasive Carcinoma

There is often a marked decrease in cellularity of the carcinoma, even when there is not a marked decrease in size. However, carcinomas prior to treatment also vary greatly in cellularity and a change in cellularity can only be determined with certainty if the pretreatment carcinoma is available for comparison (Fig. 56-3). Tumor cellularity is used in some systems for the evaluation of response (Table 56-1; e.g., Miller-Payne, Residual Cancer Burden [RCB]) (14,15).

Histologic Appearance and Grade of the Invasive Carcinoma

The majority of cancers do not change in appearance after treatment, except for diminished cellularity. A few cancers may appear to be of higher grade (generally due to enlarged tumor cells with pleomorphic and bizarre nuclei from treatment effect) and in rare cases the cancer may be of lower grade due to a decrease in the mitotic index. A change in grade can only be assessed by comparing the pre- and post-treatment specimens. The prognostic significance of change in grade after therapy is unknown.

Lymphovascular Invasion (LVI)

In some cases a complete response occurs for invasive carcinoma in the stroma but LVI remains. This finding confers a poor prognosis (16). Tumor cells in lymphatics should be included when determining post-treatment cellularity.

In contrast, the skin changes of inflammatory carcinoma often resolve with treatment and dermal LVI may no longer be seen.

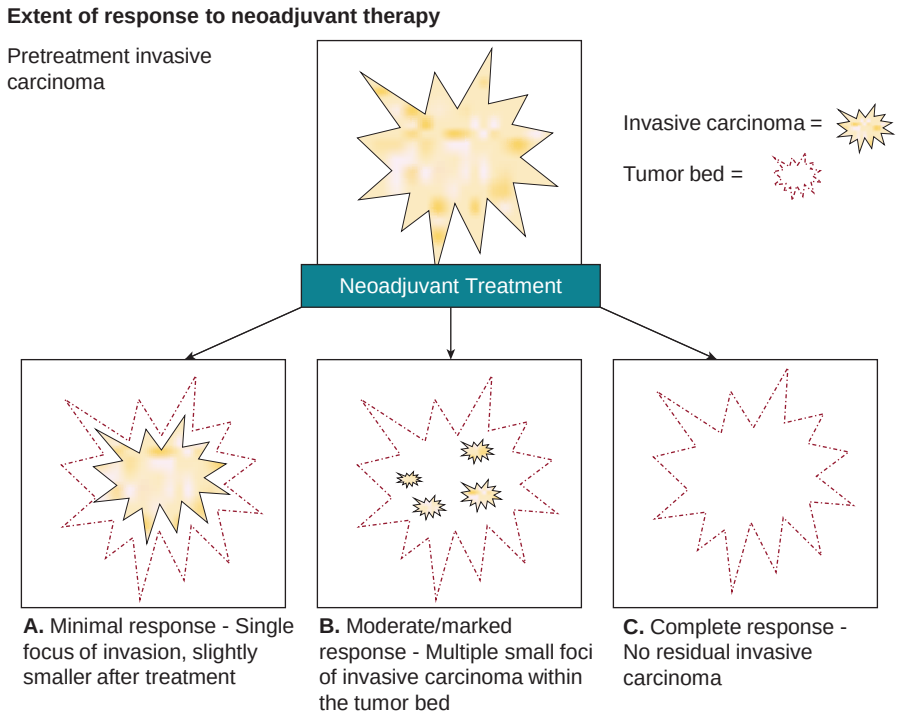

FIGURE 56-2 The initial response to treatment results in a narrow fibrotic rim and a slight decrease in tumor size **(A)**. This may be the only evidence of treatment effect in poorly responsive cancers. When a more marked response is present, the residual tumor is present as small nests or scattered individual cells across the tumor bed **(B)**. Cellularity and the number of tumor foci are methods to communicate the extent of residual cancer. In some cases, there will be no residual invasive carcinoma present **(C)**. However, this can only be ascertained if the prior tumor site is marked with a clip and the area is identified on gross examination.

Margins

Margins can be more difficult to evaluate after NAT. The extent of the tumor bed can be difficult to determine on imaging by the radiologist, grossly by the surgeon, and microscopically by the pathologist when there has been a pronounced response to treatment. The significance of tumor bed at the margin is unclear in patients with a pCR. If there is residual invasive carcinoma or DCIS within the tumor bed, tumor bed at the margin indicates the possibility that all carcinoma has not been removed and this finding should be reported.

Lymph Node Metastases

The response in the breast and in the lymph nodes is generally similar. However, the response in the lymph nodes is more predictive of survival than the response in the breast (17,18).

Metastases with little or no treatment response are easily identifiable. If there has been a marked response, only scattered tumor cells may be present in a fibrotic scar or associated with a prominent histiocytic infiltrate (Fig. 56-4). In nodes with a complete response, only fibrous tissue may remain. However, about one-third of pretreatment

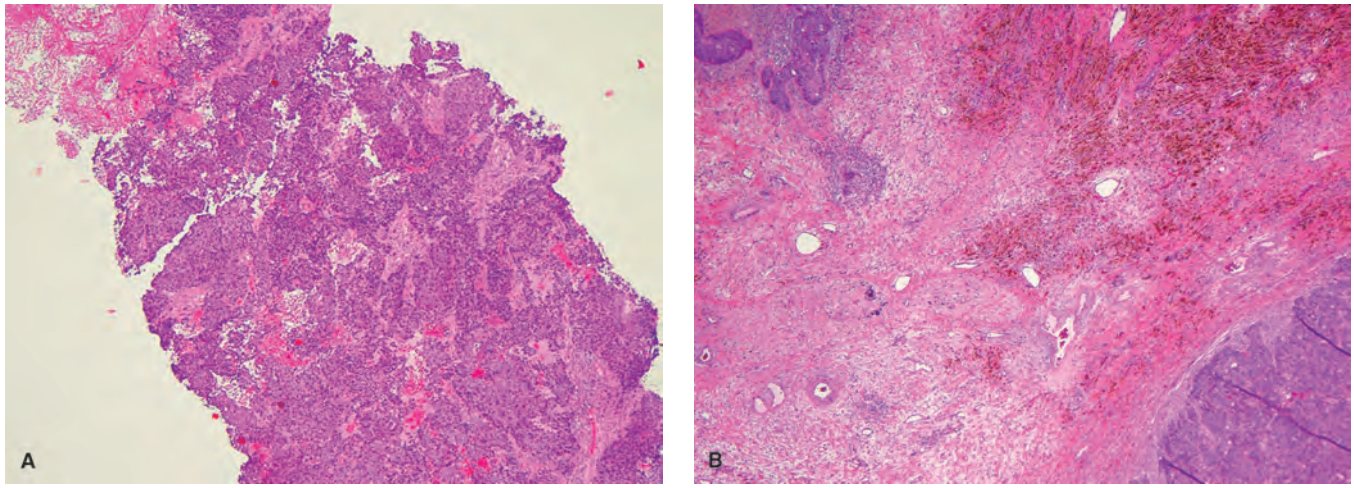

FIGURE 56-3 The most common therapy-related change in cancers is a decrease in cellularity. Before treatment, this high-grade invasive ductal carcinoma is highly cellular (>90%) and focal necrosis is present on the core needle biopsy **(A).** After treatment, the excision shows multiple nests of tumor within a tumor bed with fibrosis and hemosiderin deposition **(B)**.

TABLE 56-1

Systems for Evaluating Breast Cancer Response to Neoadjuvant Therapy

Name of System	*Factors Evaluated for Breast Carcinoma*	*Factors Evaluated for Lymph Node Metastases*	*Definition of pCR*	*No. of Categories of Response*
NSABP B-18 (20)	Treatment effect	Present/absent Size of metastasis	No invasive carcinoma	Three in breast
Sataloff (17)	Treatment effect	Present/absent Treatment effect	Total or near total therapeutic effect	Four
Pinder (8)	% Residual carcinoma	Present/absent Response	No invasive carcinoma in breast and nodes	Five in breast Four in nodes
Miller-Payne (14)	Percent reduction in cellularity compared to the pretreatment carcinoma	Not included	No invasive carcinoma in breast	Five
Modified Nottingham Prognostic Index (MNPI) (29)	Size Post-treatment grade	Present/absent Number	Most favorable class can include residual carcinoma	Continuous value divided into three classes
AJCC (y) (11)	AJCC T — post-treatment	AJCC N — post-treatment	No invasive carcinoma in breast or nodes (including ITCs)	Six
AJCC (y) — pre- and post-treatment (12)	AJCC T — pre- and post-treatment ER status, Grade	AJCC N — pre- and post-treatment	No invasive carcinoma in breast or nodes (including ITCs)	Six
Neoadjuvant Response Index (NRI) (13)	Change in AJCC T	Change in AJCC N	No invasive carcinoma in breast and nodes	Continuous value from 0 to 1
Residual Cancer Burden (RCB) (15)	Size of tumor bed in two dimensions and % cellularity of invasive carcinoma	Present/absent Number, Size	No invasive carcinoma in breast and nodes	Four (but also calculates RCB as a continuous value)

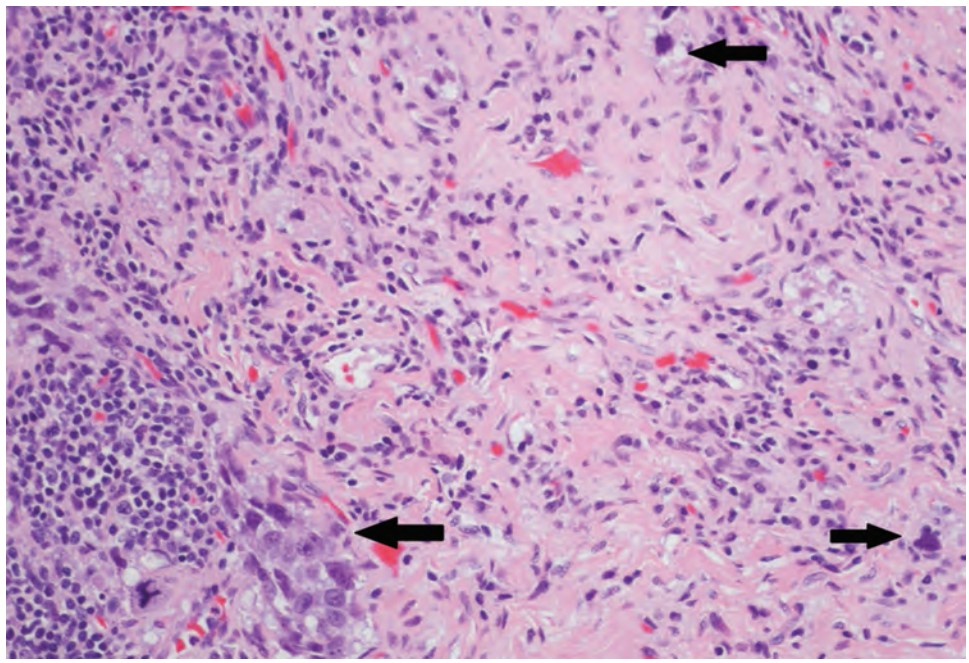

FIGURE 56-4 Lymph node metastases in the absence of therapy are typically highly cellular. After treatment, a marked response may be present. In this case the residual metastatic tumor cells (*arrows*) are surrounded by fibrous scarring, indicative of treatment effect. However, any residual carcinoma in nodes is a poor prognostic factor.

documented lymph node metastases completely resolve leaving only a normal-appearing lymph node (19). Therefore, the nodal status prior to treatment (i.e., whether or not the cancer had metastasized to nodes or not) cannot be determined with certainty in all patients if the nodes are only examined after treatment.

The significance of the size of a metastatic deposit in a lymph node depends on whether or not the patient has received NAT. In the absence of treatment, patients with macrometastases (> 0.2 cm) have a worse prognosis compared to patients with micrometastases or isolated tumor cells (ITCs). However, small metastases in treated patients are indicators of incomplete response and these patients have the same prognosis as patients with macrometastases (18,20,21). Immunohistochemical stains for keratin on nodes negative on H&E stains have not been shown to have prognostic importance, but only small numbers of patients have been studied (22,23). According to current AJCC guidelines, these nodes are classified as yp N0 (i+), but this finding precludes classifying the response as pCR.

Tumor Markers

In the majority of cases, ER, PR, and HER2 results remain the same before and after treatment. Changes occur more frequently if therapy targeting the marker is used (24,25). Changes in marker status may occur due to several reasons (Fig. 56-5):

Tumor heterogeneity with limited tumor sampling. The amount of tumor available for evaluation either before or after treatment may be very limited. Small sample size may result in differences in interpretation. However, in the absence of treatment the results on core needle biopsies are concordant with the results on excision greater than 95% of cases for ER and HER2 (24). NAT results in an increased number of cases with discordant results, depending on whether or not targeted therapy is used for the marker evaluated.

Multiple cancers/tumor heterogeneity with selection by treatment. Treatment is often more effective for cancer cells expressing targetable markers. For example, in about one-third of patients, residual carcinomas after HER2 targeted therapy no longer exhibit HER2 overexpression by immunohistochemistry or fluorescence *in situ* hybridization (FISH) (25). Because gene amplification is no longer present, this is likely due to selection of HER2 negative clones rather than temporary downregulation of gene expression. Loss of HER2 after targeted therapy has been reported to be associated with a poorer prognosis (25).

A core needle biopsy may not detect ER positivity in the pretreatment cancer. However, if an ER-positive subclone (or second ER-positive cancer) is present prior to treatment (but not detected by core needle biopsy), this component of the carcinoma may remain after treatment as hormone receptor–positive cancers are less likely to demonstrate a complete response to chemotherapy.

Change due to treatment. In some cases therapy likely alters gene expression. For example, over 70% of carcinomas that express PgR are found to be PgR negative after treatment with an aromatase inhibitor (AI), but similar changes are not seen for ER (24). In contrast, fewer than 10% of cancers become PgR negative after treatment with tamoxifen. An AI results in lower estrogen levels, causing downregulation of ER-regulated genes. It is likely that loss of PgR is a change in gene expression rather than selection of a PgR-negative subclone. This change has not been clearly linked to treatment response or survival.

When there has been an alteration in tumor markers after treatment, it is not known whether the pre- or post-treatment expression profile will be more predictive of the pattern in future recurrences or distant metastases. The clinical significance of the loss of a marker is unclear as the loss may be transient (if due to changes in gene expression) or may not occur in all residual or metastatic carcinoma (if due to selection by the treatment). Therefore, loss of a marker after therapy should not be used as an indication to withdraw targeted therapy.

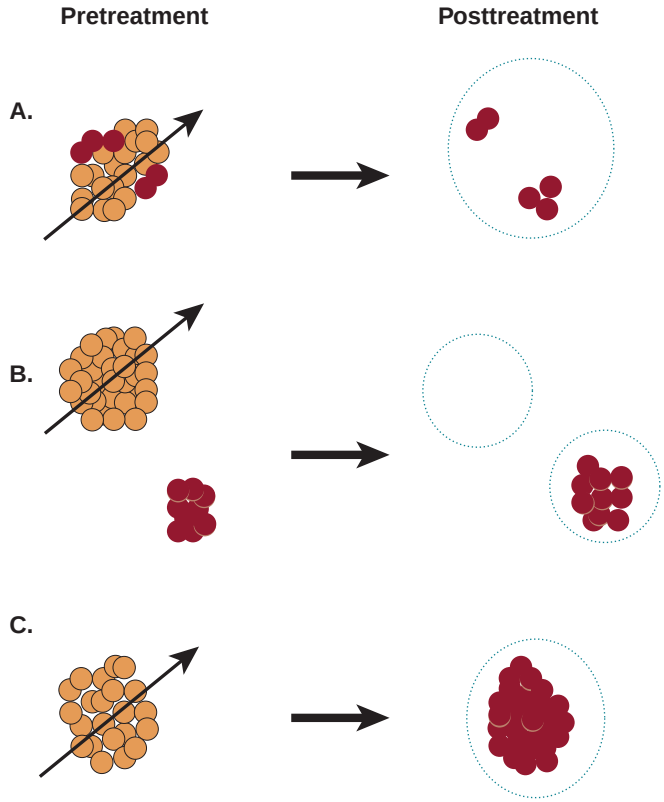

FIGURE 56-5 The results for biologic markers (e.g., ER, PR, HER2) on pretreatment core needle biopsy (*thin arrows*) may be different from the post-treatment residual carcinoma in the tumor bed (*dotted circles*). Carcinomas can be heterogeneous for biologic markers as represented by yellow circles (positive or negative) and red circles (opposite result). **(A)** Heterogeneity may not be detected initially and it is possible for treatment to select for subclones of cells with a different expression pattern. **(B)** Some patients may have multiple cancers with different expression patterns with different responses to treatment. **(C)** In some cases, treatment may cause a change in gene expression in tumor cells. It is unknown if such changes would be transient or permanent.

In contrast, gain of a marker may identify an additional treatment modality that would be beneficial to the patient. For example, patients with carcinomas negative for ER and PgR prior to treatment but positive after treatment benefit from hormonal therapy and have an improved prognosis (24,26). HER2-negative cancers that are found to be HER2 positive after treatment are very rare (<10% of cancers after NAT) and there are too few patients to determine if there is a benefit of HER2 targeted therapy.

Changes in proliferation as determined by immunoperoxidase studies for Ki-67 (MIB-1) have been suggested as a means to measure response to therapy, in particular for hormonal agents, as inhibition of proliferation is the goal of

treatment and pCR is uncommon. Decreased proliferation after treatment is predictive of improved survival (27).

SYSTEMS FOR EVALUATING PATHOLOGIC RESPONSE

Numerous systems for classifying the pathologic response of breast cancers to treatment have been developed and shown to be predictive of disease-free and overall survival (Table 56-1). All of the systems recognize a category of pCR and a category of little or no response. The challenge is to classify the 55% to 80% of carcinomas that undergo a partial response. The number of categories of partial response range from one to four, or the degree of response may be expressed by a continuous variable. The systems vary according to the definition of pCR, evaluation of the breast and/or lymph nodes, extent of residual cancer versus a change in the extent of cancer, and the use of additional non-treatment-related factors, discussed next.

Definition of pCR

A pCR is the most straightforward category of response to define and is often used to compare the results of trials of NAT. A common definition of pCR requires no residual invasive carcinoma in the breast and no metastatic carcinoma in the lymph nodes (9–11). Some systems allow an "almost pCR" (i.e., minimal residual disease). However, any amount of residual disease is challenging to quantify and it would be difficult to define such a category consistently across multiple studies and different observers. A true pCR should be recognized as a separate clearly defined category.

Residual DCIS decreases disease-free survival (due to local recurrences) but not overall survival (2,28). Therefore, in many systems residual DCIS does not preclude a pCR in the breast. Distinguishing DCIS from treatment-related nuclear atypia in areas of epithelial hyperplasia may be difficult in some cases. The issue of whether or not nodes with isolated tumor cells should be included as a pCR is also debated. The existing data support that small metastases after treatment have the same prognostic importance as larger metastases, although additional studies using immunohistochemistry to find single cells may not add additional information (20–23). Isolated tumor cells currently would not be considered a pCR in the nodes.

Breast and/or Lymph Node Evaluation

Some systems only evaluate response in the breast (e.g., Miller-Payne) whereas others evaluate both the breast and the lymph nodes (e.g., AJCC (y), Pinder, RCB, Neoadjuvant Response Index [NRI]) (8,11–15). Because of the prognostic importance of nodal response, systems that do not include this information will misclassify some node-positive patients as having a good prognosis. However, if a positive node is excised before treatment, systems that require evaluation of response in the nodes cannot be accurately assessed.

Residual Cancer or Change Due to Treatment

Some systems, such as RCB, only quantify the amount of cancer remaining after treatment (15). In order to determine the degree of response, one would need to know the equivalent RCB group prior to treatment. Other systems compare the pretreatment carcinoma to the post-treatment carcinoma to give a direct evaluation of response (e.g., Miller-Payne, AJCC (y), NRI) (11–13). These latter systems require knowledge of the pretreatment cellularity (Miller-Payne) or the pretreatment clinical stage (AJCC (y) or NRI).

Features Evaluated

No method utilizes all available prognostic factors. Most methods use either tumor size or tumor cellularity as the predominant factor for response in the breast and the presence of metastases in the lymph nodes. Treatment response in the nodes may or may not be included. Other features used by some methods are ER status, grade, and AJCC stage (Table 56-1). Factors such as LVI and HER2 status have not been incorporated.

Hormonal Therapy or Chemotherapy

In the majority of studies, classification of tumor response has been developed to evaluate cancers treated with chemotherapy. Cancers treated with neoadjuvant endocrine therapy often decrease in size clinically with prolonged treatment, but pCR is rare and does not identify a group with an improved prognosis. The preoperative endocrine prognostic index (PEPI) is a system specifically designed for neoadjuvant endocrine therapy (27). This system uses post-treatment tumor size (AJCC T1/2 vs. T3/4), nodal status (positive or negative), ER status (positive or negative), and Ki-67 score to divide patients into three risk groups.

The optimal system that employs all aspects of response has not yet been developed. Additional studies will be required to compare current systems, to create improved systems with better predictive value, and to determine the reproducibility of the categories.

CONCLUSIONS

NAT is being used more commonly in early-stage breast cancers and may become the standard of care for patients eligible for systemic therapy. NAT provides valuable information for patients, clinicians, and researchers. The pathologist plays a key role in determining the extent and types of response to therapy. To obtain the maximum amount of information about treatment effect, careful pretreatment tumor and lymph node sampling and close communication among surgeons, pathologists, radiologists, and medical oncologists is mandatory.

CHAPTER 57

Local-Regional Therapy following Systemic Treatment

Thomas A. Buchholz and Kelly K. Hunt

CHAPTER CONTENTS

INTRODUCTION

The sequencing of systemic treatments prior to performing definitive breast cancer surgery has become increasingly common. This approach, often referred to as neoadjuvant systemic therapy, was once reserved for patients who presented with inoperable disease. The initial studies of neoadjuvant chemotherapy demonstrated high response rates and success in converting inoperable disease to disease more amenable to modified radical mastectomy. After this initial success, the focus of research concerning neoadjuvant treatments moved toward investigating whether neoadjuvant chemotherapy could permit breast-conservation therapy in selected patients whose local-regional disease at the time of initial diagnosis would require mastectomy. This strategy also proved to be successful and as clinicians became more familiar with its use, neoadjuvant systemic treatments were extended to patients with early-stage breast cancer. Indeed, some practitioners currently prefer the neoadjuvant approach for any patient for whom chemotherapy is known to be indicated as part of treatment based on the stage of disease or biologic parameters of her disease at the time of diagnosis.

As neoadjuvant treatments have become more common, a number of questions concerning optimizing local-regional therapy have arisen. As noted, one of the first of these questions concerned whether a greater percentage of patients could be safely treated with breast conservation if systemic treatments were given prior to surgery. This question has been the subject of large randomized phase III trials, the results of which consistently have indicated that breast-conservation rates are higher with neoadjuvant chemotherapy use (1). On the basis of these trials, neoadjuvant chemotherapy is now considered to be an appropriate standard for patients who desire a breast-conserving approach but who present with a large primary tumor or unfavorable tumor-to-breast-size ratio.

More recent local-regional treatment clinical trials for patients treated with neoadjuvant chemotherapy have focused on the management of the axilla. Specifically, a number of studies have evaluated whether sentinel lymph node surgery can safely be performed after neoadjuvant treatments rather than at the time of diagnosis for patients who present with clinically lymph node-negative disease. Performing sentinel lymph node surgery after chemotherapy rather than before could decrease overall rates of required axillary dissections. This is because a lower percentage of patients would have pathologically positive sentinel lymph nodes if they first were treated with systemic treatments (i.e., some patients with microscopically positive lymph nodes would have these foci of disease eradicated by the neoadjuvant treatment). Subsequently, surgical trials have investigated whether postchemotherapy sentinel lymph node surgery could be used in patients who present with clinically positive lymph nodes, in the hope that some of these patients who subsequently become clinically lymph node–negative after tumor response to neoadjuvant systemic treatment can avoid an axillary dissection.

The increased use of neoadjuvant chemotherapy has also raised a number of questions within the field of radiation oncology. Indications for radiation and treatment field designs have been historically based on the pathological extent of disease. For example, decisions concerning the use of radiation for regional lymphatic treatment and indications for postmastectomy radiation have historically been based on the number of positive lymph nodes, something that cannot be accurately determined with clinical staging. The ASCO and ASTRO consensus statements regarding the use of postmastectomy radiation recommend the use of radiation for patients with four or more pathologically involved lymph nodes and these recommendations were based on data from patients treated with surgery first (2,3). Neoadjuvant systemic treatment has the potential to change the pathological extent of the disease in the primary tumor site and the regional lymphatics in nearly all patients and it is unclear how these changes should affect radiation treatment decisions. Therefore, neither the ASCO nor the ASTRO consensus statements were able to address what are appropriate indications for postmastectomy radiation use for patients treated with neoadjuvant chemotherapy.

This chapter will focus on local-regional treatments for patients treated with neoadjuvant systemic therapies. We will review the randomized and nonrandomized data from studies investigating the use of breast conservation after neoadjuvant chemotherapy or hormonal therapy, evaluate the role of sentinel lymph node surgery for patients treated

with neoadjuvant systemic treatments, and review indications for postmastectomy radiation and regional lymph node radiation for patients treated with neoadjuvant treatments. In aggregate these data will highlight that there remain many controversial areas of local-regional treatment management for patients undergoing neoadjuvant systemic treatments. However, local-regional treatment after neoadjuvant chemotherapy remains a very exciting area of clinical research in that data from the initial studies suggest neoadjuvant therapy has the potential to further personalize local-regional treatment decisions. Specifically, it may be feasible to selectively use aggressive local therapies for patients with a poor response to chemotherapy while minimizing the morbidities associated with local-regional treatments for patients with an excellent response. The newly proposed clinical trials to investigate this hypothesis will also be reviewed.

BREAST CONSERVATION

The clinical response rates of primary tumors to neoadjuvant chemotherapy approach 80% to 90%, depending on the biological subtype of disease (4). Potentially, this could convert a large tumor that would require mastectomy into a size that is eligible for a breast-conserving approach. In addition, for patients with moderate-size tumors, the response may permit a more optimal aesthetic outcome after breast-conservation therapy. For both of these considerations to be feasible, the volume of surgical resection would have to be smaller and directed at the residual nidus rather than the original extent of disease.

In some instances, neoadjuvant chemotherapy successfully shrinks large primary tumors to smaller volumes such that the residual nidus of tissue can be resected with good or excellent aesthetic outcomes. However, in other cases tumors respond but the residual disease is diffuse, multifocal, and scattered throughout the original tumor volume. In the early 1990s investigators from MD Anderson examined 143 mastectomy specimens from patients given neoadjuvant chemotherapy to determine patterns of residual disease and their relationship to clinical factors. Only 23% of tumors had clinical and pathological features that would have predicted success with breast conservation. Important criteria included resolution of skin edema, favorable clinical response to neoadjuvant treatment, lack of multicentricity, and lack of extensive lymphovascular space invasion (5). These data highlighted that breast-conservation surgery would be feasible in only selected patients and that careful selection criteria should be used. These data were supported by the heterogeneity of outcome seen in the initial clinical trials, which varied according to the selection criteria used for their populations. For example, studies that included patients with positive surgical margins or inflammatory breast cancer reported higher rates of local recurrence (6,7). In addition, higher rates of local recurrence were noted in studies that attempted to eliminate surgery completely for the patients who achieved complete clinical resolution of disease (8). In contrast, the studies that had more stringent selection criteria and well-coordinated multidisciplinary teams reported excellent outcomes (9,10).

These institutional experiences helped set the stage for two large randomized trials that directly compared the outcome of patients treated with neoadjuvant chemotherapy versus adjuvant chemotherapy. The National Surgical Adjuvant Breast and Bowel Project (NSABP) B-18 study randomized 1,523 patients with operable breast cancer to 4 cycles of doxorubicin and cyclophosphamide (AC) either before or after surgical treatment (1,11,12) and the European Organisation for Research and Treatment of Cancer (EORTC) 10902 trial randomized 698 patients to 4 cycles of fluorouracil, epirubicin, and cyclophosphamide chemotherapy to be given as neoadjuvant or adjuvant treatment (13). Because the trials did not have an exclusive focus on rates of breast conservation, both studies included patients who were considered candidates for initial breast conservation and candidates who would require an initial mastectomy. The summary of the results of both studies are shown in Table 57-1. Both studies found that rates of breast conservation were higher in the neoadjuvant chemotherapy arm compared to the adjuvant chemotherapy arm (1,11,13). In the B-18 study, the improvement in breast-conservation rates from 60% to 68% for patients treated with neoadjuvant chemotherapy showed that 20% of initial mastectomy candidates (8% of 40% patients) could undergo breast-conservation surgery after neoadjuvant chemotherapy. As shown in Table 57-1, both studies reported that the overall ipsilateral breast recurrence risk in patients treated with neoadjuvant chemotherapy was not statistically different from that in patients treated with surgery first (1,11,13). However, in the B-18 study, the breast recurrence rate in a subset of patients who initially would have required a mastectomy but were treated with breast conservation after a favorable

TABLE 57-1

Outcome of Breast-Conservation Therapy in Randomized Prospective Clinical Trials Comparing Neoadjuvant and Adjuvant Treatments

Trial	*Breast-Conservation Rates*	*Local-Regional Recurrence Rates (first events only)*	*Survival Rates*
NSABP B-18 (51)			
(1,523 patients)			16 y
Neoadjuvant	68%	13%	55%
Adjuvant	60%	10%	55%
		p = .21	p = .90
EORTC 10902 (52)			
(698 patients)		10-year estimate	10 y
Neoadjuvant	35%	20%	64%
Adjuvant	22%	20%	66%
		HR 1.0–1.1	p = .54
		p = .97	

response to neoadjuvant chemotherapy was twice that of the patients with smaller tumors who were treated with surgery first (15.7% vs. 7.6%, respectively) (1). In addition, a meta-analysis of the 9 randomized studies comparing neoadjuvant and adjuvant chemotherapy reported that the use of neoadjuvant chemotherapy was associated with an increase in the relative risk of local-regional recurrence relative to adjuvant chemotherapy (relative risk [RR] 1.22, 95% confidence interval [CI] 1.04–1.43) (14). However, this analysis may have less relevance to modern treatment approaches in that it included trials in which surgery was not performed and radiation alone was used as the sole local-regional treatment. In the trials in which surgery was not used after neoadjuvant treatment, the relative risk was 1.53 and the 95% CI was 1.11 to 2.10) (14).

A second and more recent meta-analysis by Mieog and colleagues examined 10 studies and also demonstrated that overall survival was not different between patients receiving neoadjuvant versus adjuvant chemotherapy (HR 0.98, 95% CI 0.87–1.09) (15). In terms of the question of safety of breast-conserving therapy (BCT) after chemotherapy the meta-analysis reported that the mastectomy rate was decreased by 17% in patients receiving neoadjuvant chemotherapy. It is likely that this is an underestimation of the rate of downstaging as many of the women in these studies were likely breast-conserving therapy candidates before they received neoadjuvant chemotherapy. However, the rate of conversation from mastectomy to breast conservation depends in part on the T stage of disease. Ironically, it is the larger T3 tumors that have a higher conversation rate to breast conservation than the T1 or T2 tumors. This is because most T1 or T2 tumors are candidates for breast conservation at the time of diagnosis and it is factors beyond tumor size (e.g., diffuse microcalcificaitons throughout the breast) that lead to recommendations for mastectomy. These factors may be more difficult to overcome with neoadjuvant chemotherapy. In the B-18 trial the breast-conservation rate was no marked different between the adjuvant and neoadjuvant arms for the patients with T1–T2 disease; however, the use of neoadjuvant chemotherapy in the population with T3 disease resulted in an increase in the rate of breast conservation from 3% to 22% (11). Similarly, in the EORTC10902 trial, they looked at the surgical plan prior to starting chemotherapy in the group randomized to neoadjuvant chemotherapy and prior to starting chemotherapy 23% of patients who were thought to require mastectomy were able to have breast-conserving therapy (13). The meta-analysis by Mieog and colleagues showed that there were no differences in local-regional recurrences for patients receiving neoadjuvant or adjuvant therapy when stratified by the type of surgery performed (15). They also looked at patients in the EORTC trial and NSABP-18 trial who were downstaged to breast conservation and found no difference in local-regional recurrence rates for patients who were planned to undergo breast conservation and those who were downstaged enough to become breast-conservation candidates.

Studies from the Istituto Nazionale Tumori in Milan and the University of Texas MD Anderson Cancer Center (9,10) have provided additional data suggesting breast conservation is safe for appropriately selected patients with larger primary tumors that respond favorably to neoadjuvant chemotherapy. The Milan group noted an 85% breast-conservation rate in 536 patients treated with neoadjuvant chemotherapy for a primary tumor 2.5 cm in diameter or larger and reported an excellent 8-year rate of breast recurrence of 6.8% (9). In the initial MD Anderson series, 340 carefully selected patients were treated with breast-conservation therapy after showing a favorable response to chemotherapy (10) had a 5- and 10-year local recurrence rates were 5% and 10%, respectively, despite the fact that 72% of patients initially had clinical stage IIB or III disease. These investigators identified four factors that were independently associated with breast cancer recurrence and local-regional recurrence: clinical N2 or N3 disease, lymphovascular space invasion, a multifocal pattern of residual disease, and residual primary tumor larger than 2 cm in diameter (10). Eighty-four percent of patients had none or just one of these factors and the recurrence rate at 10 years in this group was only 4% (16). In contrast, the 4% of patients with three of these factors had a recurrence rate of 45%. Women with primary clinical T3 or T4 disease were at very low risk of recurrence if the tumor shrank to a solitary nidus or showed a pathologic complete response (pCR), but among patients with T3 or T4 tumors that left a multifocal pattern of residual disease, the breast cancer recurrence rate was 20% (10).

When interpreting the local-regional outcome results of breast conservation after neoadjuvant chemotherapy for patients with advanced disease, it is important to consider that patients with stage III breast cancer are at risk for local-regional recurrence even when mastectomy is performed. In addition, patients with advanced disease are at significant risk for distant metastases, which is an additional incentive to avoid removing the entire breast when breast-conserving surgery can be done with acceptably low recurrence rates. To compare local-regional treatment outcomes with those achieved with mastectomy, the investigators from MD Anderson Cancer Center applied the four prognostic criteria associated with breast recurrence in patients treated with neoadjuvant chemotherapy and breast conservation to a cohort of patients treated with neoadjuvant chemotherapy, mastectomy, and postmastectomy radiation (17). These investigators found that for patients who had none or one of these factors, the results with either local-regional treatment approach were excellent and equivalent. Among patients with two factors, a nonsignificant trend was evident toward fewer local-regional recurrences with mastectomy, and for the small cohort of patients with three or four factors, mastectomy with postmastectomy radiation provided a statistically significant benefit compared to breast conservation.

The previously described MD Anderson Prognostic Index based on the factors of clinical N2–N3 disease, lymphovascular invasion, residual pathologic tumor size greater than 2 cm and multifocal residual disease on pathology was more recently validated in an independent patient dataset (18). This study utilized a contemporary population of 551 women who had neoadjuvant chemotherapy, mastectomy, or breast-conserving surgery and radiation treated from 2001 to 2005 and who were not included in the original analysis. For patients undergoing breast-conserving therapy the 5-year local-regional recurrence-free survival rates were 92%, 84%, and 69% when the prognostic index was 0 (n = 91), 1 (n = 82), 2 (n = 38) or 3 or 4 (n = 13) (p = .01). Similar to the previous results, the 5-year local-regional recurrence-free survival rates were similar between patients undergoing mastectomy or breast conservation when the prognostic score was 0, 1, or 2, but mastectomy had an improved local-regional outcome when the prognostic index score was 3 or 4.

A common question raised with respect to performing breast-conserving therapy after neoadjuvant chemotherapy is what volume of breast tissue should be resected. Some tumors will shrink concentrically while others form more of a honeycomb pattern with small pockets of residual disease over the volume of original tumor size. To evaluate this, Boughey et al. studied whether preoperative chemotherapy was able to reduce the volume of tissue excised and the number of breast operations performed (19) and reported that in

patients with T2 or T3 tumors, significantly less tissue was resected when patients received neoadjuvant chemotherapy ($p < .004$ for volume of tissue resected). At a median follow-up time of 33 months there were only two cases of ipsilateral breast recurrence, one in the neoadjuvant group and one in the adjuvant group, leading them to conclude that it is not necessary to excise the entire prechemotherapy volume of tissue. Therefore, using chemotherapy in the preoperative setting can afford a better overall cosmetic outcome for patients.

Recently, the NSABP updated its experience of breast conservation after neoadjuvant chemotherapy by combining the data from such patients enrolled on B-18 and B-27 and retrospectively analyzing their outcome. The 10-year local-regional recurrence rate was 10.3% in the 1,100 patients treated with neoadjuvant chemotherapy, lumpectomy, and whole breast irradiation (20). In a multivariate analysis, age under 50, positive clinical nodal status, and pathological positive lymph nodes and lack of a complete response in the breast predictive of higher rates of local-regional recurrence. The highest rates of local-regional recurrences were in patients who presented with clinically positive lymph nodes and were found to have pathologically positive lymph nodes after neoadjuvant chemotherapy.

Finally, a recently published study from MD Anderson evaluated the outcome of 2,984 patients who underwent segmental mastectomy and whole breast radiation over a period of approximately 20 years and compared those who underwent surgery first ($n = 2,331$) versus those who had surgery after neoadjuvant chemotherapy ($n = 652$) (21). Due to selection biases, the neoadjuvant group had a higher percentage of patients who were younger, had more advanced stage of disease, had high-grade disease, and had estrogen-receptor (ER)- negative tumors. Neoadjuvant chemotherapy resulted in a pathologic complete response in 20% of patients and downstaging in many others as evidenced by the fact that 93% of patients presented with clinical stage II or stage III disease and only 46% had stage II or stage III disease on final pathology ($p < .001$). With a median follow-up of over 7 years in both groups, the local-regional recurrence-free survival rates were excellent in both groups. Specifically, the 5- and 10-year local-regional recurrence-free survival rates in patients undergoing surgery first noted to be 97.1% and 94.3%, respectively, and in patients receiving neoadjuvant chemotherapy they were 93.4% and 90.3%, respectively. Multivariate analysis revealed that age less than 50, clinical stage III disease, grade III disease, and either ER-negative disease or patients with ER-positive disease who did not receive hormonal therapy were factors associated with local-regional recurrence. Additionally, multifocal disease on final pathology, the presence of lymphovascular invasion, and close or positive margins were also significant factors. When neoadjuvant chemotherapy was added to the model it was not significant, suggesting that after controlling for these other adverse factors there was no difference with respect to local-regional recurrence in patients receiving neoadjuvant chemotherapy compared to those who undergo upfront surgery.

The investigators also evaluated local-regional recurrence-free survival rates by presenting clinical stage and found there were no differences in recurrences among the stage I, stage II, or stage III patients with respect to treatment sequence. Finally, they then evaluated patients by the number of those adverse factors that were identified on multivariate analysis and found that the majority of patients had none of these factors present or only one or two factors present. There were no significant differences in local-regional recurrence-free survival in patients with zero, one, two, or three factors, between the surgery first and neoadjuvant chemotherapy patients. There were too few patients with four, five, or six adverse factors for meaningful analysis. They therefore concluded that neoadjuvant chemotherapy downstages a significant number of patients with clinical stage II or stage III disease and that appropriately selected patients can achieve high rates of local-regional control with breast-conserving therapy with either upfront surgery or neoadjuvant chemotherapy. Finally, their data indicated that the local-regional recurrence after breast conservation was driven by biologic factors and not the timing of chemotherapy delivery.

Our institutional approach is to utilize ultrasound of the breast and regional nodal basins at diagnosis in addition to diagnostic mammography. A clip is placed to mark the primary tumor site and the patient is followed with ultrasound imaging during the chemotherapy treatment. At the completion of chemotherapy repeat ultrasound and mammogram are performed to evaluate for any residual mass or other radiographic abnormality. Calcifications associated with the primary tumor, residual radiographic abnormalities, and the marker clip are targeted for resection with a margin of normal tissue. We perform intraoperative assessment of the specimen using radiographic and pathologic correlation. A whole specimen radiograph is obtained and the segmental resection specimen is then marked for superior, inferior, medial, lateral, anterior, and posterior margins with different colors of ink. After the specimen is inked, it is sectioned and radiographed and correlated with gross pathologic examination (Fig. 57-1). This allows for intraoperative identification of areas in which additional margin reexcision may be beneficial.

NEOADJUVANT HORMONAL THERAPY

There are fewer data concerning the long-term outcome of patients treated with hormonal therapy prior to surgery. In part this is because most patients treated with neoadjuvant systemic treatments for ER-positive breast cancers have disease extent that necessitates both chemotherapy and hormonal treatments. However, interest in neoadjuvant hormonal therapy has increased after reports from studies that found patients with ER-positive disease have a lower probability of achieving a pCR with chemotherapy compared to those with ER-negative disease (22). In fact, in patients with lobular breast cancer, in whom over 90% of tumors are ER-positive, the rates of pCR with neoadjuvant chemotherapy is 5% or less (23). In addition, some patients with ER-positive breast cancer that is locally advanced and/or lymph node positive at presentation will have significant comorbid medical conditions and therefore not be ideal candidates for neoadjuvant chemotherapy. For such patients, treatment with neoadjuvant hormonal therapy is a reasonable option (24).

Responses to neoadjuvant hormonal therapy occur over a longer period of time compared to those seen with neoadjuvant chemotherapy. The rates of pCR with hormonal therapy are lower than typically reported in neoadjuvant chemotherapy trials but comparable to the rates achievable with neoadjuvant chemotherapy in patients with ER-positive disease. After aromatase inhibitors became available for postmenopausal patients with ER-positive disease, neoadjuvant hormonal therapy trials were developed to directly compare the activities of various agents. A 330-patient randomized trial conducted in the United Kingdom (IMPACT trial) compared 3 months of anastrozole, tamoxifen, or the combination and found response rates of 36% to 39%, with

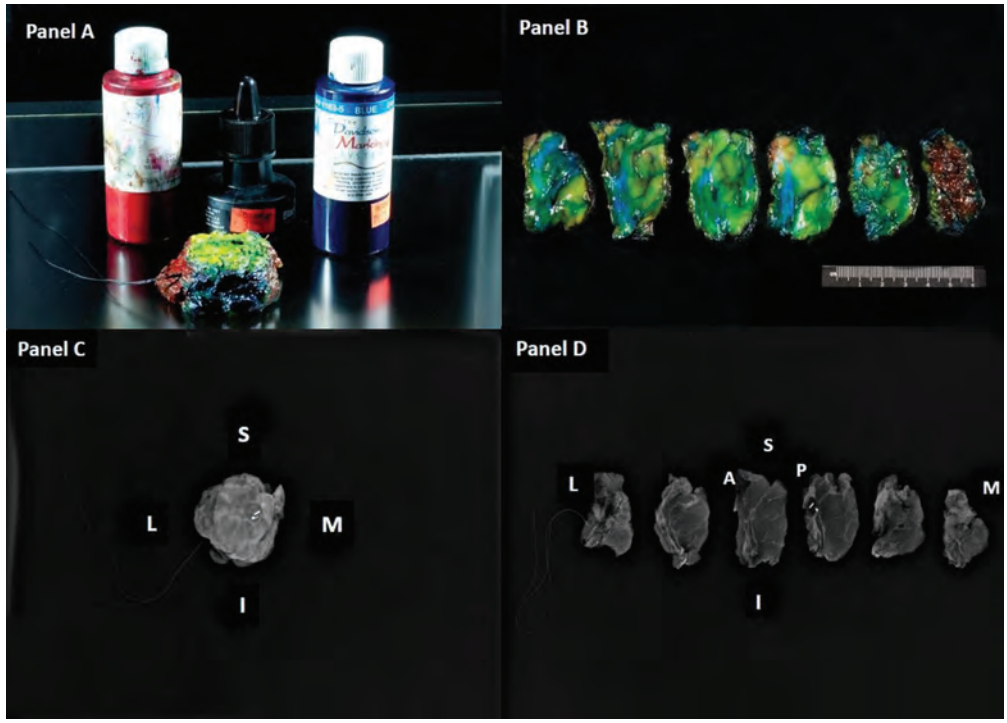

FIGURE 57-1 Specimen processing of the partial mastectomy specimen after neoadjuvant chemotherapy. Panel A demonstrates the partial mastectomy specimen that has been inked with different colors to denote the margins of resection. Panel B demonstrates the partial mastectomy specimen following sectioning. Grossly there are no significant abnormalities that would suggest residual tumor. Panel C demonstrates the whole specimen radiograph which illustrates the clip that was placed at the time of the initial tumor biopsy and the radioactive I-125 seed that was placed after chemotherapy for intraoperative tumor localization at the time of surgery. Panel D demonstrates the sectioned specimen radiograph and illustrates the clip and the I-125 radioactive seed in the fourth section. There are some densities noted in the superior aspect of the specimen and around the clip that will be targeted for pathologic assessment to determine if there is residual disease following chemotherapy. A, anterior; I, inferior; L, lateral; M, medial; S, superior; P, posterior.

only 1% to 3% achieving a clinical complete response (25). In the subgroup of 124 patients who were not candidates for breast conservation at diagnosis, the rates of breast conservation after 3 months of neoadjuvant hormonal therapy were highest in the anastrozole alone arm. An Italian trial randomized patients to 3 months of anastrozole versus tamoxifen and also noted a higher rate of breast conservation after treatment with anastrozole alone versus tamoxifen alone. The overall response rates were similar to those in the UK study (26). Eiermann and colleagues conducted a multicenter phase III trial (P024 trial) comparing 4 months of neoadjuvant tamoxifen or letrozole for women with ER-positive disease who not felt to be candidates for breast conservation at the time of initial diagnosis. Breast-conserving surgery was achieved in 45% of patients in the letrozole group compared with 35% in patients who received tamoxifen (p = .022) (27). Letrozole was effective in tumors with all levels of ER expression, whereas tamoxifen was effective only in tumors with higher levels of ER expression (28). Ellis and colleagues later described the Preoperative Endocrine Prognostic Index (PEPI), a tool for assessing long-term clinical outcomes based on response to preoperative endocrine therapy. The PEPI score was developed utilizing patients from the P024 trial and validated with patients from the IMPACT trial (29). The four components of the PEPI score include pathologic size of the primary tumor, pathologic nodal status, posttreatment Ki-67 level, and posttreatment ER status (Allred score). The PEPI score stratified patients with respect to relapse-free and breast cancer specific survival outcomes and identified a very favorable group (PEPI 0) that may not benefit from chemotherapy.

In the American College of Surgeons Oncology Group (ACOSOG) Z1031 trial, investigators compared the aromatase inhibitors anastrozole, letrozole, and exemestane head to head in a neoadjuvant trial of 16 weeks of aromatase inhibitor therapy in patients with stage II or III ER-positive breast cancer (28). There were 377 postmenopausal women with strongly enriched (Allred score 6–8) ER-positive tumors enrolled with the primary end point being clinical response. The three agents were similar in terms of their clinical response rates and overall 51% of patients who were deemed to be mastectomy-only candidates at registration and 83.1% of those thought to be marginal candidates for breast conservation were able to have breast-conserving surgery after aromatase inhibitor therapy. Gene expression profiling demonstrated that luminal A tumors were more likely to have favorable characteristics after neoadjuvant endocrine therapy; however, some had increases in Ki-67 on therapy suggesting that this approach could be used to triage patients to alternative treatment strategies after

short-term endocrine therapy exposure. This approach was used in the Z1031 cohort B study which routed patients with a Ki-67 over 10% after 2 to 4 weeks of neoadjuvant aromatase inhibitor therapy to neoadjuvant chemotherapy versus immediate surgery. This strategy is also incorporated in the Alternate trial, a phase III trial randomizing patients to neoadjuvant therapy with anastrozole, fulvestrant, or the combination which is expected to open to accrual in the summer of 2013. A 4- or 12-week tumor biopsy with a Ki-67 level over 10% will be used to categorize patients as having "endocrine resistant" tumors who will then be triaged to neoadjuvant chemotherapy. The PEPI score will be validated in the patients with "endocrine responsive" tumors who will continue on the neoadjuvant endocrine therapy for 6 months prior to proceeding to surgery. Surgical outcomes and the ability to increase breast-conservation rates with a longer course of endocrine therapy in patients with tumors enriched for favorable biologic characteristics are important secondary end points of this trial.

APPROACH TO THE AXILLA AFTER NEOADJUVANT THERAPY

In addition to demonstrating higher rates of breast conservation, an interesting finding of the NSABP B-18 study was that fewer patients in the preoperative chemotherapy arm had pathologically positive axillary nodes (40%) as compared with the patients who underwent surgery first (58%). Traditionally, axillary lymph node dissection (ALND) has been utilized for posttreatment axillary staging and regional control in patients receiving neoadjuvant chemotherapy. As more patients with operable breast cancer are being offered systemic treatment in the neoadjuvant setting, controversy has arisen with respect to the most appropriate axillary staging procedure and the timing of that intervention. Since imaging studies have not proven to be sufficiently sensitive in detecting subclinical involvement of nodes in patients with a clinically node-negative axilla, sentinel lymph node (SLN) surgery has been suggested as a tool for staging the axilla in patients planned for neoadjuvant chemotherapy. There continue to be two camps with respect to the timing of SLN surgery, those that favor pretreatment SLN surgery and those that favor posttreatment SLN surgery. The advantages to performing SLN surgery prior to chemotherapy are that it offers classical TNM staging and the false-negative rate is well established for SLN surgery in the upfront surgery setting. The disadvantages are that the patient will require two operations (upfront SLN surgery and posttreatment primary tumor resection). If the SLN is positive, the patient will be committed to ALND and one loses the ability to assess response in the axillary nodes to chemotherapy. The points in favor of performing SLN surgery following neoadjuvant chemotherapy include one operation for the primary tumor and the nodal basin, fewer positive lymph nodes after chemotherapy which results in fewer ALNDs (less morbidity), and the ability to assess response in the breast and axilla to the preoperative regimen (prognostic information). The disadvantages of using SLN surgery after chemotherapy are that the effect of chemotherapy on lymphatics is unknown, the reported false-negative rates are higher in this setting than in those with upfront surgery, and it is unclear which patients should receive nodal radiation (loss of prognostic information).

The largest single-institution experience with sentinel lymph node surgery after neoadjuvant chemotherapy was reported from MD Anderson Cancer Center by Hunt et al. In this study there were 3,746 patients with clinically node-negative invasive breast cancer who underwent sentinel node biopsy between 1997 and 2007. Of these patients, 3,171 (84.7%) underwent SLN surgery as a first intervention and 575 (15.3%) underwent SLN after chemotherapy (30). A sentinel node was identified in 3,690 (98.5%) patients and the identification rate was higher when a combination or dual-agent mapping technique was utilized versus single-agent (99% vs. 97.5%, $p < .0001$). The identification rate was slightly improved in patients undergoing surgery first (98.7%) versus patients undergoing chemotherapy first (97.4%) but there was no impact on identification rates with respect to age, T size, histology, tumor location, diagnostic biopsy type, or surgery type. The false-negative rates were assessed in patients who had SLN surgery and also planned for completion ALND. In the surgery-first group there were 22 false-negative events in 542 patients for a rate of 4.1%. In the chemotherapy-first group there were 5 false-negative events in 84 patients for a rate of 5.9%. There was no statistically significant difference between the false-negative rates in the surgery-first group versus the chemotherapy-first group ($p = .39$). The authors did find that a false-negative event was more likely when fewer than two sentinel nodes were removed ($p = .001$) and when blue dye alone was used for the mapping procedure ($p < .0001$). There was no impact of age, T size, location, biopsy type, surgery type, or timing of sentinel lymph node surgery on false-negative rates. Similar to the NSABP-18 trial this study noted that patients undergoing surgery first had a higher incidence of positive SLNs stage for stage when compared with patients undergoing chemotherapy first. This was most significant in the patients with T2 tumors who had a rate of 36.5% ($p < .0001$) positive SLNs versus 20.5% in patients undergoing chemotherapy first and in patients with T3 tumors where the positive SLN rate was 51.4% in those with upfront surgery versus 30.4% in patients receiving chemotherapy first ($p = .04$). Along with these differences in nodal positivity rates, the authors also noted that the need for ALND was lower in patients undergoing chemotherapy first versus those undergoing surgery first in those with both T2 and T3 tumors. Importantly, there was no difference in local or regional recurrence rates between the two groups with a median follow-up of 47 months in the surgery-first group and 55 months in the chemotherapy-first group.

Mamounas and colleagues reported a retrospective analysis on SLN surgery in 428 patients enrolled in NSABP B-27, a multicenter trial that included patients who presented with either clinically node-negative or clinically node-positive disease prior to chemotherapy (31). They found a false-negative rate of 11% but noted that it decreased to 8% when radiocolloid was utilized. There was no statistically significant difference in the false-negative rates between clinically node-positive and clinically node-negative patients (12.4% vs. 7.0%, respectively, $p = 0.51$) but there was no requirement to document that palpable nodes were positive with needle biopsy at the time of registration.

The results of a prospective multicenter trial examining the role of SLN surgery after neoadjuvant chemotherapy were reported by Classe, et al. (32) These investigators studied both clinically node-negative and clinically node-positive patients who had lymphatic mapping and SLN biopsy performed with a combination of radiocolloid and blue dye. The identification rate was 90% and the false-negative rate was 11.5%. The investigators noted that patients with palpable axillary nodes (N1) had a lower identification rate (81.5% vs. 94.6%, $p = .008$) and a higher false-negative rate compared with patients with clinically negative nodes (N0) (15% vs. 9.4%, $p = .66$).

There have been two meta-analyses performed evaluating SLN biopsy after chemotherapy, the first reported by Xing

et al. (33), who included 21 studies in their analysis and a total of 1,273 patients. The identification rates ranged from 72% to 100% with a pooled estimate of 90%. The false-negative rates ranged from 0% to 33% with a pooled estimate of 12%. Based on the summary of their results, the authors concluded that SLN biopsy was reliable for surgical staging following neoadjuvant chemotherapy. A more recent meta-analysis from Kelly et al. (34) examined studies published between 2000 and 2007 which included a total of 24 studies with 1,799 patients. The identification rate was 89.6% and the false-negative rate was 8.4%. Again the authors concluded that SLN surgery was a reliable tool for assessing the lymph node status following the use of neoadjuvant chemotherapy.

Although the NSABP B-27 subgroup analysis and the French multicenter study included patients with clinically node-positive breast cancer, the majority of studies examining the use of SLN surgery after chemotherapy have been in clinically node-negative patients. The population of patients presenting with node-positive disease confirmed at diagnosis prior to administration of neoadjuvant chemotherapy has been less well studied with respect to accuracy of SLN surgery. It has been well documented that patients with positive lymph nodes can be converted to lymph node–negative with neoadjuvant chemotherapy and this rate has increased with combination anthracycline- and taxane-based chemotherapy regimens (4,35). Dominici et al. recently reported that 74% of patients with *HER2*-positive breast cancer converted to node-negative disease after receiving an anthracycline and taxane regimen concurrently with trastuzumab (36). With increasing pCR rates in the axillary nodes and the fact that these patients will receive adjuvant radiation therapy as a component of their treatment, there has been significant interest in exploring the role of SLN surgery in staging the axilla following chemotherapy in patients who initially present with confirmed node-positive disease.

One of the first reports on the use of SLN surgery after chemotherapy in patients with node-positive disease at diagnosis was from Shen et al. (37). In this retrospective analysis, 69 patients were treated between 1994 and 2002 and of these 56 had SLN surgery with completion ALND. There were 10 false-negative events in the 40 patients with residual node-positive disease after chemotherapy for a false-negative rate of 25%. This high false-negative rate suggested that SLN surgery was not reliable in this patient population. On pathologic assessment of the SLNs, it was noted that patients without any treatment effect (fibrosis, ghost cells, etc.) were more likely to have a false-negative SLN. A follow-up study by Alvarado et al. (38) analyzed this question further with a series of 150 patients treated between 1994 and 2010 who all had proven axillary lymph node metastasis at diagnosis and then received neoadjuvant chemotherapy. The identification rate was 93% in this group of patients and in 111 patients who had sentinel lymph node dissection and axillary lymph node dissection performed, there were 15 false-negative events for a rate of 20.8%. It did appear that patients who had normal nodal morphology by ultrasound examination after chemotherapy had a lower false-negative rate; in addition, multivariate analysis revealed that fewer sentinel lymph nodes removed (less than two) and small initial tumor size were associated with a false-negative event.

The use of SLN surgery after neoadjuvant chemotherapy in patients with initial node-positive disease has been studied in two large prospective trials recently reported in abstract form at the San Antonio Breast Cancer Symposium. The American College of Surgeons Oncology Group (ACOSOG) Z1071 trial was a phase II study that included women with clinical T0 to T4, N1–2, M0 breast cancer receiving neoadjuvant chemotherapy who had node-positive disease documented by fine-needle aspiration or core needle biopsy (39). Following chemotherapy all patients had SLN surgery with completion ALND. The primary end point of the trial was the false-negative rate which was predetermined to be 10% as an acceptable false-negative rate in this patient population. There were 756 patients enrolled from 2009 to 2011. The false-negative rate in women with clinical N1 disease with two or more SLNs removed was 12.8%. This rate was reduced to 11.1% when a combination blue dye and radiocolloid technique was utilized. The investigators concluded that SLN surgery following chemotherapy was a useful technique for staging the axilla after chemotherapy when surgical standards were utilized including dual tracer technique and removal of more than two SLNs.

Another study that was recently reported was from the German SENTINA (SENTInel NeoAdjuvant) trial group (40). This was a four-arm prospective multicenter trial evaluating the timing of SLN biopsy in patients receiving neoadjuvant chemotherapy. The patients were categorized into four different groups according to the clinical staging of the axilla prior to chemotherapy treatment. Patients with a clinically node-negative axilla underwent SLN biopsy before chemotherapy and if the SLN was negative they had no further surgery after chemotherapy (arm A). If the SLN was positive (arm B) the patients had SLN biopsy again after chemotherapy. Patients who were clinically node-positive prior to chemotherapy (cN1) had SLN biopsy if they converted to clinically node-negative with chemotherapy (arm C) and had ALND if they remained clinically node-positive after chemotherapy (arm D). The false-negative rate in arm C patients was 14.2%. In a multivariate analysis the number of SLNs removed was a significant predictor of the false-negative rate. In the patients who had SLN biopsy before and after chemotherapy (arm B) the false-negative rate was 51.6%. The results of SLN surgery after chemotherapy in multicenter trials are summarized in Table 57-2.

In conclusion, sufficient data exist to demonstrate that sentinel lymph node surgery after neoadjuvant systemic treatment is an appropriate standard of care for patients who present with clinically negative lymph nodes. This technique offers the advantages of improved convenience and costs in avoiding a separate surgery prior to neoadjuvant treatment and results in fewer overall axillary lymph node dissections. For patients who present with clinically positive lymph nodes who convert to lymph node–negative disease after neoadjuvant systemic treatment, the use of sentinel lymph node surgery without an axillary dissection remains controversial and should be used selectively. It is clear in the patients who present with clinically node-positive disease that surgical technique is critical in lowering the false-negative rate of SLN surgery after chemotherapy.

IMPACT ON RADIATION TREATMENT DECISIONS

It has been established that adjuvant radiation after mastectomy and regional lymph node irradiation benefit a large percentage of breast cancer patients with lymph node–positive breast cancer. Meta-analyses of the trials evaluating patients treated with mastectomy indicated that adjuvant radiation significantly reduced recurrence and improved survival for patients with lymph node–positive disease and did not provide a clinically relevant benefit for patients with lymph node–negative disease (41,42). In addition, the recently presented Canadian MA.20 trial that evaluated patients treated with breast conservation, most of whom had lymph node–positive disease, showed a lower rate of

local-regional recurrence and improvement in disease-free survival for patients randomized to breast and regional lymph node radiation versus radiation just directed to the breast (43). However, none of the patients entered into these important randomized trials were treated with neoadjuvant systemic treatments, therefore how the response to chemotherapy should affect radiation treatment decisions remains in question.

When neoadjuvant chemotherapy was introduced in breast cancer management it predominantly was used in patients with locally advanced, inoperable, and inflammatory breast cancer. For such patients, radiation treatment to the breast or chest wall and the regional lymph nodes was considered to be an important component of treatment. However, more recently neoadjuvant chemotherapy has been commonly used in earlier-stage disease, which has raised new questions regarding the indications for radiation therapy. For patients with clinical stage I or II disease, historically the decision to administer radiation therapy after mastectomy or its use to treat regional lymphatics was made predominantly on the basis of the pathological extent of disease. As noted previously, neoadjuvant chemotherapy changes the extent of pathological disease in 80% to 90% of cases, and fewer data are available to determine how the posttreatment pathological information should guide decisions regarding radiation treatment. One of the initial studies to investigate this question compared the local-regional recurrence risk associated with the pathological extent of disease after neoadjuvant or adjuvant systemic treatments, mastectomy and no postmastectomy radiation. This study reported that for any pathological lymph node status or primary tumor size the local recurrence was higher among patients treated with chemotherapy first compared to those treated with surgery first (44). This is not particularly surprising; in the neoadjuvant chemotherapy group, the pathologic examination represented residual disease after treatment, whereas in those treated with surgery first, the extent of disease represented untreated cancer. However, these findings imply that the risk of local-regional recurrence for patients given neoadjuvant chemotherapy is determined by both the pretreatment clinical stage and the extent of residual disease as determined by pathologic assessment after chemotherapy.

Information concerning potential indications for postmastectomy radiation therapy for patients treated with neoadjuvant chemotherapy is limited and derived from retrospective analyses. The largest data source for determining predictors of local-regional recurrence in patients treated with neoadjuvant chemotherapy and mastectomy comes from the retrospective study of 1,946 patients treated on the NSABP B-18 and B-27 trials (20). In both of these studies, radiation use was not recommended for patients treated with mastectomy. The 10-year rate of local-regional recurrence for these patients was 12.6%. In a multivariate analysis, clinical T3 disease, clinically node-positive disease, pathologically positive lymph nodes after neoadjuvant chemotherapy, and lack of a complete response of the breast primary were independent predictors of local-regional recurrence. For patients who presented with T1 or T2 disease, the risk of local-regional recurrence was over 10% if pathologically positive lymph nodes were present after neoadjuvant chemotherapy but much lower if lymph nodes were negative after neoadjuvant chemotherapy. For patients with T3 disease, lymph node status after chemotherapy again predicted for local-regional recurrence. Cohorts with a less than 10% local-regional recurrence rate included those with clinical T3N0 disease and who had pathologically negative lymph nodes and those with T3N1 disease who had a pathological complete response.

Limited data are also available concerning the efficacy of postmastectomy radiation in patients treated with neoadjuvant chemotherapy. One of the first published studies investigating this issue compared the outcomes of 579 patients who received neoadjuvant chemotherapy, mastectomy, and radiation therapy with those of 136 patients who were treated with neoadjuvant chemotherapy and mastectomy (45). Patients in this study had been treated in prospective trials but radiation therapy was not a randomized variable in any of the trials, so significant imbalances in the prognostic factors were present between the two groups. Patients with worse disease characteristics were more often referred for and treated with radiation therapy, as evidenced by the higher percentage of patients with stage III clinical disease stage in the radiation group. Despite this, the local-regional recurrence rate was found to be significantly lower in the group treated with postmastectomy radiation therapy than in the group treated with neoadjuvant chemotherapy and mastectomy without radiation (10-year local-regional recurrence rates were 8% and 22%, respectively, $p = .001$). For patients with clinical stage III disease or extensive disease after chemotherapy, radiation led to significant improvements in local-regional recurrence and overall and cause-specific survival rates. Multivariate analyses indicated that use of radiation was independently associated with a lower risk of local-regional recurrence (hazard ratio [HR] for not receiving radiation therapy 7.0, $p < .0001$) and a lower risk of death due to breast cancer (HR for not receiving radiation therapy –2.03, $p < .0001$) (45).

The same group of investigators has also shown that among patients with stage III disease who achieved a pCR, the local-regional recurrence rate for those treated with radiation therapy was 7% versus 33% for those who did not receive radiation therapy ($p = .040$) (46). Radiation use in these patients was also associated with an improvement in survival. Finally, this group also tried to address which patients given neoadjuvant chemotherapy for clinical stage II breast cancer should receive radiation therapy. They examined 132 such patients who had not received radiation therapy and found that the small number of patients with clinical T3N0 disease and those with four or more positive lymph nodes had high rates of local-regional recurrence (47). However, the 42 patients with clinical stage II disease who had one to three positive lymph nodes after neoadjuvant chemotherapy had a relatively low rate of local-regional recurrence (5-year rate of 8%).

Investigators from the University of Miami also examined the outcome of postmastectomy radiation in 464 patients treated with neoadjuvant chemotherapy. They reported a local-regional recurrence rate of 6%, but noted that advanced presenting clinical stage, a high degree of residual pathological disease after neoadjuvant treatment, and ER-negative disease all independently predicted for higher rates of local-regional recurrence (48).

Additional retrospective analyses of single-institution small studies were recently compiled in a critical review performed in an attempt to provide further insights into radiation indications (49). This study identified 24 relevant studies, 23 of which were retrospective and conducted in single institutions. The authors reported the following cohorts of patients had low risk of local-regional recurrence without radiation and therefore could potentially be spared postmastectomy radiation: patients over the age of 40 with clinical stage II, estrogen-receptor-positive disease with pathologic zero to three positive nodes without lymphovascular invasion or extracapsular extension. This study provides recommendations that are consistent with an early statement of the science report for the National Cancer Institute (50).

In aggregate, these findings suggest that recommending postmastectomy radiation therapy is reasonable for all patients with clinical stage III disease and those with positive lymph nodes after treatment with neoadjuvant chemotherapy. Clearly, however, additional studies are needed to quantify the local-regional recurrence risk for patients who present with T1 or T2 disease and have zero to three positive lymph nodes after neoadjuvant chemotherapy.

Future Directions

A major potential advantage of using neoadjuvant systemic treatments would be to permit the tailoring of local-regional treatment recommendations based on disease response. Specifically, based on the data available to date it is reasonable to ask whether patients with a very favorable response could potentially avoid the toxicities of more aggressive local-regional therapies. Two recently activated phase III trials investigate this concept; one with respect to axillary management and one with respect to avoidance of postmastectomy or regional lymph node radiation.

The recently approved axillary management trial is being led by the Alliance Group (A11202 trial). This trial will study patients who present with node-positive disease and who continue to have positive SLNs after chemotherapy despite no longer having clinical evidence of gross residual lymph node disease. Patients will be randomized to the current standard of care of performing axillary lymph node dissection plus breast or chest wall and nodal irradiation versus avoidance of axillary lymph node dissection and use breast or chest wall and nodal irradiation to eradicate potential residual microscopic disease within the undissected lymph nodes. If this trial is able to achieve equivalence results, the avoidance of an axillary dissection for patients will likely result in less patient morbidity and lower costs.

The radiation trial for patients being treated with neoadjuvant chemotherapy is being led by NSABP and RTOG (NRG 9353 trial). This study will enroll patients with initial node-positive disease who convert to node negative with chemotherapy (determined by SLN surgery or ALND). Eligible patients for this study will include those with clinical T1-3N1 disease who have pathologically negative lymph nodes after neoadjuvant chemotherapy. All patients treated with breast conservation will receive radiation to the breast and the study will randomize these patients to the addition or omission of regional lymph node radiation. For patients treated with mastectomy, randomization will be between radiation to the chest wall and draining lymphatics versus no radiation. The schema of these trials is shown in Figure 57-2.

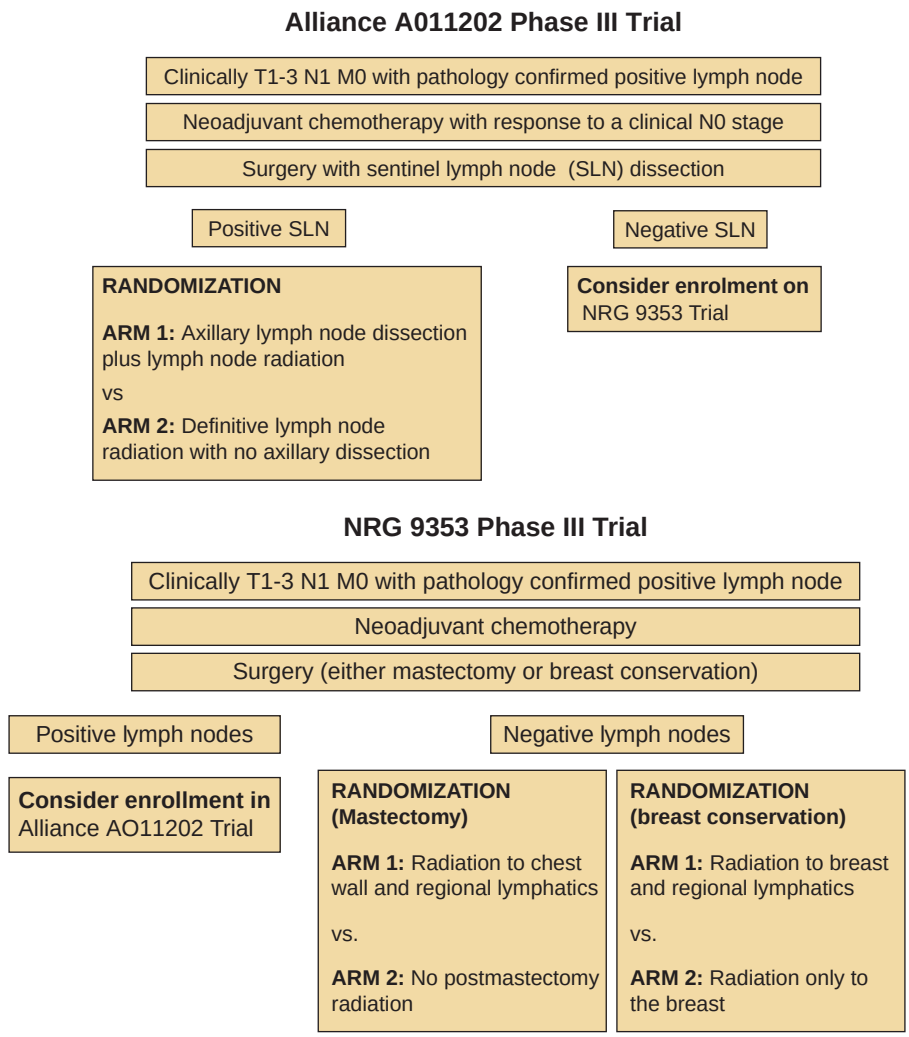

FIGURE 57-2 Schema of the Alliance A11202 trial and the NRG 9353 trial.

MANAGEMENT SUMMARY

- Preoperative or neoadjuvant systemic therapy has been shown to increase the use of breast-conserving therapy and can decrease the use of axillary dissection.
- The use of preoperative systemic therapy in patients with operable breast cancer has created new challenges for breast surgeons and radiation oncologists. There are as yet few results from randomized clinical trials testing local treatments.
- Clinical and radiological assessment of the extent of primary cancer before and after preoperative chemotherapy is important. Physical examination, mammography, and ultrasonography are the standard methods of assessment, but their performance characteristics in predicting a pathologic complete response are not optimal.
- MRI may provide a better means to assess response. Studies are underway to test this. Other newer imaging methods are being tested as well.
- A core needle biopsy should be performed on all suspicious abnormalities found in the ipsilateral and contralateral breasts before chemotherapy. Radiopaque clips should be placed within all malignant tumors to provide localization for subsequent surgical removal.
- Surgical resection of the tumor bed to confirm the clinical or radiographic impression of complete response is an essential part of management.
- SNB can be performed either before or after preoperative chemotherapy. There are potential advantages and limitations with each approach, but increasingly SNB after neoadjuvant systemic is the standard of care for patients who present with clinically negative lymph nodes.
- The use of SNB after neoadjuvant systemic therapy for patients who present with clinically positive lymph nodes who convert to negative nodes is currently under investigation.
- In patients treated with breast-conserving surgery, clearly negative margins of resection should be obtained. Even in patients with a pathological complete response in the breast, breast RT should be used.
- For patients treated with mastectomy, chest wall and regional nodal RT should be considered for patients who present with clinical stage III disease or have histologically positive axillary nodes after preoperative chemotherapy. With some possible exceptions, patients with clinical stage I or II disease at presentation who have a pCR after preoperative chemotherapy do not require PMRT. The use of PMRT in patients with clinical stage I or II disease at presentation who have negative nodes but residual disease in the breast is uncertain.

CHAPTER 58

Locally Advanced Breast Cancer

Gabriel N. Hortobagyi, Funda Meric-Bernstam, and Eric A. Strom

CHAPTER CONTENTS

DEFINITION

Locally advanced breast cancer (LABC) remains an important public health problem and a challenging management problem around the world (1). In groups of women who participate in periodic screening programs, the incidence of LABC is lower than 5%, whereas in medically underserved areas of the United States, and in many developing countries, LABC represents 40% to 60% of newly found malignant breast neoplasms (2–3). It can be estimated that between 400,000 and 550,000 new cases of LABC are diagnosed around the world every year.

LABC includes large primary tumors (>5 cm, T3 in the AJCC Cancer Staging System) (4), tumors of any size associated with skin or chest wall involvement (T4), tumors with fixed or matted axillary lymph nodes (N2), and those with involvement of the ipsilateral infraclavicular and supraclavicular lymph nodes (N3). Operationally, even moderate-sized tumors, 3 to 5 cm in size, located in a small breast are best treated with similar combined-modality approaches. The management of patients with LABC has evolved substantially over the past four decades, and this chapter will summarize current therapeutic options.

HISTORICAL PERSPECTIVE

Adjuvant systemic treatments have become integral components of the curative management of primary breast cancer (5). Postoperative adjuvant chemotherapy, hormone therapy, and trastuzumab produce highly significant reductions in odds of recurrence and death from breast cancer for patients of any age, with node-negative or node-positive tumors. The effectiveness of systemic therapy varied markedly, however, based on predictors of therapeutic benefit. Thus, only patients with estrogen and/or progesterone receptor-positive breast cancer benefit from endocrine therapy; only patients with overexpression or amplification of HER2 benefit from trastuzumab. In addition, the efficacy of chemotherapy is several-fold greater in patients with negative hormone receptors than in patients with positive hormone receptors.

Randomized trials designed for stage III breast cancer suggested that adjuvant systemic therapies also decreased the probability of recurrence and death in this group of patients (6). Most of the information about the management of LABC is based on phase II trials. Therefore, the levels of evidence on which many of the recommendations made in this chapter are based are lower than the levels of evidence that support adjuvant systemic therapy.

Historically, patients with LABC treated with surgery only fared poorly: although surgical resection was technically possible in most patients with LABC, 10 years after diagnosis more than 80% of patients had succumbed to the disease (6). On the basis of this experience, Haagensen and Stout defined the concepts of operable and inoperable breast cancer (7).

Subsequent to Haagensen's landmark publication, patients with inoperable tumors were treated with radiation therapy alone or associated with surgical resection (6). However, the large doses of radiation necessary to optimize local control, were often associated with long-term complications, including skin and chest wall fibrosis, skin ulceration, pulmonary fibrosis, rib necrosis or resorption, brachial plexopathy, and lymphedema of the arm (8,9).

It was on this background that the initial combined modality treatment approaches were developed, in parallel with the postoperative adjuvant chemotherapy programs.

There is general agreement that combinations of systemic and local/regional therapies represent the standard of care for all patients with LABC.

DIAGNOSIS AND STAGING

Most LABCs are easily palpable and even visible. Many represent neglected primaries present for months or sometimes years before the initial diagnosis. Patients may be aware of the breast or lymph node abnormality, but because of fear, denial, or lack of access to appropriate healthcare, they delay seeking medical attention. However, some LABCs present with diffuse infiltration of the breast and without a dominant mass. On mammographic or sonographic assessment they often appear as large areas of calcification, or parenchymal distortion; sometimes skin thickening is also present. Occasionally, even large lesions are mammographically and sonographically silent and magnetic resonance imaging (MRI) is needed for definitive imaging.

A core needle biopsy usually establishes the histologic diagnosis; incisional biopsies are seldom required. Some recommend a full-thickness skin biopsy (punch biopsy) when inflammatory breast cancer (IBC) is suspected. However, although the presence of dermal lymphovascular tumor emboli is pathognomonic of IBC, lack of dermal involvement does not exclude it. If an experienced cytopathologist is available, the diagnosis of malignancy can be confirmed by fine-needle aspiration cytology (FNAC); nuclear grade, flow cytometry, estrogen- and progesterone-receptor status and HER-2/neu can all be assayed on FNAC samples, and so can most other proposed prognostic indicators (Ki-67, etc.). However, FNAC cannot differentiate invasive from noninvasive tumors. If palpable regional nodes exist, a positive fine-needle aspirate of a node confirms the presence of invasive breast cancer. Once the diagnosis is established, the extent of tumor involvement needs to be ascertained. Bilateral mammogram serves to assess the known primary tumor and to rule out the presence of multifocal and multicentric disease and synchronous bilateral cancer or contralateral metastases. Sonography serves to further define tumor dimensions and to detail any regional lymph node involvement. Sonographic examination preferably should include, in addition to the breast and axillary area, the infraclavicular, supraclavicular, and internal mammary lymph node chains. The extra-axillary nodal basins are commonly involved in LABC. Our recent review of 865 patients with LABC staged by ultrasound showed a 37% probability of infraclavicular, supraclavicular, or internal mammary involvement (10). For lesions poorly defined by mammography or sonography, MRI can be helpful. Bilateral MRI is used at some institutions for baseline assessment of extent of tumor involvement, additional foci of cancer, and following neoadjuvant systemic therapy to assess response to therapy. This is particularly true of some subtypes of breast cancer that are frequently mammographically occult, such as invasive lobular cancer or inflammatory breast cancer. Accurate imaging evaluation at baseline and following systemic therapy is critical to guide optimal local/regional therapy planning and for assessment of response. A biochemical survey, chest radiograph, and bone scan complement a complete physical examination, with quantitative documentation of all palpable abnormalities. Abdominal imaging (computerized tomography [CT] or sonography) is recommended to rule out intraabdominal metastases. Areas of increased radionuclide uptake on bone scan are assessed by radiographs, MRI, or CT scanning. Other tests are indicated only by specific symptoms or for investigational purposes. Increasingly, positron emission tomography (PET) combined with CT is also being employed to assess extent of disease and rule out metastatic deposits at the time of diagnosis.

DEVELOPMENT OF COMBINED MODALITY STRATEGIES

Systemic therapy was introduced in the management of inoperable breast cancers more than 40 years ago (11,12). Surgery or radiotherapy, or both, followed systemic therapy in these trials. For optimal utilization of all treatment modalities, all interested specialists (radiologist, pathologist, and surgical, radiation, and medical oncologists) should review the diagnostic data, examine the patient, and determine the optimal type and sequence of therapies before any treatment is implemented. Treatment strategies that include neoadjuvant systemic therapy have several potential advantages: early initiation of systemic therapy, *in vivo* assessment of response, and reduction in the extent of primary tumor and regional lymphatic metastases. The potential (theoretical) shortcomings include delay in local treatment, induction of drug resistance, and unreliability of clinical staging. The practical advantages have exceeded, by far, the disadvantages. The ability to monitor response to therapy by serial measurements of the primary tumor, and the reduction in tumor volume that often permits breast conservation, are the two major clinical advantages of these treatment strategies. However, neoadjuvant systemic therapy also represents an unparalleled research platform, facilitating biomarker discovery, such as identification of predictors of response, pharmacodynamics markers of response (early tumor changes that predict response), and biomarkers associated with residual, therapy-resistant disease. Further, neoadjuvant systemic approach can allow for testing of the efficacy of novel combination therapies, expediting drug development.

Neoadjuvant Chemotherapy (NACT)

The first clinical trials with NACT (also called induction chemotherapy, primary chemotherapy, or preoperative chemotherapy) started in the late 1960s, but the earliest reports were published in the 1970s (11,12). Since then, multiple reports have documented the effectiveness of primary systemic therapy in patients with LABC (summarized in reference 6). Most reports of combined modality therapy of locally advanced breast cancer are based on anthracycline-containing combination chemotherapy regimens (see also Chapter 44, Adjuvant Chemotherapy). Administration of combination chemotherapy produces major reductions in tumor volume in 60% to 90% of patients. Tumor reduction has been consistently documented in both the primary tumor and the enlarged regional lymph nodes (6,11–18,). Although mixed responses (response in the primary tumor and no response in the regional lymph nodes, or vice versa) have been reported, they are uncommon (18–20). Clinical complete remissions have been reported in 10% to 20% of patients with LABC treated with anthracycline-containing combination chemotherapy regimens (6,18–21). Response rates, and especially complete response rates, improve if a taxane is added, especially in sequential regimens. The median number of cycles required to achieve a partial remission was reported to be four, and for a complete remission, five (13). Pathological complete remission (pCR) (20–21) is uncommonly obtained with chemotherapy in ER positive tumors, and is rare after neoadjuvant endocrine therapy. Since the introduction of trastuzumab, a number of reports indicated that, in combination with chemotherapy, trastuzumab produces pCR rates ranging from 20% to 70% in HER2-amplified or overexpressing breast cancers (22). Clinical measurements of breast masses

are often inaccurate, and there is substantial interindividual variation among examiners (23). Therefore, imaging methods are often used to more reliably document extent of disease (24). The combination of physical examination with either mammography or ultrasound gives measurements that closely approach those achieved by histopathology, and it reduces error rates in serial monitoring of response to systemic therapy (24). MRI may also be used to determine extent of disease (25). The determination of clinical complete remission requires that no residual disease be present by physical examination and by imaging (mammography and/or ultrasound) in the breast or regional lymph nodes (17). Even following these criteria, only half to two-thirds of patients thought to have a clinical complete remission are found to have a pathologic complete remission (i.e., no residual disease) (17,18,20,21,24). Furthermore, a third of patients with no residual disease by histologic examination will have residual clinical or imaging abnormalities that preclude the diagnosis of clinical complete remission. Patients who achieve a histologically documented complete remission have a markedly improved long-term prognosis compared with patients who achieve incomplete or no responses (17,21,26). Furthermore, these patients are often excellent candidates for breast-conserving strategies, with or without surgical intervention (27). In recent years, in addition to refinements to the sequential evaluation of extent of disease during therapy utilizing mammography, sonography, and MRI, positron emission tomography (PET) has been evaluated. Several authors have reported that not only does PET (usually in combination with CT, PET/CT) identify metastatic lesions not found by other imaging modalities (28) but also it is a very sensitive tool to monitor the functional status of the tumor. Thus, changes in PET imaging, such as marked reductions in standardized uptake values, are under evaluation for early determination of response to neoadjuvant systemic therapy (29).

Most initial reports of combined-modality treatment of LABC were based on anthracycline-containing combination chemotherapy regimens, such as doxorubicin, and cyclophosphamide (AC) or fluorouracil, doxorubicin/epirubicin, and cyclophosphamide (FAC or FEC). Over the past two decades, multiple reports have documented the benefits of the use of anthracycline and taxane combinations (27,30,31). These newer regimens were reported to have marked antitumor activity, with overall response rates in the 80% to 95% range. Unfortunately, the reported clinical and pathologic complete remission rates were only modestly higher than those reported with older combinations. Table 58-1 summarizes prospective randomized trials that compare anthracycline- and taxane-containing regimens with anthracycline-containing combinations without a taxane (26–27, 30–40). In several randomized trials in which a taxane was administered sequentially, after the initial four cycles of an anthracycline/cyclophosphamide-containing neoadjuvant regimen, a significant increase in pathologic complete remission was reported (26,32). In a small, multicenter trial conducted on patients with LABC, the increase in clinical and pathologic complete response rate was associated with improved disease-free and overall survival rates (32–41). Of note, both responders and nonresponders to the initial anthracycline-containing combination benefited from crossover to docetaxel. The National Surgical Adjuvant Breast and Bowel Project (NSABP) protocol B-27 included a crossover to docetaxel after four cycles of neoadjuvant doxorubicin and cyclophosphamide (AC); the addition of docetaxel resulted in significant increases in overall and complete response rates, pathologic complete response rates, and increased breast-conserving surgery rates (26). However, while there was a borderline improvement in relapse-free survival, the primary endpoint of the study, improved disease-free survival, was not significantly altered. However, this study was underpowered to detect clinically significant differences in survival. It is estimated that for each 10% increase in pCR rate a 2.6% improvement in survival might be observed (26). Other drugs under investigation in the neoadjuvant setting are gemcitabine, vinorelbine, platinum analogs, ixabepilone, eribulin, trastuzumab, pertuzumab, trastuzumab emtansine, bevacizumab, and lapatinib. Single-agent trastuzumab was reported to achieve a 23% partial response rate after three weeks of treatment in patients with LABC in one study and a 45% response rate in another (42,43). In combination with a taxane or vinorelbine, or two-drug combination chemotherapy regimens, clinical CR rates of 24% to 59% were reported (22,44,45). The corresponding pCR rates ranged from 18% to 45%. In a small randomized trial of sequential paclitaxel followed by fluorouracil, epirubicin, and cyclophosphamide, with or without trastuzumab, pCR rate increased from 26% to 65% with the addition of trastuzumab (46). These results

TABLE 58-2

Effective and Well-Tolerated Induction Chemotherapy Regimens

Regimen—Drugs	*Doses, Route, and Day of Administration*	*Frequency and Number of Cycles*
Dose Dense AC-T		
Cycles 1–4		
Doxorubicin	60 mg/m^2 IV, day 1	Every 2 weeks × 4 cycles
Cyclophosphamide	600 mg/m^2 IV, day 1	Every 2 weeks × 4 cycles
Perfilgrastim	6 mg SQ, day 2	Every 2 weeks × 4 cycles
Cycles 5–8		
Paclitaxel[a]	175 mg/m^2 IV, day 1	Every 2 weeks × 4 cycles
PACLITAXEL/FAC		
First 3 months		
Paclitaxel[b]	80 mg/m^2 IV, day 1	Every week × 12 weeks
Final 3 months		
5-Fluorouracil	500 mg/m^2 IV, day 1	Every 3 weeks × 4 cycles
Doxorubicin	50 mg/m^2 IV, day 1	Every 3 weeks × 4 cycles
Cyclophosphamide	500 mg/m^2 IV, day 1	Every 3 weeks × 4 cycles
TAC		
Docetaxel	75 mg/m^2 IV, day 1	
Doxorubicin	50 mg/m^2 IV, day 1	Every 3 weeks × 6 cycles
Cyclophosphamide	500 mg/m^2 IV, day 1	Every 3 weeks × 6 cycles
Perfilgrastim	6 mg SQ, day 2	Every 3 weeks × 4–6 cycles
TC		
Docetaxel	75 mg/m^2 IV, day 1	Every 3 weeks × 4–6 cycles
Cyclophosphamide	600 mg/m^2 IV, day 1	Every 3 weeks × 4–6 cycles
REGIMENS WITH TRASTUZUMAB		
DOSE DENSE AC-TH		
Cycles 1–4		
Doxorubicin	60 mg/m^2 IV, day 1	Every 2 weeks × 4 cycles
Cyclophosphamide	600 mg/m^2 IV, day 1	Every 2 weeks × 4 cycles
Perfilgrastim	6 mg SQ, day 2	Every 2 weeks × 4 cycles
Cycles 5–8		
Paclitaxel	175 mg/m^2 IV, day 1	Every 2 weeks × 4 cycles
Trastuzumab	4 mg/kg IV, day 1, followed by 2 mg/kg IV	Weekly for 1 year
TCbH		
Docetaxel	75 mg/m^2 IV, day 1	Every 3 weeks × 6 cycles
Carboplatin	AUC = 6 IV, day 1	Every 3 weeks × 6 cycles
Trastuzumab	8 mg/kg IV, day 1, followed by 6 mg/kg	Every 3 weeks for 1 year

[a]Paclitaxel, 80 mg/m^2 IV every week × 12 weeks can be substituted.
[b]Docetaxel, 100 mg/m^2 IV every 3 weeks × 4 cycles can be substituted (before or after FAC).

were confirmed by a larger randomized trial that included 235 patients with HER-2/neu-positive primary breast cancer (47). A large, multicenter confirmatory study has completed accrual patients with T2 and T3, HER-2-positive breast cancer (ACOSOG protocol Z1041). Gianni and collaborators also reported the initial results of a four-arm randomized trial comparing neoadjuvant docetaxel plus trastuzumab with docetaxel plus pertuzumab, docetaxel plus both antibodies, or the two antibodies without chemotherapy (48). Pathological complete remission rates were 31%, 23%, 49%, and 18%, for the four arms, respectively, indicating that combining the two antibodies with chemotherapy provides the best result, while the two antibodies without chemotherapy were able to eradicate the primary tumor in almost 20% of patients.

Table 58-2 lists the more commonly used effective and well-tolerated neoadjuvant chemotherapy regimens.

NEOADJUVANT ENDOCRINE THERAPY

Most of the clinical investigation with neoadjuvant systemic therapy was conducted with cytotoxic therapy. More limited information is available about neoadjuvant endocrine therapy (see also Chapter 55, Preoperative Endocrine Therapy for Operable Breast Cancer). For patients with estrogen receptor-positive (ER+) breast cancer neoadjuvant endocrine therapy is an appropriate option. The initial trials used tamoxifen and included patients selected on the basis of old age or comorbidity that precluded chemotherapy (49,50). The

results suggested that neoadjuvant endocrine therapy was therapeutically effective and produced marked reduction in tumor volume in 40% to 60% of patients. A significant minority of tumors progressed during neoadjuvant endocrine therapy; thus, close monitoring is required so that early progressors are identified promptly and appropriate regional therapy (or crossover to chemotherapy) can be implemented. Several studies also concluded that tamoxifen alone was insufficient therapy for patients with primary and locally advanced breast cancer, and that appropriate surgery and/or radiation therapy was needed for optimal local and systemic control (51,52). Endocrine therapy should be restricted to patients with hormone receptor–positive breast cancer. More recent trials compared selective aromatase inhibitors with drugs in the same family or with tamoxifen (53). Greater antitumor efficacy was observed with aromatase inhibitors compared to tamoxifen (53). In general, response to neoadjuvant endocrine therapy occurs in 35% to 50% of patients with hormone receptor–positive breast cancer, but fewer than 5% achieve pCR. Response rates to neoadjuvant endocrine therapies in this setting are lower than response rates to anthracycline/taxane based chemotherapy in unselected patients with LABC (52); pCR rates with neoadjuvant chemotherapy for patients with ER+ breast cancer are observed in 5% to 14%, several-fold lower than for patients with ER– breast cancer. Early progression is observed more frequently after neoadjuvant endocrine therapy (12% to 17%) (53) than after neoadjuvant chemotherapy (5% to 10%) (6). The poor prognosis for patients with LABC indicates that all treatment modalities are needed for optimal results, so all patients with positive estrogen and/or progesterone receptor assays should receive adjuvant endocrine treatment as part of multidisciplinary therapy. Whether there is a subset of patients with hormone receptor–positive LABC that does not benefit from, and therefore does not require, NACT is under active investigation.

Considerations for Imaging

A common denominator underlying clinical decisions about appropriate surgical treatment for LABC is the importance of accurate imaging. It is important at initial presentation to estimate tumor size and determine if the patient is a good candidate for NACT. During and after NACT, imaging of the primary tumor and the axillary lymph nodes is used to assess treatment response and aid in surgical planning.

Standard Imaging Modalities After NACT

Mammography and US have been shown to offer accurate predictions of pathologic tumor size in patients with small invasive ductal carcinomas without an extensive intraductal component, provided the patients have not received NACT (54,55). In patients who have received NACT, however, there have been widely disparate reports on the accuracy of these imaging approaches for predicting residual pathologic tumor size (24). Overall, as reviewed in the report from Chagpar and colleagues (54), physical examination appears to be at least as accurate as mammography or US in estimating residual tumor size, with correlation coefficients ranging from 0.42 to 0.73, compared to a range of 0.33 to 0.65 for mammography and 0.29 to 0.60 for US. However, the false negative rate associated with physical examination has been reported to be almost 60% (54), indicating that many small tumors might be missed using this approach. Similarly, the false positive rates from US and mammography may be 50% or higher, suggesting that these imaging approaches may pick up inflammatory or fibrotic changes induced by chemotherapy. The mixed reports about the usefulness of US and mammography in assessing residual tumor size have driven the search for more accurate imaging modalities. There is interest in using magnetic resonance imaging (MRI), as well as new approaches involving functional imaging and the tools of nanotechnology as well as additional refinements to mammography and US.

MRI for the Assessment of NACT Response

MR images of breast lesions are captured before and after the injection of a gadolinium-based contrast agent. Because malignant lesions are typically more vascular than benign lesions, they tend to take up the contrast agent faster. They can also be distinguished from benign lesions by having spiculated rather than smooth edges. MRI originally suffered from an unacceptably high rate of false positives, but improved algorithms for combining morphologic and kinetic data have greatly improved this picture, with specificity now ranging from 81% to 99% (55) (see Chapter 13). MRI is especially being pursued as an early predictor of pCR. Data from the ACRIN 6657/I-SPY trial demonstrated that change in MRI tumor measurements after one cycle of anthracycline-based NACT was a better predictor of pCR than clinical examination (56).

MRI may allow a more precise estimation of residual tumor than mammography or ultrasound (56,57). Despite its sensitivity, however, the ability of MRI to detect a complete pathologic response has shown great variability in different series, presumably because the limits of detection for MRI do not allow the identification of very small foci of *in situ* or invasive disease. For this reason, a negative report on MRI should be evaluated conservatively, and properly used only to assess a patient's candidacy for breast-conserving therapy (BCT). Further, a larger tumor extent on MRI in a patient who is eligible for breast conservation based on mammography or ultrasound should also be interpreted with caution. For this reason, several institutions, including MDACC, only selectively use MRI for patient management.

Other Approaches to Breast Imaging

Positron emission tomography (PET) produces images that reflect metabolic and physiologic functions occurring in living cells. A positron-emitting radionuclide is attached to a molecule (such as ^{18}F-fludeoxyglucose = FDG) that is ingested or metabolized at a high rate in the rapidly growing cancer cells. FDG-PET is very specific for the detection of malignant breast tumors, and problems with spatial resolution and "noise" from normal tissue can be reduced by using a small parallel pair of detector heads placed directly above and below the breast (58). A general problem with PET is the lack of anatomical specificity. This problem can be resolved by running the scan concurrently or sequentially with an alternate anatomical imaging modality. Andrade and colleagues (59) used hybrid PET/CT imaging to assess response to neoadjuvant chemotherapy in 45 patients with primary breast cancer. They were able to demonstrate a sensitivity of 90.9% and a specificity of 83.3% for the prediction of clinical response by PET/CT. Mammography can also be used as an anatomical imaging adjunct for PET; using the small parallel detector heads, the scan can be run concurrently or sequentially with mammography without releasing the breast compression (58) (see Chapter 14).

APPROACHES TO LOCAL THERAPY

The administration of NACT as the first modality of treatment, before surgical therapy is instituted, is favored by most experts for the management of stage III and most large stage II breast cancers (60). NACT results in major objective

responses and downstaging for approximately 70% to 95% of patients (6,14,17,18,61). Only 3% of patients experience tumor progression during NACT (62), this rarely (0.5%) leads to an increase in the scope of surgery required or inoperability (63). Surgical therapy may require a total mastectomy or only breast-conserving surgery (also referred to as wide excision, lumpectomy, or quadrantectomy), both with an axillary surgery (see also Chapters 33, Mastectomy; 35, Breast-Conserving Therapy, and 38, Axillary Dissection).

Considerations for Breast-Conserving Surgery

The use of NACT has become standard management for patients with LABC, in part because it frequently reduces the size of the primary tumor enough to allow previously inoperable tumors to become operable. For selected patients, (i.e., complete resolution of skin edema [peau d'orange], adequate reduction in the tumor size, no extensive intramammary lymphatic invasion, absence of extensive suspicious microcalcifications, and no evidence of multicentricity), BCT can be an appropriate local treatment option. In patients meeting these criteria, the local recurrence rate and 10-year overall survival after BCT are equivalent to those seen in early stage breast cancer patients (64).

As with any curative breast cancer surgery, the primary goal is to completely remove the tumor with negative margins. This is a potential problem in LABC patients treated with NACT because approximately 30% of these patients (and up to 60% of those treated with trastuzumab) will achieve a clinical complete response, making it difficult to locate the tumor site during surgery (65). In addition, nearly two-thirds of the patients with a clinical complete response will prove to have residual tumor on final pathology, so it is critically important to be able to precisely localize and remove the original tumor site and ensure that the surgical specimen has clean margins (65). This can be accomplished by the placement of a metallic marker in the tumor under US or mammographic guidance either at initiation of therapy (65), or when the tumor has shrunk to less than 2 cm in size during chemotherapy. Placement of two or more markers should be considered for multifocal disease in patients who are interested in breast conservation.

If the marker(s) is placed before the initiation of NACT, the tumor may shrink eccentrically, leaving the marker on the edge of the residual tumor, rather than in the epicenter. Platinum is preferable to the stainless steel rods that were originally used because it is more compatible with MRI. The marker is inserted with a long needle and a blunt stylet under US guidance. Alternatively, we may use stereotactic clips, which are much smaller in size. Mammography is performed immediately after marker implantation to precisely document the position of the marker in relation to the tumor.

At the beginning of surgery a guide wire is inserted by the radiologist under US or mammographic guidance to indicate the location of the marker. Bracketing with two or more guidewires is used for patients with extensive calcifications or multifocal disease at the onset. Surgical excision does *not* attempt to remove the pre-chemotherapy volume of tumor. Rather, the goal is to remove any residual lesion with 1 cm of clear margins or, if there is no detectable residual lesion, a 2-cm specimen with the metal coil in the center. When the specimen is removed, the orientation is designated. Margins are inked; a multicolor inking system may be used to identify the superior, inferior, lateral, medial, anterior, and posterior surfaces (Fig. 58-1). In pathology, a specimen radiograph is

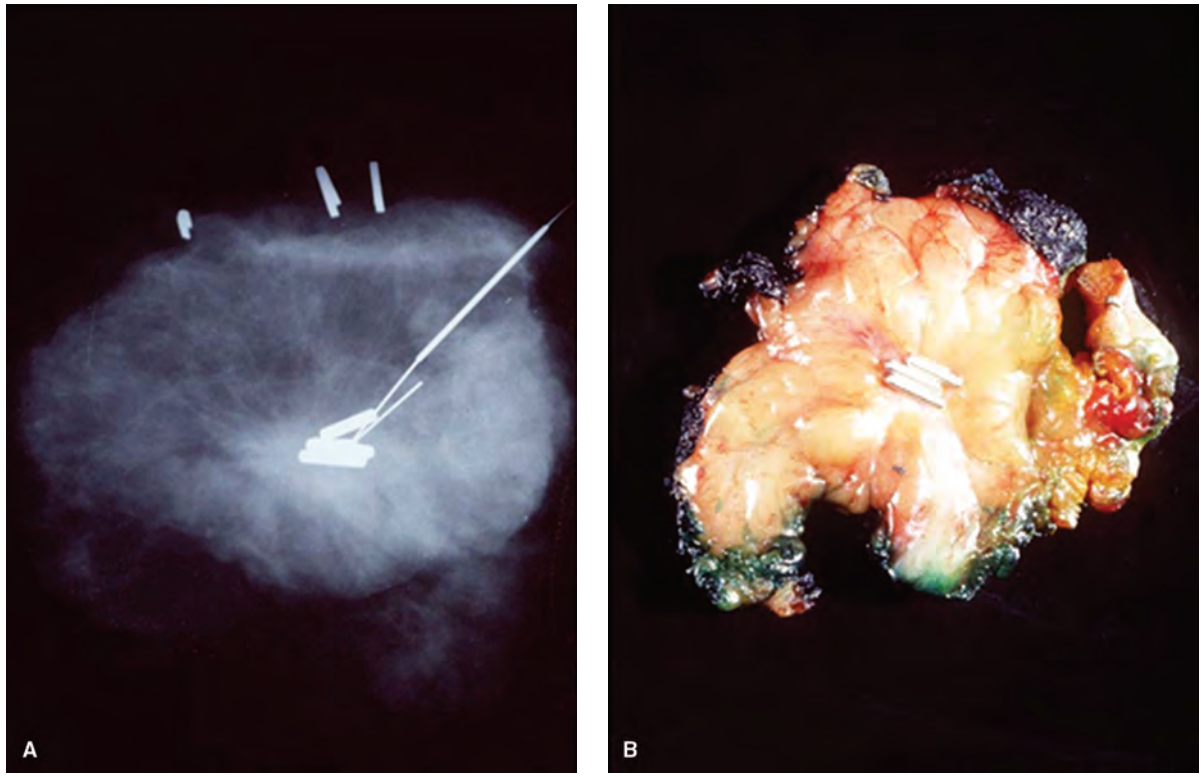

FIGURE 58-1 **(A)** Specimen radiograph showing position of metal markers and guidewire inside the excised specimen. **(B)** Metal markers in the sectioned specimen. (Photographs courtesy of Dr. Henry Kuerer and Dr. Peter Dempsey.)

taken to verify the presence of the marker within the excised specimen. While the patient is still in surgery, the specimen may be sectioned, with the order of all sections maintained so that the site of any positive or close margin can be identified and the surgeon can remove additional tissue from this area to obtain a negative margin.

The clinical definition of LABC has traditionally included tumors of any size that are associated with skin or chest wall involvement, classified as T4 in the AJCC Cancer Staging System (4). Classification of a tumor as T4b indicates the presence of noninflammatory skin changes, including edema, ulceration of the skin of the breast, or presence of satellite skin nodules confined to the same breast. Such skin involvement has been associated with a poor prognosis, and these patients traditionally have been recommended for mastectomy, under the assumption that local failure rates would be unacceptably high with BCT. However, emerging data suggests that carefully selected patients with noninflammatory T4b disease may be candidates for breast conservation.

Shen and colleagues (66) looked at local control and long-term survival in 33 patients with noninflammatory T4b disease treated with breast conservation therapy. The median tumor size at study entry was 7 cm (range 2–12 cm), and all patients had one or more types of skin involvement. After a median of 4 cycles of neoadjuvant chemotherapy (NACT), 28 patients had a complete or partial clinical response, and 28 patients showed a complete resolution of skin changes. At a median follow-up time of 91 months, only five patients (6%) had developed a locoregional recurrence (LRR), similar to rates observed in patients without noninflammatory skin involvement who received BCT after NACT. The 5-year overall survival rate was 78%, superior to most published survival data for patients with noninflammatory T4b disease, likely reflecting the careful selection criteria that were used.

This demonstrates that skin involvement at presentation is not an absolute contraindication for BCT, especially when found in combination with superficial smaller tumors and if negative margins can be achieved. This is true even for selected patients with skin ulceration, among the most alarming of symptoms and one that is usually associated with long-neglected locally advanced disease. For example, tumors of the inframammary fold can be quite small (≤1 cm) and present with skin ulceration. The direct skin involvement might occur as a result of the tumor's location very close to the skin surface. These patients can be treated conservatively with en bloc excision of the involved skin if the tumor demonstrates direct tumor invasion/ulceration, with favorable outcomes.

There have been concerns about the risk of LRR with breast-conserving surgical treatment (BCST) after neoadjuvant chemotherapy. However, multiple studies have demonstrated that BCT for locally advanced breast cancers after NACT is feasible and, if appropriate selection criteria are applied, safe and associated with high local control rates (14,67–70). When patients who underwent surgery after NACT were evaluated at MDACC, clinical N2 or N3 disease, residual pathologic tumor size more than 2 cm, a multifocal pattern of residual disease, and lymphovascular space invasion in the specimen were associated with higher risk of LRR in two independent cohorts (63,71). For patients undergoing BCT, the 5-year LRR-free survival rate was 92% if patients had none or only one poor prognostic factor, 84% when they had two unfavorable factors, and 69% when they had three or four factors. The 5-year LRR-free survival rates were similar between patients undergoing mastectomy or BCT when patients had 0, 1, or 2 poor prognostic factors. In patients who had 3 to 4, the 5-year LRR-free survival was significantly lower for patients treated with BCT compared with mastectomy (69% vs. 93%, p = .007) (71). Although, these factors do not represent absolute contraindications for BCT, they highlight a high-risk patient group in whom caution should be exercised in local-regional treatment planning.

Considerations for Management of the Axilla after NACT

LABC encompasses patients with clinical N2/N3 as well as clinically N0 patients with large primary tumors. Ultrasound of the regional node basins with percutaneous biopsy of suspicious nodes can assist in better regional staging of patients with LABC in several ways: in patients who have clinically node-negative axillae, by identifying, ultrasonographically, suspicious nodes that are involved and demonstrating their involvement by biopsy, and in patients with clinically node-positive disease, pathologically confirming nodal involvement as well as by determining extent of regional nodal involvement by assessing supraclavicular, infraclavicular, and internal mammary lymph node basins.

SLNB has become widely accepted and used because it offers accurate assessment with a substantially reduced occurrence of the morbidities usually associated with complete axillary lymph node dissection (e.g., edema, reduced mobility, pain, etc.). Most studies in SLNB have been performed in patients with early stage disease. However, there is increasing experience with use of SLNB in patients with clinically node-negative tumors with larger, non-inflammatory breast cancers. Although there was some initial controversy about use of SLNB in patients who were initially clinically N0 and then underwent NACT, a meta-analysis has demonstrated acceptable SLNB false-negative rates in such patients (72) and studies have shown adequate local-regional control with SLNB only in initially clinical N0 patients who underwent SLNB after NACT (73).

Patients with pathologically demonstrated nodal involvement at presentation are offered axillary lymph node dissection at completion of NACT, even if they have a complete clinical response in the breast and axilla. However, with the increasing utilization of targeted therapies, it is likely that pCR rates in the axilla will increase over the next decade. Notably, it has been shown that 74% of HER2 positive patients with axillary metastases confirmed by ultrasound-guided FNAC who received trastuzumab-containing NACT followed by breast surgery with complete axillary lymph node dissection were found to have a complete axillary response (74). ACOSOG Z1071 evaluated the role of sentinel node biopsy following NACT in women with clinically node-positive disease at presentation, and cooperative group studies are planned to determine the feasibility of less invasive strategies in selected patients with clinical nodal involvement and subsequent NACT.

Considerations for Reconstructive Surgery

Many patients with LABC will become good candidates for BCT after NACT, but some will still need or prefer to undergo a mastectomy. Current reconstructive techniques using autologous tissue flaps offer excellent cosmetic results without compromising long-term outcomes (see Chapter 36). Ideally, breast reconstruction can be carried out during the same surgery as the mastectomy, lessening the cost and the risk of multiple surgeries. However, there are potential restrictions to immediate reconstructions in patients with LABC that both physician and patient need to understand and discuss.

Patients with LABC are known to have a high risk of chest wall recurrences following mastectomy alone (75). For this reason, most are recommended for radiation therapy

(RT) of the chest wall and the axilla following surgery. The optimal sequencing of RT and reconstruction is controversial. Immediate breast reconstruction can be an important factor in recovery, contributing to a more positive body image. On the other hand, there has been concern that a reconstructed chest mound might interfere with the delivery of the proper radiation dose, especially to the internal mammary nodes, or that there might be volume loss and asymmetry in the flap as a side effect of the RT.

A report by Tran and colleagues (76) examined both early and late complications from RT in patients with a free transverse rectus abdominis myocutaneous (TRAM) flap breast reconstruction. Of 102 patients in the study, 32 had immediate TRAM flap reconstruction before RT and 70 had RT before delayed TRAM flap reconstruction. Mean follow-up times for the immediate reconstruction and delayed reconstruction groups were 3 and 5 years, respectively. There was a slightly higher rate of early complications from RT in patients who received delayed reconstruction, but the differences were not significant. Late complications, including fat necrosis, volume loss in the flap, and contracture in the flap, were significantly more common in patients with immediate reconstruction. Fat necrosis occurred in 44% of patients with immediate reconstruction compared with 9% of patients with delayed reconstruction. No patients with delayed reconstruction experienced volume loss or contracture, versus 88% and 75%, respectively, of patients receiving immediate reconstruction.

Foster and coworkers (77) argue that immediate breast reconstruction has minimal morbidity and that complications tend to be minor. Their study involved 35 patients who received immediate Transverse Rectus Abdominis Myocutaneous (TRAM) flap reconstruction followed by RT. At a minimum follow-up time of 1 year, they reported fat necrosis in 3 patients, two of whom developed volume loss of the flap and required additional surgery. Two patients had cellulitis, one developed a periumbilical hernia, and one experienced fascial laxity of the lower abdomen. Although the median follow-up time was 48 months, no data were presented about long-term cosmetic outcomes. In addition, there was no comparison group of patients who received RT prior to a delayed reconstruction.

Although most authors acknowledge that radiotherapy to an immediate reconstruction may impair the final cosmetic outcome for some patients, until recently there was no information about the impact of immediate reconstruction on radiotherapy planning. An MDACC study compared 110 patients who had mastectomy with immediate reconstruction and postoperative radiotherapy with contemporaneous stage-matched patients who had undergone mastectomy without intervening reconstruction (78). Each of the radiotherapy plans were assessed for completeness of coverage and avoidance of adjacent critical structures. Of the radiotherapy plans scored after reconstruction, 52% had compromises compared with 7% of matched controls ($p < .0001$). Left sided radiotherapy plans had larger compromises after immediate reconstruction than right sided ones. Because of this, the potential for compromised Post Mastectomy Radiation Therapy (PMRT) planning should be considered when deciding between immediate versus delayed reconstruction.

Overall, the timing of reconstructive surgery has remained somewhat controversial for patients who are known to need PMRT at the onset. At MD Anderson Cancer Center, reconstruction is either deferred until after the completion of RT in patients with LABC who receive a mastectomy, or performed with a tissue expander to facilitate preservation of the breast skin envelope, with the intent of subsequently performing an autologous reconstruction.

ROLE OF RADIATION THERAPY IN LABC

Comprehensive irradiation is an effective therapy to eliminate occult deposits of tumor in local and regional tissues after surgical removal of macroscopic tumor. Patients with stage III breast cancer have a 30% to 50% risk of local-regional recurrence when surgery or radiation is used as the sole local treatment (11,16,17,79,80). This level of risk indicates the need to administer radiation therapy after a total mastectomy and certainly after breast-conserving surgery (see also Chapters 35 and 42). For operable stage III breast cancer, the postoperative administration of chemotherapy and radiotherapy resulted in improved local control and overall survival rates, compared to the use of either adjuvant treatment alone. Advanced regional nodal involvement, poor response to chemotherapy, ER- tumors, extracapsular tumor, and involvement of the skin or nipple are associated with particularly high locoregional recurrence rates (81). For local/regional treatment to be effective, it must encompass all the volumes at risk, and it must eliminate any tumor cells therein. For LABC, this means treating the entire soft tissue of the chest wall, including any residual breast tissue, the surrounding skin, the connective tissue, and the regional lymphatics. Most local recurrences occur on the chest wall, followed in order of frequency by the axillary and supraclavicular chain and, infrequently, the internal mammary chain. Failure in the dissected axilla is unusual, provided no gross disease remains (82). In the presence of known residual disease, higher doses of radiation therapy are required, with the consequent increase in acute and long-term complications. For this reason, if there is residual disease after induction chemotherapy, surgical excision is preferred, particularly for disease that is larger than 1cm, followed by radiotherapy.

From a technical perspective, successful treatment planning results in field arrangements that accomplish the following four objectives:

1. Broad coverage of the chest wall;
2. Inclusion of the undissected nodal basins including the internal mammary, axillaryapical, and supraclavicular nodes;
3. Minimization of lung irradiation; and
4. Minimization of heart irradiation.

Most commonly, the chest wall is treated at MD Anderson Cancer Center with lateral tangential fields of 6-MV or combined 6- and 18-MV photons abutted to a medial electron beam field. Alternate field arrangements using only electrons or only photons may be used for treatment of patients with appropriate anatomic configurations. CT planning with heterogeneity correction is routine, but inverse-planned Intensity Modulated Radiation Therapy (IMRT) is not favored by the MD Anderson Breast Radiation Oncology group because of the limitations of current planning software to accurately model the dose in thin chest walls and the tendency for these plans to result in irradiation of large regions of the uninvolved thorax. In locally advanced breast cancers the internal mammary chain will contain tumor in more than 25% of patients subjected to Internal Mammary Chain (IMC) dissection (83). Thus, an adjacent, matching electron beam field is typically used to treat the lymph nodes of the internal mammary chain. With this technique, the left ventricle can be completely excluded from the irradiated volume, and a maximum of 2 to 3 cm of lung is treated (Fig. 58-2). Alternatively, a series of electron beam fields can be used to treat the chest wall and internal mammary nodes. The undissected lymphatics of the axillary apex and supraclavicular fossa are treated with low-energy photons or electrons. This field may frequently need to be expanded in patients with advanced presentations (especially if known supraclavicular

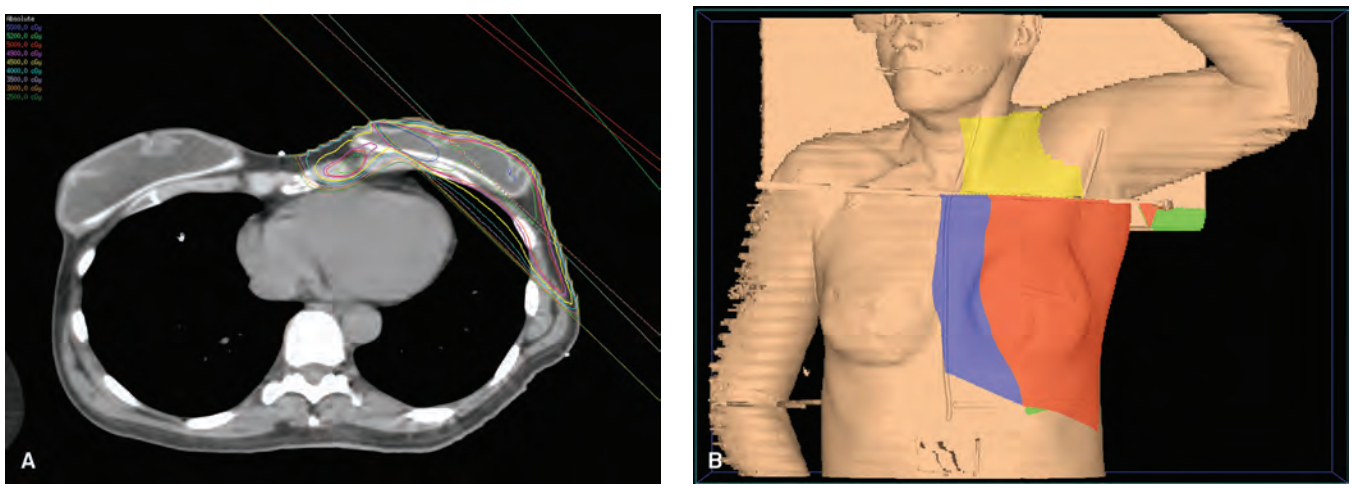

FIGURE 58-2 **(A)** Left postmastectomy radiotherapy isodose distribution. Use of multiple adjacent fields allows minimization of heart and lung volume. A tissue expander, placed at mastectomy, has been deflated to optimize radiotherapy planning. **(B)** Left postmastectomy radiotherapy field projections.

adenopathy has been documented) to cover all regions at risk (84). Fifty Gray is delivered in 25 fractions, followed by a boost to the chest wall, to a total dose of at least 60 Gy. Areas of initial nodal involvement not removed at surgery are also treated to 50 Gy followed by electron boosts to the site of original disease to achieve a total dose of 60 Gy for a complete response and 66 Gy for minimal residual disease. At these higher doses, care should be employed to avoid sensitive structures like spinal cord or brachial plexus. Combined-modality therapy offers excellent local control to 90% or more of those with stage IIIB or IIIC breast cancer who have no gross residual disease, and an even higher proportion of those with stage IIIA disease (17). However, if any part of the multidisciplinary treatment strategy is suboptimal, it compromises the efficacy of the entire program. All patients with Stage III breast cancer should receive postmastectomy RT even if a pathologic complete response is achieved by initial chemotherapy. Patients with clinical stage II breast cancer at the time of diagnosis and residual positive lymph nodes after neoadjuvant chemotherapy should also be considered for postmastectomy radiation therapy.

Unfortunately, a small minority of patients with advanced breast cancer will not respond to initial therapy. These patients present a difficult management problem because of tumor ulceration, necrosis, and superinfection, or regional consequences in the neck or brachial plexus. Radiotherapy, with or without concurrent chemotherapy, is an important tool to provide local symptom palliation for these individuals.

SEQUENCING TREATMENT MODALITIES

There are many possible ways to combine or sequence the therapeutic modalities used for breast cancer. The high incidence of distant metastases in patients with LABC makes the early introduction of systemic therapy imperative. Whether simultaneous chemotherapy and radiotherapy result in improved local and distant control compared to sequential administration of chemotherapy and radiotherapy remains to be established (85). Therefore, most combined-modality strategies for inoperable LABC start with induction chemotherapy, usually with an anthracycline and taxane-containing multidrug regimen. The extensive experience our group has acquired over the past four decades suggests that neoadjuvant chemotherapy followed by surgical resection, adjuvant chemotherapy, and consolidation radiotherapy is a well-tolerated, safe, and effective sequence of therapies for patients with LABC (17). In recent years, we have modified this sequence slightly on the basis of two important observations: the first, that the ability to monitor response (or lack of response) to systemic chemotherapy helps guide treatment. If there is no response, or progression of the tumor is demonstrated, the treatment being used can be stopped so that additional toxicity can be avoided, and another, non–cross-resistant chemotherapy regimen can be introduced. The second observation indicates that both responders and nonresponders to neoadjuvant chemotherapy benefit from a fixed crossover to another, non–cross-resistant regimen (32). Therefore, we now administer all chemotherapy before surgical resection, and we consistently use two chemotherapy regimens in sequence: FAC and a taxane-containing regimen. We and others have documented an increase in overall and pathologic complete response rates with this approach and have reduced the percentage of patients with primary resistance to neoadjuvant chemotherapy (26,32,38). Whether this increase in response is related to longer duration of chemotherapy or to the introduction of a second chemotherapy regimen has not been fully defined, although the limited data that exist seem to support the second explanation. Increased frequency and quality of objective responses is usually associated with down staging, thus facilitating the surgical procedure, and sometimes permitting breast conserving surgery even in patients with LABC. Whether administering all chemotherapy before surgery is better than administering some before and some after surgery has not been definitely established. The only large, prospective trial where these two approaches could be compared was NSABP B-27. In this study there was a trend favoring giving all chemotherapy up front, although this difference was not definitive (26). Because B-27 included only operable breast cancer, the relevance of these results to LABC is uncertain. It can also be stated that there is no apparent superiority (be it conceptual or empirical) to administering some chemotherapy before and reserving some for postoperative administration.

TABLE 58-3

Selection Criteria for Breast-Preserving Surgery after Neoadjuvant Chemotherapy

Patient desires BCT
Availability of radiotherapy
Family and/or social support systems available
Resolution of skin edema
Healing of skin ulceration
Residual solitary tumor size of <5 cm
No collagen vascular disease
No extensive intramammary lymphatic invasion
Absence of extensive suspicious microcalcifications
No known evidence of multicentricity
Clear surgical margins

The addition of trastuzumab to the preoperative treatment of patients with HER2-positive breast cancer has further increased overall and complete response rates (22,44–48). The addition of trastuzumab to multimodality treatment has also improved locoregional control. Adjuvant endocrine therapy should be administered to all patients with hormone receptor–positive breast cancer.

There are multiple patient and tumor characteristics that must be considered in the process of selecting candidates for breast-conserving therapy. There are very few absolute contraindications to breast-conserving therapy, although each of the factors listed may increase moderately the risk of recurrence within the breast. Selection of patients with LABC for breast-conserving therapy should be done with caution, and implemented only by groups with experience in combined-modality therapy. The MD Anderson Cancer Center criteria to select patients for breast-conserving surgery after neoadjuvant chemotherapy or endocrine therapy are listed on Table 58-3. All criteria must be fulfilled before breast-conserving surgery is offered.

The radiotherapeutic technique for breast conservation in patients with LABC is particularly challenging because the target volume extends beyond the intact breast to include the regional lymphatics. This involves the use of multiple adjacent fields. Ideally, the use of noncoplanar beams with precise matching techniques is used when photon fields abut one another. Typically, the breast and undissected lymphatics will be treated to a dose of 50 Gy in 25 fractions over five weeks' time, followed by a 10-Gy boost to the tumor bed, which had been marked intraoperatively with clips. In patients with LABC downstaged with systemic therapy, our current practice is to design treatment fields on the basis of the original extent of disease.

TOLERANCE AND TOXICITY

Combined modality regimens have been well tolerated, and no increase in surgical complications has been reported (86). Over the past two decades we have elected to administer all chemotherapy (usually eight to nine cycles, or 24 to 27 weeks) before the surgical intervention. The expected acute toxic effects of combination chemotherapy are observed with the same frequency and intensity as in the postoperative adjuvant setting (18,26). In studies with simultaneous radiotherapy and chemotherapy, slight increases in hematologic toxicity and enhancement of acute radiation effects (erythema, moist desquamation) have been reported. Simultaneous administration of chemotherapy (especially anthracycline-containing regimens) and radiotherapy impairs, to some extent, the cosmetic results of breast-conserving therapy. Although some impairment of cosmesis is also observed with the sequential use of chemotherapy and radiotherapy, this effect is not clinically important for most patients (87). For patients with left breast cancer, synergistic cardiac toxicity is a danger with simultaneous anthracycline and radiation therapy (88). Sequential administration of chemotherapy and radiotherapy, a modification in radiotherapy techniques, and careful attention to the total dose of anthracyclines minimizes the risk of cardiac toxicity. The administration of doxorubicin by 48- or 96-hour continuous infusion schedules, the use of a cardiac protector (such as dexrazoxane), or using a less cardiotoxic anthracycline (epirubicin or a liposome-encapsulated anthracycline) also reduces the risk of cardiac toxicity substantially.

SURVIVAL EFFECTS OF COMBINED MODALITY STRATEGIES

The bulk of the information regarding the multidisciplinary treatment of stage III and LABC was obtained from uncontrolled phase II trials; therefore, the effects of the various components of these treatments on survival are tentative at best, and definitive conclusions might not be reached. For patients with inoperable stage III or inflammatory breast cancer, randomized trials including a control arm without systemic therapy will never be conducted. The results of phase II trials compare favorably to the outcomes of historical control series, or literature controls, suggesting higher 5- and 10-year survival rates, especially for the worst prognostic subgroups (6) or for patients with supraclavicular lymph node involvement (17,89), and patients with T4 primary lesions. Figure 58-3A shows the disease-free survival of patients with stages II, IIIA, and IIIB treated at MD Anderson Cancer Center with induction chemotherapy followed by surgery, radiotherapy, and adjuvant chemotherapy, with a maximum follow-up now exceeding 20 years. Figure 58-3B shows the overall survival curves from the same three groups of patients. The median relapse-free and overall survival times for patients with stages II and IIIA breast cancer treated with combined-modality therapy at our institution have not been reached at 240 months. This is in contrast with a median relapse-free survival of 102 months for similar stage IIIA patients treated with surgery and radiotherapy at our institution in earlier years. Similarly, the median overall survival has not been reached for patients with stages II and IIIA breast cancer treated with chemotherapy, surgery, and radiotherapy, whereas it was 140 months for patients treated without systemic therapy. It is generally accepted that patients with stage III breast cancer treated with local therapy followed by postoperative adjuvant chemotherapy have a significant relapse-free (5,90) and overall survival advantage over those treated with only local therapy. The results of randomized trials comparing neoadjuvant (or preoperative) chemotherapy with postoperative chemotherapy in operable breast cancer, suggest that the two approaches are therapeutically equivalent (18,91,92) (Table 58-4).

In both studies, the chemotherapy regimen given before or after surgery was the same. In both studies, the relapse-free survival and overall survival curves of the neoadjuvant and adjuvant chemotherapy-treated groups were superimposable. No randomized trials comparing preoperative to postoperative systemic therapy have been conducted in patients with LABC. As both randomized trials in operable breast cancer included patients with T3 lesions, it is unlikely that the results of similar trials conducted in patients with LABC would be any different.

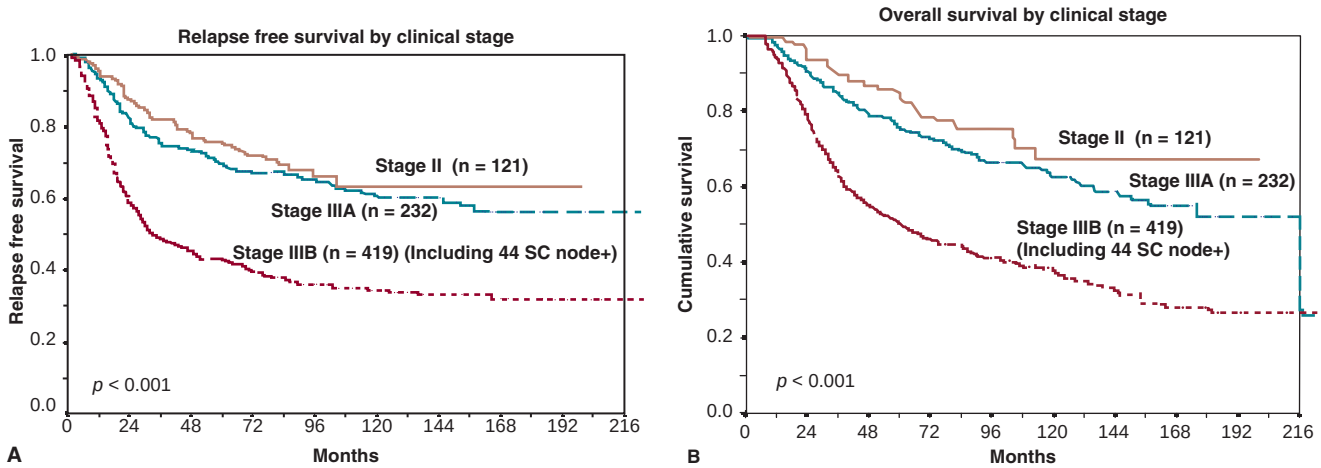

FIGURE 58-3 Patients with stages II, IIIA, and IIIB breast cancer were treated with three to four cycles of neoadjuvant chemotherapy (FAC), followed by surgical resection, radiotherapy, and adjuvant chemotherapy between 1973 and 1995 on four consecutive prospective clinical trials (n = 772 [including 44 patients with supraclavicular of infraclavicular lymph node involvement at the time of diagnosis]). **(A)** Relapse-free survival curves. **(B)** Overall survival curves.

For decades it was considered that patients with ipsilateral supraclavicular or infraclavicular lymph node involvement at presentation had overt metastatic disease and were incurable. Brito el al. reported that such patients treated with combined modality treatments such as those described for LABC in this chapter have outcomes similar to other patients with LABC, and that 32% survive without evidence of recurrence or progression for 10 years or longer (89). As a result of that observation and confirmation from other studies, patients with supraclavicular involvement at presentation, but no other evidence of distant metastases were moved to the Stage III category in the most recent edition of the AJCC Staging Manual (4).

PROGNOSTIC FACTORS

The ability to predict outcome changes with the efficacy of the treatments used. For LABC treated with regional therapies only, large tumor size, presence of involved axillary lymph nodes, involved supraclavicular lymph nodes, skin edema, inflammatory breast cancer, diffuse primary tumor, and short duration of symptoms were predictive of decreased relapse-free and overall survival rates (7,93,94). Evaluation of the prognostic value of axillary lymph node involvement after NACT showed that the number of involved nodes was the best predictor for both relapse and death in a multivariate analysis (95). The pathologic nodal subgroups of 0, 1 to 3, 4 to 10, and greater than 10 positive lymph nodes after NACT predicted a prognostic distribution similar to that found in previously untreated patients. Other important and independent factors found in this study by multivariate analysis were clinical tumor stage at presentation, clinical response to NACT (Fig. 58-4), and menopausal status. Other investigators have reported clinical response to NACT, or its surrogate, histologically detected extent of residual disease, as an important prognostic indicator (96).

Response (and especially complete response) to NACT was reported to occur significantly more often in patients with poorly differentiated tumors (96,97). Response rates were also higher in patients with hormone receptor–negative tumors (98). Provocative data from pilot studies suggested that responses were more common in patients with aneuploid tumors and in those with high proliferative fraction (99,100). Retrospective analyses of randomized clinical trials have suggested that tumors that overexpress the HER-2 oncoprotein might be relatively resistant to the CMF combination and to hormonal therapy with tamoxifen (101), while higher doses of doxorubicin might be more effective in this same group (102).

TABLE 58-4

Survival of Patients with Stage II–III Breast Cancer after Combined Modality Programs Based on Neoadjuvant Chemotherapy Followed by Local Treatment

					Survival %	
Reference	*Treatment Program*	*No. of Patients*	*% Rendered Disease-Free*	*Median Survival (months)*	*3 Year*	*5 Year*

Results of Randomized Trials

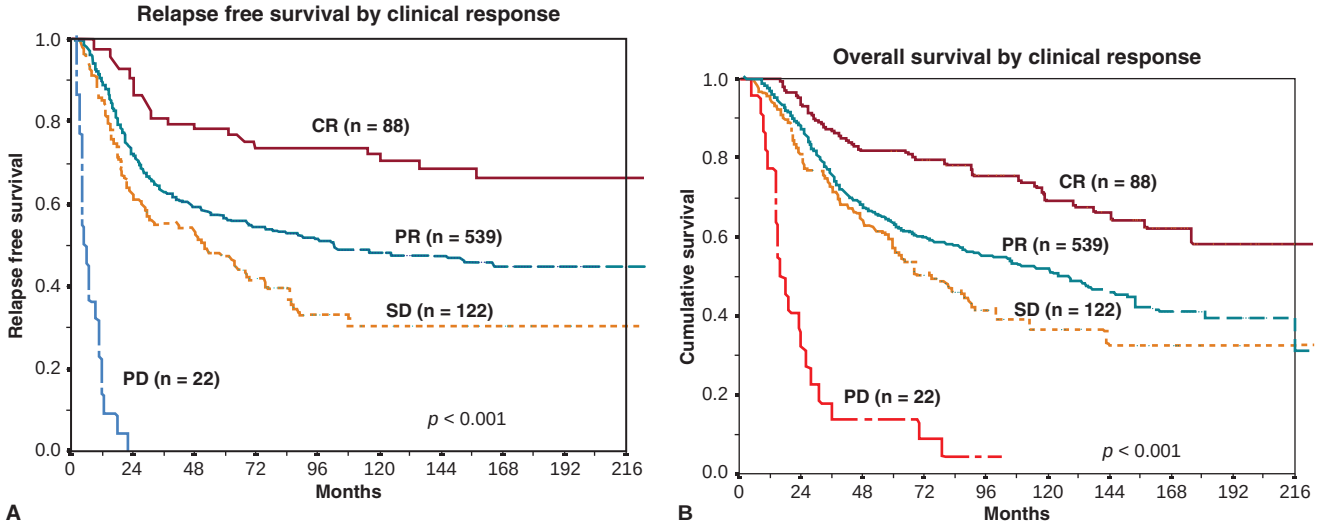

FIGURE 58-4 Clinical response to neoadjuvant chemotherapy (n = 771; response could not be evaluated in one patient). **(A)** Correlation with relapse-free survival. **(B)** Correlation with overall survival. CR, clinical response; PR, pathology response; SD, stable disease; PD, progressive disease.

Other studies have assessed the prognostic importance of various factors in terms of relapse-free and overall survival. Initial TNM stage, clinical tumor size, clinical nodal stage, and histologic grade have been shown to correlate with both endpoints in univariate analyses (13,17,36). In multivariate analyses, histologic/nuclear grade, both clinical and surgical nodal stages, initial tumor size, and response to neoadjuvant chemotherapy were significant predictors of disease-free survival (17,93,95), whereas tumor size, nodal status, grade, and response to neoadjuvant chemotherapy correlated with overall survival (17,93,95). The most important predictor of outcome in our institutional experience is pathologic complete response, defined as complete absence of residual invasive cancer in the surgical specimen, including the axillary lymph nodes (Fig. 58-5). A recent meta analysis conducted by the FDA reached identical conclusions (103).

Local control is related to response to neoadjuvant chemotherapy and to initial stage of the disease (Fig. 58-6). Although our initial clinical trials suggested that a mastectomy should be performed if the tumor was (or became) operable, more recent clinical trials offered the option of breast-conserving surgery if downstaging was of sufficient magnitude. Our experience confirms that if selection criteria are strictly followed, optimal local control can be obtained after neoadjuvant chemotherapy and breast-conserving surgery.

PROSPECTS FOR THE FUTURE

Much progress has been made in the management of locally advanced breast cancer, but much remains to be accomplished. The taxanes (paclitaxel, nab-paclitaxel, and docetaxel) have been effectively incorporated into the management of metastatic breast cancer, and multiple reports suggest that they contribute to the curative regimens in locally advanced and early breast cancer. Anthracycline–taxane combinations are effective in locally advanced breast cancer. New cytotoxic agents, with demonstrated antitumor efficacy against metastatic breast cancer, continue to be developed (104): gemcitabine, capecitabine, liposomal

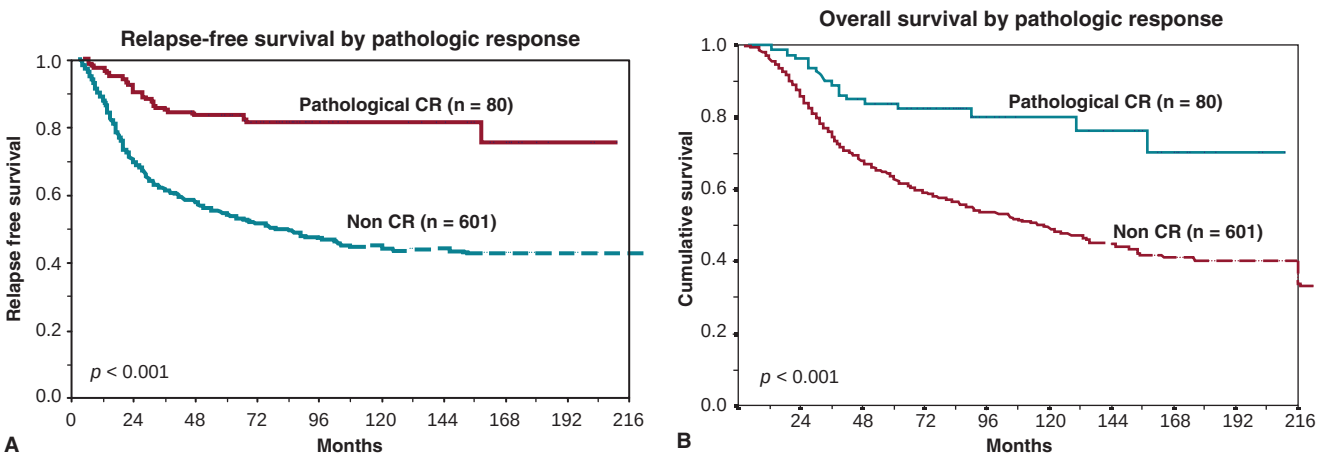

FIGURE 58-5 Pathologic complete response (n = 681; 91 patients did not have surgical resection). **(A)** Correlation with relapse-free survival. **(B)** Correlation with overall survival. CR, clinical response; PR, pathology response; SD, stable disease; PD, progressive disease.

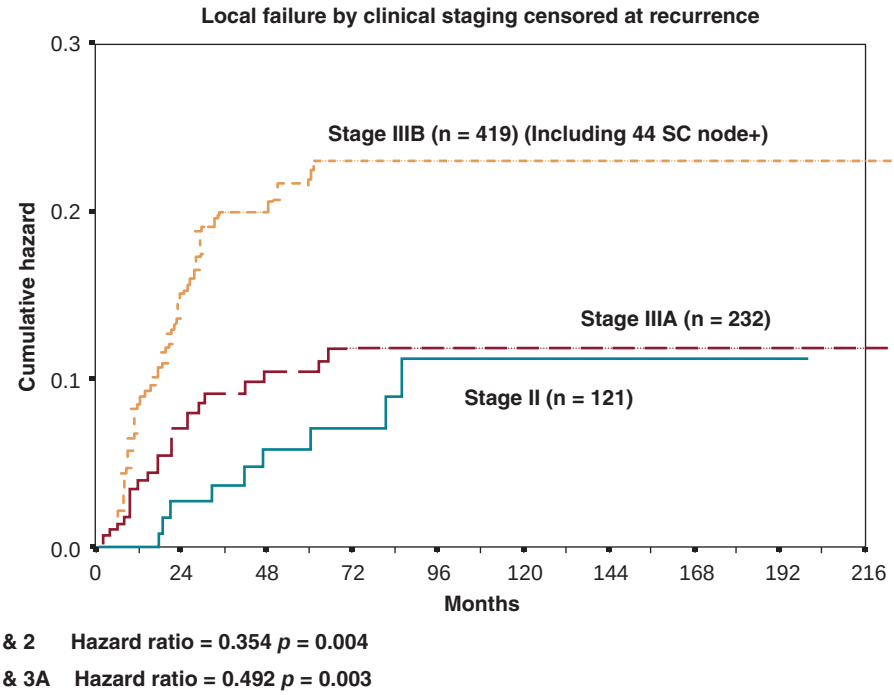

FIGURE 58-6 Cumulative rate of local/regional recurrence as first event by clinical stage (n = 772). Patients who developed distant metastases without local/regional recurrence were censored at the time of the metastases.

doxorubicin preparations, several antifols, ixabepilone, and eribulin have shown modest activity, in the 20% to 45% range, in metastatic breast cancer and clinical investigation is ongoing in the neoadjuvant and adjuvant setting.

While progress in the development of cytotoxic agents continues, there is increased emphasis on the development of molecularly targeted therapy. Trastuzumab (Herceptin), a monoclonal antibody against the extracellular domain of the HER-2 oncoprotein demonstrated clear-cut antitumor activity in patients with HER2-amplified (or overexpressed) metastatic breast cancer (105) and resulted in significant prolongation of overall survival in combination with chemotherapy in randomized clinical trials (105). The mature results of six multicenter, randomized clinical trials of trastuzumab used in the adjuvant setting demonstrate that the addition of trastuzumab to chemotherapy reduces annual odds of recurrence by about 50% and annual odds of death by one-third. The addition of trastuzumab to neoadjuvant chemotherapy of patients with HER2-positive operable or locally advanced breast cancer led to significant increases in the proportion of patients achieving a pathological complete remission, in some cases as high as 65%. Other HER2-directed agents, including the tyrosine kinase inhibitor lapatinib and pertuzumab, also reported to have important clinical activity in metastatic and locally advanced breast cancer and synergize with trastuzumab, resulting in enhanced antitumor efficacy (22,44,46–48). Studies testing lapatinib alone and in combination with trastuzumab in the neoadjuvant and adjuvant settings are ongoing. A randomized trial of pertuzumab in combination with trastuzumab and chemotherapy compared to trastuzumab and chemotherapy in the neoadjuvant setting demonstrated significantly increased pCR rates for the double antibody arm. On that basis, the FDA granted accelerated approval to trastuzumab and pertuzumab combined with docetaxel in the neoadjuvant setting. A large, adjuvant trial focused on the same question is currently ongoing.

The efficacy of sequential local and systemic treatments in combined modality therapy for locally advanced breast cancer makes these approaches the standard of care for these high-risk groups of patients (Fig. 58-7). Using these approaches as a platform, ongoing trials assess the efficacy of limited surgery, both breast-conserving surgery and sentinel lymph node biopsy, in patients with LABC. Ongoing work is testing several modifications of radiotherapy technique to minimize toxicity without compromising outcome. There is renewed interest in assessing the contribution of neoadjuvant endocrine therapy in the multidisciplinary approach to LABC. There is need for developing more effective predictive markers for response to systemic therapy; candidate approaches under investigation include genomics and proteomics.

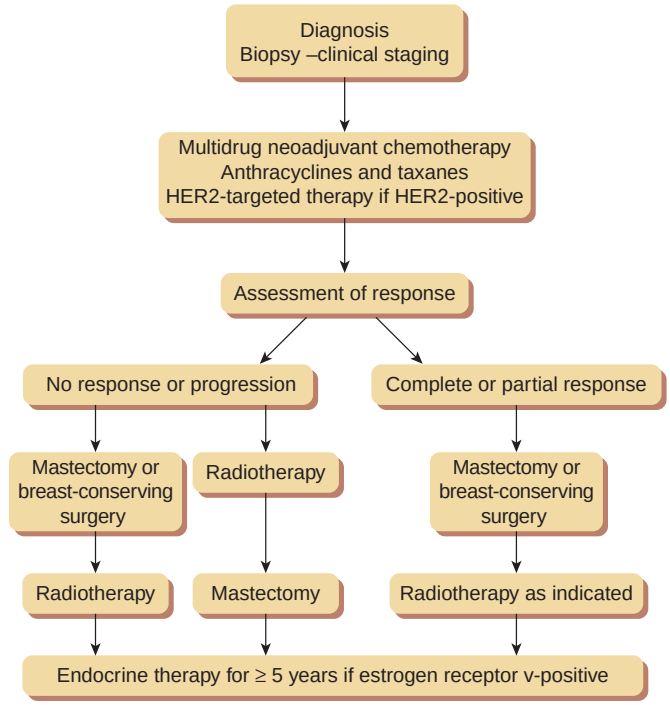

FIGURE 58-7 Flow diagram for the treatment of patients with locally advanced breast cancer.

The prevention of LABC might be the most effective approach to reduce mortality from this disease. Over the past 50 years, the frequency of LABC decreased to less than 5% of newly diagnosed breast cancer in populations with access to mammographic screening. Public and professional education emphasizing the importance of early diagnosis, the identification of women at high risk, and the systematic use of screening mammography might further decrease the frequency with which we find this high-risk lesion and contribute to the cure of breast cancer.

Combined-modality therapy that includes induction systemic therapy (chemotherapy with anti-HER2 agents and/or endocrine therapy for the properly selected subgroups) permits optimal local control with less radical surgical and radiotherapeutic intervention and leads to improved disease-free and overall survival rates. By downstaging primary and regional tumors, breast conservation becomes an option for many patients. In addition, the multidisciplinary management of stage III and locally advanced breast cancer provides an excellent biologic model to assess the effects of systemic therapy on the primary tumor. On the clinical side, this provides *in vivo* assessment of response, and the possibility of modifying subsequent therapy on the basis of this evaluation of response.

These strategies, developed for the management of LABC, are being successfully applied to earlier primary breast cancer.

MANAGEMENT SUMMARY

- Baseline physical exam, mammography, and ultrasound are essential to demonstrate tumor extent and identify multifocal, multicentric, and contralateral disease, if present. MRI might be needed in some patients to accurately define tumor boundaries. Staging for distant metastases at the onset can guide therapy.
- The regional lymph node-bearing areas should be carefully imaged, and suspicious nodes sampled with image-guided fine-needle aspiration biopsy.
- Close and continued interaction between all therapeutic and diagnostic specialists is needed to deliver optimal therapy.
- Combined-modality treatment, starting with neoadjuvant systemic therapy, represents the treatment of choice for patients with Stage IIIB breast cancer.
- Patients with triple-negative LABC should start with combination neoadjuvant chemotherapy.
- Any third-generation chemotherapy regimen that has been validated in the adjuvant setting can be appropriately used in the neoadjuvant setting.
- HER2-targeted therapy should be administered in combination with chemotherapy to all patients with HER2-positive cancers as an integral part of neoadjuvant treatment. Dual anti-HER2 inhibition with chemotherapy might be the optimal choice.
- Patients with hormone receptor–positive breast cancer, especially those with HER2-normal tumors with low proliferative rate, respond less well to chemotherapy; neoadjuvant endocrine therapy should be strongly considered.
- Patients who receive neoadjuvant systemic therapy should be closely monitored.
- Treatment must be individualized depending on molecular subtype of breast cancer and the response to, and the tolerance for, systemic therapy.
- Repeat imaging after the final dose of chemotherapy is indicated to assess response and determine appropriate surgical therapy. During treatment, if there is clinical uncertainty regarding disease progression, imaging may aid in the evaluation.
- Endocrine therapy should be administered following definitive local therapy to all patients with estrogen and/or progesterone receptor-positive cancers.
- Carefully selected patients with LABC can undergo breast-conserving therapy.
- Radiotherapy should be administered to all patients, even those with a pCR.
- For patients with locally advanced and inflammatory breast cancer, delayed autologous breast reconstruction is preferred.

CHAPTER 59

Inflammatory Breast Cancer

Beth Overmoyer and Lori J. Pierce

CHAPTER CONTENTS

DEFINITION AND DIAGNOSTIC CRITERIA

Historical Perspective

The term "inflammatory breast cancer" (IBC) was first introduced by Lee and Tannenbaum in their sentinel 1924 manuscript, to describe a rare, rapidly progressing breast cancer with characteristic features of inflammation seen among 28 cases at Memorial Hospital (1). They discussed the grave prognosis of breast cancer when associated with inflammatory changes, as first described by Sir Charles Bell in 1812 (1a); "When a purple color is on the skin over the tumor accompanied by shooting pains, it is a very unpropitious beginning." Throughout time, this form of breast cancer was referred to as "mastitis carcinomatosa" (1b), "carcinoma mastitoides" (1c,1d), and "acute carcinoma of the breast" (1e,1f).

The historical identification of IBC is important as a reminder of the evaluation and acceptance of classic clinical criteria that differentiates it from other forms of locally advanced breast cancer (LABC). More recently, there has been increased awareness concerning the distinctive clinical and pathologic nature of IBC, which has resulted in earlier identification of the disease, enhanced understanding of its unique biologic elements, and utilization of these features to develop improved therapies resulting in a superior disease response. It is anticipated that a greater understanding of IBC will also lead to advances in the treatment of non-IBC, because successful treatment of a virulent form of disease in general, often results in therapeutic progress for less aggressive disease.

Clinical-Pathologic Characteristics

Inflammatory breast cancer is a rare subtype of breast cancer, accounting for 1%–5% of breast cancer in the United States (2,3). Between 1988 and 1990 and 1997 and 1999, the incidence of IBC increased from 2.0/100,000 women-years, to 2.5/100,000 women-years ($p < .001$), which translates into a rate of 1.23% per year (4). IBC can also rarely present in male patients, and all pathologic subtypes of invasive adenocarcinoma of the breast can be associated with IBC, though invasive ductal carcinoma is the most common type (5).

"Primary" IBC presents as LABC in a previously unaffected breast, characterized by a rapid onset of symptoms within approximately 3 months. This rapid onset of symptoms and signs distinguishes primary IBC from LABC with inflammatory changes. The clinical features of IBC consist of enlargement of the breast with associated tenderness and warmth, often without a palpable mass (Fig. 59-1). Extensive nodal involvement is often clinically assessable, involving fixed ipsilateral axillary, supraclavicular, and internal mammary nodal groups, as well as frequent extension to contralateral axillary lymph nodes (6,7). Erythema of the skin,

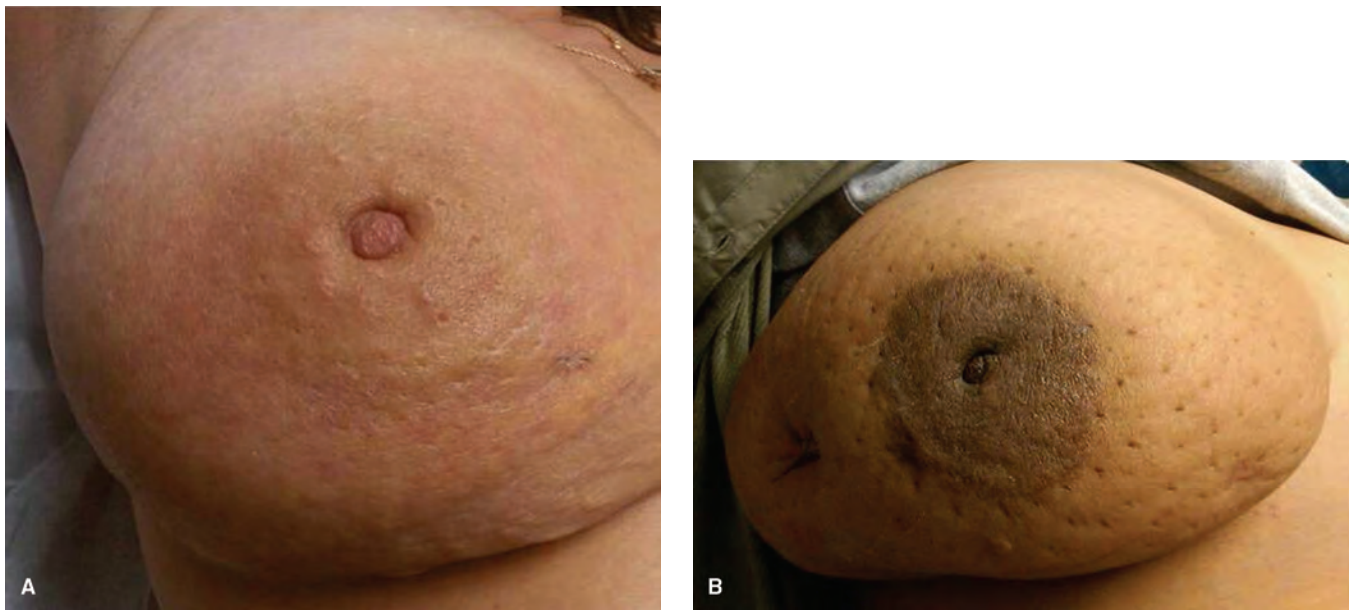

FIGURE 59-1 Classic clinical features of inflammatory breast cancer. **(A)** Erythema, edema (peau d'orange). **(B)** Enlargement of the breast.

involving approximately one-third or more of the breast can vary in character from faint pink, to red or purple; either diffuse or developing in a serpiginous fashion (8). The extent of erythema may eventually extend into the contralateral breast via dermal lymphatic extension. Edema or induration of the skin, with pitting of the hair follicles, is often described as peau d'orange (orange peel-like in consistency) (6,9). Ulceration of the skin and/or nipple is quite rare. This classic appearance of the breast is not due to inflammatory infiltrates, but rather to lymphatic occlusion from tumor emboli present in the papillary and reticular dermis of the skin. Pathologic confirmation of dermal lymphatic involvement is not required for the diagnosis of IBC, and because of skip regions within the breast, dermal lymphatic invasion can be confirmed in only 75% of IBC skin biopsies. The irregularity of the dermal lymphatic involvement contributes to the characteristic feel of "ridges" within the breast.

Primary IBC is differentiated from "secondary" IBC which is clinically and biologically similar; however, secondary IBC arises as a breast cancer recurrence in the breast or chest wall of a patient with a previous history of treated non-IBC. In the past, there have been inconsistencies in the definition of IBC and this has complicated the analysis of epidemiologic studies and clinical trials. However, recently there has been a consensus agreement on defining the clinical characteristics of IBC which has permitted the differentiation from non-IBC LABC, and has improved the interpretation of clinical outcomes of IBC (10). Acceptable diagnostic criteria for IBC are based upon both clinical and pathologic features and include the International Classification of Disease for Oncology (ICD-0-2, 8530/3 for IBC) and the American Joint Committee on Cancer (AJCC) staging criteria (3,11). According to the AJCC staging criteria, the tumor in IBC is classified as T4d, and staged as IIIB, IIIC, or IV based upon extent of nodal involvement and evidence for distant metastasis.

Epidemiology

Based upon data from the Surveillance, Epidemiology, and End Results (SEER) Program, patients with IBC usually present at an earlier age compared with non-IBC LABC; approximate mean age at diagnosis 58 years and 66 years, respectively (3). The incidence of IBC increases to the age of 50 years, then plateaus, regardless of hormone receptor (HR) status, whereas the incidence of non-IBC continues to increase after age 50 years, especially among estrogen receptor (ER) positive disease (2,4). The incidence of IBC is higher among African American women compared with Caucasian women (3.91/100,000 women-years compared with 2.5/100,000 women-years, p <.001), and has geographic variation within the United States and globally (12). For example, SEER data from 1992–2002 demonstrated the frequency of IBC documented in the Los Angeles Tumor Registry as 2.45% whereas the frequency of IBC in the Connecticut Tumor Registry during the same period was 1.49% (4). Internationally, there is an increased frequency in the Middle East and Northern Africa, e.g., 11% occurrence in Egypt, 5%–7% in Tunisia (decreased from 50% using stringent diagnostic criteria), 10% in Pakistan, and 17.5% in Nigeria; versus 2.9% in Spain, 5.4% in France, and 0.6%–2% incidence in Italy (4,7,13–15). Other epidemiologic features that have been associated with a higher incidence of IBC include living in a high poverty county within the United States, having a high BMI (regardless of menopausal status, though there is a propensity of developing IBC while premenopausal), an earlier age of menarche, and earlier age of first full-term pregnancy (16–18). A familial or genetic linkage for IBC has not been borne out.

Approximately 30% of patients with IBC present with distant metastasis at the time of initial diagnosis (stage IV), based upon SEER data examined from 2004–2007 (19). Among individual institutions, the incidence ranges from 26% (City Hospital, Nottingham, UK) to 40% (MD Anderson Cancer Center); however, all data supports a significantly higher occurrence of stage IV disease at presentation with IBC than with non-IBC (20,21). Compared with non-IBC LABC, the 2-year breast cancer specific survival (BCSS) for IBC was 84% vs. 91% (p < .0001) (22). This translated into a hazard ratio of 1.43 risk of dying of breast cancer among patients with IBC vs. non-IBC LABC (p = .008). Among the SEER cases from 1990 to 2008, the median BCSS for non-IBC LABC was 13.4 years versus 4.75 years among patients with IBC (23).

These data support the importance of accurate diagnosis for IBC which carries a significantly poorer prognosis compared with non-IBC LABC.

Imaging

The imaging employed during the evaluation of IBC serves to identify the extent of disease within the breast and regional lymph nodes, determine spread to the ipsilateral pectoralis muscle or contralateral breast, to detect distant metastasis, and assess disease response to treatment. As in non-IBC, mammography is utilized as an initial diagnostic procedure, wherein the affected breast demonstrates skin thickening (from dermal lymphatic involvement), diffuse increased breast density, and trabecular distortion due to edema. Although most patients with IBC do not present with a palpable breast mass, in a large retrospective study of 80 patients with IBC, 80% of the patients displayed mammographic abnormalities in the affected breast, such as architectural distortion, asymmetry, multi-focal densities (masses), or suspicious calcifications (41%) (24). Microcalcifications often become more evident with effective treatment that results in a decrease in the density of the breast parenchyma (25). Occasionally, the mammographic findings are subtle and can only be detected by direct comparison with the contralateral breast. IBC appears to be a predominately unilateral breast disease, with previous reports of bilateral cancers now being attributed to non-IBC LABC.

Mammographic differentiation between IBC and non-malignant inflammation of the breast can be complicated by the patient's inability to undergo adequate compression of the breast due to pain. For this reason, ultrasonography is often utilized to assess skin thickening and regional lymph node involvement as well as identify areas within the breast that can successfully undergo biopsy via ultrasound guidance. In contrast to mammography, these abnormalities can be identified in 95% of patients with IBC (24). Ultrasound is more sensitive at detecting abnormal anatomic changes within the axillary lymph nodes, and color Doppler sonography can be used to assess intratumoral vascularity, however, microcalcifications cannot be detected via ultrasound.

A review of 4 studies evaluating the efficacy of magnetic resonance imaging (MRI) in IBC described skin thickening and enhancement (98% and 94%, respectively), and more commonly than a discrete mass, the parenchyma contained an infiltrative mass associated with a reticular/dendritic pattern of enhancement in 78% of patients (25). The retrospective study by Yang et al. found MRI detection of multiple breast masses with heterogeneous internal enhancement associated with a washout in 97% of their 80 patients (24). Overall, MRI was found to be the most accurate imaging modality for IBC, not only useful in detecting the primary cancer (98% vs. 68% with mammography), but also in imaging axillary lymph nodes and determining cancer involvement of the pectoralis muscle (26). In addition, MRI imaging posttreatment has the highest correlation with pathologic disease response compared with other modalities, such as mammography and ultrasonography (25).

The use of PET/CT (fused positron emission tomography and computed tomography) in breast cancer remains controversial; however, pretreatment imaging with PET/CT among patients with IBC has resulted in the detection of new areas of distant metastasis in 44% of 62 patients with IBC evaluated in one retrospective analysis (27). The extent of pretreatment nodal involvement detected by PET/CT imaging resulted in changes in the posttreatment radiation therapy fields in 18% and 14% of IBC patients in two independent retrospective analyses, though the clinical impact of these therapeutic modifications remains unknown. These data suggest that PET/CT may be considered as an imaging modality in the initial evaluation of IBC; however, confirmatory data is needed prior to recommending it as a standard approach (27,28).

The current armamentarium of breast imaging is associated with some ambiguity in the evaluation of IBC, both in terms of diagnostic information as well as confirming disease response. Novel molecular targeting agents are currently being explored in IBC with the goal of demonstrating more sensitive and specific non-invasive evidence of disease response to systemic treatment (29).

BIOLOGIC CHARACTERISTICS

Breast cancer is a heterogeneous disease characterized by expression of specific molecular markers that control the biologic phenotype of the disease. IBC has been shown to express specific molecular characteristics that are more uniformly associated with this disease, and have thus permitted the characterization of IBC based upon biologic criteria rather than from purely histologic or clinical classification. A greater understanding of these distinctive mechanisms that coordinate the progression of IBC will allow the development of more successful targeting agents designed specifically for this disease.

Gene Expression Profiling

High-throughput molecular technologies, such as DNA microarray-based expression profiling, have revealed the full complement of breast cancer cell-of-origin subtypes (i.e., Luminal A, Luminal B, basal-like, HER2-overexpressing) within IBC; however, IBC has a propensity for segregating into the more proliferative molecular subtypes, such as the basal-like (triple negative, i.e., ER-negative, PR-negative and HER2-negative) and HER2-overexpressing subtypes. Bertucci et al. first demonstrated the same heterogeneity of cell-of-origin subtypes within 37 IBC tumor samples and 1 IBC cell-line (SUM-149) (30). Compared with 44 non-IBC LABC tumor samples, 24% of IBC samples were HER2-overexpressing and 22% were basal-like, versus 14% HER2-overexpressing and 19% basal-like. These findings were confirmed in a subsequent analysis from Van Laere et al., wherein 16 pretreatment IBC tissue specimens exhibited all of the different cell-of-origin subtypes, yet 50% of the IBC samples segregated into the combined basal-like and HER2-overexpressing clusters compared with only 17% of the non-IBC samples (31). A principal component analysis of variability of gene expression in the entire sample set revealed that approximately 30% of the variation between IBC and non-IBC samples was related to the cell-of-origin subtype, suggesting the presence of other genetic factors that significantly contribute to the IBC phenotype.

Several investigators have attempted to discover a specific IBC gene signature; however, the results have been inconclusive. A RT-PCR analysis of mRNA expression among 36 pretreatment IBC tumor specimens identified 48 genes involved in cellular proliferation, signal transduction, apoptosis, and angiogenesis (32). Interestingly, the investigators found no difference in the expression of inflammatory cytokines, except IL-6, supporting the conclusion that the inflammatory characteristics of IBC were due to dermal lymphatic occlusion by tumor emboli and not by classical inflammatory mechanisms. They also identified a 3-gene expression signature that was associated with a poor prognosis in IBC. Van Laere et al. expanded their original work and identified an IBC signature that was associated with NF-κB activation, although the association of NF-κB target genes appeared to be linked to ER negative breast cancer as well as with IBC

(33,34). Within their IBC gene signature, several genes were identified that were linked to insulin-like growth factor (IGF) signaling, which is supported by several molecular analyses described later in this chapter.

The Baylor group identified a hyperproliferative gene profile involving fatty acid and lipid metabolism, the Bcl2-BAX apoptotic pathway, and genes associated with increased cell turnover (35). When their signature was compared with the Van Laere IBC signature, only 5 genes overlapped, and when the signature was compared with the Bertucci signature, only 1 gene was similarly over-expressed (30,33). Other studies examining specific IBC gene signatures have identified clusters of oncogenes that encode proteins involved in protein translation and transport, adaptation to hypoxia, and activation of mammalian target of rapamycin (mTOR) signaling (36,37). These heterogeneous gene profiles examined the tumor epithelium, whereas investigators from the National Cancer Institute (NCI) explored gene expression signatures among the tumor stroma of 52 IBC tissue specimens and found an enrichment of genes involved in intracellular protein transport and localization, protein secretion, mRNA translation, and GTPase signaling (38). The investigators proposed that the IBC phenotype was more easily distinguished by its stromal signature than the tumor epithelial signature. All of these studies demonstrate a significant heterogeneity within IBC, and although a specific IBC gene expression signature has not been established, these investigations have revealed certain molecular markers and signaling pathways that have consistently been linked to the pathophysiology of IBC.

Traditional Molecular Features: HER2, Hormone Receptor, TP53

Although there is a considerable focus on elucidating the unique biologic profile of IBC, the traditional molecular features of breast cancer play an important role in understanding the pathophysiology, prognosis, and treatment options associated with IBC. Clinical evaluation of patients with IBC supports the findings seen with gene expression profiles, i.e., IBC is more frequently found to be triple negative and HER2 positive (39,40). One-hundred and eight patients with LABC from the Leuven University Hospital in Belgium were identified and classified as IBC (49) or non-IBC (59), and compared with non-IBC LABC, IBC patients were more likely to have HER2 positive disease; 35% versus 19% (p = .07) (41). In a larger registry dataset from the California Cancer Registry (1999–2007), the receptor status and clinical outcome was assessed among 2,014 IBC patients, 1,268 non-IBC LABC patients, 3,059 patients with metastatic breast cancer (MBC) and 73,758 non-T4 breast cancer patients (42). Patients with IBC were more likely to have HR negative disease (both ER and PR negative) compared with the other groups of breast cancer patients: 40% (IBC), 31% (non-IBC LABC), 25% (MBC), 18% (non-T4); whereas IBC patients were more likely to have HER2 positive breast cancer: 40% (IBC), 35% (non-IBC LABC), 35% (MBC), 22% (non-T4). Patients with HR negative IBC had an inferior overall survival (OS) and BCSS compared with HR positive IBC, whereas HER2 status was not found to be prognostic for a worse OS among patients with IBC, but was prognostic for a more favorable BCSS (hazard ratio [HR] = 0.82). These associations, i.e., a more favorable prognosis with HR positive IBC and absence of an adverse prognosis with HER2 positive disease, are also supported by retrospective data from MD Anderson Cancer Center, the Institut Gustave Roussy, and the Aga Khan University Medical Center (7,43,44). The more favorable disease outcome associated with HER2 positive disease is attributed to the effective therapy with trastuzumab discussed later in this chapter.

In addition to an increased incidence of HER2 overexpression, IBC is often associated with a higher frequency of mutations in the tumor suppressor gene p53 (TP53) compared with non-IBC (7). Wild-type TP53 is intimately involved in maintaining genomic stability by functioning as a transcription factor for genes involved in cell-cycle progression, DNA repair, and apoptosis. Common TP53 mutations are missense or nonsense mutations, and often result in the accumulation of p53 protein in the cytoplasm or nucleus demonstrated by immunohistochemistry (IHC); however, direct complimentary DNA (cDNA) sequencing can also detect up to 20% of TP53 mutations that are not identified by IHC (45,46). Using these methods, Turpin et al. examined 161 patients from the Hospital Saint Louis and found 57% of the 63 IBC tumors exhibited TP53 mutations compared with 37% of the 27 non-IBC LABC (40). Another evaluation of the immunohistochemical profile of IBC using tissue microarray techniques found 45% of 86 IBC tumor specimens contained TP53 mutations versus 23% of the 552 non-IBC samples (39). This study also confirmed the increased incidence of triple negative IBC and HER2 positive IBC compared with non-IBC (54% vs. 24% and 40% vs. 12%, respectively). Some, but not all of the studies which demonstrate a prevalence of TP53 mutations in IBC have correlated this finding with an adverse prognosis (46–48). A single institution retrospective analysis from the MD Anderson Cancer Center found that among 59 patients with IBC, 58% had TP53 positive tumors which corresponded to a shorter 5-year progression-free survival (PFS) (35% vs. 55%) and OS (44% vs. 54%); neither were statistically significant (49). A similar retrospective examination from the Japanese Foundation for Cancer Research did not find such a correlation (50).

Distinctive Molecular Features: RhoC GTPase, WISP3

Recent investigations into the unique molecular properties of IBC have elucidated several genetic features that are critical to the development of its highly metastatic phenotype. RhoC GTPase is a member of the RAS superfamily of G proteins that are involved in several aspects of cellular function including cell cycle control, cell migration and epithelial cell polarity, cell survival, and angiogenesis (51). Dysregulation of these processes is associated with increased metastatic potential in pancreatic cancer, melanoma, and breast cancer. Original exploration of differentially expressed genes in IBC was performed on the triple negative IBC cell-line, SUM149 and validated among 29 IBC and 19 non-IBC tumor samples under the direction of van Golen et al (52). This search led to the demonstration of overexpression of RhoC GTPase in 90% of the IBC specimens compared with 38% of the non-IBC tumors (p = .0095). The overexpression of RhoC GTPase was 91% concordant with a decrease in expression of WISP3 (Wnt-1 inducible signaling pathway protein 3), a member of the CCN (Cyr61, CTGF, Nov) family of tumor suppressor genes that function to modulate insulin-like growth factor-1 (IGF-1) mediated cellular growth, and proliferation (53). WISP3 was originally named LIBC or "Lost in Inflammatory Breast Cancer" because it was expressed in only 20% of the IBC specimens examined compared with 79% of the non-IBC tumors (p = .0013) (52).

Overexpression of RhoC GTPase in transfected cell lines resulted in a phenotype that mimics IBC similar to the IBC cell-line SUM149, including its tumorigenic ability (54). These experiments led to a greater understanding of the potential role of RhoC as an IBC oncogene, in addition to its known

ability to stimulate angiogenesis, aid in the formation of stress fibers and focal adhesion, and to stimulate actomyosin-mediated cell contraction leading to increased cellular mobility. Recent data from the van Golen laboratory have also shown an increase in several PI3K/Akt signaling pathways due to a downstream effect of activated RhoC on PI3K/Akt-1 associated genes (55). These signaling pathways control cytoskeletal polarity and cellular mobility. C-Met activation may also contribute to enhance PI3K pathway signaling in IBC due to increased expression of c-Met expression in IBC (56).

Given the greater than 90% rate of concordance of WISP3 suppression with RhoC expression observed in human IBC, Kleer et al. transfected immortalized human mammary epithelial (HME) cells with antisense WISP3 constructs resulting in the inhibition of WISP3 and subsequent overexpression of RhoC (57). This molecular pattern of WISP3 modulating RhoC expression produced a statistically significant increase in cellular proliferation and in VEGF production. Transfection of the IBC cell-line SUM149 with WISP3 resulted in suppression of angiogenesis by reducing levels of VEGF, FGF2, and IL-6 (58). Restoration of WISP3 function also caused a decreased rate of cellular proliferation, anchorage-independent growth, and invasive capabilities manifested by reduced tumor formation when injected into athymic nude mice. One potential mechanism of WISP3 protein function is directly related to its secretion into extracellular spaces, thus functioning to regulate IGF-1 signaling leading to diminished growth of IBC cells (59). This constellation of function attributed to WISP3 supports its classification as a tumor suppressor gene of IBC.

The WISP3 negative/RhoC positive phenotype detected by both IHC and RT-PCR has consistently been found to be associated with IBC compared with non-IBC human tumor samples evaluated in Tunisia (26/41 = 66% of IBC vs. 10/86 = 12% non-IBC) (60). RhoC overexpression has also been demonstrated in 40/46 (87%) of Egyptian IBC tumor samples versus 11/64 (17%) of non-IBC tumors (61). This reliable molecular arrangement, seen in IBC, supports investigation into modifying the expression/function of RhoC or WISP3 as a therapeutic target (62).

The Pathophysiology of Tumor Emboli: E-cadherin, MUC-1, eIF4GI

The establishment of an IBC xenograft model (MARY-X) from a patient with IBC has been instrumental in elucidating some of the principal features of the pathophysiology of IBC. MARY-X was developed in 1999 and exhibited classical characteristics of erythema of the murine skin and tumor emboli exclusively involving lymphovascular spaces in nude/SCID mice (63). The carcinoma is triple negative but is EGFR (epidermal growth factor receptor) and TP53 positive. MARY-X overexpresses the membrane bound adhesion molecule E-cadherin and cell-surface MUC-1 glycoprotein up to 10–20 times greater than in non-IBC xenograft models. When further examined, the carcinoma within the lymphovascular spaces were spheroids, exhibiting significant homotypic tumor cell adhesion due to overexpression of E-cadherin along the entire membrane surface of the carcinoma (64). Although MARY-X overexpressed MUC-1, it was a dysfunctional protein, with decreased cell-surface sialyl-Lewis X/A residues which bind to E-cadherin. This contributes to the absence of tumor cell heterotypic adhesion to the endothelial cells causing visible retraction of the tumor emboli from the endothelial wall lining of the lymphovascular structures. The pattern of these effector molecules results in the ability of IBC to form tight adhesive tumor emboli that lack the ability to adhere to the endothelial wall of vasculature, thus enabling a more metastatic phenotype. Alpaugh et al. confirmed the overexpression of E-cadherin and MUC-1 in human IBC specimens and also found that the tumor emboli were retracted from the endothelial lining of the vasculature in these human samples (63–65).

The E-cadherin adhesion complex remains structurally and functionally intact in IBC, with overexpression of its associated α-catenin and β-catenin membrane-bound proteins as part of its E-cadherin/α,β-catenin functional axis (65). In MARY-X, when this axis is disrupted, the spheroids disassociate and apoptosis occurs suggesting that the intact E-cadherin/α,β-catenin functional axis is necessary for the survival of IBC cells. These characteristic spheroids are also present and functional in the pulmonary metastasis that develops in the MARY-X xenograft, supporting the hypothesis that this structural integrity is necessary and maintained throughout the progression to metastasis that occurs in IBC.

Gene amplification results in increased MUC-1 expression whereas alterations in other factors involved in mRNA transcription and translation contribute to the higher E-cadherin levels. eIF4GI is a translation initiation factor which, when combined with eIF4E and eIF4A, forms a complex (eIF4F—eukaryotic initiation factor 4E) that contributes to the initiation of cap-dependent mRNA translation (66). Silvera et al. examined 77 breast cancer samples and found overexpression of eIF4GI in 80% of the 37 IBC specimens (67). Through a series of studies performed on the SUM149 IBC cell line, suppression or silencing of eIF4GI resulted in a reduction of E-cadherin attached to the IBC surface membrane due to increased E-cadherin degradation. Increased stability of E-cadherin occurs with membrane association through its interaction with the protein p120 catenin. Silencing of eIF4GI also results in a reduction in the translation of p120 mRNA by more than 60%. Overexpression of eIF4GI appears to be essential for the development and survival of IBC tumor emboli and supports its invasive properties by promoting increased translation of mRNAs with internal ribosome entry sites (IRESs), such as the p120 mRNA.

The Stem-cell Phenotype of Inflammatory Breast Cancer

The MARY-X spheroids and tumor emboli have been likened to the human embryonal blastocyst which overexpresses the E-cadherin axis and is the source of embryonal stem cells (ES). This similarity in physiology, i.e., the presence of cellular anchorage independence and enhanced ability to migrate and metastasize, prompted several studies that demonstrated a strong association between IBC and breast cancer stem cells. MARY-X expresses the stem-cell marker phenotype which includes CD44+/CD24-/low (100% of cells), strong CD133 surface expression (>90% of cells), high activity of aldehyde dehydrogenase (ALDH) (23% of cells) (68). Molecular pathways which sustain the stem cell state, such as Notch signaling through the Notch 3 receptor, are also increased in MARY-X compared with non-IBC carcinomas that primarily utilize Notch 1 and Notch 4 expression to enhance Notch signaling (69). Increased tumorigenicity and self-renewal was primarily evidenced in the subpopulation of MARY-X which exhibited both high ALDH expression and enhanced Notch 3 signaling.

Xiao et al. also confirmed a higher level of CD133 membrane expression and Notch 3 nuclear expression in human IBC tumor samples compared with non-IBC samples (88% vs. 8%, and 76% vs. 8%, respectively), regardless of molecular subtype of IBC. The high prevalence of CD44+/CD24-/low phenotype among human IBC was confirmed by Polyak's laboratory where they examined tumor specimens from all

subtypes of IBC and found that >80% expressed the stem-cell phenotype of CD44+/CD24-/low, regardless of whether they were triple negative or of luminal subtype (70). In addition to the Notch signaling pathway, both the NF-κB/RAS/MAPK and the IL6/JAK2/STAT3 pathways have been found to play an important role in mammary stem cell survival and have enhanced activation in IBC, making them potential therapeutic targets for this disease (34,70–73).

Angiogenesis and Lymphangiogenesis in Inflammatory Breast Cancer

Early investigation of IBC determined this subtype of breast cancer to have significantly greater angiogenic and lymphangiogenic properties compared with non-IBC. Histologically, Colpaert et al. found a significant increase in microvessel density as determined by the Chalkley method ($p < .0001$), and a greater percentage of proliferating endothelial cells (EPC) among the 35 human IBC tumor specimens compared with 104 non-IBC specimens (19% vs. 11%, respectively, $p = .014$) (74). A correlation was found between EPC and expression of the hypoxia marker carbonic anhydrase IX (CA IX) on tumor emboli, whose transcription is regulated by hypoxia inducible factor 1 (HIF-1). This evidence suggests an adaptation to hypoxia within the IBC tumor emboli, supported by intense angiogenesis. However, hypoxic signals are not the sole stimulant of the intense angiogenesis seen in IBC. RhoC, which is overexpressed in IBC, is a potent activator of angiogenesis, and the overexpression of eIF4GI in IBC results in the increased translation of specific IRES containing mRNA that encode VEGF, regardless of hypoxic signals (75). IBC tumor cells express a genetic profile that is associated with survival during hypoxia even when it does not exist.

RT-PCR analysis of 16 IBC and 20 non-IBC tumor specimens revealed a significantly higher expression of the mRNA involved in the Ang1/Tie2 pathway among the IBC samples (Ang-1, Tie-1, Tie-2) (76). This pathway supports the survival of endothelial cells and vascular expansion. In addition, the mRNA expression of KDR (the receptor for vascular endothelial factor A [VEGF-A]) and FGF-2 was also significantly higher among the IBC specimens, supporting a more active angiogenic process among IBC compared with non-IBC. Other molecular profiling studies of IBC supported an increased expression of genes involved in angiogenesis (32). IBC is also associated with a higher expression of all of the lymphangiogenesis mRNAs (VEGF-C, VEGF-D, Flt-4, Prox-1, Lyve-1), supporting activation of the Flt-4 signal transduction pathway that induces lymphangiogenesis. This was confirmed by the demonstration of a greater percentage of proliferating lymphatic endothelial cells among the IBC specimens compared with the non-IBC specimens. Significant investigation is ongoing in determining whether the presence of IBC tumor emboli in lymphovascular spaces occurs by classic lymphovascular invasion, or whether the IBC tumor cells stimulate the formation of encircling vascular channels from adjacent myoepithelial cells or stromal stem cells; a process known as lymphovasculogenesis. Regardless of pathophysiology, the highly angiogenic presence in IBC lends itself as an excellent therapeutic target, as described later.

TREATMENT OPTIONS FOR INFLAMMATORY BREAST CANCER

The poor prognosis associated with IBC stimulated intensive research focusing on unraveling the unique molecular biology of this disease in an attempt to develop more specific and effective therapies. These novel therapies will be discussed later in this chapter. The current therapeutic armamentarium does not differ significantly from that utilized for non-IBC LABC and the next sections will review the current tri-modality approach to treatment.

LOCOREGIONAL THERAPY FOR INFLAMMATORY BREAST CANCER

Locoregional Treatment in Inflammatory Breast Cancer: An Historical Perspective

Early surgical series of patients presenting with clinical findings consistent with IBC in the pre-chemotherapy era demonstrated consistently poor outcomes despite aggressive surgical resection. Haagensen reported his initial experience with IBC in a series of 20 patients treated with radical mastectomy (77). Due to difficulty in achieving negative margins, the rate of locoregional failure (LRF) was high at 50%. Rates of systemic failure were higher, thus survival was poor with a median survival 15.5 months after surgery and no 5-year survivors. Similar results were reported by others as summarized by Treves in an editorial where a table of 6 radical mastectomy series revealed 4 of 262 patients survived 5 years when treated by radical mastectomy alone, translating into a cumulative 5-year OS of 1.5% (78). These results supported the classification of IBC as a categorically inoperable disease because, as noted by Haagensen, "when no cures can be expected, and no definite evidence of prolongation of life can be shown, it seems entirely unreasonable to treat these patents by radical mastectomy" (77).

These experiences led to radiotherapy (RT) as sole management of IBC. The extent and bulk of local-regional disease required the delivery of high radiation doses to extended radiation fields. The ability to tolerate treatment necessitated a protracted RT course pioneered by Baclesse in France (79). Fletcher and Montague at MD Anderson Cancer Center published results using a protracted course of up to 100 Gy over 12 weeks delivered initially with 250 kV orthovoltage prior to 1955 and later with Cobalt 60 teletherapy (80). Using this regimen, the authors reported a 40.5% rate of LRF in 47 patients with IBC with 18% alive at 3 years and 12% alive at 5 years. Increased rates of late complications including severe breast fibrosis, breast and chest wall necrosis, and brachial plexopathy were observed.

Despite the use of high doses of RT in patients with IBC, rates of local control remained disappointing. Dose response data from a series of 62 IBC patients treated at Massachusetts General Hospital demonstrated 14/15 failures when the total dose was less than 60 Gy, with increasing control with higher doses. However, despite doses in excess of 80 Gy, gross disease greater than 10 cm could not be controlled (81). Similarly, Perez et al. demonstrated poor tumor control with high dose RT, with approximately 50% LRF with doses of 70 to 75 Gy. In attempts to improve tumor control, preoperative RT was utilized to render locoregional disease operable followed by radical mastectomy (82). Zucali et al. reported the outcomes of 454 patients with inoperable Stage III disease treated with either RT alone or RT followed by radical mastectomy (83). The median survival in the overall series was improved with the combination of RT and surgery compared to RT alone (3.9 years vs. 2.1 years). Only 12 of 70 patients with IBC, however, were able to undergo surgery, and the median survival of the IBC patients was only 1.2 years. Thus, systemic failure remained the predominant pattern of failure independent of type of locoregional treatment.

Radiotherapy or Mastectomy Following Neoadjuvant Chemotherapy

As discussed later in this chapter, neoadjuvant chemotherapy (NAC) has become the mainstay of treatment for IBC to reduce the rate of metastatic spread. It also plays a pivotal role in optimizing locoregional control. Among responders, rates of locoregional tumor control with NAC followed by RT were improved compared to RT alone; LRF, however, remained substantial (84,85). In a report comparing outcomes in 60 patients treated with RT only compared to 91 patients and 79 patients treated with successive induction chemotherapy regimens followed by RT at the Institut Gustave Roussy, Rouesse et al. reported 4-year rates of LRF of 53% with RT alone versus 32% and 31% with induction chemotherapy and RT (p = .01) (85).

The question of whether RT or mastectomy (M) alone after NAC resulted in better outcomes was tested in a small randomized trial from Tunisia (86). In this study in which 83 patients with IBC received induction CMF (cyclophosphamide, methotrexate, 5-flurouracil), only 57 patients completed therapy with a significant improvement in stage-specific DFS compared to patients treated in an earlier study without NAC. However, no significant difference in disease-free interval was observed between patients treated with M or RT.

The Effectiveness of Mastectomy Combined with Radiotherapy

From results acquired over a 30-year period, Perez et al. reported improved rates of locoregional control with trimodality therapy, with LRF as isolated failure or component of failure occurring in 70% treated with RT alone, 63% with chemotherapy and RT, 24% with RT and surgery, and 21% with triple therapy (82). Fleming et al. from MD Anderson Cancer Center analyzed outcomes in 178 women with IBC treated with anthracycline-based NAC followed by local therapy (87). The addition of M to RT significantly improved local control compared to RT only, with rates of LRF of 16.3% with M+RT compared to 35.7% with RT only after chemotherapy (p = .015). A benefit in both DFS and OS was observed by the addition of M only among patients achieving either a complete or partial clinical response to induction chemotherapy.

As shown in Tables 59-1 and 59-2, the outcomes from various retrospective series differ greatly by regimens used but improved rates of local control, 5-year DFS and OS appear to be associated with the addition of M to RT. However, selection biases confound interpretation of the results. There are no randomized comparisons between RT only and M+RT following NAC. However, a recent population-based analysis of curative treatment strategies for IBC in British Columbia found that M was increasingly utilized (with chemotherapy and RT) from 1980 through 2000, with only 33% of patients undergoing M from 1980–1985 compared with 78% from 1996–2000 (88). On multivariate analysis, incorporating M into locoregional therapy was associated with significantly improved locoregional relapse-free survival (RFS). Ten-year locoregional RFS for patients undergoing M after chemotherapy, M before chemotherapy, and no M were 62.8%, 58.6%, and 34.4%, respectively (p = .0001). In a recent consensus statement from an international expert panel on IBC, primary systemic chemotherapy, surgery (i.e., modified radical mastectomy) and RT was felt to be the standard treatment plan (10).

To optimize locoregional control with M, chemotherapy should be delivered until areas of skin inflammation have resolved prior to proceeding with surgery and any breast and nodal masses which were fixed at presentation are operable. If breast or nodal disease remains inoperable after systemic therapy, preoperative RT is strongly recommended to convert fixed lesions to technically operable disease. Extended RT fields can also help to achieve microscopically negative margins, an important factor in optimal locoregional control. A series by Curcio et al. of 28 patients with IBC identified margin status as a prognostic indicator for local control, DFS and OS (89). Three-year results for OS, DFS, and local control were 47%, 38%, and 60% with negative margins and 0%, 17%, and 32% with positive margins (p < .05). In a separate review of multiple factors predictive of LRF in 256 patients with IBC, surgical margin status remained an independent predictor of outcome on multivariate analysis, with negative margins associated with a 91% rate of locoregional control compared to 68% with positive or unknown surgical margins, p = .0005 (90). If the extent of disease and surgical operability is unclear based upon physical findings, radiologic studies such as CT or PET/CT should be strongly considered.

The sequencing of RT, that is, preoperative or postoperative RT, does not appear to affect locoregional outcome in patients with technically operable disease after NAC (88,91).

In the population-based study from British Columbia, the timing of RT (early vs. late) resulted in 10-year locoregional RFS of 52.2% and 49.7% (p = .72) with no difference in BCSS (88). In the absence of benefit with preoperative RT, postoperative treatment is recommended so RT dose can be tailored, as necessary, to operative findings.

Radiation Therapy Following Mastectomy

Patterns of disease failure have largely dictated the locoregional target volumes to be irradiated in IBC (82,92,93). In a series of 10 patients with IBC whose disease progressed after M but prior to receiving or completing RT, 6 progressed at the chest wall and in regional lymphatics other than the dissected axilla (92). In a review of the sites of LRF in 20 of 61 patients with IBC who experienced a LRF, including those previously irradiated, 85% of the recurrences included the chest wall and 20% included the regional lymphatics but excluded the axilla. Other series have also demonstrated LRF predominantly outside of the axillary bed in IBC patients treated with axillary dissection (82,93). Therefore, the chest wall (including the mastectomy scar), supraclavicular and infraclavicular nodes, and the internal mammary nodes (IMN) should be irradiated. The decision whether to irradiate the axillary bed should be based upon the results of the axillary dissection and the extent of axillary involvement.

The skin is an important target in IBC and tissue equivalent bolus should be placed daily on the skin of the chest wall to lessen the skin-sparing of megavoltage beams. The goal should be to achieve a brisk erythematous skin reaction at the chest wall. Prior studies have suggested a trend for higher rates of local recurrence when brisk erythema has not been achieved (92). In a recent study from Memorial Sloan-Kettering Cancer Center, high rates of locoregional control were, in part, attributed to the aggressive use of daily bolus (94).

The rates of locoregional tumor control in IBC have significantly differed by initial response to chemotherapy, with significant improvements among patients with a complete clinical response (cCR) or partial clinical response (cPR) compared to patients with less than a partial disease response (88,90,92,95). In a large review of IBC patients treated from 1977 through 2002, the strongest predictor for locoregional control was clinical response to NAC, with a 5-year locoregional control rate of 95% for patients with a cCR, 86% for those with a cPR, and 51% with less than a partial response (90). Dose and choice of fractionation also impact rates of locoregional control particularly in disease not responsive to chemotherapy. Standard fractionation at 2 Gy/day to 50 Gy to the chest wall and regional nodes generally followed by a 10 Gy boost in 2 Gy fractions to the mastectomy scar is commonly used and has resulted in 5-year locoregional rates of 72% to 87% (82,90,94,96). Hyperfractionated RT, where the total dose is divided into smaller fractions delivering more than 1 dose daily, offers the theoretical benefit of preventing tumor repopulation between radiation fractions and is appealing in rapidly proliferating disease. Experiences with hyperfractionated regimens (such as 66 Gy in 1.5 Gy bid fractions over 4.5 weeks) or a more accelerated hyperfractionation regimen (44.2 Gy in 1.7 Gy bid fractions over 2.5 weeks) have suggested a trend toward improved locoregional control when compared to once daily fractionation, particularly 1.8 Gy daily (92,96). There has never been a prospective trial comparing dose or fractionation in IBC but a recent analysis by Bristol et al. from MD Anderson Cancer Center demonstrated no difference in rates of control between 60 Gy in 2 Gy fractions and 66 Gy in 1.5 Gy bid fractions in patients with a cCR or a cPR. Control rates were improved with hyperfractionated therapy in patients with less than a partial response and patients with positive, close, or unknown margins. Grade 3 and 4 late complications were greater in patients treated to the higher dose using hyperfractionated RT. Based upon this analysis and others, 50 Gy in 2 Gy fractions to locoregional targets followed by a 10 Gy boost to the mastectomy scar is recommended as standard therapy with consideration of higher doses and possible hyperfractionation in the presence of risk factors strongly predictive for LRF.

Controversies in Local Disease Management

Management of the axilla is an important component of the locoregional treatment of IBC. While the use of sentinel node surgery following NAC in early stage disease or non-IBC LABC is somewhat controversial (see Chapter 58 on Locally Advanced Breast Cancer) (96a), there is little controversy in IBC. Detection rates of sentinel nodes in IBC have ranged from 75% to 80% with false negative rates of 18% to 33% following isosulfan blue dye injection only (97,98). Concerns of technical difficulties due to blockage of the lymphatics by tumor emboli and inability of blue dye to reach the sentinel node(s) appear warranted. As systemic therapies improve

for IBC, sentinel node surgery should be further studied; however, at this time, axillary dissection remains the standard of care in IBC.

Another area of controversy is whether immediate reconstruction is appropriate with IBC. Primary concerns with immediate reconstruction relate to the delay in initiating postoperative RT due to wound healing and the difficulties sometimes experienced in delivering comprehensive RT in the presence of a reconstructed breast mound. Other concerns include poor cosmesis following immediate RT, particularly if tissue-equivalent bolus is used to decrease the skin-sparing effect of megavoltage radiation. Although some institutions offer immediate breast reconstruction to patients with IBC, it is the authors' preference to delay reconstruction until all therapy has been completed.

Unlike the data presented in Chapter 58 on Locally Advanced Breast Cancer, breast preservation for IBC following NAC with or without preoperative RT remains a subject for further investigation (96a). In a prospective study from the National Cancer Institute of 107 patients with LABC including IBC, chemohormonal neoadjuvant therapy was given to maximal response followed by local therapy (99,100). For patients with less than a cCR, local therapy consisted of M+RT while patients with a cCR underwent multiple incisional biopsies throughout the breast. If no residual disease was identified, patients were offered breast conserving surgery (BCS) and if disease was present, M+RT was performed. Of the 46 patients with IBC, 33% (15/46) had a pathologic complete response (pCR) as defined by multiple negative incisional biopsies and were treated with BCS. With a median follow-up of 16.8 years for live patients, 40% of patients with IBC treated with BCS had LRF compared to 23% treated with M+RT (p = .52) (99). Of note, a cosmetic analysis was performed among 25 patients treated with breast conservation in an earlier report (100). Forty-four percent (11/25) had a fair cosmetic result and 12% (3/25) had a poor result, with marked fibrosis, retraction, and severe volume loss, with one patient requiring mastectomy due to severe breast pain. The 3 patients with poor cosmesis had IBC with results attributed, in part, to use of bolus on the skin of the intact breast.

Others have attempted to use not only response to NAC but also response to RT as a means to select those patients amenable to breast preservation (95,101). In a report from Medical College of Virginia, patients with IBC received NAC followed by accelerated hyperfractionated RT for a total dose of 63 to 66 Gy over 4 to 5 weeks (95). An evaluation to assess persistent or residual disease was performed at 1 month using physical examination, mammography, and multiple needle aspirates, and those with residual operable disease underwent M. Using this algorithm, 50% of patients were treated with BCT and locally controlled with 2-year median follow-up.

In a report of alternating chemotherapy and RT where 3 2-week courses of RT were delivered between successive courses of chemotherapy ("sandwich" therapy) in 124 women with IBC, 82% of patients achieved a cCR by the end of treatment, and local relapse rates were 26% at 10 years and 33% at 20 years (101). Complications were considerable, with 54% of patients developing severe (grade 3) breast fibrosis with markedly retracted breast tissue. Nine percent had symptomatic pneumonitis requiring intervention, 4% developed a brachial plexopathy, and 11% developed rib fractures.

Other series have included brachytherapy implants to improve rates of local control while others have used lumpectomy to excise gross disease remaining after NAC (102,103). There are clearly many variables when considering a conservative approach for IBC to optimize tumor control and cosmesis while minimizing late complications. For these reasons, at this time, it is recommended that BCS for IBC only be offered within the context of a clinical trial.

Future Directions in Local Therapy

With NAC, M, and RT, rates of locoregional control for IBC have dramatically improved and yet for those whose disease is not rendered operable by chemotherapy (or preoperative RT) and for the 15%–30% of patients who recur locally following tri-modality therapy and are at risk for uncontrolled locoregional disease, quality of life can be significantly compromised. The rates of recurrence or persistent disease following NAC and RT for IBC suggest not only chemoresistance but also radioresistance. Laboratory investigations suggest an inherent radioresistance in IBC cell lines (104). These cell lines provide pre-clinical models for study of new agents to improve radiation sensitivity.

Investigation of radiation sensitizers, agents that can increase the biologic effectiveness of a given dose of radiation, are desirable in IBC. In a Phase II trial of 28 patients with inoperable disease including 5 with IBC, concomitant administration of capecitabine and standard dose RT (50 Gy) resulted in an 82% rate of operability (105). These results compared favorably to the 60% operability observed in historical controls treated at the same institution with RT alone. In another study of 14 patients (8 with IBC) with inoperable anthracycline- and taxane-resistant disease, concurrent RT and 5-FU or capecitabine with vinorelbine resulted in 100% operability (106). While these results are preliminary, they are encouraging and emphasize the importance of exploiting mechanisms of radiosensitization in clinical trials.

In addition to investigating use of chemotherapy drugs as radiosensitizers, new agents are also being studied for potential sensitizing effects with RT for IBC. One such class of drugs currently under study is PARP (poly [adenosine diphosphate-ribose] polymerase) inhibitors. PARP enzymes play a critical role in DNA repair such that inhibition of function results in DNA single strand break and secondarily double-strand break accumulation. Radiation also causes DNA damage; thus, treatment with PARP inhibitors could potentiate radiation effect. Radiosensitization with PARP inhibition has been demonstrated in multiple *in-vitro* and *in-vivo* studies and is now being tested in a multi-institution, Phase I study including patients with IBC in which patients are treated with concurrent post-mastectomy RT and escalating doses of PARP inhibitor (Pierce L, Jagsi R, personal communication). The degree of clinical radiosensitization and toxicities observed will be carefully documented in preparation for the next generation of PARP inhibitor and RT trials.

SYSTEMIC THERAPY FOR INFLAMMATORY BREAST CANCER

Conventional Neoadjuvant Chemotherapy: Anthracyclines, Taxanes, Dose-Intensity

The benefit of neoadjuvant systemic therapy (NST) in the treatment of IBC includes facilitating the rapid control of locoregional disease while concurrently reducing the risk of developing systemic metastasis. The acceptance of NST as the primary treatment for IBC transformed its previously dismal outcome and tri-modality therapy (systemic treatment followed by local therapy, i.e., mastectomy/radiation therapy) has become the current standard treatment approach for IBC (Table 59-2) (107,108). Because of the rarity of this disease, the majority of clinical trials investigating the efficacy of NAC include not only patients with IBC but

also patients with non-IBC LABC which confounds the interpretation of therapeutic efficacy specifically for IBC. A consistent surrogate for DFS and OS utilized among these studies is the incidence of pCR noted at the time of mastectomy. The definition of pCR varies among the clinical trials, which also confounds the interpretation of efficacy across published studies. One of the initial retrospective analyses which confirmed the benefit of using primary NAC for IBC was performed by Perez et al. who evaluated 179 patients with IBC treated with 4 different regimens administered between 1958 and 1989; 86 patients received tri-modality therapy with cyclophosphamide, doxorubicin, and 5-FU (CAF) as its NAC base (82). Tri-modality therapy resulted in an improved 5-year DFS equaling 40% compared with that seen with radiation and surgery (24%) or with radiation with or without chemotherapy (6%).

Subsequent studies attempted to determine the optimal combination of NAC for the treatment of IBC. Several studies confirmed the importance of anthracycline-based NAC for IBC (109–111). Bauer et al. compared the outcomes of 2 cohorts of patients with IBC: 28 patients treated between 1973 and 1988 received CMF with or without vincristine and prednisone (VP) and 10 patients treated after 1988 received FAC (110). The median OS was significantly improved when anthracyclines were added, compared with CMF/VP (30 months vs. 18 months, respectively, p = .02), as was the 3-year OS (41% vs. 14%, respectively) and 3-year DFS (46% vs. 0%, respectively). The introduction of taxanes into the NAC armamentarium also resulted in improved outcomes. A retrospective review of 6 sequential clinical trials involving 240 patients with IBC treated at MD Anderson Cancer Center from 1973 and 2000, compared disease outcomes among patients treated with anthracycline-based NAC with or without paclitaxel (T) (112). The median PFS was improved with the addition of T (33 weeks with T vs. 26 weeks, p = .18), as was the median OS (52 weeks with T vs. 41 weeks, p = .11). Statistical significance was demonstrated in the ER negative sub-population. Horvath et al. also retrospectively compared their experience of anthracycline-based NAC versus docetaxel (D) with epirubicin (E) and found an improved 3-year OS with the taxane-based NAC; however, statistical significance was not achieved (75% with DE vs. 61%) (Table 59-3) (113).

Currently, the standard NAC for IBC includes an anthracycline- and taxane-based regimen, although the optimal combination or sequence of these agents has not been established. In early stage breast cancer, increased dose-intensity of chemotherapy has shown improved efficacy, and several single arm studies suggested the possibility of benefit in IBC; however, randomized trials have not been as encouraging, possibly because of the overall poor prognosis associated with IBC (85,114–116). The neoadjuvant AGO-1 study evaluated 6 cycles of combination ET every two weeks (dose-dense chemotherapy = DD-CT) or every 3 weeks (conventionally-dosed chemotherapy = CD-CT) administered to a total of 668 patients with LABC, then subsequently analyzed the outcome specifically among the 101 patients with IBC (117,118). Overall, the pCR rate was superior in the DD-CT group compared with CD-CT (18% vs. 10%, respectively) which translated into a superior estimated 5-year DFS (70% vs. 59%) and estimated 5-year OS (83% vs. 77%). However, after a median 6 year follow-up, the benefit of the DD-CT was not seen among the IBC subgroup compared with the CD-CT group; neither with respect to pCR rate (11% DD-CT vs. 10% CD-CT), recurrence rate (55% vs. 51%), or OS (41% died vs. 33%).

The continued high rate of relapse seen in IBC following conventional NAC stimulated greater investigation into higher doses of chemotherapy, such as those used in conjunction with autologous stem cell transplant (HDCT/ASCT). The few studies that focused on IBC utilized conventional anthracycline-based NAC followed by HDCT/ASCT (119–122). As seen in non-IBC treatment, the overall efficacy of this intensive treatment approach does not outweigh the associated toxicity and currently remains highly investigational.

Neoadjuvant Targeted Therapies: HER2-directed, Anti-angiogenic

The prevalence of HER2 positive IBC lends itself to the incorporation of NST that specifically target HER2. The majority of the published literature evaluating HER2 directed therapy with NAC, combines the outcome of both non-IBC LABC and IBC into a single analysis of efficacy (123–126). In addition, most of these trials included less than 20 patients with IBC among their LABC cohort. However, the overall benefits of adding two humanized-monoclonal antibodies against HER2, trastuzumab and pertuzumab, to NAC in LABC, support the current recommendation of using these therapies as primary treatment for HER2 positive IBC.

Trastuzumab, the humanized-monoclonal antibody against HER2, has been evaluated in several NST trials that

include IBC patients. One of the earliest studies that evaluated the added efficacy from trastuzumab added to NAC for HER2 positive LABC, the NOAH (NeOAdjuvant Herceptin) trial, included an appreciable number of IBC patients (n = 63) and performed a subset analysis of their outcome (127,128). All patients received an intensive schedule of NAC including doxorubicin, paclitaxel, and CMF, with the HER2 positive patients (n = 135) randomized to receive additional trastuzumab. A third component of the study included HER2 negative patients receiving the same NAC. Treatment with NAC concurrent with trastuzumab was associated with a significant benefit in event-free survival (EFS) among the IBC patients, with a hazard ratio of 0.27 (95% CI = 0.11–0.65). The pCR rate was 48% (no invasive disease in breast or lymph nodes) with the addition of trastuzumab compared with 13% treated with NAC alone (p = .002). A recent retrospective review from the Cleveland Clinic Foundation found that among 34 patients with HER2 positive IBC, 23 (68%) received trastuzumab and NAC resulting in fewer patients developing distant metastasis (8/23 = 35%) compared with 5/11 (45%) who were treated with NAC alone (93).

The majority of studies focusing on the oral small molecule tyrosine kinase inhibitor against HER2 and EGFR, lapatinib, have involved patients with metastatic IBC. Forty-nine of 126 (39%) highly pre-treated patients with HER2 positive recurrent or refractory IBC experienced a partial disease response with single agent lapatinib (129). Prior treatment with trastuzumab was not related to disease response with lapatinib; objective response rate of 35% (33/94) with prior exposure compared with 48% (15/31) without prior trastuzumab. Correlative studies established an association between response to lapatinib and co-expression of HER-2 and HER-3 along with lack of p53 expression (130). Based on these encouraging results with a single targeting agent given to a highly pre-treated patient population, combination lapatinib and paclitaxel was investigated as NST for 49 patients with HER2 positive IBC (131). Central pathologic review confirmed HER2 positivity in 32 patients, 17 of whom achieved a clinical response permitting surgical resection (mastectomy). Among these 17 patients, 3 patients (18%) attained a pCR (no invasive disease in the breast or axilla, DCIS permitted).

The phase 3 trial GeparQuinto, compared the impact on pCR using trastuzumab or lapatinib combined with 4 cycles of epirubicin and cyclophosphamide (EC) followed by 4 cycles of docetaxel (T), (ECH-TH vs. ECL-TL, respectively). (R1) Among the 620 patients, 13% had IBC, with 42 IBC patients randomized to ECH-TH and 41 randomized to ECL-TL. The results overall demonstrated an inferior pCR rate with lapatinib vs. trastuzumab (30.3% vs. 22.7%, p = .04). This trend was also seen among the IBC patients, though the difference did not reach statistical significance (odds ratio for achieving a pCR ECH-TH vs ECL-TL = 0.72). These less than auspicious results with single agent lapatinib combined with chemotherapy are also demonstrated in other NST trials for non-IBC patients, supporting the recommendation that lapatinb should not be used as a single HER2 targeting agent combined with NAC for HER2-positive IBC.

Pertuzumab is another humanized monoclonal antibody that blocks heterodimer formation of HER2, most importantly with HER3, and binds to a different domain on HER2 than trastuzumab. NeoSphere is a multicenter randomized phase II trial examining the efficacy of adding pertuzumab to trastuzumab and docetaxel for NST for patients with operable breast cancer, non-IBC LABC, or IBC (132). Given the diversity of prognosis associated with these different stages of breast cancer, the specific efficacy of this regimen for IBC is difficult to assess. Twenty-nine IBC patients out of a total of 198 (15%) were randomized in this 4-arm trial. Most importantly, the overall pCR rate was superior with the dual HER2-targeting regimen of pertuzumab, trastuzumab, and docetaxel (29%), and although the specific effects on IBC were not reported, this combination is likely to be effective in the IBC population. An ongoing clinical trial for HER2 positive IBC using dual HER2 blockade with pertuzumab, trastuzumab, and paclitaxel is evaluating this premise (Overmoyer B, *Personal communication*) (132a). Although recent reports of effective therapy using dual HER2 blockade without chemotherapy are exciting, this approach as NST for IBC remains highly investigational (133).

The important contribution of angiogenesis to the pathophysiology of IBC has prompted investigation into utilizing this biologic component as a therapeutic target. Clinical trials in IBC with anti-angiogenic agents have also incorporated correlative studies which facilitate a greater understanding of this disease and apply this knowledge to the future development of more successful therapies. One of the early phase IB studies involved 18 patients with stage III or IV IBC treated with SU5416 (NSC 696819) a small molecule tyrosine kinase inhibitor against the VEGF receptor Flk/KDR (VEGFR-2) in combination with single agent doxorubicin (134). Seventeen patients were able to proceed to mastectomy (89%); however, there were no pCRs. Among patients with stage III disease (10/18), the median OS was 47 months. DCE-MRI (dynamic contrast-enhanced magnetic resonance imaging) demonstrated a decrease in tumor blood flow with treatment and there was a reduction in tumor microvessel density, yet plasma levels of VEGF increased with treatment. Changes in soluble endothelial adhesion molecules also occurred with this combination of anti-angiogenic therapy and chemotherapy; ICAM-1 (intracellular adhesion molecule-1) levels increased and E-selectin levels decreased. Only the baseline ICAM-1 levels were correlated with the event free survival (EFS). SU5416 was associated with 22% cardiac toxicity when combined with doxorubicin and is no longer being produced.

The effect of angiogenesis inhibition by SU5416 on tumor blood flow as demonstrated by changes in DCE-MRI was confirmed by a study of 21 patients with either stage III or IV IBC (1 patient had non-IBC LABC) treated with a humanized monoclonal antibody against all isoforms of VEGF, bevacizumab (135). The reduction in DCE-MRI parameters continued when bevacizumab was combined with docetaxel and doxorubicin. One patient achieved a pCR and with a median potential follow-up of 27 months, the median OS had not been reached. VEGFR-2 activation at two tyrosine phosphorylation sites (951 and 996, i.e., pVEGFR-2) was assessed prior to and after treatment with bevacizumab. A 67% median decrease in pVEGFR-2 occurred with bevacizumab administration, and persisted with the addition of chemotherapy. CD31 encodes an endothelial cell adhesion molecule involved in cellular signaling and motility, and its expression on IBC vascular endothelium was down-regulated with bevacizumab and corresponded to disease response (136). Tumor VEGF-A levels also corresponded with disease response, with higher baseline levels associated with a more favorable response.

Early data from a phase II trial (PACS 09/Beverly 1) of bevacizumab combined with more extensive chemotherapy (FEC followed by docetaxel) among 100 patients with IBC demonstrated an overall pCR rate of 27%, which was primarily attributed to the HR negative subgroup; 38% (21/55 HR negative) versus 13% (6/45 HR positive) (137). Although these trials and others involving bevacizumab in NST for IBC, have not demonstrated the anticipated enhanced disease response, the correlative studies have provided confirmation that targeting the angiogenesis pathway is still potentially effective and deserves further investigation (126,138,139).

Based upon the interaction of HER2 activation and subsequent downstream signaling of VEGF expression, trastuzumab and bevacizumab were combined with chemotherapy (FEC followed by docetaxel) and used as NST for 52 patients with HER2 positive IBC (Beverly-2) (140). The pCR rate of this combination of dual targeted therapy with NAC was 68% (35/52); however, the impact upon clinical endpoints (DFS, OS) is not yet mature. A note of caution from this study pertains to potential cardiac toxicity in that the incidence of cardiac failure was 8%.

Future Directions: Neoadjuvant Targeted Therapies

Although the advent of NAC for the treatment of IBC brought about significant improvements in OS compared with primary local therapy alone, a greater understanding of the unique molecular mechanisms involved in the biology of IBC has led to the pursuit of novel agents targeting these specific pathways. The improvement in clinical outcomes that occur when HER2 targeting agents are combined with chemotherapy support this approach in the treatment of IBC, i.e., chemotherapy alone is not sufficient treatment for this disease; specific molecular targeting agents must be included. Several clinical trials are either ongoing or have recently been completed (results pending) that have used novel agents targeting VEGFR, PDGF (pazopanib, sunitinib), FGFR3 (TK128/dovitinib), EGR1, HER2 (afatinib), CK2 (CX-4945) and RAS pathways (tipifarnib) (141). To advance this approach even further, many laboratories are involved in investigating novel therapies involving IBC cell-lines and xenograph models (72,126). There are too many exciting advances to thoroughly discuss in this chapter; however, ongoing studies are addressing targeting Notch signaling, inactivating RhoC, JAK2/STAT3 inhibition, suppressing the Akt/mTOR pathway, and suppressing ALK (anaplastic lymphoma kinase) expression, to name a few (62,70–73,75,142). The goal of this work is to unravel the specific details of the unique biology of IBC in order to identify the optimal treatment and continue to improve the prognosis of this virulent disease.

MANAGEMENT SUMMARY FOR THE TREATMENT OF INFLAMMATORY BREAST CANCER

- IBC is rare and presents with a rapid onset of symptoms, usually occurring within three months, and characterized by the following clinical features: erythema usually involving one-third or more of the breast; edema of the skin of the breast (peau d'orange); breast enlargement, often without a palpable mass; and the breast may be warm or tender.
- Breast imaging should be performed, including mammogram and ultrasound, to detect sites within the breast that could be biopsied to confirm adenocarcinoma of the breast. Breast MRI is often more successful in determining extent of disease with IBC. (See Chapter 58 on Locally Advanced Breast Cancer.) (96a)
- A biopsy confirmation of adenocarcinoma of the breast is necessary. Skin biopsy is optional and should not be used to confirm the diagnosis of IBC. Diagnosis is based upon the presence of the clinical signs (noted above) in the setting of adenocarcinoma of the breast.
- IBC is highly metastatic, therefore complete staging is necessary, including: CT chest, abdomen, pelvis; bone scan (not necessary if PET is used). FDG PET/CT may be considered to identify unsuspected nodal involvement or distant metastasis, but should not replace standard staging studies. CNS imaging should be performed if symptoms exist. Biopsy confirmation of distant metastasis is recommended.
- A multi-modality evaluation should occur, including medical oncology, radiation oncology, and surgery prior to initiating therapy.
- Neoadjuvant chemotherapy is given, usually containing an anthracycline- and taxane-based regimen. Standard adjuvant chemotherapy regimens should be used off clinical trial (4–6 months duration). If HER2 positive disease is present, trastuzumab and pertuzumab should be added to the NAC as outlined in standard regimens. Systemic therapy should continue until all signs of skin inflammation (edema and erythema) have resolved and the breast and axillary masses are operable.
- A complete mastectomy with axillary lymph node dissection should follow completion of NST. Reconstruction of the breast should be delayed.
- If the breast or nodal disease remains inoperable after NST, then radiation therapy should be given prior to surgery as described above. Otherwise, radiation therapy is given following mastectomy using standard radiation therapy fields determined by CT planning, with a tissue equivalent bolus placed daily on the skin of the chest wall to induce a brisk erythematous skin reaction. The chest wall (including mastectomy incision), supraclavicular, infraclavicular, and internal mammary lymph nodes should be irradiated. The decision to irradiate the axillary bed following axillary dissection should be individualized.
- Standard adjuvant endocrine therapy should be given if the disease is ER and/or PR positive. This should begin following surgery and is based upon accepted guidelines. Adjuvant trastuzumab should be given to complete one year of treatment for HER2 positive disease.

CHAPTER 60

Preoperative Systemic Therapy for Breast Cancer

Marc E. Lippman

Preoperative (or neoadjuvant) systemic therapy for breast cancer is a rapidly changing field with complex issues surrounding appropriate patient selection, management, and research considerations. Unquestionably, patients require coordinated multidisciplinary care with input from radiologists, surgeons, radiation oncologists, and medical oncologists for optimal outcomes.

Substantial data do not exist suggesting that preoperative therapy has superior survival to postoperative systemic therapy, but there are other potential benefits for the patient. Preoperative systemic therapy is indicated for patients with locally advanced breast cancer—T4 tumors or N2 or N3 nodal disease—to convert them to operable. While not formally demonstrated in randomized clinical trials, survival rates for locally advanced breast cancer have increased substantially with preoperative systemic therapy. For patients with unicentric cancers, which are too large relative to the size of the breast to allow cosmetically acceptable breast-conserving surgery (BCS), preoperative chemotherapy will allow BCS in at least one-third of these patients. The lack of reliable methods for evaluating the extent of residual disease in the breast after preoperative chemotherapy remains an obstacle to increasing rates of BCS, even as pathologic complete responses to newer drug combinations and targeted therapy become more frequent. In patients with clinically negative nodes at presentation, sentinel node biopsy after chemotherapy accurately stages the axilla, and this approach has been shown in randomized trials to decrease the need for axillary dissection. There is more controversy regarding the management of patients who present with clinical nodal metastases that appear to resolve with preoperative chemotherapy. Two recent prospective trials investigating the accuracy of sentinel node biopsy in this setting (1,2) reported false negative rates of 18% to 21% with the removal of 2 sentinel nodes. False negative rates decreased below the 10% threshold if 3 or more nodes were removed, but the median number of sentinel nodes identified in large multicenter trials of sentinel node biopsy prior to chemotherapy is 2. At the present time, axillary dissection remains the standard management for patients presenting with clinically involved (and histologically confirmed) nodal metastases, pending the results of additional trials discussed below. Outside of clinical trials, there is little justification for preoperative systemic therapy for tumors suitable for management by established means of breast conservation with appropriately administered systemic adjuvant therapy or in patients who require mastectomy due to multicentric disease. In fact, optimal guidelines for postoperative radiation therapy, which are reasonably well established for breast cancers managed by surgery first, are far less clear for patients staged after the completion of preoperative systemic therapy and are the subject of intense investigation. Particularly unclear at this time are optimal recommendations for treatment of clinically or pathologically positive nodes that become either clinically negative or pathologically negative after preoperative systemic therapy. In general, there is wide agreement that radiation therapy is required for essentially all patients rendered operable and downstaged by systemic therapy; however, there remains a substantial lack of clarity of how best to treat formerly involved lymph node areas. A major potential advantage of using neoadjuvant systemic treatments would be to permit the tailoring of local-regional treatment recommendations based on disease response. Specifically, based on the data available to date, it is reasonable to ask whether patients with a very favorable response could potentially avoid the toxicities of more aggressive local-regional therapies. Two recently activated phase III trials investigate this concept; one with respect to axillary management and one with respect to avoidance of postmastectomy or regional lymph node radiation.

The recently approved axillary management trial is being led by the Alliance Group (A11202 trial). This trial will study patients who present with node-positive disease and who continue to have positive sentinel lymph nodes (SLNs) after chemotherapy (plus anti-HER2 therapy if HER2-positive) despite no longer having clinical evidence of gross residual lymph node disease. Patients will be randomized to the current standard of care of performing axillary lymph node dissection plus breast/chest wall and nodal irradiation versus avoidance of axillary lymph node dissection and use of breast/chest wall and nodal irradiation to eradicate potential residual microscopic disease within the undissected lymph nodes. If this trial is able to achieve balanced results, the avoidance of an axillary dissection for patients will likely result in less patient morbidity and lower costs.

The radiation trial for initial node-positive patients being treated with neoadjuvant chemotherapy (plus anti-HER2 therapy if HER2-positive) is being led by NSABP and RTOG (NRG 9353 trial). This study will enroll patients with initial node-positive disease who convert to node-negative with chemotherapy (determined by SLN surgery or axillary lymph node dissection [ALND]). Eligible patients for this study will include those with clinical T1–3N1 disease who have pathologically negative lymph nodes after neoadjuvant chemotherapy. All patients treated with breast conservation will receive radiation to the breast, and the study will randomize these patients to the addition or omission of regional lymph node radiation. For patients treated with mastectomy, randomization will be between radiation to the chest wall and draining lymphatics versus no radiation.

Within the confines of prospective clinical trials—with the potential availability of tissue sampling prior to, during, and after therapy—the efficacy of novel targeted therapies can be explored in detail. It is certainly clear that responses to novel treatments can be assessed objectively in this setting along with critical information that may more accurately predict which patients will benefit from therapy.

It has been proposed that the ability to induce a pathologic complete response (pCR) may be a surrogate for long-term event-free and overall survival and that, plausibly, preoperative systemic therapy could be used as a means of validating therapy efficacy sooner and on fewer patients than in the adjuvant setting. Clearly, this approach could lead to a vastly less expensive and time-consuming approval process for new agents. However, it is important to state that in the randomized preoperative systemic therapy trials that have been reported to date, differences achieved in rates of pCR have not uniformly translated into improved event-free survival rates for the group with a higher pCR rate. This is a dismaying and somewhat unexpected result given the clear association between pCR and improved outcome for any individual patient. This may or may not change when (hopefully) more effective therapies are explored in the future.

Multiple reports have plainly established that preoperative therapy that results in a pathologic pCR is associated with a substantially better survival for the individual patient. However, the most appropriate way to diagnose a pCR is not completely agreed upon. Whether or not residual ductal carcinoma in situ (DCIS) should be an exclusion criterion for a pCR is unsettled, as is residual microscopic axillary lymph node (ALN) disease. We believe that while "almost" pCR may well be a gratifying pathologic response for patients and physicians alike, validated systems are needed to assess the degree of response to preoperative systemic therapy and its prognostic value. These systems are covered in Chapter 56, Pathologic Assessment of Treatment Response after Neoadjuvant Therapy. The two most widely used systems are Miller-Payne (3) and the Residual Cancer Burden (4).

There are significant differences in successful induction of pCR's based in part on the breast cancer subtype. TNBC and HER2-positive cancers have substantially higher pCR rates than Luminal A (ER-positive, PR-positive, HER2-negative breast cancers). There is general consensus that essentially all systemic chemotherapy regimens should include a taxane and most regimens employ an anthracycline as well. There have been few, if any, studies suggesting that there are important differences in efficacy between established adjuvant therapy regimens and those which are efficacious in the preoperative setting so any well-validated adjuvant regimen is appropriate absent data tying a specific combination to a specific molecular subtype.

To date, HER2-targeted therapy is the only adjunct to chemotherapy that has been proven to improve outcomes. Multiple studies are underway exploring agents additional to trastuzumab, and this area should be followed closely to assure ideal therapy for HER2-positive patients. (The NEOSPHERE and NEOALTTO randomized neoadjuvant trials looking at pertuzumab plus trastuzumab or lapatinib plus trastuzumab together with taxol showed a doubling of the pCR rate compared to the single agent targeted therapy.) Recently reported results using dual HER2 blockade without any cytotoxic drugs has suggested similar pCR rates to those achieved with intensive chemotherapy plus trastuzumab, which, if validated, will be a very exciting development.

Multiple trials are underway exploring a variety of other potential targets, including trials investigating novel drugs such as PI3K inhibitors (NeoPHOEBE / NCT01816594), PARP inhibitors (NeoPARP / NCT01204125), multikinase inhibitors such as sunitinib and pazopanib (NCT00849472, NCT00887575), and IAP (Inhibitor of Apoptosis Protein) antagonists such as LCL161 (NCT01617668).

In Luminal A patients, rates of pCR are very low while responses to endocrine therapy, particularly aromatase inhibitors, are reasonable, and a high proportion of patients will downstage. Thus, very serious consideration should be given to preoperative endocrine therapy. This is a particularly attractive approach in elderly patients with advanced breast cancers that appear to be more a result of neglect than aggressiveness. Such patients are often not ideal for aggressive chemotherapy treatment. Responses can be slow and gradual, and careful assessment over a period as long as 6–12 months may be needed.

SECTION IX

Special Therapeutic Problems

CHAPTER 61

Male Breast Cancer

Sarika Jain and William J. Gradishar

CHAPTER CONTENTS

EPIDEMIOLOGY

Male breast cancer (MBC) is a rare disease worldwide. As a result of its rarity, it is treated similarly to female breast cancer but important differences exist. In the United States, it is estimated that 2,190 men will be diagnosed with breast cancer and 410 will have died from this disease in 2012. MBC accounts for less than 1% of all breast cancers and less than 0.5% of all male cancer deaths in the United States (1). Globally, the highest male incidence rate was observed in Israel at 1.24 per 100,000 man-years followed closely by the Philippines, Italy, and France. The lowest male incidence rate was recorded in Thailand at 0.16 per 100,000 man-years followed by Japan, Singapore, and Colombia (2).

The worldwide female-to-male incidence rate ratio of breast cancer is 122:1 (2). MBC compared to female breast cancers occur later in life with higher stage, higher grade, and more estrogen receptor–positive tumors. The median age of onset of MBC is 72 years of age, compared to 61 years in women (3). According to the United States Surveillance, Epidemiology, and End Results (SEER) registry database, the incidence rate of MBC was slightly increasing from 1975 to 2004 (from 0.9 to 1.2 cases per 100,000 men at risk). A rapid increase in female breast cancer incidence was observed in the mid 1970s to mid 1990s in the United States and Europe largely due to the greater use of mammographic screening. Mortality rates in the late 1980s and 1990s tended to be lower than three decades earlier, likely owing to advances in diagnostics and therapeutics (4). The most recent SEER database analysis shows a decrease in breast cancer incidence and mortality in both men and women, but the trends were greater for women. Comparing patients diagnosed from 1996 to 2005 versus 1976 to 1985 and adjusting for age, stage, and grade, MBC death declined by 28% among men and 42% among women (5).

Racial/ethnic differences also exist. In the United States, the ratio of female-to-male breast cancer is approximately 100:1 in whites and 70:1 in blacks. Age-adjusted incidence rates per 100,000 men are highest in blacks (1.65), intermediate in whites (1.31), and lowest in Hispanics (0.68) and Asian/Pacific Islanders (0.66). Blacks are also diagnosed at an earlier age and at a more advanced stage compared to other ethnicities (6). Similar to black women, black men have an increased breast cancer-specific mortality even after adjustment for clinical, demographic, and treatment factors (7).

The distribution of tumor subtypes is also different across racial/ethnic groups. In the largest population-based study evaluating breast tumor subtypes in 606 patients with MBC, 82.8% of white men (95% CI, 79.3%–86.4%) had hormone receptor positive tumors, 14.6% had HER2-positive tumors (95% CI, 11.3%–18%), and 2.6% had triple negative breast cancer (95% CI, 1.1%–4%). In contrast, among blacks, 73.3% had hormone-receptor positive tumors (95% CI, 60.4%–86.3%), 17.8% had HER2-positive tumors (95% CI, 6.6%–29%), and 8.9% had triple negative tumors (95% CI, 0.6%–17.2%); whereas, among Hispanics, 77.6% had hormone-receptor positive tumors (95% CI, 67.6%–87.6%), 16.4% had HER2-positive tumors (95% CI, 7.6%–27.5%), and 6% had triple negative tumors (95% CI, 0.3%–11.6%). Among the patients with hormone receptor-positive tumors, black and Hispanic men were more likely to have PR-negative tumors than white men. No statistically significant differences in survival were observed according to tumor subtype (p = .08). Among hormone receptor-positive patients, blacks experienced the worst survival (8).

RISK FACTORS

Several risk factors are associated with the development of MBC, including endocrine, nutritional, and genetic factors (Table 61-1). In a large retrospective review of a United States Veterans Affairs database assessing 642 cases of MBC, conditions associated with increased risk of MBC included diabetes, orchitis/epididymitis, Klinefelter syndrome, and gynecomastia. Among blacks, cholelithiasis emerged as a significant risk predictor (9). A large prospective study found family history,

TABLE 61-1

Risk Factors Associated with Male Breast Cancer (MBC)

Endocrine
Gynecomastia
Testicular conditions
Liver disease
Diabetes mellitus
Nutritional/lifestyle
Obesity
Low physical activity
Alcohol use
Genetic
Family history
Klinefelter syndrome
BRCA carrier (*BRCA2* > *BRCA1*)
Cowden syndrome
Li-Fraumeni syndrome
HNPCC (Lynch) syndrome

history of bone fracture, obesity, and low physical activity to be positively associated with MBC. Some of these identified risk factors are common to female breast cancer and suggest an importance of hormonal mechanisms (10).

The strongest risk factor for MBC is Klinefelter syndrome (9). This rare condition results from the inheritance of an additional X chromosome (XXY). Men with this condition have atrophic testes, gynecomastia, high serum levels of gonadotropins (follicle-stimulating hormone, luteinizing hormone), and low plasma levels of testosterone. It is hypothesized that the increased estrogen-to-testosterone ratio could in turn lead to abnormal hormonal stimulation of cell proliferation in mammary ductal epithelium. Of the few epidemiologic studies conducted in this area, the largest cohort study of 3,518 men with cytogenetically diagnosed Klinefelter syndrome found 19- and 58-fold increases in incidence of, and mortality from, MBC, respectively, compared to the general population. Alteration of hormone levels, particularly the elevated ratio of estrogen-to-testosterone, administration of exogenous androgens, gynecomastia, and genetic factors are possible explanations for the high risk. Additional studies are needed to delineate which patients with Klinefelter syndrome are at increased risk for MBC, and the importance of patient education, self-examination, and regular examinations should be enforced (11).

Chronic liver diseases such as cirrhosis, chronic alcohol injury, and schistosomiasis have been associated with an increased risk of MBC. Cirrhosis limits the ability of the liver to metabolize endogenously produced estrogen, leading to a relative hyperestrogenic state with an imbalance in the estrogen-to-testosterone ratio (12). Similarly, ethanol, which has been associated with an increased risk of breast cancer in females, is a metabolic modifier for mammary epithelium and may promote the most carcinogenic pathway of estradiol metabolism to catechol estrogen. Very few cases of MBC have been documented in patients with chronic liver diseases, possibly due to the shortened lifespan associated with these disorders. Results from some studies have not found an association between liver cirrhosis and MBC (9).

Gynecomastia, when related to states of estrogen excess, has been associated with MBC. Gynecomastia is most often drug-related, and several medications that cause gynecomastia have been associated with an increased risk of MBC. Breast cancer has been described in three men who were prescribed finasteride, a drug approved for the treatment of benign prostatic hyperplasia. Cases of MBC have also been reported with digoxin, thioridazine, and spironolactone, and in male-to-female transsexuals who were castrated and given high doses of estrogen (13).

Testicular conditions have also been associated with an increased risk of MBC. These include orchitis, undescended testis (cryptorchidism), and testicular injury. Other conditions associated with an increased estrogen-to-testosterone ratio such as thyroid disease and marijuana use have not firmly established a link to MBC.

Experimental evidence suggests that prolactin may promote tumorigenesis in animal models; however, physiologic states of prolactin excess in humans (e.g., multiple pregnancies) do not confer an increased risk of breast cancer and may be protective. Several case reports have described the development of MBC in association with a prolactinoma, a setting in which low plasma testosterone levels are often observed (14). The association between prolactin excess and MBC remains unclear.

Androgens may convey a protective effect by inhibiting cell proliferation in breast tissue. In some reports, mutations in the DNA-binding domain of the androgen receptor (AR) gene have been implicated in the development of MBC. Conversely, a pathologic case study that analyzed tumor material from two series of patients with MBC without clinical evidence of androgen insensitivity reported no AR gene mutations. In a study of 43 MBC patients, AR expression by immunohistochemistry inversely correlated with survival (15).

Approximately 5% to 10% of female breast cancer cases are thought to be hereditary, with the majority of these cases associated with mutations in two genes: breast cancer type 1 and 2 susceptibility genes (*BRCA1* and *BRCA2*). These genes are inherited in an autosomal dominant pattern and confer a lifetime risk of female breast cancer ranging from 50% to 85%. Approximately 15% to 20% of MBC is associated with a positive family history for the disease compared to only 7% of the general male population (16).

BRCA2 mutations are more frequent than *BRCA1* mutations. In an Italian series of 50 *BRCA* carriers, 92% harbored the *BRCA2* mutation compared to 8% with the *BRCA1* mutation (17). Inherited mutations in *BRCA* do not increase the risk of breast cancer to the same degree in males as in females. The breast cancer risk also appears to be higher with *BRCA2* mutations as opposed to *BRCA1*. Men who carry a *BRCA2* mutation have an approximate 6.5% cumulative risk for breast cancer by age 70, which is 100-fold higher than the general male population. A paucity of data exists correlating the risk for MBC in *BRCA1* carriers. One Dutch and one American family have been described that carried the *BRCA1* mutation; each had one case of MBC as well as multiple associated female breast cancer cases. A report from the National Cancer Institute Cancer Genetics Network suggests that the cumulative risk of breast cancer by age 70 in men harboring a *BRCA1* mutation is 1.2% (95% CI, 0.22%–2.8%) (16).

The classification of molecular subtypes based on immunohistochemical profiles as proposed in female breast cancer, is still controversial in MBC. In one report of 382 MBCs including 50 *BRCA* carriers, the immunophenotypic profiles differed between 4 *BRCA1*- and 19 *BRCA2*-asssociated patients, in whom complete ER, PR, and HER2 status was available. Of the 4 *BRCA1*-related MBC cases, 3 showed a luminal A subtype and 1 a triple negative tumor. Of the 19 *BRCA2*-related MBCs, 7 were luminal A, 9 luminal B, and 3

HER2-positive. Notably, all 7 triple negative tumor cases were *BRCA2* mutation negative. In a multivariate logistic model, *BRCA2*-associated MBCs showed positive association with high tumor grade (OR 4.9, 95% CI, 1.0–23.9) and inverse association with PR expression (OR 0.19, 95% CI, 0.04–0.92), suggesting that the *BRCA2* subgroup is characterized by a more aggressive phenotype (17).

Genetic mutations other than *BRCA* may predispose males to developing breast cancer. Cowden syndrome, an autosomal dominant cancer susceptibility syndrome, is associated with germline mutations in the tumor suppressor gene *PTEN* located on chromosome 10. This syndrome is characterized by multiple hamartomas and an increased risk for both male and female breast cancer and thyroid malignancies. Two cases of MBC have been reported with germline *PTEN* mutations and the Cowden syndrome phenotype. Other hereditary syndromes associated with MBC include Li-Fraumeni syndrome, caused by the *TP53* mutation, and hereditary nonpolyposis colorectal cancer (Lynch) syndrome, caused by mutations in the mismatch repair genes (18).

Recent genome-wide association studies (GWAS) identified common single nucleotide polymorphisms (SNPs) that influence female breast cancer risk. A GWA study of MBC compromising 823 cases and 2,795 controls were genotyped and validated in an independent sample set, and the SNP RAD51B was found to be significantly associated with MBC risk (19). Other studies have found genetic variants that influence susceptibility to breast cancer, which differ between male and female breast cancer.

Guidelines from the National Comprehensive Cancer Network (NCCN) recommend that genetic testing be offered to men who develop breast cancer as well as to families with a known *BRCA* mutation, a case of MBC, or the presence of female relatives with a history of breast or ovarian cancer that suggests the presence of an inherited breast or ovarian cancer syndrome. Furthermore, adherence to recommended screening guidelines for prostate cancer is advised, as males with *BRCA2* mutations have an elevated risk of prostate cancer.

CLINICAL FEATURES

Similar to cancer in women, MBC typically presents as a painless lump. The mass is usually subareolar and less often in the upper outer quadrant. A slight predilection exists for the left breast. Nipple involvement is a fairly early event, occurring in 40% to 50%, with retraction in 9%, discharge in 6%, and ulceration in 6%. Bilateral MBC is very rare with a reported incidence of 1.5% to 2% of all MBCs (20). Infrequently, MBC presents as an axillary nodal metastasis without a palpable breast lump. Other findings on examination for malignancy include fixation to skin or muscle and breast tenderness (21).

The majority of breast lesions in males are benign, with gynecomastia as the most common etiology. Other pathologic lesions in the male breast are related to the cutaneous and subcutaneous tissue and can include lipoma, breast abscess, metastatic lesion to the breast, and other primary malignancies such as sarcoma (22). Gynecomastia has been found in up to 55% of male breasts in a series of autopsy specimens (21). As opposed to MBC, gynecomastia usually presents as bilateral, symmetrical breast enlargement with irregular borders in the absence of axillary lymphadenopathy or fixation to the chest wall. On mammography, MBC is usually subareolar and eccentric to the nipple. In contrast, gynecomastia appears as a round or triangular area of increased density positioned symmetrically in the retroareolar region. Calcifications are rarer and coarser than those occurring in female breast cancer. Because of the low incidence of MBC in the general population, there is no role for screening mammograms in men. One report described a male *BRCA2* carrier who was diagnosed with breast cancer by screening mammography; clear guidelines have not been established for this population (23).

DIAGNOSIS

The first step in the evaluation of a suspicious breast mass in a male is mammography. A mammogram can usually distinguish between malignancy and gynecomastia and is abnormal in 80% to 90% of MBCs. Mammographic features of malignancy include a dense mass generally without calcifications and often with spiculated, indistinct, or microlobulated margins. Sonography usually reveals an irregularly-shaped hypoechoic mass, as seen in female breast cancers. Any cysts that are discovered on imaging should be sampled, as simple cysts are rare in men and are associated with neoplastic papillary lesions. Likewise, radiologic features such as a well-defined lesion that would suggest a benign finding in a female are unreliable in men and require biopsy. In one series, MBC was manifested as a well-defined mass in 15% of cases using mammography and in 23% using sonography (24).

Several studies have suggested that mammography added no diagnostic information to the combination of physical examination and pathologic evaluation. In one retrospective analysis of 134 male patients with a history of a breast lump between 2001 and 2003 and undergoing mammographic imaging, only four cases of breast cancer were diagnosed. All four patients presented with a painless lump, for a mean duration of 7 months, and breast cancer was suspected due to clinical examination and confirmed by biopsy (25). The use of breast MRI has not been widely studied in MBC, and no prospective data exists for its use in screening or diagnosis of MBC.

Once a suspicious breast mass is identified, biopsy is required to confirm the diagnosis and to assay for ER, PR, and HER2 status. Fine needle aspiration (FNA) is a reliable procedure, and has been shown to avoid surgical biopsy in 59% of cases. However, in one report of 153 FNAs of the male breast, 13% did not provide sufficient tissue for diagnosis (26). Compared to FNA, core needle biopsy offers a more definitive histologic diagnosis, avoids inadequate samples, and usually distinguishes between invasive and *in situ* cancer.

PATHOLOGY

The most common histopathologic type of MBC is invasive ductal carcinoma, similar to female breast cancer, and accounts for 85% of all MBC cases. Conversely, invasive lobular carcinoma is much less frequent in males compared to females, constituting only 1.7% of MBCs (27). The rarity of lobular carcinoma in males may be due to the lack of acini and lobules in normal male breast tissue. Ductal carcinoma *in situ* (DCIS) accounts for 20% to 25% of all cases of female breast cancer. In contrast, the frequency of DCIS in men ranges from 0% to 17%, with an average of 7%. Few case reports of lobular carcinoma *in situ* (LCIS) exist in the published literature. Paget's disease of the breast has a higher incidence in males (5%) compared to females (1% to 4%) and appears to have a worse 5-year survival in men (28).

Likewise, invasive papillary carcinoma is more common in males (2% to 4%) than in females (1%). All other subtypes of breast cancer, including inflammatory breast cancer, have been reported in men (29).

Immunohistochemical and molecular characteristics of MBC have shown a greater incidence of hormone receptor positivity and significantly less frequent overexpression of HER2/neu. In females with breast cancer, tumors are ER-positive in 77% of patients compared to 92% of ER-positive tumors in males. The incidence of HER2 overexpression is only 2% to 15% in MBC; approximately 18% to 20% of all female breast cancers overexpress HER2 (30).

More information has become available regarding molecular markers in MBC. In a series of 134 cases of MBC, tumor samples were analyzed for ER, PR, HER2, AR, the protooncogene p53, the cell cycle regulatory protein cyclin D1, and a marker of apoptosis bcl-2, among others. According to immunohistochemically-defined molecular subtypes, the vast majority of cases were classified as luminal A (75%), whereas 21% of tumors were luminal B. No HER2-driven cases were identified, as all HER2-positive cases (3%) showed ER positivity and were classified as luminal B. The remaining 4% of cases were basal-like (31). Expression of AR (81%), bcl-2 (75%), and cyclin D1 (77%) were very common, in line with previous studies. Approximately half of the tumors were positive for p21 (48%) and BRST2 (56%). The most important downstream effector of p53, p21, is a universal cyclin/cyclin-dependent kinase inhibitor which inhibits proliferation and has been associated with worse disease-free survival. Overexpression of p21 has been seen more frequently in MBC than in female breast cancer. In contrast, p53 accumulation (15%) was rare, somewhat lower than other reports in which up to 54% of samples were p53-positive. Expression of the basal markers CK5/6 (9%), CK14 (1%), and EGFR (12%) were encountered infrequently. This study also elucidated the clinical relevance of several biomarkers in MBC. PR-positive and bcl-2-positive tumors showed favorable histologic features, while HER2-positive, Ki-67-positive, and p21-positive tumors correlated with higher grade and mitotic count. p53 and BRST2 significantly predicted the presence of lymph node metastases, and PR-negativity and p53 accumulation emerged as independent predictors of decreased survival (32).

TREATMENT OF LOCALIZED AND LOCALLY ADVANCED DISEASE

Surgical Management

The treatment of localized invasive early stage breast cancer in men follows the same general principles as in women. The current operative procedure of choice in MBC is a total mastectomy with sentinel lymph node (SLN) biopsy. Traditionally, the preferred approach was a modified radical mastectomy (MRM). Although randomized studies have not been conducted in men, retrospective data suggest the equivalence of radical mastectomy and MRM in terms of local recurrence and survival, and studies in women also support the equivalence of these two procedures. The only exception is extensive chest wall muscle involvement in which radical mastectomy may be of benefit if neoadjuvant chemotherapy does not sufficiently reduce the tumor burden. Breast conserving therapy (lumpectomy followed by breast irradiation) is a possible option for men with breast cancer. However, the lack of adequate surrounding breast tissue and the central location of tumors precludes this approach in some.

The literature suggests that MRM is used in approximately 70% of male patients, followed by radical mastectomy (8% to 30%), total mastectomy (5% to 14%), and lumpectomy with or without radiation (1% to 13%). Radical mastectomy was more commonly used in older series, likely reflecting practice patterns as well as later stage at diagnosis (30). In a review of more recent data from the SEER database, of 1,541 cases of MBC, almost 20% were treated with breast conservation. Though these SEER data do not include information on local recurrence rates, in one retrospective study of seven patients treated with breast conserving therapy with a median follow-up of 67 months, there were no local recurrences (33).

Axillary nodal involvement is a strong predictor of both local recurrence and metastatic risk and is present in approximately 50% of men with breast cancer. As such, surgical assessment of the axillary nodes is an essential component of primary treatment. In early-stage breast cancer in women, SLN biopsy has emerged as a less morbid alternative to a full axillary lymph node dissection (34). In an experienced center, the SLN accurately predicts the status of the remaining regional nodes, and a negative SLN eliminates the need for a complete axillary node dissection. In an effort to understand the predictive value of SLN biopsy in men, several retrospectives studies have been carried out. The European Institute of Oncology (IEO) investigated 32 MBC patients with clinically negative axillary lymph nodes who underwent a SLN biopsy. Preoperative lymphoscintigraphy and subsequent imaging successfully identified the SLN in all patients, with a mean number of 1.5 SLN removed per patient. A total of 26 patients (81%) had negative SLN; lymph node metastases were found in 4 patients and micrometastases in the remaining 2 patients. After a median follow-up of 30 months, no axillary recurrence events occurred (35). Memorial Sloan-Kettering Cancer Center reported their experience in 78 patients with MBC. SLN biopsy was successful in 76 (97%), yielding a similar failure rate as in female breast cancer. Negative SLNs were found in 39 of 76 (51%) patients. Of these, three (8%) were found to have a positive non-SLN during intraoperative palpation. Positive SLNs were found in 37 of 76 (49%) patients. The two patients who failed SLN biopsy underwent a complete axillary node dissection. At a median follow-up of 28 months, there were no axillary recurrences (36). Recent data from the American College of Surgeons Oncology Group Z0011 study suggest that patients with clinically staged T1N0 or T2N0 breast cancer with less than 3 positive sentinel lymph nodes can forgo completion axillary node dissection, as long as adjuvant therapy and whole breast irradiation are part of the treatment plan. Although this study did not include men, there are case reports of men utilizing this technique (37).

These retrospective and single institution experiences with SLN biopsy in men are comparable to those in women. A joint expert panel of the Breast International Group and the North American Breast Cancer Group concluded that total mastectomy with SLN biopsy is the established standard of care (30). An expert panel convened by the American Society of Clinical Oncology (ASCO) concluded that the use of SLN biopsy in MBC was "acceptable."

Adjuvant Radiation Therapy

There are limited data assessing the role for, and clinical impact of, adjuvant radiation therapy in men. In several series, postoperative radiation therapy was administered to some patients but the technical aspects of radiotherapy varied between series and over time, making any assessment of clinical impact difficult. Men are more likely to

be offered postmastectomy chest wall radiation therapy (PMRT) due to concern of adequate surgical margins even in small tumors and the higher incidence of nipple or skin involvement. Prospective studies of PMRT have demonstrated a survival advantage in women with node-positive breast cancer, though their generalizability to MBC is unclear. In one series with 75 MBC cases, 29 (39%) did not undergo PMRT and 46 (61%) completed PMRT. Patients who received PMRT demonstrated no benefit in overall survival but significantly better local recurrence-free survival compared with those who did not receive radiation therapy (38). A retrospective study from Johns Hopkins suggests that similar indications for PMRT should be applied to both men and women with breast cancer (39). As with female breast cancer, PMRT is recommended for men with four or more positive lymph nodes (N2/N3) or locally advanced (T3/T4) primary tumors.

There is less agreement on radiation treatment for fewer positive nodes. Data from a combined analysis of two Danish trials and the NCIC CTG MA.20 trial demonstrated a survival benefit from PMRT in patients with fewer than four positive nodes. Therefore, radiation therapy should also be considered in men with one to three positive lymph nodes.

Adjuvant Systemic Therapy

Recommendations for adjuvant endocrine therapy, chemotherapy, or biologic therapy following surgical resection of the primary tumor in MBC are based largely on the benefits derived from these interventions in women with early-stage breast cancer. The low incidence of MBC precludes robust clinical trial development and timely completion to assess the efficacy of adjuvant therapy.

Because most MBCs are hormone receptor-positive, adjuvant tamoxifen for five years is often recommended. Prospective trials to confirm this approach are not available, however retrospective studies support a survival benefit from tamoxifen in MBC. In one report, 39 patients who received tamoxifen demonstrated improved 5-year actuarial survival and disease-free survival compared to a historical control group who underwent mastectomy alone (61% vs. 44% and 56% vs. 28%, respectively) (40).

Tamoxifen is generally well-tolerated but several studies indicate that a large proportion of men discontinue treatment before five years. A recent retrospective review from MD Anderson Cancer Center evaluating 64 MBC patients treated with adjuvant tamoxifen demonstrated a high rate of adverse events. At a median follow-up of 3.9 years, 34 (53%) patients experienced one or more toxicities, most commonly weight gain (22%) and sexual dysfunction (22%). Thirteen (20.3%) patients discontinued tamoxifen due to toxicity, including ocular complaints (1 patient), leg cramps (1 patient), neurodegenerative deficits (2 patients), bone pain (2 patients), sexual dysfunction (3 patients), and thromboembolic events (4 patients) (41). In a study of 116 men, adherence to tamoxifen decreased from 65% at year 1% to 18% at year 5. Factors associated with low adherence were lack of social support, age ≤ 60 years, and side effects. Compared to men who were adherent to tamoxifen, those with low adherence had significantly diminished overall survival (98% vs. 80%, respectively, $p = .008$) and disease-free survival (95% vs. 73%, respectively, $p = .007$). Sixty-four patients experienced side effects, including fatigue, anxiety, sleep disorders, decreased libido, and weight gain (42). Conversely, in a recent, large, population-based study of 158 cases of MBC, adjuvant tamoxifen was prescribed to 109 patients, and only 14 (11.7%) patients discontinued therapy due to toxicity, similar to a matched female control group (43).

Aromatase inhibitors are an established adjuvant treatment for postmenopausal female breast cancer and have been shown to be more effective than tamoxifen in preventing recurrence. In a retrospective study of 257 men with hormone-receptor-positive breast cancer, overall survival was significantly better with tamoxifen compared to an aromatase inhibitor at a median follow-up of 42.4 months. After adjusting for patient and tumor characteristics, aromatase inhibitor treatment was linked to a 1.5-fold increase in risk of mortality compared to tamoxifen (HR 1.55; 95% CI 1.13–2.13, $p = .007$). These findings may be related to insufficient suppression of estrogen levels in men by aromatase inhibitors, as 20% of estrogen is produced by the testes. Moreover, aromatase inhibitors lead to an increase in FSH and testosterone level, which may in turn increase the rate of aromatization (44). As such, tamoxifen remains the preferred agent in MBC when hormone therapy is indicated.

Studies concerning adjuvant chemotherapy are similarly limited in MBC. One report of 11 patients with stage 2 or 3 MBC treated with adjuvant cyclophosphamide, methotrexate, and 5-fluorouracil (CMF) showed favorable outcomes compared with historical controls. At the National Cancer Institute (NCI), 31 patients with axillary node-positive, stage 2 MBC were treated with adjuvant CMF chemotherapy for up to 12 cycles. At a follow-up of 20 years, the overall survival was shown to be 65% at 10 years, 52% at 15 years, and 42% at 20 years (45).

There are no data on the benefit of anthracyclines or taxanes in men with breast cancer.

The Oncotype DX breast cancer 21-gene assay using standardized quantitative RT-PCR was validated in women with early stage, node-negative hormone receptor positive breast cancer to estimate the likelihood of chemotherapy benefit. In a genomic study of 347 male and 82,434 female breast cancer patients with estrogen receptor positive tumors, the patterns of expression of the Oncotype DX genes were more similar than different between males and females. The proportion of tumors with low risk of recurrence based on the Recurrence Score was 53.6% in males versus 53.4% in females, intermediate risk of recurrence was 35.2% in males versus 36.3% in females, and high risk of recurrence was 11.2% in males versus 10.3% in females. Of note, mean expression of ER, PR, and proliferation genes (Ki-67, MYBL2, Survivin, Cyclin B1, and STK15) were higher in males. In conclusion, current recommendations for adjuvant chemotherapy options in women with early-stage breast cancer should be considered for men.

Trastuzumab, a humanized monoclonal antibody directed against the HER2 protein, was associated with a significant survival benefit in women with HER2-positive breast cancer, when combined with chemotherapy. The incidence of HER2 overexpression/amplification in MBC appears to be low, and there are no prospective data evaluating survival outcomes with adjuvant trastuzumab in MBC. In a study with 147 stage 1 to 3 MBC cases, 9 patients were known to overexpress HER2, and only 5 of these patients received trastuzumab with chemotherapy (43). Nonetheless, its use should be considered in men with HER2-positive breast cancer.

TREATMENT OF METASTATIC DISEASE

Hormonal manipulation has played a central role in the initial management of metastatic MBC due to the high incidence of hormone receptor positivity. Multiple reports of orchiectomy as treatment of metastatic MBC indicate response rates between 32% and 67%, with a median survival of 56 months in responding patients versus 38 months

in nonresponding patients. Other ablative surgical procedures have been evaluated in metastatic MBC, either as primary treatment or at the time of disease progression after orchiectomy. Adrenalectomy and hypophysectomy are associated with response rates of 76% and 58%, respectively. These surgical procedures are rarely used today due to the associated morbidity and the introduction of medical management of metastatic disease.

Tamoxifen is the endocrine treatment of choice in metastatic disease. Objective response rates as high as 81% have been reported in ER-positive MBC with tamoxifen treatment (46). Other agents, including aminoglutethimide, megestrol acetate, androgens, antiandrogens, steroids, and luteinizing hormone-releasing hormone (LHRH) analogs are associated with 50% to 70% response rates in ER-positive MBC.

Aromatase inhibitors are very active in women with hormone receptor-positive metastatic breast cancer, but their roles for men are less clear. One study of 15 patients treated with an aromatase inhibitor reported a complete response in 2 patients, partial response in 4 patients, and stable disease in 2 patients (response rate of 40%); activity correlated with significant reductions in estradiol levels (47). Current data suggest that aromatase inhibitors may be considered following progression on tamoxifen. The German Breast Group will conduct a prospective, randomized multicenter phase II study (GBG-54 MALE) evaluating tamoxifen with and without an LHRH analog versus an aromatase inhibitor with an LHRH analog in MBC. The role of fulvestrant, a selective estrogen receptor downregulator, is less clear. One case series described 14 men treated with fulvestrant in the second to fourth-line setting. In all cases, fulvestrant was well tolerated. Partial response was noted in 3 (21%) patients, stable disease in 7 (50%) patients, with a median overall survival of 62 months (48).

Treatment with chemotherapy should be considered for patients with ER-negative tumors, for those with rapidly progressing disease, and for patients refractory to hormone therapy, similar to principles for initiating chemotherapy in women. HER2-directed therapies including trastuzumab, pertuzumab and lapatinib, have not been formally studied in metastatic MBC. Using these agents in HER2-positive metastatic MBC is reasonable considering the significant survival benefit seen in women with metastatic breast cancer.

PROGNOSTIC FACTORS

Male and female breast cancers are staged according to the American Joint Committee on Cancer (AJCC) Staging System. Similar to women with breast cancer, stage, tumor size, and axillary lymph node status are important factors influencing outcome. This was illustrated in a report derived from the SEER database of 1,541 men with breast cancer. The breast cancer-specific mortality increased by stage: 1% *in situ,* 5% stage 1, 15% stage 2, 38% stage 3, and 57% stage 4 (49).

Molecular subtyping of breast cancer has emerged as a significant predictor of outcome in women. Because MBC is rare, large series elucidating the significance of molecular subtyping is lacking. Some studies have found the distribution of tumor subtypes in MBC to be different compared with female breast cancer, which may point to important differences in biology and outcomes (31). Furthermore, in one study of 197 patients, HER2 positivity was not associated with poorer outcome, even though the majority of patients had not received adjuvant chemotherapy or trastuzumab. Larger studies are required to validate these findings.

The risk of a contralateral breast cancer and second primary non-breast cancers appears to be increased in men with breast cancer. In a review of 4,873 MBCs from the SEER database, 93 (2%) were identified with a second MBC and 1,001 (21%) with a second primary cancer. This underlines the importance of continued long-term surveillance for a second breast cancer and appropriate screening for non-breast cancers in men.

Some reports have suggested that MBC has a worse prognosis than female breast cancer. From the SEER database, 6,157 cases of MBC were compared to 877,885 cases of female breast cancer from 1973 to 2008. Survival was significantly higher in female breast cancer compared to MBC but improved over time in MBC (1 year, 96% vs. 91%; 3 years, 85% vs. 80%; 5 years, 77% vs. 68%, respectively) (3). Conversely, in a case-control study of 144 patients (72 female, 72 male) with early-stage breast cancer, male patients received systemic therapy comparable to that received by their female counterparts. Disease-free and overall survival were similar, suggesting that male sex is not a poor prognostic factor for treatment outcomes (50).

Race/ethnicity may also influence breast cancer prognosis and treatment. It is known that black women have poorer survival when compared to white women. From the SEER data, one report illustrated that black and Asian men had lower 1 to 5 year survival compared to white men, despite similar treatment modalities. Notably, black and Asian men had a higher incidence of poorly differentiated histology compared to white men (19%, 20%, and 13%, respectively) (3). In an analysis of 510 MBC cases (456 white, 34 black), black men were approximately 50% less likely to undergo consultation with an oncologist and subsequently receive chemotherapy, however results did not reach statistical significance. After multivariate analysis, breast cancer-specific mortality hazard ratio was shown to be more than tripled for black versus white men (7).

MANAGEMENT SUMMARY

- A suspicious breast mass in a man must be evaluated by tissue sampling. Needle biopsy is the preferred method of diagnosis.
- Total mastectomy with SLN biopsy is the established surgical approach for most male cancers.
- Chest wall and regional lymph node irradiation should be given using the same criteria developed for use in women.
- Adjuvant systemic therapy recommendations are similar to those for women with the same stage of disease. For hormone receptor-positive tumors, adjuvant tamoxifen with or without chemotherapy should be recommended. Current recommendations for adjuvant chemotherapy options for women with early-stage breast cancer should be considered for men. Trastuzumab is indicated for HER2-positive MBC.
- In patients with metastatic disease, tamoxifen should be utilized as first-line treatment in hormone receptor-positive metastatic disease. The role for aromatase inhibitors and fulvestrant remains unclear. Chemotherapy should be recommended for rapidly progressing disease, hormone receptor-negative, or hormone-refractory disease. HER2-directed therapy should be used in HER2-positive advanced breast cancer.

CHAPTER 62

Phyllodes Tumors

Kristine E. Calhoun, Kimberly H. Allison, Janice N. Kim, Habib Rahbar, and Benjamin O. Anderson

CHAPTER CONTENTS

PHYLLODES NOMENCLATURE

Phyllodes tumors are fibroepithelial breast tumors capable of a diverse range of biological behavior. Also termed "phylloides tumors" or "cystosarcoma phyllodes," these lesions are similar to benign fibroadenomas in their least aggressive form, but with an increased propensity for local recurrence following excision. Although the original term, "cystosarcoma phylloides," coined by Johannes Müller in 1838 was used to describe the tumor's grossly fleshy physical appearance, it was not intended to indicate metastatic potential as is typically implied by the term "sarcoma" (1). Phyllodes tumors in their most aggressive form, however, can recur locally and distantly, typically degenerating into a sarcomatous lesion lacking an epithelial component (2). Fortunately, this malignant form of phyllodes is uncommon, with fewer than 5% of lesions ever developing distant metastases (3). Various histologic classification schemes have been used to subtype phyllodes based on histologic features that have been associated with clinical behavior. The World Health Organization (WHO) recommends classification of phyllodes into three subtypes as follows: benign phyllodes, borderline phyllodes (also known as "low grade malignant") and malignant phyllodes (also known as "high grade malignant") (4).

PATHOLOGIC CHARACTERISTICS

Macroscopic Appearance

Nonmalignant phyllodes tumors typically have a gross appearance similar to fibroadenomas, presenting as a circumscribed, round or oval mass that lacks a true histologic capsule but which generally can be easily shelled out from surrounding tissues. Malignant forms have less circumscription and often gross infiltration of surrounding breast tissue. In contrast to the classic stellate, depressed gross appearance of an invasive carcinoma of the breast, phyllodes tumors typically bulge from the surrounding tissue when cut and have a multi-nodular, fleshy appearance. Most phyllodes tumors are detected in the 1 to 2 cm range but there are reports in the literature of lesions ranging from less than 1 cm up to 40 cm (5).

Microscopic Appearance

Histologically, phyllodes tumors have a broad range of appearances, from those that resemble fibroadenomas to others that appear as outright sarcomatous lesions. Like fibroadenoma, phyllodes tumors are fibroepithelial lesions composed of both stromal and epithelial components, with both layers capable of manifesting a range of histopathologic

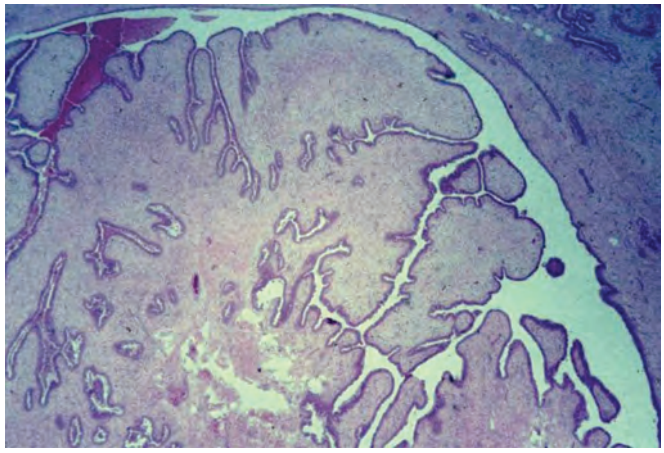

FIGURE 62-1 Phyllodes tumor illustrating characteristic "leaf-like" architecture. This histopathology image is from the borderline phyllodes tumor surgical case shown in Figure 62-5.

changes. The characteristic "leaf-like" architecture of phyllodes tumors is the result of a stromal proliferation with formation of elongated cleft-like spaces lined by epithelium that extend into cystic spaces (Fig. 62-1). This leaf-like, or intracanalicular, growth pattern may not be present in all tumors, particularly those toward the malignant end of the spectrum, where the epithelial component is typically minimal or absent (Fig. 62-2). The epithelium is generally single layered, but hyperplasia, atypical hyperplasia, *in situ* carcinoma, and/or epithelial metaplasia may be seen as well (6–7). It is the stromal characteristics rather than the epithelial features, however, which determine WHO subclassification and clinical behavior of phyllodes tumors.

Histologic Classification

Numerous studies have attempted to determine which histologic features of phyllodes tumors are useful in predicting clinical behavior (8–12). The WHO classification of phyllodes tumors is based on characterization of multiple features of the stromal component of the lesion including degree of stromal cellular atypia, mitotic activity per 10 high-power fields (hpfs), presence or absence of stromal overgrowth, defined as a single 40X field of pure stroma devoid of epithelium, and infiltrative versus circumscribed tumor margins (Table 62-1). Benign phyllodes tumors (low-grade lesions) are characterized by increased stromal cellularity with no more than mild to moderate cellular atypia, circumscribed tumor margins, low mitotic rates (generally less than 4/10 hpf), and a lack of stromal overgrowth. Borderline phyllodes tumors are characterized by a greater degree of stromal cellularity and atypia, microscopically circumscribed or infiltrative borders, and mitotic rates in the 4–9/10 hpf range, but a lack of stromal overgrowth (Fig. 62-3). Malignant phyllodes tumors (high-grade lesions) are characterized by marked stromal cellularity and atypia, infiltrative borders, high mitotic rates (generally greater than 10/10 hpf), and areas of stromal overgrowth (Fig. 62-2). Over 50% of lesions are classified as benign in most large series. Alternatively, some authors continue to refer to tumors as low-, intermediate-, or high-grade lesions as advocated by Azzopardi and Salvadori (13,14). Unfortunately, some tumors do not fit neatly into one of these three categories and tumors can have a range of behaviors within each category.

Immunohistochemistry

There has been interest in identifying immunohistochemical markers that can predict outcome. However, most of the markers identified to date are associated with grade of phyllodes lesions and have not proven to have clinical utility in predicting outcome. Increased MIB1 (Ki-67), p53, c-kit (CD117), and EGFR expression have all been associated with higher grade lesions (15–22). To date, no marker has been found to conclusively and reproducibly classify lesions or predict recurrence and metastasis.

Molecular Characteristics of Phyllodes Tumors

Due to their similarity to fibroadenomas, and the heterogeneity that can exist in any given phyllodes tumor, many theorize that phyllodes tumors arise from preexisting fibroadenomas. Studies have suggested phyllodes tumors can progress from fibroadenomas based on clonal analysis of the stroma and loss of heterozygosity analyses (23,24). Whether all phyllodes tumors originate as fibroadenomas or conversely start *de novo* is still a matter of debate.

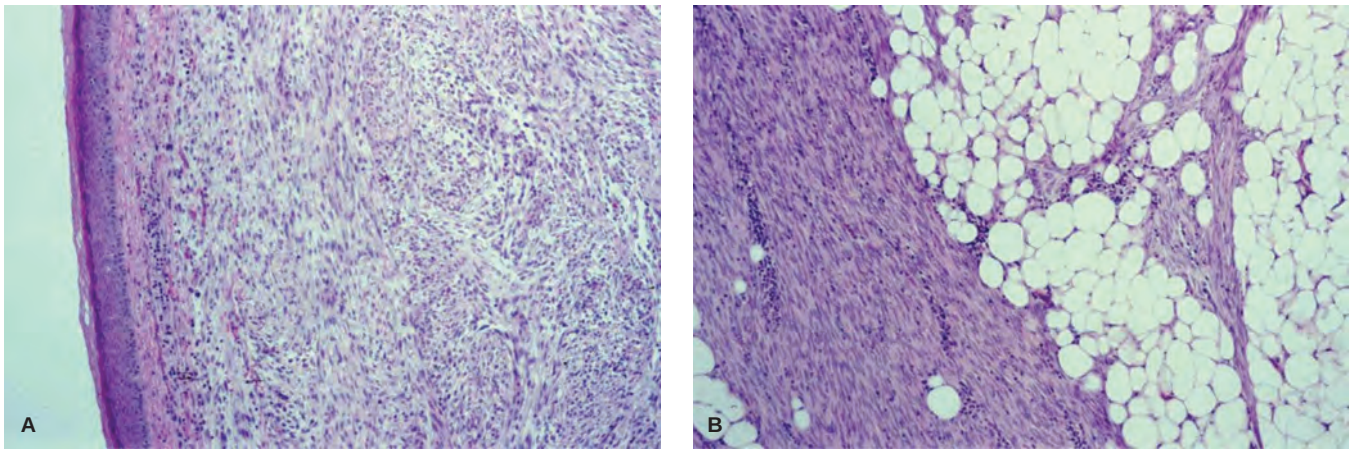

FIGURE 62-2 Recurrent malignant phyllodes tumor showing **(A)** dermal infiltration and **(B)** stromal overgrowth with infiltration of surrounding fatty breast tissue. Note the loss of epithelial elements from this recurrent tumor. These histopathology images are from the surgical case illustrated in Figure 62-8.

TABLE 62-1

Histologic Features Used in the WHO Classification of Phyllodes Tumor Subtypes

Histologic Features	*Benign*	*Borderline*	*Malignant*
Stromal cellular atypia	Mild	Marked	Marked
Mitotic activity	<4 10 hpf	4–9 10 hpf	≥10 10 hpf
Stromal overgrowth	Absent	Absent	Present
Tumor margins	Circumscribed	Circumscribed or infiltrative	Infiltrative

More recent gene expression profiling data looking at the spectrum of phyllodes tumors supports the categorization of phyllodes tumors into benign, borderline, and malignant categories (25). Genes important in differentiating these categories are related to matrix production, cell adhesion, epidermis formation, and cell proliferation. Chromosomal changes associated with malignant phenotypes of phyllodes tumors have also been identified, with 1q gains being more common in the borderline and malignant categories and in general increasing numbers of chromosomal alterations with increasing malignancy. However, because these changes are often unique, characteristic genetic changes that could be useful in classification and prognosis have not yet been reproducibly identified.

Differential Diagnosis

The differential diagnosis for benign phyllodes tumors includes cellular fibroadenoma and juvenile fibroadenoma. Distinction of benign phyllodes tumors from fibroadenoma variants can be challenging. Cellular fibroadenomas have increased stromal cellularity, generally lack the prominent intracanalicular (leaf-like) growth pattern of phyllodes tumors and have a negligible mitotic rate (although some authors allow for rare mitotic figures up to 3/10 hpfs). Juvenile fibroadenomas are similar but are characterized by pronounced epithelial hyperplasia. Phyllodes tumors can also be quite heterogeneous, with areas indistinguishable from classic fibroadenoma and other areas of more clearly atypical stromal elements.

On the malignant end of the spectrum, the main differential diagnosis includes metaplastic carcinoma. This differential can be especially challenging when a malignant spindle cell lesion is present without identifiable epithelial elements. Usually, identification of a typical infiltrating ductal carcinoma or residual phyllodes tumor architecture can help distinguish between metaplastic carcinoma and phyllodes tumor. For cases in which only malignant stroma is present, a panel of immunostains including cytokeratins can also assist in this differential diagnosis.

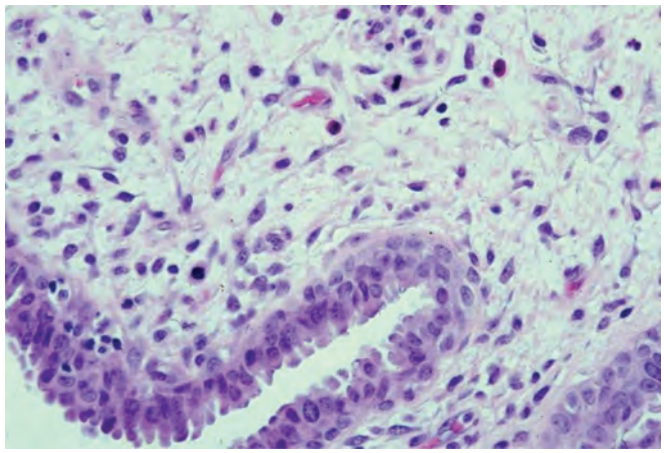

FIGURE 62-3 Borderline phyllodes tumor demonstrating intermediate level of mitotic activity and lacking stromal overgrowth. This histopathology image is from the surgical case illustrated in Figure 62-5.

CLINICAL CHARACTERISTICS

Incidence

Phyllodes tumors are uncommon breast masses, accounting for 0.3% to 1% of breast tumors in females. In one review of 8,567 breast cancer cases treated between 1969 and 1993, only 32 cases of phyllodes tumors (0.37%) were identified among 31 patients (26). More recent series have reported numbers ranging from 33 to 821 patients (27–29). A population-based study from California noted a higher risk in Latino than in white or Asian women (30), while another study found a propensity for higher grade tumors among Hispanic patients (31). Phyllodes tumors have been reported in males but are extremely rare, occurring in conjunction with gynecomastia and lobular development in male breast tissue (32).

Most patients with phyllodes tumors tend to be in their 40s, a decade or so older than women diagnosed with palpable fibroadenomas. While those with benign phyllodes lesions are typically up to a decade younger than those with malignant tumors, these tumors have been reported in prepubertal females as well as elderly patients (Fig. 62-4).

Clinical Presentation

Typically, phyllodes tumors present as painless, palpable masses in the breast that demonstrate continuous growth, although some individuals may report rapid growth in a previously stable, long-standing nodule (3). Often, the history will be that of a breast mass with rapid clinical progression, growing to a relatively large size in a matter of a few months.

The mass may produce visible bulging when tumors expand quickly (Fig. 62-5A). Although tumors may grow quickly, rapid growth does not necessarily indicate malignancy. Shiny, stretched, and attenuated skin with varicose veins can overlie a phyllodes tumor as it pushes against the skin. In neglected cases, skin ulceration may develop from ischemia secondary to stretching and pressure. Such skin changes can occur with all types of lesions, so while ulceration associated with carcinoma is an indication of malignant behavior (T4 lesion), it is not necessarily an indication of a malignant phyllodes tumors. The nipple may be effaced, but invasion and/or retraction is unusual (3), as is bloody nipple discharge.

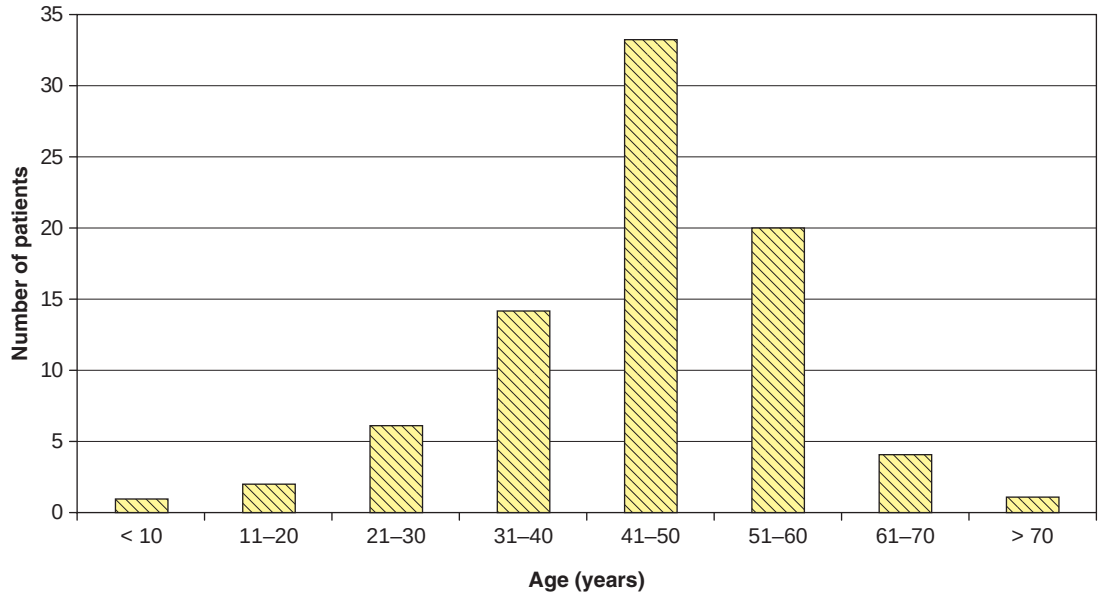

FIGURE 62-4 Age distribution of women diagnosed with phyllodes tumors. (Modified from Salvadori B, Cusumano F, Del Bo R, et al. Surgical treatment of phyllodes tumors of the breast. *Cancer* 1989;63(12):2532–2536.)

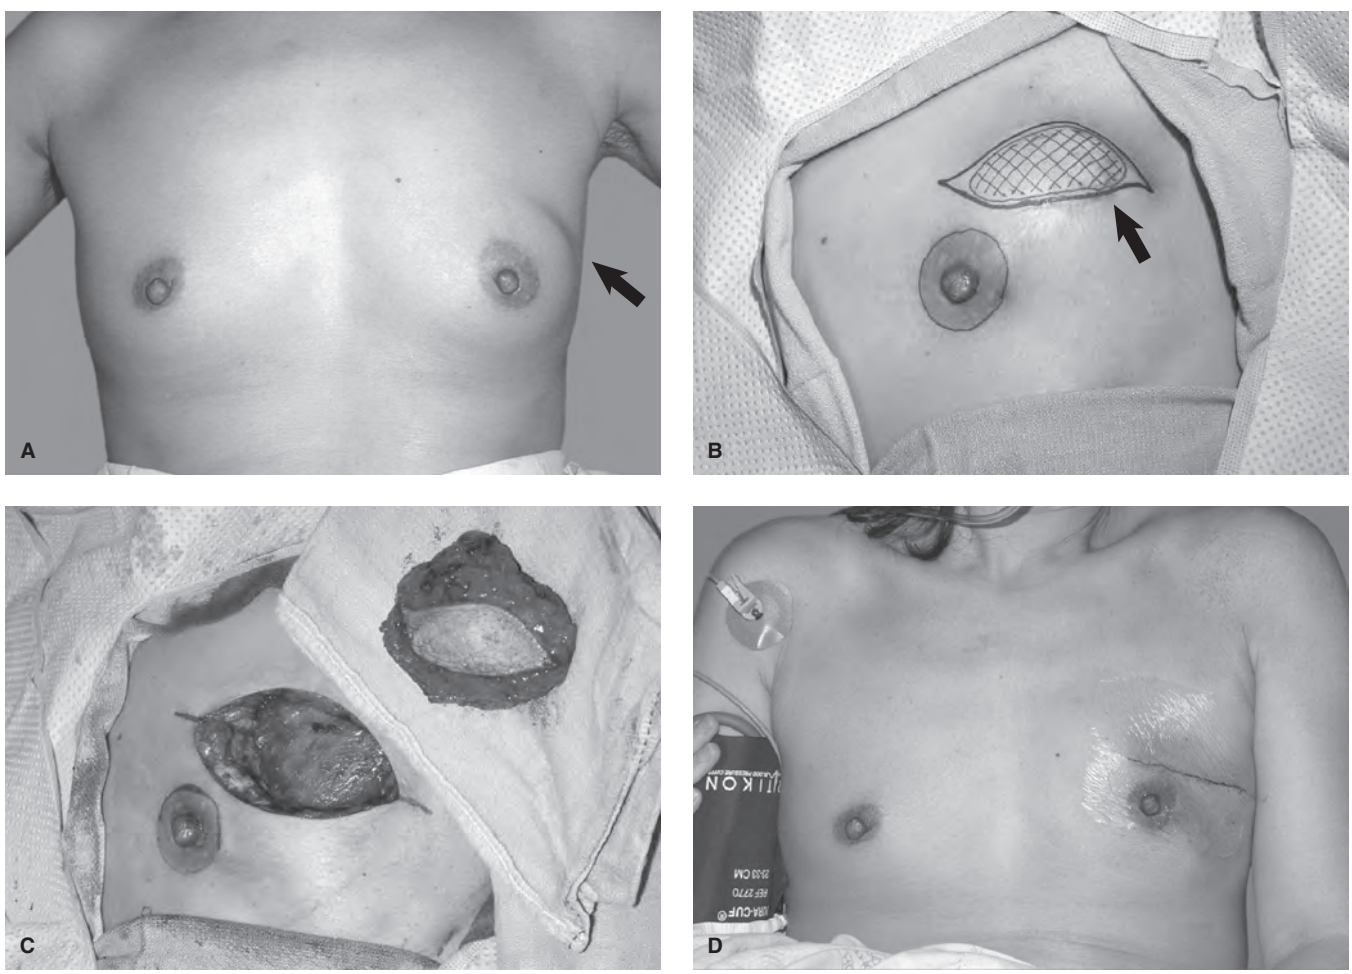

FIGURE 62-5 Presentation and excision of a primary phyllodes tumor. A 44-year-old female presented with a palpable mass in the left upper outer quadrant, which had grown from 2.4 to 5.2 cm over 6 months. Imaging and core needle sampling at first presentation were interpreted as "fibroadenoma." The final pathology on excision was a borderline phyllodes tumor. **(A)** Preoperative presentation with bulging mass apparent on inspection. The mass is located in the upper outer quadrant (*arrow*). **(B)** Operative preparation showing the borders of palpable tumor (*hatch marks*) and planned skin excision (*outer line*), which is located immediately superficial to the mass. **(C)** Operative excision down to level of pectoral fascia. **(D)** Postoperative closure with flap advancement mastopexy closure.

Risk Factors

No clear risk factors for the development of phyllodes tumors have been identified in the general risk population. Patients with germline p53 mutations (Li-Fraumeni syndrome) are at increased risk for developing these lesions, but this represents only a small portion of diagnosed tumors (33).

Associated Tumors and Bilaterality

Bilateral phyllodes tumors (synchronous or metachronous) have been reported but are uncommon. An Memorial Sloan Kettering Cancer Center (MSKCC) series of 293 patients found only 10 individuals (3.4%) with bilateral lesions (34). Typically, concurrent tumors have similar histology, but in one documented case, a patient presented with a benign phyllodes tumor in one breast and a synchronous malignant phyllodes tumor in the other (35).

Patients can present with phyllodes tumors as well as separate noninvasive (36) or invasive breast carcinoma lesions (37). Occasionally, foci of intraductal and/or invasive carcinoma may also be found in association with a malignant phyllodes tumor (38). Because phyllodes tumors are so uncommon, it is unclear if there is any physiologic connection between these and other breast tumors when they occur in the same patient, such as a familial genetic abnormality predisposing to both lesions. Finally, pregnancy associated phyllodes tumors are rare, with fewer than 10 reported in the literature (39).

DIAGNOSIS

Clinical Features

Preoperative clinical suspicion of a phyllodes tumor is helpful but, because the lesions resemble fibroadenomas both on imaging and tissue sampling, this can be challenging. Short of being suspicious due to the large size of the mass or rapid growth of a pre-existing lesion, the majority of phyllodes tumors will be diagnosed postoperatively. In an individual series of 21 cases, only 6 (29%) were successfully identified before surgery on the basis of clinical features and/or preoperative diagnostic investigations (40). Most phyllodes tumors, therefore, are surgically "shelled out" (enucleated) at initial intervention, resulting in the inadequate surgical margins associated with an increased risk of local recurrence in the absence of additional surgery.

Imaging Features

On imaging, phyllodes tumors commonly resemble large fibroadenomas (Fig. 62-6A), and there are no distinct imaging characteristics that can reliably distinguish benign from malignant phyllodes tumors (41). Like fibroadenomas, phyllodes tend to present mammographically as round, oval, or lobular-shaped masses with circumscribed margins (Fig. 62-6B), and occasionally contain calcifications (41,42). Sonographically, phyllodes tumors present as oval or round-shaped, hypoechoic, well-circumscribed, solid masses (Fig. 62-6C) that may contain scattered cystic regions (41–43). Although large size (>3 cm) and presence of intramural cystic regions or clefts make the diagnosis of phyllodes tumor more likely, these features can also be present in fibroadenomas. Thus, any circumscribed mass presenting on imaging with large initial size or significant interval growth warrants excision to rule out phyllodes tumor.

On magnetic resonance imaging (MRI), phyllodes tumors typically present as oval, round, or lobular shaped masses with smooth margins and intrinsic high signal intensity on T2- weighted images (Fig. 62-7). On dynamic contrast-enhanced images, both phyllodes and fibroadenomas most commonly exhibit slow initial phase enhancement with persistent and progressive delayed phase enhancement, a pattern typical of a benign process (Fig. 62-7B,C) (44). Although MRI may more accurately delineate the true extent of disease prior to surgery, there is little data to support the routine use of MRI for imaging phyllodes tumors. MRI may be most helpful when mastectomy is being considered and the full extent of the tumor is difficult to determine from standard imaging. Because a pathologic hallmark distinguishing phyllodes from fibroadenomas is greater cellularity, an emerging MRI technique sensitive to cell density, called diffusion-weighted imaging, could prove useful in the future for predicting phyllodes tumor risk on imaging (45).

Fine Needle Aspiration (FNA) and Core Needle Biopsy

Image-guided needle sampling of phyllodes tumors often yields histologic features that can be ambiguous. In the case of FNA, cytologic features suggestive of phyllodes, such as hypercellular stromal fragments and multinucleated giant cells, are not specific enough to be used as the sole diagnostic criteria in making this distinction (46,47). In addition, because cytology of tumors with cystic degeneration shows foamy macrophages, apocrine cells, and thick fluid in the background, aspirates from some phyllodes tumors may erroneously be labeled "fibrocystic change" resulting in diagnostic error on FNA (48). Ultimately, the final pathologic assessment frequently hinges on examination of the complete surgical excision specimen. Perhaps the greatest role of image-guided biopsy in cases of suspected phyllodes is to provide the surgeon a preoperative pathologic index of suspicion that will guide surgical technique. Lesions that definitively can be diagnosed as phyllodes tumors on image-guided sampling can be excised with wide margins, whereas more equivocal lesions on pathology may be enucleated for definitive diagnosis (if clinical suspicion is also low) as is typically performed for fibroadenomas.

TREATMENT

Surgical Excision and Margins

The core principle of local therapy for all classifications of phyllodes tumors is local excision to negative margins to achieve definitive local control. Most studies advocate at least a 1-cm margin, which has traditionally been accepted as an adequate resection. Mangi and colleagues found that recurrence correlated with excision margin, showing that among 40 patients, local recurrence occurred in 5, each of whom had margins less than 1 cm following definitive resection. These 5 patients remained free of disease after reexcision to a 1-cm margin (49). The desired 1-cm margin width is based on retrospective analysis. Because these lesions are rare, any trial to study optimal margin width is impractical. A pseudocapsule of dense, compressed, normal tissue containing microscopic projections of the lesion commonly surrounds phyllodes tumors. As a result, more tissue typically needs to be removed in order to achieve the desired histologic margin than might be predicted on the basis of preoperative physical examination or imaging findings (50). Some authors actually argue that 2-cm should be considered the standard of care for desired surgical margin for excision of phyllodes tumors, with a goal of a 2–3-cm margin if a phyllodes tumor locally recurs (Table 62-2) (3). An investigation from Germany identified 8 of 33 patients with local recurrence, with 7 of the 8 having less than a 2-cm margin at initial resection (28). In practice, margins of 2 to 3 cm can be difficult

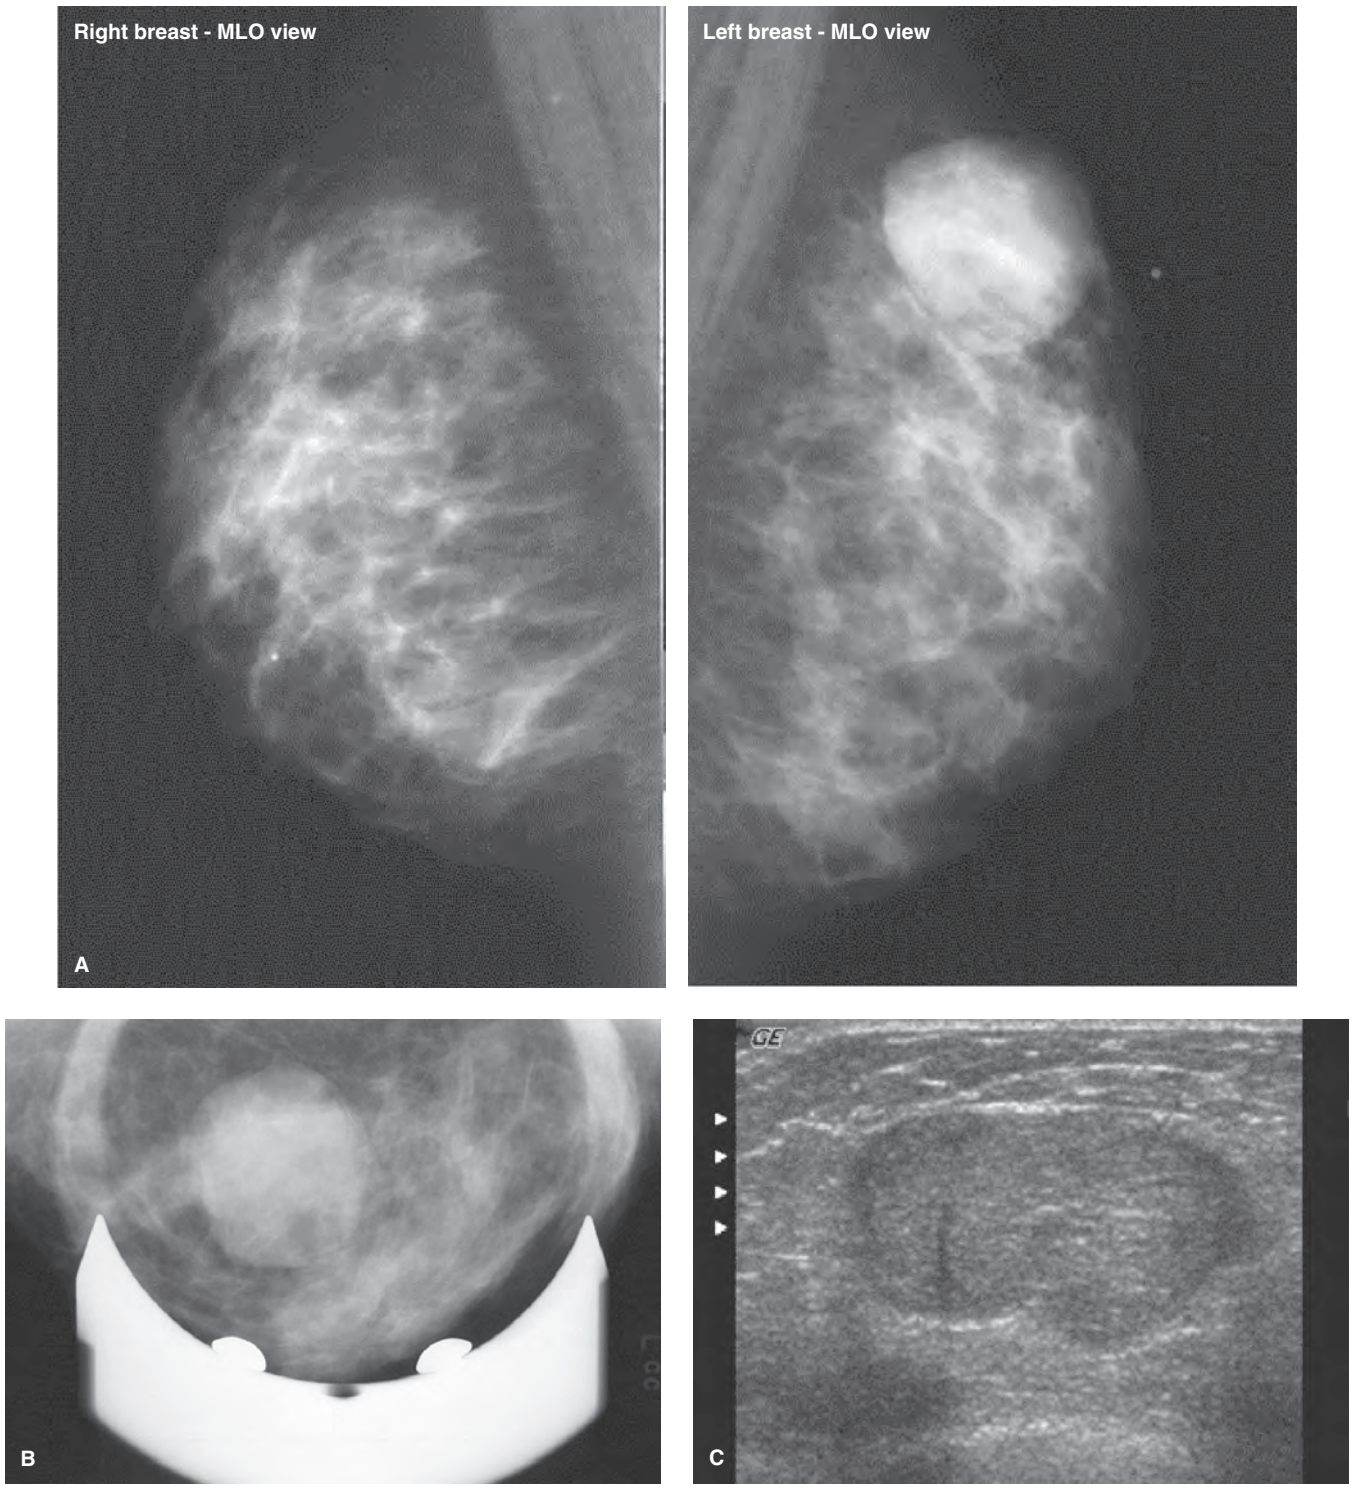

FIGURE 62-6 Standard imaging studies of a phyllodes tumor. **(A)** Bilateral mammogram, MLO view, demonstrating circumscribed round mass at 12 o'clock in left breast, biopsy proven phyllodes tumor. **(B)** Spot compression mammographic view of phyllodes tumor from (A). **(C)** Ultrasound image of a 2.4-cm phyllodes tumor, showing typical sonographic features including oval shaped solid mass with circumscribed margins.

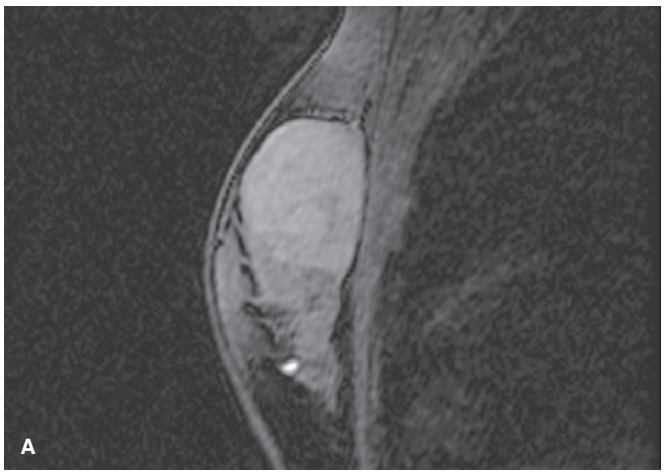
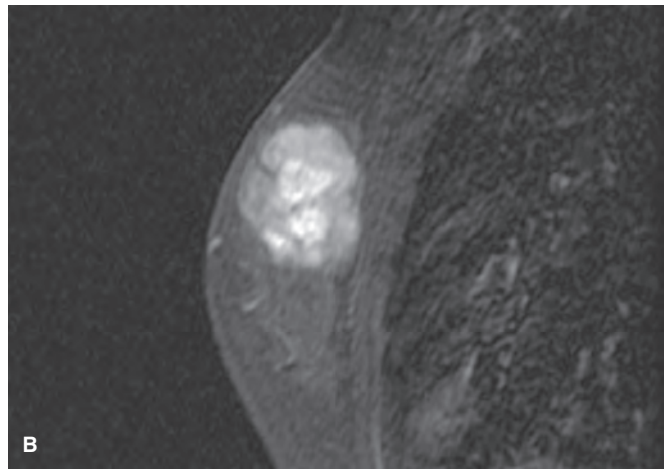
to achieve with good cosmesis, except when the breast is quite large and the tumor favorably located.

Although not the current standard of care, at least one series has reported the use of ultrasound-guided, vacuum assisted breast biopsy for management of benign phyllodes tumors. Benign tumors that were excised completely in this manner were followed, and only 1 out of 31 tumors had recurred after a mean of 6 years (51).





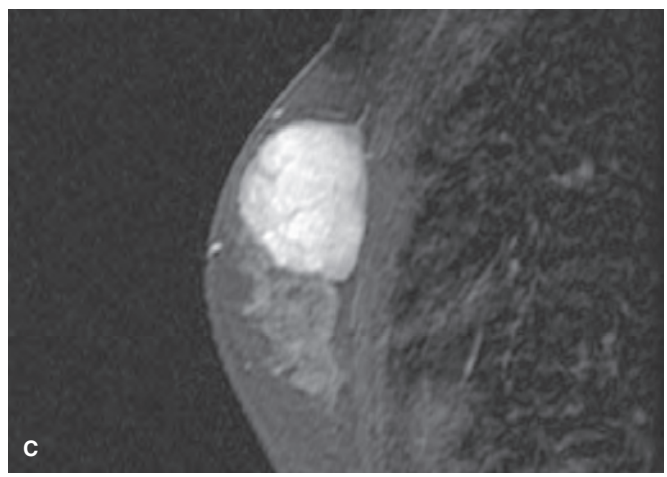


FIGURE 62-7 Sagittally-oriented MRI images of a phyllodes tumor. **(A)** Pre-contrast, **(B)** 2 minutes post-contrast, **(C)** 5 minutes post-contrast. Note the persistent and progressive enhancement of the phyllodes tumor on the delayed post-contrast images. These MRI images are from the surgical case illustrated in Figure 62-5.

Reexcision Following Narrow Margin Excision

Approximately 20% of phyllodes tumors recur locally if excised with inadequate margins. The proportion of recurrences appears to be somewhat higher with borderline or malignant varieties and lower with benign phyllodes tumors (52), with most authors demonstrating a benefit to negative margin resection for all histologic types secondary to all lesions having a propensity to recur with anything short of wide local excision (Table 62-2).

Technical Considerations in Lumpectomy

In order to achieve 1 cm or greater surgical margins with lumpectomy, special approaches may be necessary, particularly when a phyllodes tumor develops in a smaller breast. Tunneling through the fibroglandular tissue from a periareolar incision is contraindicated with phyllodes tumor excisions because of the potential for tumor seeding. Even a curvilinear incision directly over the mass without removal of skin may be too small to obtain adequate surgical margins,

TABLE 62-2

Factors Associated with Risk of Local Recurrence

or may leave excessive redundant skin behind when a large section of fibroglandular tissue is removed (Fig. 62-5A). Full thickness excisions from skin to chest wall muscle can be very helpful in achieving the 1 cm desired surgical margins. This approach allows *en bloc* removal of skin, tumor, and surrounding fibroglandular tissue in an oncoplastic fashion (Fig. 62-5B). The excision is then carried out full thickness from the skin island, widely around the mass, and down to and including the pectoral muscle fascia (Fig. 62-5C).

Breast Conservation versus Mastectomy

In the M. D. Anderson experience of 101 patients with phyllodes tumors (2), surgery included local excision with breast conservation (47%) or mastectomy (53%). Local recurrence occurred in 4 patients, with an actuarial 10-year rate of 8%. The investigators concluded that local failure was uncommon, showing that breast-conserving surgery with negative margins is the preferred primary therapy. Kleer and colleagues found that malignant phyllodes tumors have a favorable prognosis if widely excised without mastectomy (18). Multiple additional series have also failed to show a benefit to mastectomy over lumpectomy in patients who are otherwise good breast conserving therapy candidates, regardless of tumor histology, provided negative surgical margins can be achieved with lumpectomy (34).

Axillary Staging

Routine axillary dissection is unnecessary in patients with phyllodes tumors (26,53). While axillary nodes are palpable in 20% of cases, fewer than 5% will actually have histological nodal involvement (49), with one SEER study demonstrating a 3.4% incidence of node positivity among 1,035 phyllodes tumors over a 16 year period (54). In another series of 45 patients with phyllodes tumors who underwent axillary staging, none were found to have axillary metastases (55). If suspicious lymph nodes are identified clinically or on imaging studies, directed axillary ultrasound with fine needle aspiration (56) or, preferably, core needle sampling can be performed. If this work-up is negative, sentinel lymph node biopsy can be considered if there is still reason to believe that the axillary nodes are involved. In the absence of such suspicion, neither sentinel node biopsy nor axillary node dissection are considered standard care in the surgical management of the clinically node-negative patient with phyllodes tumors.

Adjuvant Radiation Therapy

Overall, the role of radiation therapy for phyllodes tumors remains unclear, with the majority of data derived from single-institution retrospective studies (57). For benign phyllodes tumors managed conservatively with surgery alone, adjuvant radiotherapy appears unnecessary when adequate margins are achieved. Similarly, most authors show that treatment of borderline and malignant phyllodes tumors with mastectomy alone yields excellent local control rates (2,58). Unfortunately, with lumpectomy alone, local control rates appear worse for borderline and malignant phyllodes patients (58). One study endorsed the use of adjuvant radiotherapy after breast conserving surgery for borderline or malignant phyllodes tumors larger than 3 cm, with local recurrence rates of 45% with conservative surgery alone (28), while another demonstrated the benefits of post lumpectomy radiotherapy in the treatment of malignant phyllodes tumors with a local failure rate as low as 12% (59). A prospective, multi-institutional study of borderline and malignant phyllodes tumors evaluated 46 patients who underwent breast conserving surgery with negative surgical margins, revealing that adjuvant radiotherapy improved local control with no recurrences reported at 56 months of median follow-up (60).

Adjuvant radiation therapy may be considered appropriate treatment for selected locally recurrent phyllodes tumors, such as following mastectomy (Fig. 62-8). Unfortunately, recurrent phyllodes tumors arise so infrequently and the biologic profiles of recurrent phyllodes tumors are so heterogeneous that no large series of locally recurrent phyllodes tumors is ever likely to be collected.

If adjuvant radiotherapy is utilized, it would be reasonable to use the guidelines for soft tissue sarcomas, which entail treating the entire breast tissue or chest wall in the radiation fields to deliver 50 to 50.4 Gy in standard daily fractions. After completion of the primary fields, treatment would proceed with a generous tumor bed or mastectomy scar boost with an additional 10 to 20 Gy.

Combined Therapy

Some reports have supported the use of combined chemoradiation following phyllodes tumor recurrence. In one case study of a locally recurrent malignant phyllodes tumor, neoadjuvant hyperfractionated radiotherapy, superficial hyperthermia, and ifosfamide were administered after the second local recurrence of this tumor. Resection of the tumor bed revealed a pathologically complete response with an actual disease free follow-up of 48 months (61).

Adjuvant Endocrine Therapy

Phyllodes tumors variably express steroid receptors, but there is no known value to adjuvant endocrine therapy with tamoxifen or aromatase inhibitors (62). There would be little rationale for using these drugs because steroid receptor protein expression decreases with increasing malignancy, they are primarily expressed by the epithelial component of phyllodes tumors, and only the stromal component of phyllodes tumors metastasizes. Overall, the systemic treatment principles of phyllodes tumors are driven by similar principles to those governing the management of soft tissue sarcoma.

Systemic Therapy

Chaney and colleagues observed that some patients, especially those with stromal overgrowth, particularly when the tumor size was more than 5 cm, had higher rates of distant failure. These authors suggested that such patients merit consideration of a trial that examines the efficacy of systemic therapy, even in the absence of metastatic involvement (2). Burton and colleagues found that two of three patients with metastases achieved effective palliation when treated with cisplatin and etoposide combination chemotherapy (62). The current National Comprehensive Cancer Network (NCCN) guidelines suggest that patients with metastases be managed according to the Soft Tissue Sarcoma Clinical Practice Guidelines in Oncology (63).

RECURRENCE AND PROGNOSIS

Local Recurrence Following Resection

Recurrence of phyllodes tumors is possible for all lesions (27,34), with recurrence rates as high as 46%. A 13-year institutional review found 27 women diagnosed with 19 (73%) benign, 3 (12%) borderline, and 4 (15%) malignant lesions. Of the 26 cases followed for a mean period of 37 months, 4 (16%) recurred at a mean time of 9 months following surgery, occurring among all histologic subtypes (1 benign, 1 borderline, and 2 malignant lesions) (64). In another series,

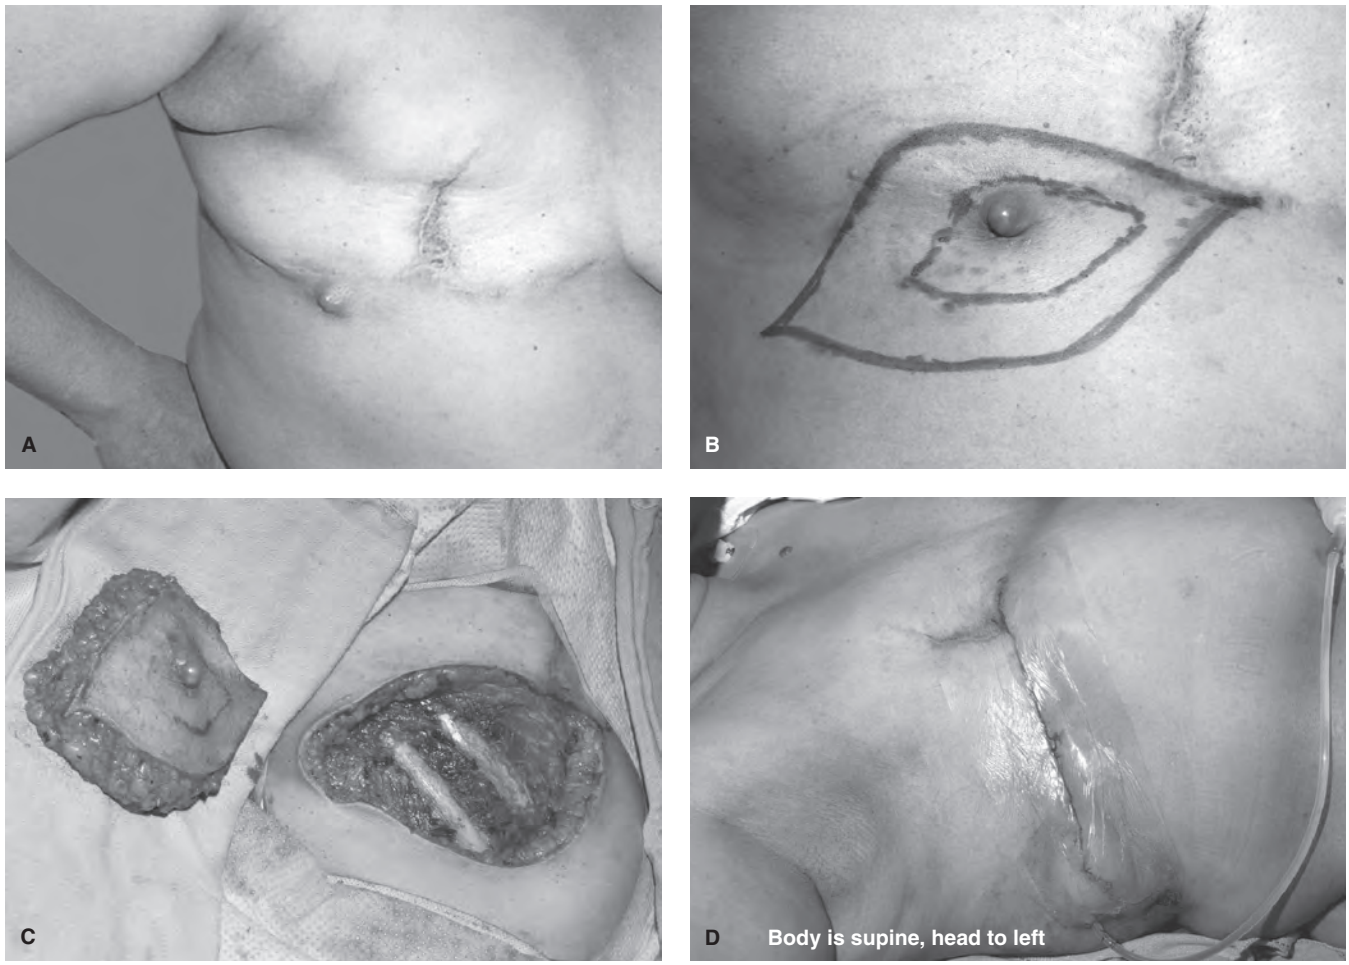

FIGURE 62-8 Presentation and excision of a malignant phyllodes tumor that recurred locally following mastectomy. At age 37, this patient had a palpable breast mass surgically shelled out. The mass proved to be a malignant phyllodes tumor and was re-excised with a partial mastectomy. The mass recurred in the lumpectomy site 15 months later. A subsequent mastectomy was performed using a three-sided incision to facilitate wide excision down to the level of skeletal muscle. Despite this second reexcision, the mass recurred again within 23 months, this time adjacent to the mastectomy incision. **(A)** Recurrent nipple-like mass growing inferior to lateral limb of mastectomy incision. In addition to the protuberant mass, the tumor extends under the skin into the surrounding soft tissue and fat. **(B)** Operative preparation showing palpable edge of subcutaneous tumor (inner ring) and planned skin excision (outer ring). **(C)** Full thickness operative excision including skin, soft tissue, and skeletal muscle excised down to the level of the ribs. **(D)** Soft-tissue advancement flap closure with subcutaneous drain.

local recurrence developed in three of 21 cases (15%) and was not associated with patient age, tumor size, or histological subtype (40). Time to recurrence corresponds to the degree of histologic differentiation. In a Milan series of 216 patients operated on between 1970 and 1989, the average disease-free interval was 32 months for benign phyllodes tumors, 22 months for malignant, and 18 months for borderline phyllodes tumors (65).

Although surgical margins remain the best predictor of local recurrence, two studies suggest that tumor necrosis is also linked to an increased local recurrence risk. "Fibroproliferation" has been defined as the presence of coexisting fibroadenoma or fibroadenomatoid change in the breast tissue surrounding a phyllodes tumor (34). In the large phyllodes series of 293 patients from Memorial Sloan-Kettering with median follow-up of 42 months, fibroproliferation was found to be significantly associated with a higher actuarial local recurrence rate. While no other series have described fibroproliferation as a local recurrence risk factor, this histologic feature was not specifically analyzed or referenced in prior studies (Table 62-2). In addition, Geisler and colleagues observed that there was a trend toward a higher rate of locoregional recurrences and metastases with high-grade lesions, but neither high grade nor large tumor size was a statistically significant predictor of recurrence or survival (26).

When phyllodes tumors recur after lumpectomy, wide reexcision is performed if possible, although management sometimes requires mastectomy. When phyllodes tumors recur after mastectomy, full thickness soft tissue excision from skin to rib cage may be necessary to achieve 1 cm

TABLE 62-3

Factors Associated with Risk of Metastatic Recurrence

margins (Fig. 62-8). Soft tissue advancement flap closure is typically necessary to close the defect (Fig. 62-8D) and, in some cases, skin grafting or more complex reconstructive approaches are needed.

Distant Metastases

In the M. D. Anderson series of 101 patients, 8 patients developed distant metastases, with an actuarial 10-year rate of 13% (2). Overall survival in the series was 88%, 79%, and 62% at 5, 10, and 15 years, respectively. For patients with nonmalignant (benign or borderline) and malignant phyllodes tumors, the overall survival was 91% and 82%, respectively, at 5 years, and 79% and 42%, respectively, at 10 years.

Prognosis is uniformly poor if metastatic disease develops. In a review of 67 reported cases of metastatic phyllodes tumors, Kessinger and colleagues reported that the average survival time after diagnosis of metastasis was 30 months. Metastatic lesions have been reported as early as initial presentation of the primary tumor and as late as 12 years after diagnosis. The longest reported survival time after development of metastatic disease is 14.5 years (66).

Stromal overgrowth, which is a required feature for malignant phyllodes tumors, is the most consistent histologic predictor of metastatic behavior (Table 62-3) (2,28,67–70). In the M.D. Anderson series, large tumor size, infiltrative borders, necrosis, and increased mitotic index were associated with increased metastatic risk, but only stromal overgrowth was an independent predictor of distant failure in multivariate analysis.

The lung is the most common site of phyllodes tumor metastases. As with sarcomas, distant pulmonary metastases may be resectable for cure in selected cases (71).

Other metastatic sites can include bone, liver, heart, distant lymph nodes, distant soft tissue locations such as the forearm, the thyroid, and the pancreas (66,70,72). Although these lesions rarely metastasize to the brain or central nervous system (CNS), such occurrences are refractory to therapy, and carry a dismal prognosis (73).

Predictive Recurrence Models

While several have been studied, no individual, or combination of, immunohistochemical tumor markers has been found to be more predictive of metastasis than standard histologic analysis. Multifactor scoring systems have been proposed to better predict recurrence risk for phyllodes tumors. Meneses and colleagues developed a system for assessing degree of histological aggressiveness based on specific histological parameters, including stromal-to-gland ratio, tumor margins, mitotic index, and degree of stromal pleomorphism (55). The relative risk for recurrence was 6.0 for intermediate (borderline) lesions and 11.4 for malignant lesions when compared with the benign category. It is unclear to what degree this system actually changes clinical management, where the principles remain those of wide surgical excision without axillary sampling or dissection.

Patient Follow-Up

After resection of a phyllodes tumor, patients should be followed for local recurrence in the original tumor bed, which generally will be apparent on clinical examination. August and Kearney recommend clinical breast examinations and breast imaging studies twice per year for the first 5 years, then on an annual basis (50). Routine breast ultrasound examination of the lumpectomy site can be considered, or can be reserved for diagnostic work-up of clinical findings. If the breast is dense and ample in volume such that ultrasound might not be able to identify a mass, our institutional preference is to consider breast MRI imaging. We have not found CT useful for imaging the breast.

MANAGEMENT SUMMARY

- Suspicion of phyllodes tumor is typically based upon clinical criteria including older patient age, rapid growth, or large tumor size.
- Mammogram and ultrasound evaluation are advised, although imaging studies often fail to distinguish phyllodes tumors from fibroadenomas.
- When preoperative tissue sampling is warranted, core needle sampling is the preferred modality.
- Surgical management consists of excision to achieve widely negative surgical margins to decrease the likelihood of local breast recurrence. The majority of studies indicate a margin of more than 1 cm is preferable, with some actually advocating for more than 2 cm.
- When phyllodes tumors are excised with positive or close margins, reexcision should be performed.
- The role of adjuvant radiation is controversial, with some studies indicating improved local control but no increased survival when used in patients with borderline or malignant tumors.
- Locally recurrent tumors may warrant adjuvant chest wall radiation following reexcision.

  Routine adjuvant systemic therapy following initial excision is not recommended. Chemotherapy for locally recurrent tumors remains questionable. When used for treatment of metastatic disease, guidelines for treating sarcoma, rather than breast carcinoma, should be followed.

CHAPTER 63

Paget's Disease

Nora M. Hansen

CHAPTER CONTENTS

Paget's disease, a rare presentation of breast cancer accounts for 1% to 3% of all breast cancers (1,2). The majority of cases are associated with an underlying malignancy and prognosis is dependent upon the stage of the underlying cancer (3). In a recent review of the Surveillance, Epidemiology, and End Results (SEER) data by Chen et al. (4), it was reported that the incidence of Paget's disease has decreased between 1988 and 2002. The age-adjusted incidence rates decreased by 49% for Paget's associated with invasive ductal cancer and by 44% for Paget's associated with ductal carcinoma *in situ* (DCIS).

The first description of Paget-like features was in 1307 by John of Arderne who recorded the several-year evolution of nipple ulceration in a male priest, with the subsequent development of a breast cancer. Velpeau is typically credited with the first clinical description of Paget's disease when, in 1840, he described the visual surface lesion of Paget's disease in two patients. It was in 1874 that Sir James Paget recorded the association of the clinical findings with an underlying breast cancer in 15 patients, although he speculated that the chronic skin condition was benign. It was Thin, in 1881, who concluded that the nipple lesion was not a benign entity, but a malignant one. He postulated that the nipple lesion contained cells that were related to the underlying cancer which had extended to the nipple through the major lactiferous sinuses which we refer to today as Pagetoid spread.

PATHOGENESIS

The pathogenesis of Paget's disease is an interesting one because there are two main theories for the origin of Paget's disease. The most widely accepted one is the epidermotropic theory, first described by Jacobeus, who suggested that the Paget cells arise in breast ducts and spread through the lactiferous sinuses to the nipple epidermis. This view is supported by several observations. First of all, it is well documented that most patients with Paget's disease have an underlying breast carcinoma which is ductal in origin and that the immunohistochemical profile and pattern of gene expression in the Paget cell and the underlying cancer are similar (5). In addition, heregulin alpha, a motility factor released by normal epidermal keratinocytes can induce chemotaxis of the Paget cells to migrate into the overlying nipple epidermis (6).

Because not all Paget's disease is associated with an underlying carcinoma, another theory, the intraepidermal transformation theory (*in situ* transformation theory) proposes that the Paget cells arise either in the terminal portion of the lactiferous duct at its junction with the epidermis or from multipotential cells in the epidermal basal layer. This *in situ* transformation theory is thought to occur in pre-existing benign intraepidermal clear cells of the nipple areolar complex, or Toker cells, which are thought to have migrated from nonneoplastic ducts (7). Support for this theory is found in the rare cases of Paget's disease without an underlying breast carcinoma or cases in which the Paget's disease and the underlying carcinoma appear to be separate tumors (8). Other studies have identified desmosomal attachments between the Paget cells and adjacent keratinocytes supporting the *in situ* development of the Paget cell (9).

Histologically, Paget's disease is characterized by the infiltration of the nipple epidermis by Paget cells, described as large pale-staining cells with round or oval nuclei and prominent nucleoli. The cells are between the normal keratinocytes of the nipple epidermis, occurring singly in the superficial layers and in clusters toward the basement membrane. Serous fluid can seep through the disrupted keratinocyte layer, resulting in the crusting and scaling of the nipple skin. Paget cells can traverse the epithelium and, thus, sometimes are found in the superficial layers. The basement membrane of the lactiferous sinuses is in continuity with the basement membrane of the skin. Paget cells do not invade through the dermal basement membrane and therefore are a form of carcinoma *in situ*. Paget's disease is often associated with a chronic inflammatory infiltrate in the dermis (Figs. 63-1 and 63-2).

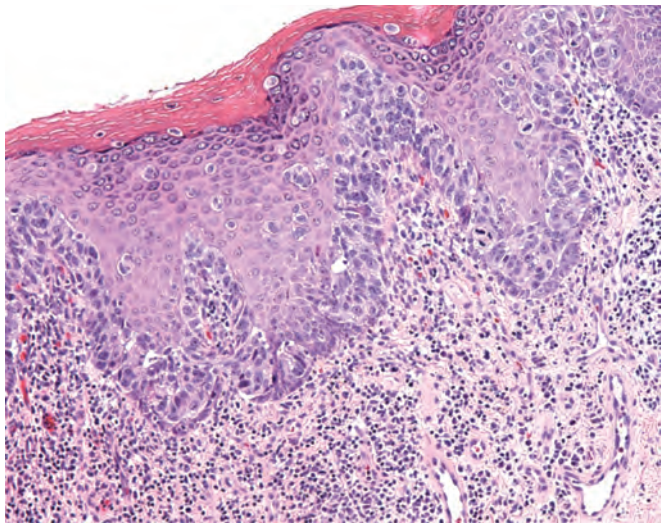

FIGURE 63-1 Section through the nipple epidermis demonstrating Paget's cells. Hematoxylin-eosin stain. Large, pale staining Paget's cells are more densely concentrated toward the basement membrane. (Courtesy of Barbara Susnik, MD, Department of Pathology, Northwestern Memorial Hospital, Feinberg School of Medicine, Northwestern University.)

INCIDENCE

The incidence of Paget's disease varies whether one refers to the pathologic or clinical entity. Paget's disease is a more common pathologic than clinical entity (1,10). Its clinical incidence ranges from 0.5% to 2.8% with a mean of 1.3% in more than 50,900 patients combined from nine studies (1,10,11). Histological evidence of Paget cells is present in 0.5% to 4.7% of nipples from breast cancer specimens (1). In a series by Lagios et. al. (10) of 3,000 consecutive breast cancer mastectomy specimens, 21 (0.7%) had clinical evidence of Paget's disease and 147 (4.9%) had Paget cells histologically, thus yielding a sevenfold difference.

Of the 158,621 microscopically confirmed female and male breast cancer registrants from the SEER registry of the National Cancer Institute, 1,775 (1.1%) had histologic Paget's disease (12). Of patients with breast cancer from this database, Paget's disease was histologically identified in 1.1% of white female patients, 1.3% of African American female patients, 1.1% of white male patients, and no African American male patients. Clinical Paget's disease has been reported in patients ranging in age from 23 to 90 years, with mean ranging from 53 to 65 years (13–17). In a further analysis of the SEER data, the mean age of women with Paget's disease was 62 years and that of the men was 69 years. This was not significantly different from female (61 years) and male (67 years) patients with ductal breast cancer. In an update of the SEER data, Paget's disease associated with both invasive and DCIS has decreased from 1988 to 2002 by 49% and 44%, respectively (4). However the number of cases of Paget's diagnosed without underlying invasive disease may be increasing. This may be accounted for the increased use of mammography and finding cancers at an earlier stage before they develop Pagetoid features.

Paget's disease is not confined to women and can occur in men but it is extremely rare. There are probably less than 50 cases described in the world medical literature and most are case reports. There was one report of bilateral Paget's disease of the male nipple with the patient being treated with bilateral mastectomies.

CLINICAL PRESENTATION AND DIAGNOSIS

The majority of patients with Paget's disease present with eczema or ulceration of the nipple and many have a prolonged period of symptoms before diagnosis. It is, therefore, important to have a high index of suspicion for Paget's when a patient presents with nipple complaints. The most common initial presentation is erythema and mild eczematous scaling which progresses to crusting, skin erosion, and ulceration, with exudation or frank discharge (Figs. 63-3 through 63-5).

The clinical differential diagnosis of scaling skin and erythema of the nipple-areola complex in addition to Paget's includes eczema, contact dermatitis, and post radiation dermatitis. Although bilateral Paget's has been reported, bilateral symptoms are most consistent with eczema or contact dermatitis. Skin changes that are confined to the areola and spare the nipple are typically attributed to eczema, although they can occur rarely in Paget's disease. The clinical

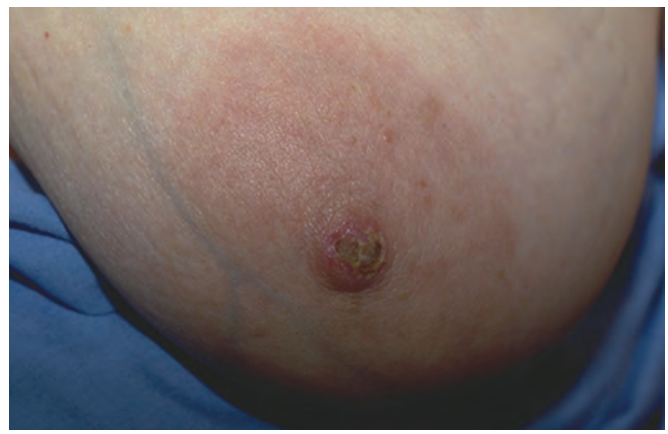

FIGURE 63-3 Paget's nipple. Erythema and crusting of nipple occupying the majority of the nipple surface.

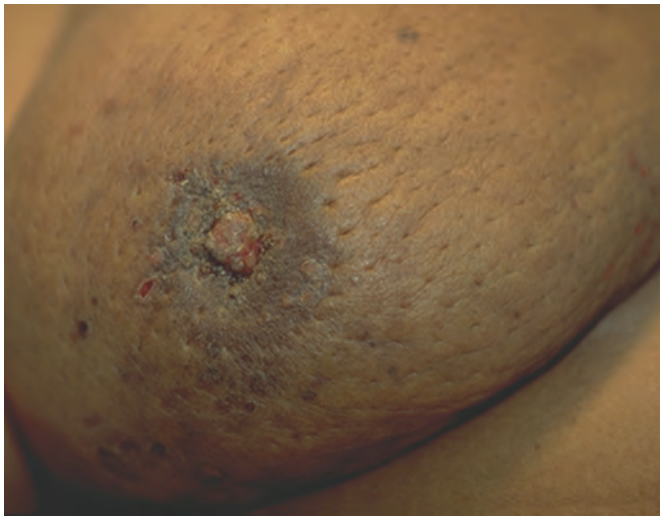

FIGURE 63-4 Paget's nipple. Ulceration of nipple with progression onto areola.

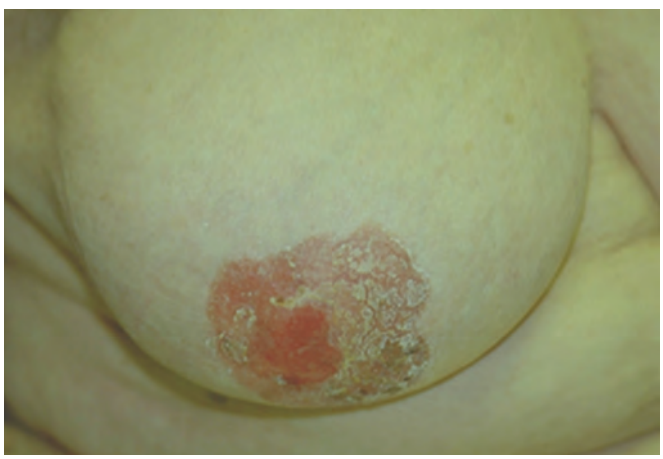

FIGURE 63-5 Paget's nipple. Advanced Paget's with crusting and ulceration extending from nipple and encompassing areola.

differential diagnosis has prompted initial topical steroid treatment, often with transient improvement of symptoms (3). Other patients have been treated with antibiotics. In patients who have been previously treated with breast conservation, Paget's disease may mimic post radiation scaling. Given the infrequency of Paget's disease in this setting, the diagnosis of Paget's disease may be delayed. Symptom duration preceding the diagnosis of Paget's disease is variable and averages 9½ weeks to 27 months, with a range of 1 week to 20 years (18). In a study from the MAYO clinic, the median duration of symptoms was 6 days with a range of 1 to 80 days, clearly a unique patient population (14).

Less common diagnoses in the clinical differential of mammary Paget's disease include nipple adenoma, papillomatosis, melanoma, Bowen's disease, and, rarely, basal cell carcinoma, squamous carcinoma, sebaceous carcinoma, Merkel cell carcinoma, infiltrating lobular carcinoma, cutaneous T-cell lymphoma, Spitz nevus, epidermotropic metastases, alteration of keratinocytes present in 10% of normal nipples. Toker cells can be distinguished from Paget cells by their lack of nuclear pleomorphism or cytologic atypia and their absence of mucin (19).

Although most patients with Paget's present with nipple changes, up to 50% will present with a palpable mass. The majority of patients who present with a palpable mass have an underlying invasive cancer and thus have a worse prognosis. Patients who present with a palpable mass also have a higher rate of nodal positivity (3,20). It has also been shown that HER2-neu overexpression has been found in both DCIS and invasive disease associated with Paget's and this may, in part, account for the poorer prognosis associated with Paget's.

The diagnosis can be obtained by scrape cytology, a superficial epidermal shave biopsy, a punch biopsy, a wedge incision biopsy, or nipple excision (19). The ideal specimen contains adequate epidermis to provide Paget cells and a lactiferous duct. Paget cells may be distributed in a patchy fashion throughout the nipple, so additional specimen sampling may be required to secure the diagnosis.

The histologic differential diagnosis of Paget's disease includes superficial spreading melanoma, squamous cell carcinoma *in situ* (Bowen's disease) and clear-cell changes of squamous cells of the epidermis (Toker cells). The cell type can be determined by immunohistochemical studies including low-molecular-weight keratins (CK7, cellular adhesion molecule 5.2[CAM-5.2]), broad-spectrum keratins, melanoma antibodies, and mucin stains (19).

Paget cells are immunoreactive for keratins (CK7, CAM-5.2, and AE1/AE3), occasionally are immunoreactive to S100 (21), and are not immunoreactive for HMB45 or high-molecular-weight keratins (22). In one study, mucin was present in 55% of 20 patients and, thus, was not informative in 45% of patients (22). Paget cells can phagocytose melanin from adjacent epidermal melanocytes and may be mistaken for melanoma if immunohistochemistry is not performed (22). Melanomas are immunoreactive for S100, are often immunoreactive for HMB45 and are only very rarely immunoreactive for low-molecular-weight (CAM-5.2), broad-spectrum keratins (AE1/AE3), or mucin stains (22). Squamous cells are immunoreactive for low-molecular-weight keratins and broad-spectrum keratins (AE1/AE3) are infrequently immunoreactive for S100 and are not immunoreactive for CAM-5.2, HMB45, or mucin stains (50). Toker cells, or clear-cell changes of the epidermal squamous cells, are a non-neoplastic DCIS, and 1% had Paget's disease only. Toker cells are concentrated within the basal layer or arranged into glandular structures growing up to the spinous layer. These clear cells of the nipple were first described by Cyril Toker in 1970 (7). On occasion these cells can be numerous and atypical and can be difficult to distinguish from malignant cells of Paget's disease. In a study by Di Tommaso et al. (7), Toker cells were identified in 10.2% of patients who underwent mastectomy. In the majority of cases the Toker cells were cytologically bland and benign, while in 27.5% of cases the Toker cells were more numerous and persistent on serial sections and referred to as hyperplastic Toker cells. In 12.5% of cases the Toker cells were hyperplastic and atypical. On immunohistochemistry Toker cells were positive for estrogen receptor and progesterone receptor and negative for CD138 and p53. In comparison Paget's cells were negative for ER and PR and positive for HER2/neu. Both Toker and Paget's cells stained positive for cytokeratin 7 and epithelial membrane antigen and negative for p63 (7).

RADIOGRAPHIC EVALUATION

In patients with clinical Paget's disease, the reported incidence of mammographic findings varies in the literature. For those patients with Paget's without a palpable breast mass,

mammography has been reported as normal in 2.5% to 100% of patients. Of the 324 patients in the 11 series, 174 (54%) had normal mammograms (2,13,15,16,23). In nine series, breast histology was evaluated for 144 patients with clinical Paget's disease and normal mammograms, with 29 patients (20%) found to have an associated invasive breast cancer, 111 patients (77%) found to have DCIS, and 4 patients (3%) found to have Paget's disease of the nipple without an associated invasive cancer or DCIS (15,23). These retrospective studies included patients accrued in the late 1970s, when xeromammography was still in use and retroareolar spot compression views were not routine.

Mammographic findings include skin, nipple, and areolar thickening, nipple retraction, subareolar or more diffuse malignant microcalcifications, and a discrete mass or architectural distortion (24). Mammography inadequately determines the existence of underlying disease in patients with Paget's. In addition, it cannot map the true distribution of the underlying pathology and, therefore, has limited value in determining the appropriate surgical procedure (24). In a more recent series from Memorial Sloan Kettering in 23 patients who had a negative mammogram, 65% had an underlying malignancy confined to the central quadrant of the breast implying that perhaps a negative mammogram may indicate suitability for breast conservation. Although the data is encouraging, the overall sensitivity of mammograms in this series was only 34%. However, if the mammogram was positive, it accurately predicted the extent of disease in 82% of patients, supporting the role of mammography in treatment planning (25).

Ultrasound may be a useful tool in evaluating the patient with Paget's, especially if the mammogram does not demonstrate any abnormalities. Using ultrasound in their study, Günhan-Bilgen (24) and colleagues confirmed the presence of tumor in 67% of patients with Paget's; of which 2% had a normal mammogram. However, in 13% of patients the mammogram did not demonstrate the mass seen on ultrasound and only documented microcalcifications. Because Paget's has been associated with multifocal and multicentric cancers in 42% to 63% of patients, it is important to evaluate the entire breast (2,23).

Breast magnetic resonance imaging (MRI) is an effective diagnostic tool to identify clinically and mammographically occult tumors and there is some evidence to suggest that it may be beneficial in the evaluation of patients with Paget's disease. There is emerging evidence that MRI can identify *in situ* disease and nipple involvement even when clinically occult (26). Recent studies have demonstrated the sensitivity of MRI in detecting breast cancer ranging from 88% to 100% (27). In cases of DCIS, contrast enhanced MRI has a sensitivity of 95% compared to 70% on mammography alone (28). There have been several small series and case reports which have evaluated the use of MRI in patients with Paget's disease. The combined series evaluated 27 patients and MRI detected the cancer in 20 of these patients of which 15 were mammographically occult (29,30). MRI failed to identify 1 invasive cancer and 4 cases of DCIS. MRI was able to accurately determine the extent of disease and, therefore, may be able to help determine which patients are best suited for breast conservation, particularly in the subset of patients with mammographically occult cancers. In another MRI study, the MRIs of 8 patients with Paget's disease were reviewed and comparative analysis of bilateral nipples were made in each patient. There was clear asymmetry with regard to both morphology and enhancement when pathologic nipples were compared to their healthy counterpart. The linear or triangular enhancement of the involved nipple was seen in all 8 patients. Nipple morphologic change consisting of flattening, areolar thickening, or asymmetry was seen in 7 of 8 patients. An associated malignancy was identified in all 8 patients undergoing MRI (31). In a recent study from the Brigham and Women's Hospital, 23 of 51 patients with Paget's had a breast MRI and 78% of those had abnormal findings. The patients with a negative MRI were found to have disease confined to the nipple areola complex (NAC). Twelve patients with a negative mammogram had disease identified by MRI, substantiating the role of MRI in patients with Paget's disease, especially when conventional imaging such as mammogram and ultrasound (US) fail to identify any abnormalities (32).

Technetium-99 methoxyisobutylisonitrile uptake is increased in breast cancer; this is thought to be due to the increased blood flow from angiogenesis and increased cellular metabolism. Several case reports have demonstrated the usefulness of ^{99m}Tc-MIBI scans in evaluating the extent of disease in patients with Paget's disease. However, this has not been a technique that has been widely adopted to date (33).

TREATMENT OPTIONS

There are various treatment options described in the literature for the management of patients with Paget's disease. These include nipple excision alone, radiotherapy alone, central lumpectomy or quadrantectomy with or without the addition of radiation therapy, and mastectomy. For many years, the concern for underlying malignancy and the potential for multifocal or multicentric disease, which has been reported in 32% to 41% of patients, led many to believe that mastectomy should be the definitive treatment for patients with Paget's disease (13). Treatment options have followed the evolution of surgical options for patients with an invasive breast cancer. For years, mastectomy with or without axillary lymph node dissection has been the standard of care for patients with Paget's disease; however, multiple randomized trials have demonstrated that breast conservation is equal in terms of survival to mastectomy and, therefore, the role of breast conservation in Paget's patients has been evaluated (34). However, in one series, 30% of patients with Paget's and no underlying mass had a peripherally located tumor and, therefore, a central lumpectomy would not have been adequate treatment (16).

Although there are no randomized trials relating specifically to Paget's, the use of breast conservation should be acceptable as long as negative margins are achieved and the patient has an acceptable cosmetic result. Several studies have shown that 20 % to 40% of mastectomy specimens have multicentric or multifocal cancers which were underestimated in the mammogram and which potentially would mandate a mastectomy in this subgroup of patients (2). In addition, although the majority of cancers associated with Paget's are centrally located, there are multiple reports depicting the variability of tumor location despite negative mammograms. Paone and Baker (35) reported that in 12% of cases, the underlying cancer was 2cm or more from the nipple while Ikeda et al. (23) reported that in 55% of patients the DCIS was located far from the nipple and in 40% of patient's multicentric disease was identified. Others have reported a 50% incidence of peripherally located tumors, the majority of those with a negative mammogram (38). Wertheim et al. (36) reported a 22% incidence of peripherally located invasive tumors in 18 cases of Paget's patients undergoing a mastectomy. Kothari et al. (13) reported a 75% rate of tumor extension beyond the central quadrant. Failure to identify peripheral cancers when patients are treated with breast-conservation surgery without irradiation may yield

increased local failure rates. Complete removal of the nipple areolar complex is mandatory in patients undergoing breast conservation regardless of the extent of nipple involvement.

BREAST CONSERVATION WITHOUT RADIATION

Breast conservation alone leads to a high local failure rate and is not recommended. There have been several series published which have reported high local recurrence rates with central lumpectomy alone. Polgar et al. (17) reported a 33% rate of local recurrence in 33 patients with Paget's disease of the nipple undergoing conservation, 30 patients had an underlying DCIS and 3 patients had Paget's of the nipple without an underlying malignancy. With a median of 6 years of follow-up, 11 patients (33%) experienced a local recurrence, of which 10 were invasive with 6 developing metastatic disease. Dixon et al. (2) evaluated 10 patients with Paget's without any documented underlying disease on imaging. The nipple areola complex was excised with an underlying cone biopsy. All patients were found to have underlying DCIS and 1 patient had an invasive cancer. Despite negative margins on pathologic exam, at a median follow-up of 56 months, 40% of patients had a local recurrence. Zurrida et al. (37) treated 31 patients with wide excision alone and 29% developed a local recurrence with a median follow-up of 60 months. Other studies have reported low recurrence rates; however, there were limited numbers of patients and the length of follow-up was not specified (35).

RADIATION WITHOUT SURGERY

Radiation treatment alone for patients with Paget's disease without a palpable mass or abnormal mammogram has been reported; however, widespread experience with such conservative treatment remains limited. Although the numbers are small, the local recurrence rates range from 0% to 17%. Bulens et al. (18) treated 13 patients with radiotherapy alone and reported no recurrence with a median follow-up of 52 months. Christiaens et al. (38) reported a 14.8% local recurrence rate in 27 patients at a median follow up of 79 months, while Fourquet (39), with the longest follow-up of 90 months, reported a 17.6% local recurrence rate. Stockdale et al. (40) treated 19 patients and 3 patients recurred, 1 with invasive cancer and 2 with microinvasive cancer. Clearly this approach should be limited to patients with minimal disease which is difficult to evaluate without surgical intervention.

BREAST CONSERVATION WITH RADIATION

If breast conservation is to be considered, the gold standard should be a central lumpectomy with postoperative radiation therapy (Figs. 63-6 through 63-8). The addition of radiotherapy has improved the efficacy of breast-conserving surgery for patients with Paget's disease. There have been several recent, retrospective, nonrandomized studies comparing breast conservation to mastectomy in patients with Paget's disease. The studies, however, are difficult to compare due to the varying presentations of the disease and the varied treatment algorithms. Initial studies only offered breast conservation to patients without a palpable mass or mammographic finding while more recent studies included all types of disease presentation. In a prospective single-arm trial by the European Organization for Research and

FIGURE 63-6 Patient with Paget's who underwent central lumpectomy with removal of NAC.

Treatment of Cancer, Bijker et al. (15) evaluated 61 patients with Paget's disease. The majority (93%) had an underlying DCIS and were treated with excision of the nipple-areolar complex and underlying breast tissue to tumor free margins followed by whole-breast radiation (50 Gy in 25 fractions). The majority of patients did not have an underlying mass (97%) or mammographic abnormality (84%). With 6.4 years of follow-up, the 5-year local recurrence rate was 5.2%. Marshall et al. (14), in an update of a previous study, reported the 10- and 15-year results for 36 cases of Paget's disease from seven institutions, none of whom had a palpable mass or mammographic abnormality. Of the 36 patients, 69% had a complete excision of the NAC, 25% had a partial resection, and 6% had a biopsy alone. Final margins were negative in 56% of cases. All patients received whole breast irradiation to a median dose of 50 Gy with a boost to the tumor bed in 97% of cases for a total medial dose of 61.5 Gy. Eighty-three percent of patients had a documented underlying malignancy, the majority were DCIS. At a median follow-up

FIGURE 63-7 Closer view of central lumpectomy prior to nipple reconstruction. Closed with vertical incision as patient plans on proceeding with left mastopexy after RT and nipple reconstruction to right breast.

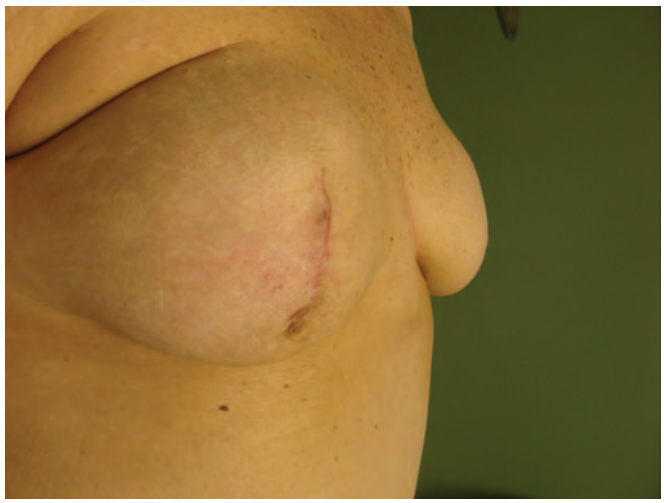

FIGURE 63-8 Patient with Paget's who underwent central lumpectomy with removal of NAC; side view demonstrating shape of breast is intact.

of 113 months, 11% were found to have a local recurrence, all of whom had a complete resection of the NAC. There were no clinical factors identified as a significant predictor of local recurrence. Actuarial local control rates for breast recurrence were 91%, 83%, and 76% at 5, 10, and 15 years, respectively. Actuarial rates for disease free survival (DFS) were 97% for 5, 10, and 15 years. Overall survival rates were 93% at 5 years and 90% at 10 and 15 years. These findings confirm that, for selected patients without a palpable mass or mammographic abnormality, breast conservation affords excellent rates of local control, disease free survival, and overall survival for patients with Paget's disease. In a study by Dalberg et al. (41), 223 patients at 13 Swedish hospitals were diagnosed with Paget's disease. The majority (79%) had an underlying malignancy diagnosed prior to surgery, 30% were invasive cancers. Nineteen percent of patients underwent breast conservation while 75% had a mastectomy and only 19% of patients were radiated. Eleven elderly patients had no surgical intervention. At 10 years, the local recurrence rate for the mastectomy patients was 8% while the conservation patients had a local recurrence rate of 16% which may, in part, be due to the low rate of postoperative radiation therapy. Risk factors associated with breast cancer recurrence and death were presence of invasive cancer and a palpable mass. Lymph node metastases was a risk factor for recurrence but not cancer death. In the largest series from the SEER data base, Chen et al. (4) reported on 1,642 patients with Paget's disease diagnosed between 1973 and 1987. Fifteen year breast cancer specific survival for conserved patients with DCIS was 92% compared to 94% for patients who had a mastectomy. For patients with invasive cancer there was an 87% 15 year breast cancer specific survival and only a 60% survival for patients who underwent a mastectomy. However, there was no difference between the groups after adjusting for tumor size and lymph node status. Only tumor size and lymph node status were significant prognostic indicators of disease specific mortality. The group from MD Anderson Cancer Center (20) reported on 104 patients with Paget's disease and demonstrated that breast conserving approaches had local control and survival rates similar to those achieved with mastectomy and a positive nodal status was the only significant predictor of disease free and relapse free survival with a disease specific survival of 47% in node positive patients and 93% in node negative patients. The local recurrence rate with breast conservation was 8% at a median follow-up of 7 years and all patients had postoperative radiation. Zakaria et al. (3) also demonstrated no difference in survival based on the surgical procedure but the presence of a palpable mass, suspicious mammogram, advanced tumor stage, invasive cancer, and axillary metastases were all associated with a worse outcome. Disease free survival decreased from 90% to 60% and 86% to 30% at 5 and 10 years respectively for patients who presented with a palpable mass and suspicious mammogram compared to those patients without a palpable mass and a benign mammogram.

The European Institute of Oncology of Milan (42) reported their experience of Paget's disease in women from May 1996 to February 2003. The majority of patients presented with typical nipple changes and 77% were associated with suspicious x-ray findings. Ninety-four percent of patients had an underlying malignancy identified. Of the 114 patients, 71 were treated with mastectomy and 43 with breast conservation. There were more locoregional recurrences in the conservation group but this did not impact on survival. Vascular invasion was the only statistically significant prognostic factor for DFS and cancer specific survival, however, tumor size greater than 2 cm and nodal involvement were associated with a worse outcome. Others have reported that younger patients were more commonly offered mastectomy compared to conservation and that the use of radiation therapy (RT) also appeared to be based on age. Similar local recurrence rates and survival rates are seen for patients treated with either breast conservation or mastectomy.

Several studies have demonstrated that patients with Paget's disease were more likely to be ER negative, PR negative with a high histologic grade and an overexpression of c-erb B2 oncoprotein was found in up to 88% of cases (4,41,42).

Breast conservation has become an alternative to mastectomy for patients with Paget's disease with acceptable local recurrence rates and similar survival rates (Table 63-1).

TABLE 63-1

Rates of Local Control after Breast Conservation in Patients with Paget's Disease

Author (Reference)	*n*	*Median F/U (Years)*	*Treatment*	*Local Recurrence (%)*	*Local Control (%)*
Bijker et al. (15)	61	6.4	Lumpectomy + RT	5.2	94.8

Morrogh (25)	19	95%	2/18 (11%)	Not Reported
Dominici (32)	26	Not reported	6	Not reported

With better reconstructive options available to patients, the loss of the NAC can be corrected and patients can have an excellent cosmetic outcome. In a study by Chung et al. (43), an immediate reconstructive technique was used in 29 women with Paget's or a subareolar cancer that necessitated the removal of the NAC along with a central lumpectomy. Using a standard Wise pattern incision for reduction mammoplasty, a central lumpectomy with removal of the NAC was performed. The inferior pedicle was deepithelialized and rotated or advanced to fill the central defect. The breast and skin flaps were then mobilized to the midline and inframammary fold and closed. The nipple reconstruction was performed after the completion of the radiation. In all 29 cases, the NAC was felt to be well centered without central depression deformities and there were no local recurrences at a mean follow-up of 3.5 years. However, there are several series which demonstrate a low rate of nipple reconstruction in patients undergoing central lumpectomy. In a study by Dominici et al. (32), only 11% of patients elected to proceed with nipple reconstruction and this data was similar to findings in the study by Marshall et al. (14). This may, in part, be related to the age of the patient, the fact that those undergoing central lumpectomy in these series were older, or that these patients placed less emphasis on cosmesis. Referral to a plastic surgeon for a more thorough discussion of the reconstructive options may, in the future, impact the patients' decision to undergo nipple reconstruction.

NODAL EVALUATION: SENTINEL NODE BIOPSY (SNB) AND AXILLARY LYMPH NODE DISSECTION (ALND)

Paget's disease is associated with an underlying malignancy in the majority of cases and although many patients have an underlying ductal carcinoma *in situ*, a substantial portion of patients may have an invasive cancer. Lymph node metastases is considered the most important prognostic indicator for patients with invasive breast cancer and all patients with invasive cancer should be offered axillary staging. Sentinel node biopsy has now replaced ALND as a less invasive procedure to stage patients with invasive breast cancer. It has been shown to be effective and accurate in detecting the presence of metastases in many single and multicenter studies (44).

Several investigators have evaluated the role of SNB in patients with Paget's disease. In the three reported series, a total of 105 patients have been evaluated (42,45,46). The sentinel node (SN) identification rate ranged from 97% to 100%. An invasive cancer was identified in 45/105 patients and a positive SN was identified in 20 of the 105 patients. None of the patients with DCIS were found to have nodal disease and 44% of the invasive patients were found to have a positive SN. In a study by Sukumvanich et al. (45) from Memorial Sloan Kettering Cancer Center, of the patients with a positive SN, 45% had additional positive nonsentinel nodes while in the study by Laronga et al. (46), the SN was the only positive node in 75% of cases. In a recent study from Brigham and Women's hospital, 51 patients with Paget's disease had surgical intervention (32). The majority of patients had a mastectomy but 37.2% of patients had a central lumpectomy. A SN was performed in 26 patients and 7 patients had nodal metastases. Fifteen percent of patients undergoing central lumpectomy had to return to the OR for a SN biopsy because of invasive disease found in the surgical specimen and the sentinel node was easily identified, confirming that a sentinel node biopsy after a central lumpectomy is feasible. In an MRI study from MSKCC evaluating MRI in Paget's disease, 19 patients (56%) had a SN biopsy with 95% success rate and 11% of patients were found to have a positive SN-(25) (Table 63-2).

Patients with Paget's disease and a known invasive cancer should be offered a SNB to evaluate their nodal status. For patients with Paget's without documented invasive disease who are undergoing a mastectomy, the addition of a SNB is a reasonable option as a subset of these patients will have an invasive component found on final pathology, thereby avoiding the need for a potentially unnecessary ALND. The role of SNB in DCIS is controversial and, therefore, patients undergoing breast conservation for Paget's without a known invasive cancer is unknown. Some clinicians may await the final pathologic evaluation and only proceed with a SNB if invasive disease is documented while others will offer a SNB at the time of breast conservation. The final decision should be made by the treating clinician and the patient.

PAGET'S DISEASE AS LOCAL RECURRENCE

Local recurrence after breast conservation can present as Paget's disease but has been considered a rare event with reports ranging from 2% to 13% (Fig. 63-9) (47). The emergence of nipple sparing mastectomy as a surgical option for a select group of patients has allowed for better aesthetic and psychological satisfaction with comparable oncologic outcomes. However, with preservation of the nipple areola complex, the possibility of a Paget's recurrence in the nipple is increased. In a study by Lohsiriwat et al. (48), there were 36 local recurrences in 861 patients who had a nipple sparing mastectomy, 19.4% were Paget's recurrence in the nipple with a median follow-up of 50 months. Complete NAC removal was performed in all 7 recurrences. The average latency from nipple sparing mastectomy to Paget's disease local recurrence

FIGURE 63-9 Patient with local recurrence of Paget's in the nipple after breast conservation.

was 32 months with a range of 12 to 49 months. At the time of the nipple sparing mastectomy, a retroareolar biopsy was performed in all cases and was negative for atypia or tumor. In all 7 cases there was no associated cancer either locally or distantly. Factors associated with a Paget's recurrence in the nipple included a primary carcinoma with ductal intraepithelial neoplasia or invasive ductal cancer with an extensive *in situ* component, negative hormonal receptor, high pathologic grade, and overexpression of HER2-neu. Therefore, in the new era of nipple sparing mastectomy (NSM), any suspicious lesion on the nipple areola complex requires prompt evaluation and Paget's should be considered and pathologic confirmation may be required. If a Paget's recurrence is identified, the NAC should be excised and any adjuvant therapy would be based on the associated pathologic findings.

PAGET'S DISEASE AND SURVIVAL

Prognosis has always been based on the underlying tumor characteristics, such as tumor size and nodal status, and has not been influenced by the presence or absence of Paget's disease. The presence of Paget's has no bearing on the staging of breast cancer as defined in the American Joint Committee on Cancer Staging (AJCC). There is limited data on whether the presence of Paget's influences prognosis. Ortiz-Pagan et al. (49) tried to address this question by comparing clinical outcomes in a contemporary cohort of age- and stage-matched patients with breast cancer with and without Paget's disease. Paget's disease in this cohort was associated with a less favorable prognostic panel with more ER negative and HER2-Neu positive cancers, was more often treated with mastectomy, and the overall survival was lower in the Paget's group compared to the control group (81% vs. 94%). When adjustments were made for local and systemic treatment, the hazard ratio (HR) was attenuated at 2.26 (95% CI, 1.74–16.27; p = .003) the 5-year DFS was similar for the two groups. Although this study was small, it does raise some interesting questions and further investigation is needed. Others have looked at survival and breast cancer associated with Paget's and found that c-molecular markers which are commonly associated with more aggressive tumor behavior and worse survival are more commonly found in patients with Paget's associated cancers (50).

MANAGEMENT SUMMARY FOR PAGET'S DISEASE

- Paget's disease is a rare presentation of breast cancer and accounts for 1% to 3% of all breast cancers.
- The majority of patients present with erythema or ulceration of the nipple.
- Diagnosis is made by either a scrape cytology or nipple biopsy.
- Radiologic workup should include mammogram with retroareolar spot compression views and ultrasound, and, if negative, MRI should be considered to evaluate occult cancer and to rule out multicentric disease.
- The majority of underlying tumors are DCIS and located centrally.
- Breast conservation in appropriately selected patients has similar outcome to mastectomy in nonrandomized trials.
- Complete removal of the nipple areolar complex is required for patients undergoing breast conservation.
- Radiation therapy is important in reducing local recurrence risk in conserved patients.
- Patients with multicentric disease or disease extending beyond the central portion of the breast should be offered mastectomy.
- Patients with known invasive cancer should be offered axillary nodal evaluation with sentinel node biopsy.
- The probability of a Paget's recurrence in the nipple is increased in patients undergoing nipple sparring mastectomy.

CHAPTER 64

Nonepithelial Malignancies of the Breast

Francisco J. Esteva and Carolina Gutiérrez

CHAPTER CONTENTS

Nonepithelial malignancies of the breast account for less than 1% of breast tumors. The most common primary nonepithelial breast cancers are sarcomas and lymphomas. Young et al. (1) evaluated the demographic and tumor characteristics of all malignant non-carcinomas of the breast using 26 population-based registries in the United States and found that of 363,801 women diagnosed with malignant breast tumors diagnosed between 1994 and 1998, only 1,401 women (0.4%) had tumors that were nonepithelial in origin. All but nine of the nonepithelial breast cancers in that study were some form of soft-tissue sarcoma. The most common nonepithelial cancer was malignant phyllodes tumor, which accounted for 61% of these diagnoses. In addition to the 363,801 malignant cancers classified as breast tumors, another 613 tumors in Young's study arose in the breast but were classified as myelomas or lymphomas; two as solitary myelomas, two as Hodgkin lymphoma, and the remaining 609 as non-Hodgkin lymphoma (1). Cutaneous melanomas arising in the breast or the skin over the breast have been reported. Despite the infrequent presentation of these nonepithelial breast malignancies, knowledge of their unique features, clinical characteristics, pathology, molecular biology, appropriate diagnostic evaluation, proper staging, and treatment is important to provide optimal patient care. Metastasis to the breast from other organs is another presentation of a mass that can be confused with primary breast cancer. When the primary site is unknown, establishing this diagnosis requires extensive pathologic examination using conventional histology, special immunohistochemistry, flow cytometry, cytogenetics, and electron microscopy. Limited data are available regarding the molecular biology of most nonepithelial malignancies of the breast.

PRIMARY SARCOMAS OF THE BREAST

Primary sarcomas of the breast are malignant tumors arising from the connective tissue within the breast and account for less than 1% of all breast malignancies. According to the Surveillance, Epidemiology, and End Results (SEER) Program of the National Cancer Institute, the annual incidence of breast sarcomas is 4.5 cases per million women (2). Sarcomas can arise *de novo* (primary) or as a consequence of treatment of an epithelial breast cancer (secondary) (3,4). Radiation therapy for breast carcinoma can lead to the development of secondary sarcomas with a latency of up to 20 years (4,5).

Malignant mesenchymal tumors of the breast are broadly composed of malignant phyllodes tumor and soft-tissue sarcoma. The stroma of phyllodes tumor develops from the hormonally sensitive periductal and intralobular stroma of the mammary gland that undergoes malignant change. Primary soft-tissue sarcomas of the breast arise from interlobular mesenchymal elements that comprise the supporting mammary stroma and exhibit histologic subtypes that do not differ from sarcomas seen in other sites in the body. In general, fibrosarcoma, angiosarcoma, malignant fibrous histiocytoma (MFH), liposarcoma, osteosarcoma, and stromal sarcoma comprise the major histological subtypes (6). The histologic distinction is still important as new molecular classification and targeted therapies are developed. Although the etiology of most soft-tissue sarcomas remains unknown, angiosarcoma of the breast has increasingly been associated with prior external beam radiation therapy of the breast and with lymphedema that occurs after radical surgery, with or without radiation, for primary breast cancer. Because of the rarity of breast angiosarcoma, only a small series of patients have been reported (7–9).

Primary breast sarcomas typically present clinically with a unilateral mass with a growth rate that often is rapid when compared to epithelial breast cancer. The size of these tumors is variable, ranging from 1 to 40 cm in most studies, with an average median size of 5 to 6 cm (10,11). The gross appearance of these tumors is influenced in part by the specific histological features, but, in general, they consist of firm, fleshy, tan to gray tissue with variable soft, cystic, and hemorrhagic areas.

Pathological grading plays a critical role in the prognosis of mammary sarcomas. The tumors vary from hypercellular,

fairly uniform spindle cell fibroblastic proliferations to atypical, highly anaplastic cells, and most tumors are intermediate to high grade. Increased mitotic activity (more than 10/10 HPF, range 0–43) and necrosis are additional findings. A diagnosis of primary breast sarcoma must be established only after a range of benign and malignant spindle cell lesions, such as fibromatosis, nodular fasciitis, fibrous histiocytoma, sarcomatoid carcinoma, and metaplastic carcinoma, have been excluded. The distinction is important for treatment and for prognosis. The pathologic evaluation of primary breast sarcomas must include extensive sampling and, in some instances, markers of differentiation, cell surface markers, immunohistochemical studies, cytogenetics, and, in some cases, electron microscopy (12,13).

Breast sarcomas differ clinically from primary breast epithelial tumors. The most common mode of spread is hematogenous, and axillary lymph node involvement is not as frequent as it is with epithelial breast tumors. The most frequent sites of initial metastases are the lungs, bone marrow, and liver (11). Breast imaging studies are nonspecific except that microcalcifications are rare, the mass is often well circumscribed, and tumors tend to be heterogeneous because of the presence of necrosis within the tumor (14,15). Diagnosis of a primary breast sarcoma requires a core biopsy, incisional or excisional. A fine needle aspiration is not adequate. Excisional biopsy is preferred, with attention to negative surgical margins. Tumor size, the presence of regional and/or distant metastases, and the tumor grade are important factors to determine the stage and prognosis (13,16).

The treatment for primary breast sarcomas is wide excision that allows adequate margins free of cancer cells (17). Axillary lymph node dissection is not recommended unless there are enlarged lymph nodes or lymph nodes that appear suspicious under ultrasound or magnetic resonance imaging (MRI). Radiation therapy and chemotherapy may be considered in patients with angiosarcomas and high-grade sarcomas because these lesions have a tendency to recur locally and can also metastasize. However, the role of adjuvant therapy in this setting is controversial. A retrospective review of 55 patients with primary breast sarcoma treated at the Mayo Clinic between 1975 and 2001 reported that adjuvant chemotherapy and radiation therapy did not improve survival although an advantage could easily be missed in such a small study (6). Responses have been reported in patients with metastatic sarcoma of the breast using anthracycline- and ifosfamide-based chemotherapy (18). The treatment regimen should be individualized and a multidisciplinary approach involving a close collaboration among the surgeon, radiation oncologist, and medical oncologist is mandatory.

Angiosarcoma of the Breast

Angiosarcoma arises in the breast more often than in any other organ, and it is also the most common soft-tissue sarcoma involving the breast (8). Angiosarcoma of the breast tends to occur in younger women at a median of 38 years. Because the disease affects younger women, an association with pregnancy has been observed; however, there is no evidence for a hormonal basis for breast angiosarcoma. A correlation has also been suggested between prior radiation therapy in the setting of breast conserving surgery and the development of angiosarcomas (11). The SEER program data compiled by the National Cancer Institute included more than 194,000 women who were treated for breast carcinoma. Among patients in the radiotherapy cohort, the relative risk of developing angiosarcoma was 15.9 (5). The median latency period between radiation for breast cancer and the diagnosis of angiosarcoma has been estimated to be about 6 years. One study failed to confirm the observation that prior radiation increased the risk of developing angiosarcoma (19). In that series, only nine cases of angiosarcoma were documented, which represents a prevalence of 5 per 10,000. Cutaneous angiosarcoma of the chest wall after mastectomy and radiation therapy may also occur (7).

Typically, patients present with a rapidly growing painless breast mass. The overlying skin may have blue or purple discoloration (20). In the largest series, containing 69 patients with breast angiosarcoma, tumor size varied between 1 and 14 cm with a median of 5.5 cm (21). In the majority of cases, the angiosarcoma forms a friable, firm, or spongy hemorrhagic tumor. In high-grade lesions, cystic hemorrhagic necrosis is usually present. Hemorrhagic discoloration in the surrounding breast tissue may indicate that the tumor extends beyond the evident mass. In some cases, the tumors have been described as poorly defined areas of thickening or induration. Microscopically, three distinct patterns of growth have been described; they reflect the degree of differentiation and were thought to correlate with prognosis although one report did not find a relationship between grade and patient outcome (9). Low-grade or type I tumors (Fig. 64-1A) are composed of open, anastomosing vascular channels that invade mammary glandular tissue and fat, producing atrophy of the terminal duct lobular units. Some prominent hyperchromatic endothelial nuclei may be found, but most often they have inconspicuous nuclei. The endothelial cells are distributed in a flat monolayer around the vascular spaces without papillary endothelial proliferation, and rare mitoses are seen. Intermediate-grade or type II angiosarcoma (Fig. 64-1B) shows scattered focal areas of more cellular proliferation consisting of well-developed papillary endothelial proliferation that may combine polygonal or spindle cells. Infrequent mitoses may be found in cellular or spindle areas. Type III or high-grade angiosarcoma (Fig. 64-1C) exhibits highly malignant features that comprise more than 50% of the tumor (22). These tumors consist of prominent epithelial tufting and solid papillary formations with cytologically malignant endothelial cells. Mitoses are readily found. Areas of necrosis and hemorrhage, so called "blood lakes," are only found in high-grade angiosarcomas. The high-grade tumors have infiltrative borders that feature low-grade vascular channels, which may lead to the erroneous diagnosis of a low-grade lesion on a core biopsy. Immunohistochemically, angiosarcomas are positive for Factor VIII related antigen, thrombomodulin, B72.3, CD31, and CD34. These reagents are useful for distinguishing angiosarcomas from carcinoma and other neoplasms. It has been reported that the level of the cell cycle protein SKp2 and the Ki-67 index as a measure of proliferation can be used to distinguish benign vascular lesions such as hemangiomas from malignant low-grade angiosarcomas (23).

Postirradiation Angiosarcomas of the Skin

The histological features of post-radiation angiosarcomas differ from primary breast angiosarcomas and mainly involve the skin with or without occasional invasion of the subjacent breast parenchyma (24,25). High-grade areas are solid, epithelioid, or spindle cell foci with slit-like spaces with intraluminal or extravasated red blood cells. In addition, regardless of the microscopic pattern, malignant cells in post-radiation angiosarcoma have poorly differentiated nuclei with prominent nucleoli and mitotic activity. Angiosarcoma in the skin and breast after radiotherapy must be distinguished from benign vascular lesions that arise in the same clinical setting and that are called *atypical vascular lesions* (AVL) (24). These lesions appear 1 to 17 years after radiotherapy as single or multiple skin nodules measuring 5 mm or less in

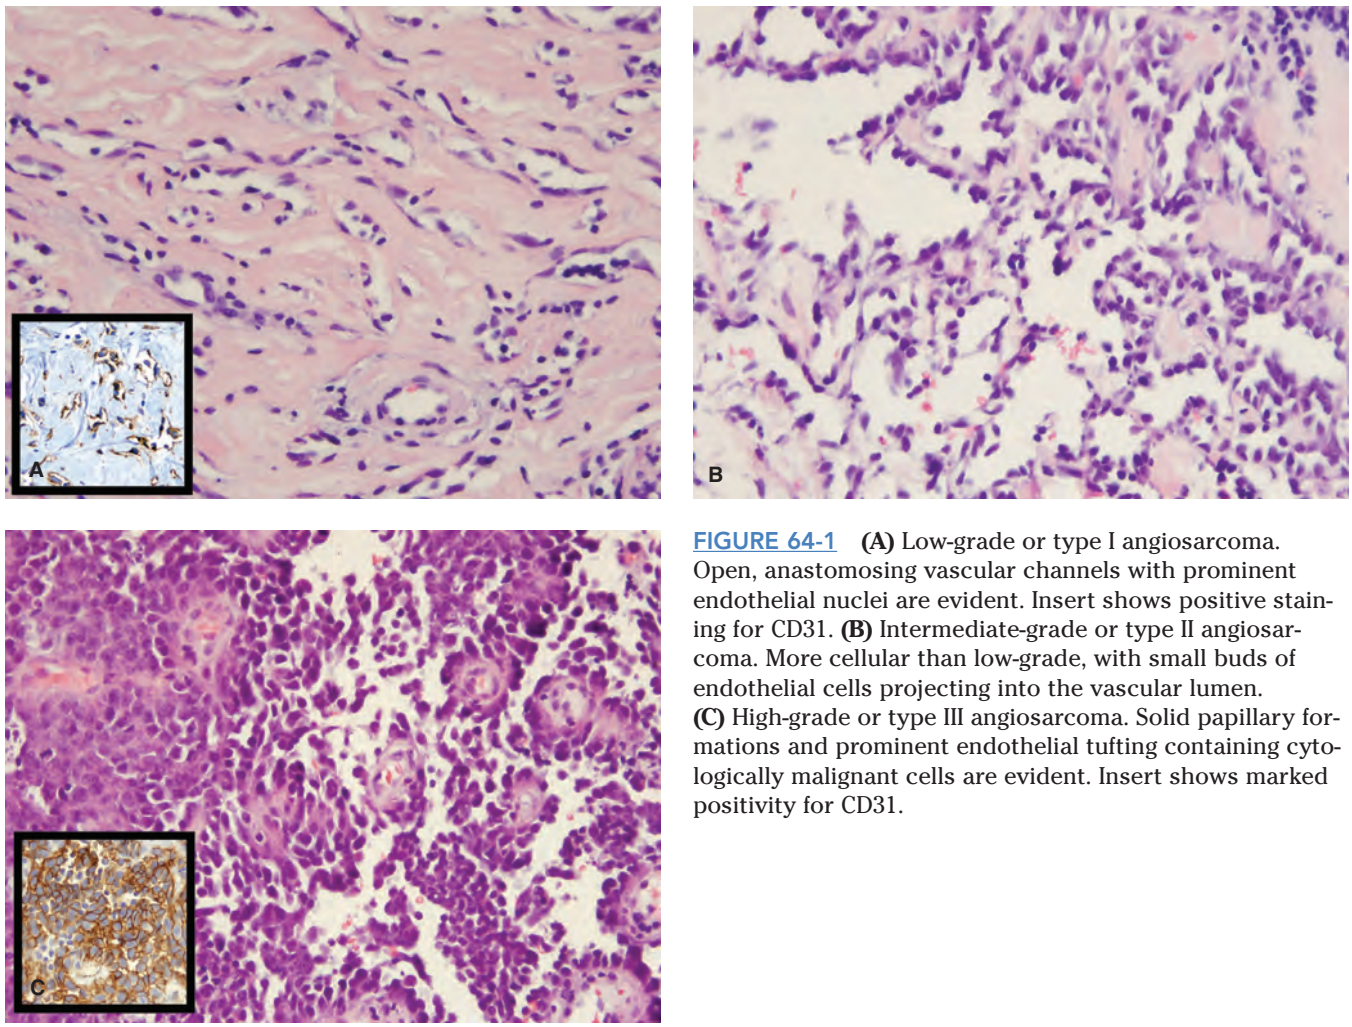

FIGURE 64-1 **(A)** Low-grade or type I angiosarcoma. Open, anastomosing vascular channels with prominent endothelial nuclei are evident. Insert shows positive staining for CD31. **(B)** Intermediate-grade or type II angiosarcoma. More cellular than low-grade, with small buds of endothelial cells projecting into the vascular lumen. **(C)** High-grade or type III angiosarcoma. Solid papillary formations and prominent endothelial tufting containing cytologically malignant cells are evident. Insert shows marked positivity for CD31.

diameter. Histologically, a focal proliferation of anastomosing vascular channels lined by a single layer of endothelial cells with occasional hyperchromatic nuclei is seen. The vascular spaces are usually empty and are limited to the superficial and mid-dermal areas. There is insufficient information to determine definitively whether AVLs can progress to sarcomas. One report suggests that AVLs may be precursors of angiosarcomas (25). Molecular analysis in a series showed that post-radiation cutaneous angiosarcoma is characterized by increased expression and amplification of MYC, whereas atypical vascular lesions do not show this alteration, questioning their role as precursors; however, cases of AVLs progressing to angiosarcoma were not studied in this report (26).

Treatment of Angiosarcomas of the Breast

The optimal surgical treatment of breast angiosarcoma is segmental mastectomy if negative margins can be achieved or total mastectomy if the former is not possible (27,28). Axillary dissection is not recommended. Patients with angiosarcomas have a worse prognosis than patients with other types of sarcoma (6). The most important prognostic markers are histologic grade (subtype) and tumor size although histologic grade was not prognostic in one study (9). However, the roles of adjuvant chemotherapy and radiation therapy are unclear. Several series suggest that adjuvant therapies do not improve disease-free or overall survival. A review of 69 patients with angiosarcoma of the breast treated at the MD Anderson Cancer Center found no improvement in survival of patients with angiosarcoma of the breast treated with neoadjuvant chemotherapy or radiation therapy. However, in this study, the response rate to anthracycline- and gemcitabine-based chemotherapy in the metastatic setting was 48%, suggesting that breast angiosarcoma is potentially a chemosensitive disease (21).

Osteogenic Sarcoma of the Breast

Extraskeletal osteosarcoma of the breast is an extremely rare tumor, accounting for 12.5% of mammary sarcomas (29). Primary breast osteosarcomas are considered highly aggressive tumors with early local recurrence and hematogenous spread (most commonly to the lungs). The most common presentation is a circumscribed and movable mass that on mammography may show osseous trabeculae or coarse calcifications. Silver et al. (30) reported a series of 50 patients with osteogenic sarcoma of the breast diagnosed at the Armed Forces Institute of Pathology (AFIP) between 1957 and 1995. The median patient age at presentation in that study was 63.2 years, and the tumor size varied from 1.4 to 13 cm at the time of diagnosis. The histological features are similar to other skeletal osteosarcomas. The most common variants observed are fibroblastic, osteoblastic, and osteoclastic. In the osteoblastic osteosarcoma, the osteoid is deposited in a fine, ramifying, lacelike, or coarsely trabecular pattern

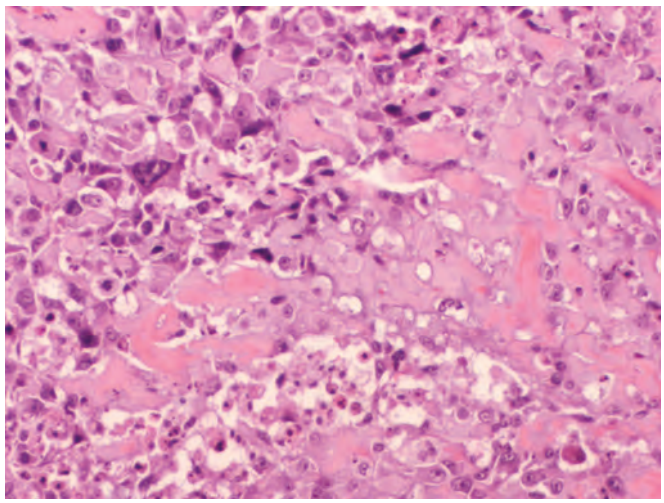

FIGURE 64-2 Primary osteosarcoma of the breast. Malignant cells with round nuclei and prominent nucleoli with lacelike osteoid are seen.

and sometimes in sheaths of osteoid or bone. Atypical cartilage has been reported in 36% of primary breast osteosarcomas. Necrotic foci can be identified in 30% of the cases. Multinucleated osteoclastic giant cells are usually present in areas of bone formation. Immunohistochemistry is helpful in ruling out a metaplastic carcinoma with heterologous elements, which expresses CAM 5.2, pancytokeratin, and high molecular weight keratin (Fig. 64-2).

The relationship between prior breast or chest wall irradiation and breast osteosarcoma is not clear. One of the patients in the AFIP series had received radiotherapy for ipsilateral breast carcinoma 9 years before presentation, but none of the other patients had been exposed to radiation therapy (30). Like other sarcomas, spread to regional lymph nodes is uncommon with breast osteosarcoma. No axillary lymph node involvement was noted in 20 patients who underwent axillary lymph node dissection in the AFIP series. Of 39 patients with follow-up, locally recurrent (n = 11) or metastatic disease (n = 15) was documented at a mean of 10.5 and 14.5 months from diagnosis, respectively, in the same study. Adjuvant radiation therapy and chemotherapy are not recommended.

A recent large international multicenter study of matrix-producing metaplastic breast carcinoma (MP-MBC) questioned the existence of primary mammary matrix-producing (MP) sarcoma, namely osteosarcoma and very rare cases of chondrosarcoma, and examined the clinicopathological features and outcomes of MP-MBC (31). In this study, the authors reviewed the published cases of MP sarcoma of the breast and the criteria to identify them, such as absence of epithelial components, the lack of over-expression of HER2 (which is frequently overexpressed in primary bone osteosarcomas), and the pattern of distant metastases (which differ from the metastatic sites of primary skeletal osteosarcoma). The conclusion of the study is that most of breast osteosarcoma and chondrosarcoma cases are in fact MP-MBC and are of epithelial origin with minimal/nondetectable residual epithelial components, once the diagnoses of phyllodes tumor and metastasis from skeletal osteosarcoma have been excluded. Complete and extensive tumor sampling, the use of a broad panel of epithelial markers, as well as discussion in a multidisciplinary team meeting are important before making the rare diagnosis of primary mammary MP sarcoma. Based on the limited data available, patients with MP sarcoma should be treated similarly to other epithelial breast carcinomas (31).

Embryonal Rhabdomyosarcoma of the Breast

Primary embryonal rhabdomyosarcomas of the breast are rare tumors that typically occur in adolescents and young women. Of the 3,500 cases of rhabdomyosarcoma registered with the Intergroup Rhabdomyosarcoma Group of the United States between 1972 and 1992, only 7 (0.2%) originated in the breast. When the data were restricted to the 423 women aged between 10 and 21 years of age, only 1.6% had rhabdomyosarcoma of breast origin. Metastatic rhabdomyosarcoma to the breast was seen in 2.6% in the same age group. The median age was 15.2 years, including primary or secondary rhabdomyosarcomas of the breast. The most common histologic subtype was alveolar rhabdomyosarcoma (32).

Histologically, alveolar rhabdomyosarcoma is composed of small, round cells that make poorly defined aggregates (Fig. 64-3). Mitoses are easily identified. The differential diagnosis, which includes malignant lymphoma and invasive lobular carcinoma, can be resolved by using immunostains for myoid, epithelial, and lymphoid markers. Cytogenetic studies may show the characteristic translocations t(2;13)(q35;q14) or t(1;13)(p36;q14) (32). The treatment of choice for embryonal rhabdomyosarcomas of the breast is surgical resection with wide tumor-free margins. Total mastectomy may provide a better outcome in some patients. There are limited data regarding the role of lymphatic mapping and sentinel lymph node (SLN) biopsy in the management of sarcomas because most sarcomas rarely metastasize to regional nodes. However rhabdomyosarcomas are usually high-grade tumors that have a propensity for regional lymph node metastases, and it has been suggested that these patients may benefit from SLN biopsy (33). Treatment of rhabdomyosarcomas is multidisciplinary and may include radiation and chemotherapy in addition to surgery. Excellent survival rates are observed in children with this disease. A five-year survival rate of 43% was reported in patients with breast rhabdomyosarcomas. These patients tend to be slightly older and have the alveolar subtype (32).

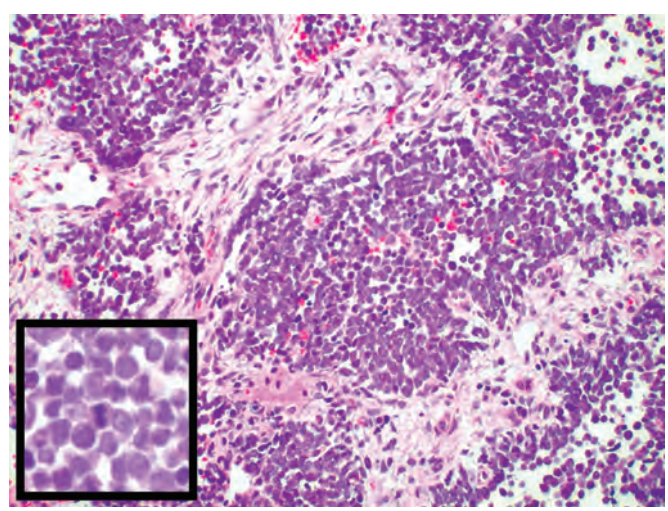

FIGURE 64-3 Alveolar rhabdomyosarcoma of the breast in a 16-year-old girl. The tumor is composed of a proliferation of small round cells mimicking a lymphoma. Molecular diagnostic pathology testing by RT-PCR showed PAX3-FKHR translocation [t(2;13)].

Miscellaneous Breast Sarcomas

A variety of other soft-tissue sarcomas can originate in the breast. They should be described, classified, and treated in a manner similar to sarcomas originating in other sites. These tumors include stromal sarcoma, leiomyosarcoma, liposarcoma, malignant fibrous histiocytoma, Ewing's sarcoma, and fibrosarcoma (11,34). These tumors are rare. Some, such as malignant fibrous histiocytoma and fibrosarcoma, are sequelae of prior postmastectomy irradiation (5,35). These tumors can occur in all age groups but tend to be more frequent in women older than 50. They present clinically as a mass although they can be found by breast imaging. Treatment of these lesions is surgical. Wide excision or total mastectomy has been performed, with the decision based on the characteristics of the tumor and the patient. The rather high local recurrence rate after wide excision in some studies suggests that total mastectomy might be preferred. Axillary dissection is not indicated because these tumors spread hematogenously (36).

Other mesenchymal tumors have been observed rarely in the breast. These include hemangiopericytoma, which has an excellent prognosis and can be treated by wide excision (37); dermatofibrosarcoma protuberans (38), which arises in the skin of the breast and can be confused with locally advanced breast cancer clinically; Kaposi's sarcoma (39); and tumors of the peripheral nerve sheath (40). These rare lesions are described in detail elsewhere (10).

Lymphedema-Associated Lymphangiosarcoma

Lymphedema-associated lymphangiosarcoma, also known as Stewart-Treves Syndrome, has been reported in women treated typically with radical mastectomy and chest wall irradiation who have chronic upper extremity edema. The incidence of lymphedema-associated lymphangiosarcoma in the United States is 1.6 per 100,000 persons (41). The pathogenic mechanism of this syndrome is unknown, but several hypotheses have been postulated. Proliferation of lymphatic vessels is often seen in areas of chronically edematous tissue. It has been suggested that the block of the lymphatics increases the expression of growth factors and cytokines, which stimulates proliferation of blood vessels and lymphatics. The association between radiotherapy and chest wall sarcomas is well known, but it is unclear whether radiation therapy contributes to this entity because most reported post-radiation sarcomas are not lymphangiosarcomas. Although postmastectomy radiation is a major predisposing factor for the development of lymphedema, other factors, such as hypertension and cardiovascular disease, have also been described as risk factors. With multimodality therapy, the 5-year survival rate for lymphedema-associated lymphangiosarcoma has been reported between 8.5% and 13.6% (42). The incidence of this complication of extensive surgery and radiation is on the decline with the increasing use of breast conservation, limited radiation, and sentinel lymph node biopsy.

PRIMARY LYMPHOMAS OF THE BREAST

Primary breast lymphomas (PBL) account for 1.7% to 2.2% of extranodal non-Hodgkin lymphomas (NHLs), 0.38% to 0.7% of all NHLs, and 0.04% to 1.0% of breast malignant neoplasms (43,44). Wiseman and Liao (45) used the following criteria to define PBL: (i) there is no prior diagnosis of extramammary lymphoma, and the breast is the primary site of disease; (ii) mammary tissue and lymphomatous infiltrate are in close association with no evidence of concurrent widespread disease; and (iii) pathology is confirmed by technically adequate specimens.

The majority of non-Hodgkin lymphomas involving the breast are B-cell neoplasms, and the most common are diffuse large B-cell lymphomas (DLBCL) (Fig. 64-4A) and extranodal marginal zone lymphoma of mucosa-associated lymphoid tissue, but other types can also be found (Fig. 64-4B) (44,46–48). Most B-cell lymphomas of the breast present as a palpable breast mass with or without enlarged axillary lymph nodes (44,46). Typically, the mass is not painful, and it is not fixed to the chest wall or skin. Skin ulceration, erythema, or

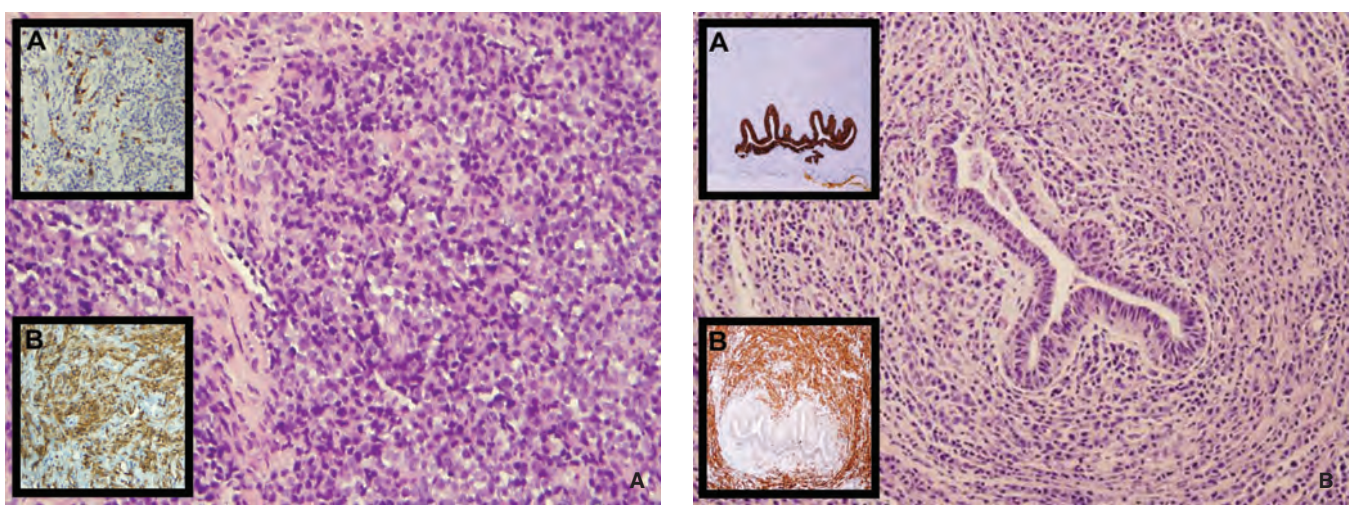

FIGURE 64-4 **(A)** Diffuse large B-cell lymphoma. The malignant cells invade the breast stroma. Insert A shows only a few cells staining with CD3. Insert B shows the majority of cells staining for CD20. **(B)** Lymphoma mimicking invasive lobular carcinoma. Insert A shows positive staining for AE1/AE3 in the normal breast duct while the neoplastic cells are negative. Insert B shows intense staining of the malignant cells with CD45, confirming the lymphoid lineage.

erosion suggests extension into the skin. When the skin is involved, a T-lymphocyte phenotype should be suspected. Other primary lymphomas that may involve the skin overlying the breasts include epidermotropic mycosis fungoides, peripheral T-cell lymphomas, or cutaneous B-cell lymphomas. Primary Hodgkin lymphoma of the breast has also been reported (44,48). Although extremely rare, a Burkitt-like lymphoma of the breast has been reported, presenting with bilateral, diffuse, and rapidly fatal disease (43,48). Cases of anaplastic large-cell lymphoma (ALCL), ALK-negative, have been reported in association with breast implants with an odds ratio of 18.2. This type of lymphoma is defined as a CD30+ peripheral T-cell neoplasm, which appears to have a better prognosis than other clinical types (49,50).

Radiographic imaging features of PBL are nonspecific, with the exception that calcifications are rare. On ultrasound, the identified lesions tend to be homogeneously hypoechoic or heterogeneously mixed hypo- to hyperechoic (51). Positron emission tomography (PET) and computed tomography (CT) scanning may be of some use in distinguishing breast lymphomas from other breast neoplasms after response to therapy and in determining remission status in the presence of minimal residual masses determined by physical examination or other imaging methods (52). Diagnosis is typically made by core biopsy of a palpable breast mass. High-grade lymphoma must be distinguished from melanoma and poorly differentiated carcinoma because curative treatment differs radically among these tumor types. Immunostaining with a broad panel of markers, including epithelial markers (cytokeratins), melanoma (S-100, human melanoma black 45 [HMB-45], and Melan A), and lymphoid markers (CD45, CD3, CD20), usually leads to the correct diagnosis. All B-cell and T-cell neoplasms express pan-B-cell (CD20, CD79a, or PAX5/BSAP) or pan-T-cell antigens (CD3, CD5, or CD45RO), respectively. B-cell and T-cell lymphomas of specific types express the appropriate markers (44). Additional molecular testing may be required to diagnose unusual entities, such as the anaplastic large-cell, ALK-negative, primary cutaneous ALCL, CD30+ T- or B-cell lymphoma with anaplastic features (49). After diagnosis, patients should be fully staged to determine extent of disease using the World Health Organization (WHO) classification of lymphoma (53). The WHO classification subdivides tumors into mature B-cell neoplasms, mature T-cell and NK-cell neoplasms, Hodgkin lymphoma, histiocytic and dendritic cell neoplasms, and posttransplantation lymphoproliferative disorders. The diagnostic evaluation should include immunophenotyping and might require cytogenetics, fluorescent in situ hybridization (FISH), antigen receptor gene rearrangement studies, and other investigations (54). Clinical staging procedures include CT scans of the chest, abdomen, and pelvis; a PET scan; and bilateral bone marrow biopsies and aspirates. Other staging studies may include CT scans of the brain, MRI scans, lumbar puncture with evaluation of cerebrospinal fluid chemistry and cytology depending on the clinical presentation and histologic subtype of lymphoma. A variety of biopsy techniques, including gastrointestinal endoscopy, bronchoscopy, mediastinoscopy, thoracoscopy, laparoscopy, thoracotomy, or laparotomy may be indicated in the process of diagnosis and staging in some patients (54).

The role of surgery in PBL should be limited to acquisition of adequate material for diagnosis, typically with a biopsy either from the breast mass or from an involved lymph node. Treatment by mastectomy offers no survival benefit or protection from recurrence (55). Rituximab plus anthracycline-based chemotherapy and involved field radiation therapy are the mainstays of treatment for PBL (48). It should be noted that most PBL reports describe patients treated in the pre-rituximab era. Systemic chemotherapy with rituximab, cyclophosphamide, doxorubicin, vincristine, and prednisone (RCHOP) is currently the standard of care for patients with DLBCL, and this regimen should be used in patients with PBL as well (56,57). Although some studies reported a high recurrence rate in the central nervous system (CNS), other studies reported low CNS involvement (44,57). Currently, prophylactic whole-brain irradiation is not recommended for PBL patients.

MELANOMA OF THE BREAST

Although melanoma can metastasize to the breast, primary cutaneous melanomas of the breast tissue or skin can also rarely occur (58). When melanomas occur in the nipple-areolar area, phagocytosis of melanin by Paget's cells distinguishes the melanomas from Paget's disease of the breast (59). The clinical presentation of melanoma involving the skin of the breast includes changes in size, pigmentation, ulceration, and bleeding of a pre-existing mole. The most important prognostic factors are the presence of regional lymph node metastases, the thickness of the primary tumor, tumor mitotic rate, and the presence of ulceration (60). As described earlier, melanoma and high-grade lymphoma can be confused with a poorly differentiated carcinoma. These tumors must be distinguished from one another to provide appropriate curative treatment. Staining with HMB-45, S-100, or Melan-A is helpful to confirm the diagnosis of melanoma (Fig. 64-5).

Treatment of cutaneous melanoma of the breast involves *en bloc* excision of the tumor or biopsy site, with a margin containing normal-appearing skin and underlying subcutaneous tissue (Table 64-1) (61). Randomized clinical trials have shown that a 1–2-cm margin of excision is adequate. Wider margins have not translated to improvement in survival. The recommended excision margins for primary melanoma of the breast are similar to other cutaneous melanomas (Table 64-1). Sentinel lymph node biopsy should be discussed with and offered to patients with melanoma of the breast following the protocol for other sites' primary

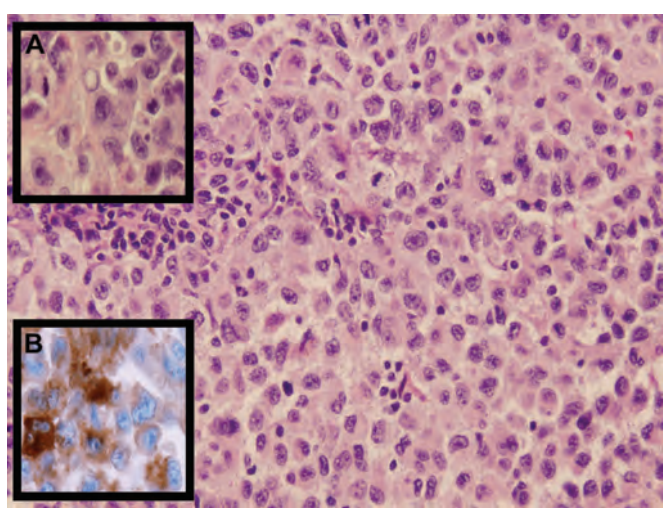

FIGURE 64-5 Melanoma of the breast. This lesion can be mistaken for a poorly differentiated carcinoma or a large cell lymphoma when melanin pigment is not readily seen. Insert A shows a characteristic intranuclear inclusion in a malignant cell. Insert B shows intense staining for HMB-45, confirming the diagnosis of melanoma.

TABLE 64-1

Recommended Excision Margins for Primary Cutaneous Melanoma

Tumor Thickness	*UK Trial (70)*[a]	*WHO Trial (71)*[a]	*Australian Trial (72)*[a]	*Dutch Trial (73)*[a]
In situ	2–5 mm	5 mm	5 mm	5 mm
<1 mm	1 cm	1 cm	1 cm	1 cm
1–2 mm	1–2 cm	1 cm[b]	1 cm	1 cm
2.1–4 mm	2–3 cm; 2 cm preferred	2 cm	1 cm	2 cm
>4 mm	2–3 cm	2 cm	2 cm	2 cm

[a]Reference numbers.
[b]For melanomas thicker than 1.5 mm, recommended excision margin is 2 cm.

melanoma: ≥1 mm in thickness and clinically normal regional lymph nodes by physical examination (60). Histopathologic and immunohistochemical assessment of the SLN improve the detection of clinically occult nodal metastases, thereby distinguishing patients who might benefit from immediate lymphadenectomy from those for whom this procedure is unlikely to be helpful. This procedure also identifies patients who might be candidates for clinical trials of adjuvant systemic therapy. Clinical trials are ongoing to determine the clinical value of a variety of molecular prognostic markers in melanoma patients undergoing SLN assessment (62,63).

METASTASES TO THE BREAST

The incidence rate of metastases to the breast from extramammary sites ranges from 1.7% to 6.6% in autopsy series and 1.2% to 2% in clinical reports (64,65). The most common presentation is the development of metastasis from the contralateral breast by a cross-lymphatic route, especially in premenopausal women. Other malignancies that can metastasize to the breast include non-Hodgkin lymphomas, leukemias, melanomas, lung cancer, gastric cancer, and ovarian cancer. Rare cases of metastases from fallopian tube cancer, ovarian dysgerminoma, renal cancer, medullary thyroid cancer, carcinoid, medulloblastoma, malignant schwannoma, and pharyngeal carcinoma have been reported (66–68).

Radiographic imaging using mammography and ultrasonography are not sufficient to determine whether a tumor is primary or metastatic. Skin thickening and axillary lymph node involvement may be apparent. A fine-needle aspiration and/or a core needle biopsy are needed to make the diagnosis. Pathologic assessment for metastases to the breast includes conventional histology, immunohistochemistry, cytogenetics, flow cytometry, and electron microscopy analysis. Clinically, it is important to differentiate bilateral primary tumors from metastatic tumors that coexist with a primary breast cancer. All suspicious lesions should be biopsied to clarify the overall diagnosis and treatment approach. Factors suggesting contralateral metastatic breast cancer include short disease-free interval, multiple breast lesions, and known metastatic breast cancer at other distant sites (68). Factors suggesting non-breast metastatic disease include location in fat or subcutaneous tissue as opposed to breast parenchyma, lack of *in situ* disease histologically, bilateral or multiple lesions, and lack of microcalcifications on mammography (64,69).

Metastatic breast cancer to the contralateral breast is treated with systemic therapy directed to the primary tumor. Palliative surgery and/or radiation therapy is often used for local control. If it is not clear whether the tumor is a primary breast cancer versus a metastasis, it should be treated with curative intent as a primary breast cancer. If the tumor is clearly metastatic but its origin is uncertain, treatment planning should take into account the most probable histologic diagnosis and primary site of the tumor as well as the potential efficacy of systemic treatments available for the presumed primary tumor. As metastases to the breast are rare and have diverse origins, a multidisciplinary approach is necessary to determine optimal treatment.

CHAPTER 65

Breast Cancer during Pregnancy and Subsequent Pregnancy in Breast Cancer Survivors

Jennifer K. Litton and Richard L. Theriault

CHAPTER CONTENTS

INTRODUCTION

Pregnancy and fertility issues have become a significant concern for younger breast cancer patients. Young breast cancer patients can be faced not only with the diagnosis and treatment of their breast cancer, but also with concerns regarding fertility, future pregnancies and, for some, breast cancer diagnosis and treatment during pregnancy. Gestational or pregnancy-associated breast cancer (PABC) is defined as breast cancer that is either diagnosed during pregnancy or within 1 year postpartum. Since women seem to be delaying childbirth to later ages than in previous generations, the incidence of breast cancer and pregnancy, as well as the importance of future pregnancies subsequent to successful treatment for breast cancer, must be considered as part of the informed decision process when discussing treatment of breast cancer with younger women. Given this special situation and the amount of reports in the literature, national societies such as the American Society of Clinical Oncology (ASCO) and National Comprehensive Cancer Network (NCCN) have both issued guidelines on how to approach the treatment of the pregnant cancer patient. We will review the diagnosis and treatment of breast cancer and concurrent pregnancy, the prognosis for those treated during pregnancy, effects of treatment for children exposed to systemic therapies in utero and, for women with successfully treated primary breast cancer, the breast cancer prognosis in relation to future pregnancies.

EPIDEMIOLOGY: BREAST CANCER AND CONCURRENT PREGNANCY

Breast cancer and cervical cancer are the most commonly diagnosed malignancies during pregnancy. In a large retrospective population-based study in California between 1991 and 1997, there were 1.3 cases of breast cancer per 10,000 live births (1). In women under the age of 50 who are diagnosed with breast cancer, approximately 0.2% to 3.8% are diagnosed during pregnancy (2,3). As women delay childbearing, the incidence of breast cancer coinciding with pregnancy may increase since the frequency of breast cancer diagnosis increases with age (4). In a population-based cohort study based on the Healthcare Cost and Utilization Project—Nationwide Inpatient Sample (HCUP–NIS), Abenhaim et al. reported 573 breast cancers identified in 8,826,137 births over a 10-year interval. The 10-year incidence was noted to be 6.5 cases per 100,000 births. The diagnosis of breast cancer was more common among women over 35 years of age (5).

In patients with breast cancer with a recent past pregnancy, some retrospective analyses have shown a worse prognosis. In a multi-institutional retrospective case-control study, Guinee et al. (6) examined the impact of recent prior pregnancy on breast cancer outcome in a group of 407 women, aged 20 to 29, with breast cancer. The women were matched for age and stage of disease and had never been pregnant. For each 1-year increment in the time between the latest previous pregnancy and breast cancer diagnosis, the risk of dying decreased by 15% (relative risk 0.85, $p = .011$) (6). In a study of 540 patients from Memorial Sloan-Kettering Cancer Center, patients with previous childbirth within 2 years of the diagnosis of breast cancer also were shown to have a worse prognosis with an adjusted relative risk (RR) of dying from the cancer of 3.1 (7). Kroman et al. from Denmark noted an increased RR of dying from breast cancer for those women who had childbirth within 2 years of diagnosis. After adjusting for age, cancer characteristics and stage, a breast cancer diagnosis within 2 years of

childbirth was significantly associated with death (RR = 1.58, 95% confidence interval 1.24–2.02) compared to patients who gave birth more than 5 years before their breast cancer diagnosis (8). These studies were not able to control for delay in diagnosis, treatment, or treatment modalities of the breast cancer. Future translational research may help identify whether or not there is a true biologic difference in breast cancers diagnosed soon after pregnancy to account for these differences. A recent case-control study concludes that current or recent pregnancy is associated with adverse pathologic features but breast cancer survival is not impaired (9).

BRCA1 and *BRCA2* Mutation Carriers and Pregnancy

Women who are more susceptible to breast cancers at younger ages, such as those with deleterious mutations in the *BRCA1* or *BRCA2* genes may be overrepresented in the population of pregnant breast cancer patients. Few studies, with small numbers of patients, have evaluated the potential increased risk in hereditary breast cancer patients (10,11). Women with genetic predispositions to cancer, such as those with *BRCA1* and *BRCA2* deleterious mutations, tend to develop breast cancer at earlier ages and therefore may be more likely to have cancer diagnosed during childbearing years.

Potentially, the relationship of number of pregnancies and age of parity may be significant in *BRCA1* and *BRCA2* mutation carriers. Antoniou et al. evaluated 457 mutation carriers who developed breast cancer and 332 mutation carriers without a history of cancer. Parous *BRCA1* and *BRCA2* mutation carriers had a lower risk of developing cancer, but only among carriers who were older than 40 years of age (hazard ratio 0.54, 95% CI 0.37–0.81). Patients with an increased age at first parity had an increased breast cancer risk if a *BRCA2* mutation carrier, but not if they were a *BRCA1* mutation carrier (12). Kotsopoulos et al. performed a matched case-control study on 1,816 pairs of *BRCA1* and *BRCA2* mutation carriers, and showed that age at first parity did not influence the development of breast cancer in mutation carriers. Also they did not show a difference between *BRCA1* and *BRCA2* mutation carriers in univariate or multivariable models (13). An Icelandic study examining 100 *BRCA2* mutation carriers did not show a decrease in risk of breast cancer in *BRCA2* mutation carriers with increased number of births as has been seen in nonmutation carriers (14). Not only was the protective effect of parity modulated in these patients, but also, in a large matched case-control study comparing 1,260 pairs of women with known *BRCA* mutations, increasing parity was associated with an increased risk of breast cancer in *BRCA2* mutation carriers compared to nulliparous women (OR 1.53, 95% CI 1.01–2.32, $p = .05$). *BRCA2* mutation carriers who were under the age of 50, when compared to nulliparous *BRCA2* mutation carriers, had a 17% increase in adjusted risk of breast cancer with each additional birth (OR 1.17, 85% CI 1.01–1.36, $p = .03$) (15).

Given the risk of a deleterious mutation in women who develop breast cancer at an early age, genetic counseling should be part of the clinical discussion and evaluation for all such patients. Having children at an early age does not appear to provide the same protective effects in patients with deleterious *BRCA1* or *BRCA2* gene mutations as for those without mutations. In fact, recent parity may increase the risk of being diagnosed with breast cancer potentially more notably in those with deleterious *BRCA2* mutations.

DIAGNOSIS OF BREAST CANCER DURING PREGNANCY

Pregnant women with breast cancer tend to present with similar physical examination findings as their nonpregnant counterparts including a palpable mass or breast thickening. Due to the physiologic changes in the breast that occur during pregnancy and lactation, including increased size and density of the breast tissue, there may be a delay in diagnosis of breast cancer as these physiologic changes can obscure detection (10). Pregnancy-associated physiologic changes in the breast may be even more pronounced in patients under the age of 30 (16). Therefore, women diagnosed with breast cancer during pregnancy often present with an advanced tumor stage and axillary lymph node involvement. Given the concern for delay of diagnosis, palpable masses or breast distortions persisting over 2 weeks should be investigated.

EVALUATION OF BREAST MASSES DURING PREGNANCY

Imaging of the Breast during Pregnancy

Mammography: Mammography should be ordered in pregnancy with abdominal shielding. With mammography the fetal radiation exposure is estimated to be 0.4 mrad (17). This level is substantially below the level of 5 rad, a level at which multiple studies have shown no known increase in congenital malformations or growth retardation (18).

Ultrasonography: Ultrasound (US) can distinguish between cystic and solid breast masses in approximately 97% of cases with no radiation exposure. One study diagnosed 100% of the breast masses as well as axillary metastases in 18 of 20 women (19). Ultrasound was also shown to be effective for evaluating response to preoperative chemotherapy in the pregnant breast (19).

Breast MRI: Magnetic resonance imaging (MRI) has not been studied for the diagnosis of a breast mass in pregnant or lactating women. Gadolinium-enhanced MRI may be more sensitive than conventional mammography; however, data regarding the safety of gadolinium during pregnancy are limited. Gadolinium has been shown to cross the placenta and be associated with fetal abnormalities in animal models (20,21). Animal studies have shown diverse fetal effects and gadolinium is considered a pregnancy category C drug (Table 65-1). There have been no controlled human studies to date, however; several studies have observed no significant toxicity when gadolinium has been given during human pregnancy. But there does remain some controversy as to the safety of gadolinium during pregnancy and therefore should be used with caution.

Staging and Diagnosis of Breast Cancer during Pregnancy

Biopsy

Any clinically suspicious breast mass requires biopsy, even if the ultrasound and mammogram are equivocal or nondiagnostic. Fine-needle aspirate (FNA) in the pregnant breast is well established. While FNA may provide cytologic confirmation of cancer, core biopsy is preferred because it can confirm invasive disease and provide tissue for biologic

TABLE 65-1

U.S. FDA Pregnancy Category Definitions

A	Controlled studies in women fail to demonstrate a risk to the fetus in the first trimester, and the possibility of fetal harm appears remote.
B	Animal studies do not indicate a risk to the fetus and there are no controlled human studies or animal studies to show an adverse effect on the fetus, but well-controlled studies in pregnant women have failed to demonstrate a risk to the fetus.
C	Studies have shown that the drug exerts animal teratogenic or embryocidal effects, but there are no controlled studies in women, or no studies are available in either animals or women.
D	Positive evidence of human fetal risk exists, but benefits in certain situations (e.g., life-threatening situations or serious diseases for which safer drugs cannot be used or are ineffective) may make use of the drug acceptable despite its risks.
X	Studies in animal or humans have demonstrated fetal abnormalities or there is evidence of fetal risk based on human experience, or both, and the risk clearly outweighs any positive benefit.

marker evaluation. Core or excisional biopsies can be performed safely with local anesthesia, with only one found report of the development of a milk fistula after a core needle biopsy (22).

Pathology of Breast Cancer Diagnosed during Pregnancy

The majority of breast cancer cases are infiltrating ductal adenocarcinomas with one prospective cohort showing 84% with poorly differentiated tumors (23). When compared to nonpregnant premenopausal women, pregnant patients are reported to have tumors with a lower frequency of ER and/or PR expression (23–26). Amplification of *HER2/neu* is seen in approximately 20% to 30% of breast cancers. In some series, *HER2/neu* amplification has been reported to be disproportionately amplified in pregnant patients (up to 58% vs. 16 % in nonpregnant counterparts) (27); however, another series show similar *HER2/neu* amplification (28%) in pregnant and nonpregnant patients (23).

Staging Evaluations during Pregnancy

The American Joint Committee on Cancer (AJCC) TNM staging system is used and, along with tumor biologic characteristics, forms the basis for treatment decisions. Staging procedures may need to be modified for the pregnant breast cancer patient with safety considerations for both the patient and the fetus. Staging is important, however, for better understanding of the full extent of disease, informing treatment recommendations, considering the potential influence of the treatment on cancer outcome and the potential impact of cancer treatment on the fetus and pregnancy. Radiation exposure for the fetus and outcomes regarding different imaging modalities are available (28).

Guidelines have been established regarding imaging and staging during pregnancy (29,30). A recent practice patterns analysis recommends an algorithm that pregnant patients with breast cancer be considered for chest CT scan if pulmonary metastases are suspected and that MRI of the abdomen and pelvis along with a bone scan may be considered if metastases at these sites are suspect (31). However, staging procedures need to be tailored to minimize fetal radiation exposure, provide adequate information to determine disease stage, and provide sufficient knowledge for informed decisions for clinicians and patients. Recommended initial staging should include the following: complete history and physical examination with special attention to breast and nodal basin examinations; comprehensive metabolic panel; and complete blood count with differential. It is important to note that pregnant patients may have anemia due to the increase in circulating plasma volume. They may have increases in serum alkaline phosphatase level that can be doubled or tripled due to the pregnancy itself. The physical examination of the breast and nodal basins needs to include tumor measurements when possible and an assessment of extent of clinical nodal involvement. Given that the sites of breast cancer metastases are most commonly bone, liver, and lung, these areas should be evaluated in the pregnant breast cancer patient who has a clinical stage II or higher breast cancer as is done in nonpregnant patients. These staging evaluations may include chest x-ray with abdominal shielding; echocardiogram prior to the use of an anthracycline-based chemotherapy regimen; ultrasound of the liver; and a screening noncontrast MRI of the thoracic and lumbar spine to exclude bone metastases. If there are concerns of liver metastases after ultrasound examination, an abdominal non-gadolinium-enhanced MRI may be considered, especially since the liver may tend to have fatty-replacement during pregnancy. Noncontrast MRI has been used routinely and safely in the pregnant patient for staging. CT scans and bone scans are not recommended for routine use due to concerns of excessive fetal radiation exposures (29). Radionuclide scanning, including bone scanning, has very limited safety data in the pregnant patient, and should be considered only if absolutely necessary with aggressive hydration and frequent voiding.

Locoregional Therapy

Surgery and Anesthesia

Breast surgery can be safely performed in all trimesters of pregnancy; however, patients and surgeons may choose to wait until after the 12th week of gestation when the risk of spontaneous abortion may be lower (29). Multiple studies evaluating the risks of anesthesia during pregnancy have not shown an increase in fetal abnormalities. Mazze and Kallen reported on a registry of 5,405 pregnant patients who had any kind of surgery during pregnancy. They observed no difference in the risk of fetal malformation when they compared the pregnant group to 720,000 women who did not have a surgical procedure during pregnancy. There was no difference in outcomes in women who had their surgeries in

the first trimester. There was, however, an increase in the frequency of low- and very-low-birth-weight infants. This was attributed to the underlying illness or trauma necessitating the surgery (32). In a Canadian report of 2,565 pregnant women who underwent surgery, Duncan et al. reported no increase in fetal abnormalities compared to a control population of pregnant women who did not have an operation (33). A recent review of surgery in the pregnant patient recommends that the preferred timing for surgical intervention is 16 to 20 weeks of gestation (34).

Although in the majority of published reports patients opt for mastectomies for breast cancer treatment due to concerns regarding radiation therapy, breast-conserving surgery is an option, especially in women in the third trimester of pregnancy who can receive radiation therapy after delivery. With the potential of preoperative chemotherapy during pregnancy, breast-conserving surgery can be done later in the pregnancy or after delivery (35).

Safety and efficacy of sentinel lymph node biopsies is currently an area of clinical interest. The sensitivity and specificity of sentinel lymph node biopsies in the pregnant woman with breast cancer has not been well established. Estimated radiation exposure to the fetus is low and calculated to a maximum of 4.3 mGy (36). However, isosulfan blue dye mapping is not recommended due to concerns of unknown effects for the fetus as well as risk of anaphylaxis for the patient. Sensitivity of sentinel lymph node mapping may be significantly decreased without using isosulfan blue. The concern with sentinel node procedure in the pregnant patient is not the technical aspects of the procedure but the accuracy of the diagnostic information obtained as a result of the procedure. Sentinel node excision has not been subjected to the same rigorous study in the pregnant population as in the nonpregnant population (37). Therefore prudent and careful clinical evaluation prior to the procedure is warranted.

Radiation Therapy

Completion of appropriate locoregional therapy should be obtained despite the diagnosis of cancer during pregnancy. If the patient meets criteria for postmastectomy radiation therapy or they have had breast-conserving surgery, radiation therapy should be administered and this is recommended only after delivery of the fetus. Radiation exposure during pregnancy may result in fetal death, malformations, growth and/or mental impairment, and induction of cancers or hereditary defects. Although actual radiation exposure at the time of treatment may be limited, a significant portion of fetal exposure can occur from internal radiation scatter from the mother, for which abdominal shielding may be ineffective. The quantity of radiation exposure to the fetus is dependent upon the energy source, field size, and distance of the fetus from the field center (38). The fetus is at the highest risk of damage to organogenesis in the first trimester and with each successive trimester would be exposed to a higher proportion of the standard 50 to 60 Gy used (18).

Information regarding clinical outcome for radiation exposure during pregnancy is limited to small series of patients treated for hematologic malignancies. Woo et al. from MD Anderson Cancer Center reported on 16 patients with Hodgkin disease treated with 3,500 to 4,000 cGy while in the second and third trimesters. This is approximately three-fourths of the total breast cancer treatment dose (39). All 16 of these women delivered normal full-term infants. Antolak and Strom reported a case of locally recurrent breast cancer treated with electron-beam radiation to the chest wall during pregnancy with a simulated fetal dose exposure with abdominal shielding to be less than 1.5 cGy (40).

Systemic Therapy

Chemotherapy

Systemic chemotherapeutic agents are designed as antiproliferative drugs. The U.S. Food and Drug Administration (FDA) delineates drugs by pregnancy risks into categories of risk describing safety for mother and fetus. Categories A and B agents generally felt to be safe for use in pregnant patients, with Category C reporting some teratogenic or embryocidal effects in animal studies but no information in humans. Category D describes positive evidence of human fetal risks (Table 65-1). Although most chemotherapeutic agents are Category D, there are data demonstrating that systemic chemotherapy can be given safely during pregnancy during the second and third trimester. Clinical consideration for the use of systemic therapies should be similar in pregnant and nonpregnant patients. Despite limited knowledge regarding pharmacokinetics of chemotherapeutic agents in breast cancer due to the physiologic changes of pregnancy (increased plasma volume, altered renal and hepatic function, and third spacing potential), several published patient cohorts have described successful administration of chemotherapies to pregnant breast cancer patients. Published reports demonstrate that first trimester chemotherapy exposure is associated with a 14% to 19% risk of fetal malformations while second and third trimester exposure is significantly safer with a fetal malformation risk of 1.3% (41). It is not recommended that chemotherapy be administered during the first trimester. Additionally, antifolates such as methotrexate have been shown to carry higher risks of teratogenesis and methotrexate is a known abortifactant (41). Therefore methotrexate and methotrexate-containing regimens such as CMF generally are not given during pregnancy.

Anthracycline-Based Chemotherapy

There are numerous case reports and series regarding different chemotherapeutic agents given during pregnancy, mostly with anthracycline-based regimens. MD Anderson Cancer Center has the largest prospective cohort of pregnant breast cancer patients treated on a standardized protocol with one published update of this ongoing prospective trial in 2006 (42). Fifty-seven women were treated with 5-fluorouracil 500 mg/m^2 intravenously on days 1 and 4, doxorubicin 50 mg/m^2 given by continuous infusion over 72 hours, and cyclophosphamide 500 mg/m^2 given intravenously on day 1 (FAC). A median of 4 cycles were administered during pregnancy. Patients were dosed upon actual weight at each visit and not dose adjusted from baseline (early pregnancy or nonpregnant) weight. Premedications included standard doses of dexamethasone, lorazepam, and ondansetron. Depending on the week of gestation at the time of delivery, most women receive four to six cycles of FAC chemotherapy during pregnancy. Chemotherapy should be held after the 35th week of pregnancy in order to avoid the potential for neutropenia at the time of delivery. All women who delivered had live births. One child has Down syndrome and two have congenital anomalies (club foot, congenital bilateral ureteral reflux). The children are healthy and those in school are doing well, although two children, including the child with Down syndrome have special educational needs. One mother died from a pulmonary embolus after a cesarean delivery (42).

Multiple retrospective case reports and series have been reported in the literature. Those with the greatest number of patients treated with chemotherapy during pregnancy are highlighted (Table 65-2).

The most recent report is from a multi-institutional, European registry that included 413 pregnant patients (43).

[a]Of the 32 patients who received surgery prior to chemotherapy. An additional 25 patients received neoadjuvant chemotherapy and were more likely (56% v. 38%) to have a stage III disease at diagnosis.
NC, neoadjuvant chemotherapy.

Chemotherapy consisted of a variety of regimens including taxanes, CMF and anthracyclines, all administered after the first trimester. The authors reported lower birthweight for infants exposed to chemotherapy in utero and they noted more complications than for those without fetal exposure. In this report preterm birth was associated with adverse events, prompting the authors to recommend that efforts to reach full-term delivery be emphasized.

Data describing the safety and use of dose-dense anthracycline-based regimens with or without taxanes during pregnancy have recently been reported by Cardonick et al. They reported on data of 10 women who received dose-dense Adriamycin/Cytoxan followed by taxane therapy during pregnancy. This group was compared with 99 patients who received "conventional" chemotherapy. Clinical chart review was used to confirm the accuracy of the data reporting for this voluntary registry study of chemotherapy exposure during pregnancy. The authors concluded that the risks of low birth weight, fetal anomalies, age at delivery, and maternal/fetal hematolgic complications did not differ between the two groups (44).

Taxane Therapy

There are case reports describing the use of taxanes (paclitaxel and docetaxel) during pregnancy. However, the use of taxanes is often delayed until after delivery due to the limited safety data during pregnancy. There are multiple case reports in the literature describing the use of taxanes during breast cancer with no apparent deleterious effects on the fetus. Zagouri et al. have conducted and reported a systematic review of taxane use for treatment of breast cancer during pregnancy. They gathered data from 50 patients and reported fetal and delivery outcomes. All patients received taxane after the first trimester. The authors noted that 77% of the neonates were "completely healthy at delivery" at mean 36 weeks. At 16 months of follow-up 90% of the infants were reported to be "completely healthy" (45). As the data continue to accrue regarding the use of taxanes during pregnancy, taxanes may become more frequently used as treatment during the second and third trimesters. The Zagouri et al. data along with the reports of taxane use during pregnancy in other malignant conditions provide some reassurance of fetal safety for use of taxanes during the second and third trimesters of pregnancy.

Biologic Agents

There have been multiple reports of trastuzumab administration during pregnancy. No fetal abnormalities have been reported; however, anhydramnios with its use has been described in 6 of the case reports and fetal death has been noted (46–52). One of the children born developed respiratory failure, capillary leak syndrome, infections, and

necrotizing enterocolitis and died from multiple organ failure 21 weeks after delivery (51). One report describes reversible heart failure in the mother but no anhydramnios in the fetus (49). Bader et al. described reversible renal failure in the fetus (52). Azim and colleagues reported on the data of trastuzumab exposure and pregnancy from the HERA trial. They grouped patients with regard to timing of tratuzumab exposure: pregnant during or within 3 months of exposure, pregnant more than three months after trastuzumab exposure, and those with pregnancy and no trastuzumab exposure. In the first group there were 16 pregnancies but only 5 continued to delivery (there were 4 spontaneous abortions and 7 induced abortions). Of those with live births there were no congenital anomalies and no reported episodes of oligohydramnios. All had term deliveries (53). Lapatinib exposure has also been described in a patient who conceived while on lapatinib. Despite approximately 11 weeks of in utero exposure, the pregnancy was uncomplicated with delivery of a healthy baby (54). Data on exposure to pertuzumab and TDM -1 have not been reported thus far. Given the very limited data of biologic agent use during pregnancy, it is recommended that they not be used as part of standard adjuvant treatment protocols.

Endocrine Therapy

Endocrine therapy, if indicated, should be initiated after delivery and completion of chemotherapy. Although there are case reports of fetal exposure to tamoxifen without with fetal damage, there are others that have reported Goldenhar syndrome (microtia, preauricular skin tags, and hemifacial microsomia) (55), ambiguous genitalia, and other birth defects as well as reports of vaginal bleeding and spontaneous abortion (29,56,57). Aromatase inhibitors are not indicated for use in premenopausal women.

Other Systemic Agents

Commonly used antiemetics are rated as pregnancy risk category C. Newer agents such as ondansetron and granisetron are rated as pregnancy risk category B and are used to manage nausea in pregnant women receiving chemotherapy. Dexamethasone also can be used for short-term for nausea prophylaxis but long-term exposure is not recommended. For neutropenia prophylaxis, there are no randomized trials evaluating the use of G-CSF (filgastrim)or GM-CSF in pregnant breast cancer patients, but G-CSF has been used in neonatal neutropenia and/or sepsis and safe use in pregnancy has been reported (58). There are no data regarding pegfilgastrim in pregnancy.

MONITORING THE PREGNANCY

Patients should be referred directly to a high-risk obstetrician. Evaluation of fetal viability prior to the initiation of therapy and confirmation of the age of the fetus must be determined prior to administering any systemic therapy. Frequent visits with well-coordinated communication among the patient, medical oncologist, surgical oncologist, and obstetrician are required. Obstetrical monitoring may include frequent ultrasonography, fetal nonstress testing, and biophysical profiles. When clinically appropriate, amniocentesis can be performed. Consideration of the timing of delivery is also important with the last administration of chemotherapy to be no less than 2 weeks from estimated date of delivery. This may minimize the risk of neutropenia for both the mother and the neonate. Pregnancy-related complications including preecclampsia and preterm labor should be treated according to standard care guidelines. Planned induction of labor or cesarean deliveries are often performed to avoid these complications (29). Of note, the MD Anderson case series had 51% vaginal deliveries (42).

BREAST-FEEDING

Many chemotherapeutic agents are excreted in breast milk and neutropenia in an infant breast-fed during maternal treatment with cyclophosphamide has been described (58,59). Therefore, breast-feeding during administration of chemotherapy, biologic therapy, endocrine therapy, and radiation therapy should be avoided.

PROGNOSIS

Many series describe advanced disease stage at diagnosis for pregnant versus nonpregnant patients. The advanced stage at diagnosis as well as delays in diagnosis and initiation of treatment may account for the apparently worse prognosis for breast cancer diagnosed during pregnancy. There are, however, some mixed results reported when comparing pregnant and nonpregnant patients.

Ribiero et al. reported on a series of 178 patients with pregnancy-associated breast cancer. One hundred twenty-one women had breast cancer during pregnancy and there was a significant decrease in survival. These women with pregnancy-associated breast cancer presented with more advanced disease including 72% with node-positive disease. Per the authors, the majority of patients received treatment postpartum and there was no description of any chemotherapy given during pregnancy (60).

Tretli et al. described 35 patients from 1954 to 1981 and matched the patients for age and disease stage at diagnosis. Twenty were diagnosed during pregnancy and 15 during lactation. The median diagnosis delay during pregnancy was estimated at 2.5 months and 6 months in the lactating group, with an RR of death for breast cancer patients diagnosed during pregnancy of 3.1 ($p < .05$). However, treatment and delay of treatment were not described in this case-control study (61). An additional retrospective multi-institutional study by Bonnier et al. evaluated 154 patients diagnosed with breast cancer between 1960 and 1993 either during pregnancy or within the first 6 months postpartum and found that breast cancer during pregnancy was an independent and significant prognostic factor for worse outcome (25). Chemotherapy was administered to some of these women; however, chemotherapies used and the time delays in starting chemotherapy were not addressed.

Other recent case-control studies cannot confirm a difference in prognosis. A case-control study from Saudi Arabia matched 28 pregnant women by age and stage of disease with 84 nonpregnant women. Adjuvant chemotherapy was given to 23 of the pregnant patients. No difference in overall or relapse-free survival was found (62). Several other studies also have shown pregnancy at the time of diagnosis is not an independent worse prognostic factor. In a Toronto-based study, there was no statistically significant difference in survival between these groups when matched for age, stage, and year of diagnosis (63). Several other studies, including one from Japan (10) and New Zealand (64), show similar results. A case-control study of pregnant women with breast cancer has been reported from MD Anderson Cancer Center. Litton et al. analyzed the outcomes of 75 pregnant women with breast cancer matched with two controls with matching on age, disease stage at diagnosis, histology, hormone receptor and *HER2/neu* status, and year of diagnosis. Disease-free and overall survival were calculated for the two groups, and were comparable . Hazard ratio estimates

actually favored improved survival for the pregnant population (65). Although some studies show a worse prognosis for pregnancy-associated breast cancer, those studies that diagnosed and treated breast cancer during pregnancy with local and systemic therapy did not show the same worse survival as older studies in which treatment often was not given until after delivery. Although many of the studies describe a worse prognosis for those women diagnosed with breast cancer in the first few months and years after a pregnancy, the grouping of women diagnosed during and after pregnancy may confound these overall results.

CONSIDERATION OF PREGNANCY TERMINATION

The decision to terminate or maintain a pregnancy is a highly personal decision that a fully informed woman should make in conjunction with her physician. Early data suggested that the combination of breast cancer and pregnancy was nearly lethal and that termination of pregnancy was warranted and even showed some possible improvement in patient survival (66). Gradually, the data regarding termination in this group of women that have emerged have shown that early termination of pregnancy does not been improve the outcome of pregnancy-associated breast cancer (67). There are two reports suggesting that early termination may have decreased patient survival (68,69). Although termination does not appear to improve survival or response to anthracycline-based therapy, some women may choose termination when diagnosed with an advanced cancer in the early weeks of pregnancy depending on their perceptions of the risks, harms, and burdens of treatment for themselves and the fetus, the viability of the fetus, and the presence or absence of detected fetal malformations.

SHORT- AND LONG-TERM COMPLICATIONS FOR THE CHILD

There is a paucity of data regarding the short-term and long-term effects of treatment for children exposed to chemotherapy for breast cancer in utero. The largest single prospective dataset reported for breast cancer during pregnancy is from the MD Anderson Cancer Center. Immediately after delivery, there may be early and reversible fetal toxicities from chemotherapy. These can include anemia, neutropenia, and alopecia. In the prospective series from MD Anderson Cancer Center, there were no miscarriages, stillbirths, or perinatal deaths. The majority of the children did not have significant neonatal complications and the frequency of complications appeared to be similar to the general population of neonates. The most common complication was difficulty breathing in 10%, and one child born at 38 weeks gestation had a subarachnoid hemorrhage 2 days postpartum. The age of children at the time of health survey ranged from 2 to 157 months. One child had Down syndrome and 2 children had congenital abnormalities (club foot, bilateral ureteral reflux). Overall, the children were healthy with 2 of the 40 children described having special educational needs (42).

Much of the children's health and outcomes data are derived from case reports of children exposed to chemotherapeutic agents for hematologic malignancies in the mother. A large study from Mexico described 84 children with follow-up of 18.7 years born to women who received chemotherapy in utero for hematologic malignancies. This review did not report any significant physical, neurologic, or psychological abnormalities (70,71). Reyonoso et al. described 7 cases of 8 children exposed in utero to chemotherapy for acute leukemia with follow-up ranging from 1 to 17 years. One of the children in a twin pregnancy was born with multiple congenital malformations and eventually developed a neuroblastoma and thyroid cancer. The other 7 children have had normal growth and development and malignant diagnoses (72). Cardonick et al. reported from a self-reporting national registry of 113 deliveries to women who received chemotherapy during pregnancy and reported a malformation rate of 3.8%, which is not higher than that reported in the general population (73).

Further evaluations of neurocognitive and cardiac function as well as prospective evaluation for future malignancies and reproductive history will need to be continued for children who have been exposed to chemotherapy in utero.

MANAGEMENT SUMMARY

The treatment of pregnancy and breast cancer should include a multidisciplinary approach with active communication among the patient, obstetrician, medical, surgical, and radiation oncologists. Appropriate diagnosis, biopsy, and imaging direct this multidisciplinary approach which can include surgery as well as preoperative or adjuvant systemic chemotherapy.

Radiation therapy and several biologic and endocrine therapies should be postponed until after delivery. Continued evaluation of the children exposed to chemotherapeutic agents in utero is warranted.

Management recommendations for the pregnant breast cancer patient are as follows:

Diagnosis

- Physical examination including nodal basins, mammography and breast and nodal basin ultrasound Biopsy core needle preferred.
- Breast imaging that includes physical examination, mammography, breast ultrasound.
- Staging that may include noncontrast MRI thoracic and lumbar spine and ultrasound based imaging.
- Pathology review that includes biomarkers.
- Genetics counseling.

Surgery

- Surgical management for breast cancer either with mastectomy or lumpectomy.
- Axillary lymph node dissection for clinically or cytologically involved nodes. Sentinel node excision based on a case-by-case clinical decision process.

Monitoring of pregnancy

- Maternal–fetal medicine evaluation of fetal growth and development.

Systemic therapy

- Chemotherapy with an anthracycline-based regimen may be considered after the first trimester and prior to the 35th week of pregnancy. Most of the data reported are with every 3-week doxorubicin given over a 72-hour infusion, such as in the FAC regimen. Taxanes have limited safety data but may be considered on a

case-by-case basis. Trastuzumab has been associated with oligo, and anhydramnios and should be avoided during pregnancy. Biologic agents should be avoided.

Radiation therapy

- To be completed after delivery as per standard guideline recommendations.

Communication

- A multidisciplinary approach to management emphasizing communication among the medical oncologist, surgical oncologist, radiation oncologist, and maternal–fetal specialist is necessary.

CHAPTER 66

Occult Primary Cancer with Axillary Metastases

Alain Fourquet and Youlia M. Kirova

CHAPTER CONTENTS

Breast cancer can sometimes present as an isolated axillary adenopathy without any detectable breast tumor by palpation or radiologic examination. These occult primary cancers are staged as T0, N1 (stage II in the Union Internationale Contre le Cancer/American Joint Committee classification). This staging requires that proper clinical *and* mammographic investigations be done to rule out the presence of a small breast tumor. If this is accomplished, axillary metastases of occult breast primary cancer represent a rare clinical entity first described by Halsted in 1907 (1).

FREQUENCY

The incidence of an occult primary tumor with axillary metastases is low. Incidence rates ranged from 0.10% to 1.0% of operable breast cancers in the largest reported series (2,3). Less than 1,500 cases have been reported in the literature since the 1950s. Because these series are limited and management policies have varied widely during this period, comparing characteristics of the patients, management, and results of treatment is difficult. Many of these patients had suspicious mammograms (4–6). Presumably, the constant improvement of the quality of mammography and ultrasonography as well as the use of magnetic resonance imaging (MRI) has decreased the rate of occult primary tumor with axillary metastases. Interpretation of these comparisons should only be done with caution.

The characteristics of the patients with T0, N1 breast cancer are similar to those of patients with typical stage II disease. The series from the Institut Curie included 59 patients treated between 1960 and 1997. The median patient age was 57 years (range, 36 to 79 years). Thirty-four patients (58%) were postmenopausal, including two patients under hormone replacement therapy. Fifteen patients (25%) had family histories of breast cancer. Twenty-eight (47.5%) had left axillary nodes, and 31 (52.5%) had right axillary nodes.

DIAGNOSIS

Axillary Adenopathy

Isolated axillary adenopathy is a benign condition in most patients. Lymphomas are the most frequently occurring malignant tumors. Adenocarcinoma in areas other than the breast may include thyroid, lung, gastric, pancreatic, and colorectal cancer (7). These tumors, however, rarely have isolated axillary metastases as the only presentation of disease. Although in the past an extensive search for primary adenocarcinoma other than breast cancer was not recommended (6,8,9), these patients, nowadays, usually have computed tomography (CT) scans of the chest and abdomen for evaluation of metastases. In addition, tumor markers may help in the diagnosis of metastatic colon or pancreatic cancers.

Axillary adenopathy usually consists of one or two involved nodes, sometimes with large diameters. The median axillary node size at presentation in the patients treated at the Institut Curie was 30 mm (range, 10 to 70 mm). The initial diagnosis of malignancy was achieved by node excision in 25 of 59 patients, by fine-needle aspiration in 26 patients, and by core-needle biopsy (drill biopsy) in 8 patients.

A primary breast cancer located in the axillary tail of the breast may be confounded with an axillary node. The presence of normal lymph node structure surrounding the foci of the carcinoma on the pathologic sample usually leads to the diagnosis of metastasis to a lymph node. The recognition of a metastatic lymph node can, however, be difficult because of massive involvement, with extension of the tumor into the axillary fat and disappearance of the lymphoid patterns.

Breast Cancer

Bilateral mammography should always be performed in the presence of metastatic adenocarcinoma in an axillary lymph node. Baron et al. (4) report an overall 44% accuracy in the diagnosis of occult breast cancer in a series of 34 patients, in which only nine mammographies were considered suspicious. Many of these tumors are missed owing to their relative small size and the fact that they are obscured on the mammogram by dense fibroglandular tissue (10). Nonetheless, any suspicious image should be removed for pathologic analysis.

Mammography and ultrasound have been the primary modalities for the diagnosis and the workup of breast cancer (10). Promising results were published of the use of MRI in characterizing nonpalpable, but radiologically detectable, breast lesions in patients (11,12). In patients with T0,

N1 breast cancer, studies have shown that MRI could detect early contrast-enhanced images in the breast. A systematic review of 7 published studies estimated that breast MRI had a 90% sensitivity and a 31% specificity in detecting the primary cancer in the breast (13). The high sensitivity of breast MRI suggests that it could be used systematically in searching for a breast primary tumor. The results of several studies of MRI in patients with occult breast cancer are shown in Table 66-1. However, because of its low specificity and the difficulties in localizing small, early contrast-enhancing foci in some instances, difficult management problems may occur. The use of MRI-directed sonographic, mammographic, or scanographic guidance (17) can help to localize the breast tumor in most patients. MRI-guided localization and biopsy can be performed (22). At the Institut Curie, 15 patients with metastatic axillary nodes, negative breast clinical examination, and without any mammographic target had breast MRI between 1997 and 2000. Early contrast-enhanced images were detected in 14 of the 15 patients (93%). A surgical excision was performed in 11 patients: in 4 patients, a second MRI-guided ultrasound examination was able to disclose and localize the breast lesion; in 3 patients localization was achieved with an orthogonal mammogram, because of the superficial localization of the lesion and the small size of the breast; and finally in 4 patients the lesion was localized using CT-scan with bolus injection. Invasive breast cancer was found in 9 of the 11 patients (82%) who underwent surgery. There is limited published experience with the use of 18F-FDG PET/CT imaging in the specific setting of occult breast cancer with axillary adenopathy (23,24). However, though it has a high specificity when detecting breast lesions, its sensitivity is low, particularly in small tumors (25). Other new breast imaging procedures are under investigation in breast cancer diagnosis (reviewed in 26): they include ionizing techniques such as scintigraphy with specific radiotracers (MIBI), non ionizing radiation imaging techniques such as color Doppler sonography (27), and optical imaging and optical imaging with fluorescent dyes coupled to probes (28). No experience has been so far reported on the use of these new techniques in the diagnosis of occult breast carcinoma.

In patients who have nonpalpable breast masses and normal imaging workup, the mammary origin of a metastatic adenocarcinoma to an axillary lymph node cannot be established with certainty. Therefore, the diagnosis of occult breast cancer can only be highly presumed based on many elements, including sex, age, isolated adenopathy, and histologic diagnosis of adenocarcinoma.

High estrogen or progesterone receptors levels found in the metastatic axillary nodes can help to confirm a primary breast tumor (29); however, three series (4,30,31) reported that 50% to 86% of occult breast cancer cases were found to be negative for estrogen receptors. Because surgical excision of the palpable node was often the first diagnostic procedure, rarely was an attempt made to analyze the receptors by biochemical methods. In a series of 80 patients with occult breast cancer and axillary metastases, Montagna et al. (32) performed the immunohistochemical analysis of estrogen (ER) and progesterone (PR) receptors, and HER2 protein on the metastatic axillary nodes. They found that 46 (58%) were ER negative and PR negative (no expression), and 20 (25%) were HER2 positive. Using these as surrogate markers of biological subtypes, they found 14 (17.5%) luminal A (ER/PR positive, HER2 negative), 6 (7.5%) luminal B (ER/PR positive, HER2 positive, 28 (35%) HER2 enriched (ER and PR negative, HER2 positive), and 31 (39%) triple negative.

Natural History

After removal of an axillary adenopathy, a breast cancer eventually developed in the untreated breast in an average 42% of patients, as reported in one review (2), with time intervals below 5 years in all cases. Patient samples were limited in these series, however, and follow-up periods varied widely. In the Royal Marsden series (33), 10/13 patients (77%) who had negative breast imaging including mammography, ultrasound, and MRI, and no breast treatment, have recurred in the ipsilateral breast at 68 months median follow-up.

The number of pathologically involved lymph nodes seen after axillary dissection is high. Table 66-2 summarizes the results in five series, reporting a median number of involved nodes was close to three. Forty patients in the Institut Curie series had an axillary dissection as initial treatment. The median number of involved nodes was 3 (range, 1 to 20). During follow-up, 16 of the 59 patients in the series had distant metastases: 4 (25%) in the brain, 5 (31%) in the liver, 3 (19%) as cervical nodes, and 3 in multiple sites. One patient had isolated bone metastases. Ten patients had contralateral disease, which occurred in the contralateral breast alone in 6 patients. Of note, 4 patients had isolated contralateral axillary node metastases.

Treatment and Results

Mastectomy with axillary node dissection has been the most commonly used treatment in patients with occult primary tumors. The combined analysis of 10 published series has shown that breast cancer was found in the mastectomy specimen in 147 of 210 patients (70%) (Table 66-3). Invasive tumors were found in 36 of 210 patients (65%).

[a]Includes six patients with superolateral quadrantectomy.

Table 66-4 shows the results of breast irradiation in several retrospective studies. The 5-year local recurrence rates in patients who received breast irradiation ranged from 7.5% to 17%, much lower than the rate in the groups who did not receive any breast treatment (36% to 66%). These data, along with the fact that nearly 50% of the patients who received no form of breast treatment will eventually have disease recurrence in the breast, support the recommendation that the breast be treated when no tumor can be detected clinically or mammographically. Whether mastectomy should be carried out in all patients, or breast conservation with whole-breast irradiation can be safely performed remains to be demonstrated. Vlastos et al. (38) retrospectively analyzed a series of 45 patients with occult breast cancer: 32 had a breast-conserving treatment with [25] or without [7] radiotherapy; 13 had a mastectomy with [7] or without [6] radiotherapy. At a median follow-up of 7 years, no differences in locoregional recurrences, distant metastases, disease-free survival, or overall survival were observed between those who had a breast-conserving treatment and those who had a mastectomy. Adjuvant systemic treatment was delivered to 84% and 46% of patients, respectively. Walker et al. (3) determined overall and cause-specific survivals of the 750 patients with occult breast cancer and axillary metastases identified in the SEER database, from 1983 to 2006. Median follow-up was 4 years. Patients with mastectomy or breast radiotherapy had significantly higher survival, but not cause-specific survival, than those with axillary lymph nodes dissection only, and those who had no locoregional treatments: 10-year rate of overall survival (OS) were 64.9%, 58.5% ($p = .02$), and 47.5%, respectively ($p = .04$); 10-year rates of cause-specific survival (CSS) were 74.6%, 71.2% ($p = .09$), and 71.9% ($p = .69$), respectively. No differences in OS or CSS were seen between the 268 patients who had mastectomy and the 202 patients who received breast irradiation.

After axillary node dissection, should irradiation be delivered to the remaining lymph nodes? Few data are available in the literature to support any treatment options. A substantial risk for nodal involvement of the upper axilla can be suspected, however, based on the fact that three involved nodes are expected to be found in one-half of the patients. In patients with axillary node involvement associated with an invasive breast cancer, irradiation of the upper axilla is typically delivered when four or more nodes are involved. Studies have shown that, in patients with axillary node involvement, postmastectomy irradiation of the chest wall and regional nodes (39), as well as breast and nodes irradiation after breast-conserving surgery (40) decreased the rate of long-term distant metastases and improved survival, even in patients who received adjuvant chemotherapy or hormone therapy. Therefore, by analogy with other stage II tumors, irradiation of the upper axilla can be recommended in these instances, providing that axillary dissection was performed. Of 59 patients treated at the Institut Curie, 58 received nodal irradiation. In most instances, only the upper axilla and supraclavicular nodes were treated after complete axillary nodal dissection, whereas the whole axilla was treated when a simple adenectomy had been performed. There were four axillary node recurrences: One was isolated, but three were associated with a breast recurrence. The indications for internal mammary node irradiation are currently much debated in patients with a breast mass and central or medial tumor or axillary involvement. Recommendations about treatment of the internal mammary nodes in patients

with occult primaries and axillary adenopathy are difficult to formulate because the evaluation of internal mammary node irradiation in this rare form of breast cancer is impossible on the basis of limited retrospective series. Because the location of the primary tumor is unknown, the Institut Curie policy supports the irradiation of the internal mammary nodes in all patients.

The reported 5-year actuarial survival rates after treatment of occult breast cancer with axillary metastases range from 36% to 79% (Table 66-5). The 5- and 10-year survival estimates in the 59 patients treated at the Institut Curie were 84.5% and 74% with a median follow-up of 151 months (range, 22 to 458 months). These figures seem higher than those observed after treatment of patients with stage II disease and detectable breast tumor. This has been emphasized by several authors (8,9,31,35,36). These survival rate estimates are, however, derived from small series of patients with various durations of follow-up and heterogeneous treatment modalities. Rosen and Kimmel (33) attempted to evaluate the results more precisely by matching a series of 48 patients with occult breast primary and axillary node metastases with a series of patients with stage II breast cancer who presented with palpable breast tumor (T1, N1 and T2, N1). Although the difference was not statistically significant, higher overall survival and size- or node status–adjusted survival rates were observed in the group of patients with occult primary tumors.

Montagna et al. (32) have compared a series of 80 patients with occult breast cancer and axillary metastases to a matched control series of 80 patients with pT1c (≤20 mm) N0. Matching was done according to age, year of surgery, number of nodes involved, ER and PR status, and HER2 status. Patients with pT1c disease had more mastectomies (18% vs. 5%). Median follow-up was 6.1 years. No significant differences were observed between the group with occult breast cancer and the group with pT1c breast cancer in overall survival, disease-free survival, cumulative incidence of locoregional recurrences, or cumulative incidence of distant metastases.

Reliable prognostic analyses are difficult to perform because of the multiple selection biases in the retrospective series and the small sample size. Rosen and Kimmel (33) showed that survival was determined by the number of axillary nodes involved; patients with fewer than four nodes involved did better than those with more than four nodes involved. This was also demonstrated in the study by Vlastos et al. (38), and by our study at Institut Curie where survival was longer in patients with less than four involved axillary nodes: the 10-year survival rates were 88% and 60%, respectively (p = .04). Baron et al. (4) showed that estrogen receptor-positive patients fared better than estrogen receptor-negative patients. In their study of the SEER database, Walker et al. (3) performed a multivariate analysis in the 470 patients who had mastectomy or breast irradiation, and showed that unfavorable cause-specific survival was associated with ER-ve disease, more than 9 involved axillary nodes, and less than 10 nodes resected, but not with the type of treatment (mastectomy or breast irradiation). Montagna et al. (32) performed a multivariate analysis of prognostic factors in their series of 80 patients with occult breast cancer. Overall survival, disease-free survival, local recurrence risk, and risk of distant metastases were increased in patients with more than 3 involved nodes. Triple negative tumor phenotype (ER 0%, PR 0%, and HER2 overexpression or amplification) was associated with impaired overall and disease-free survivals, and with an increased risk of local recurrence.

Is there a role for adjuvant systemic treatment in patients with occult primary breast cancer? As mentioned previously, because of the rarity of this disease and the multiple selection biases, the efficacy of systemic therapy in patients with T0, N1 breast cancer is impossible to ascertain. By analogy with stage II node-positive breast cancer, the general tendency is to use the same criteria (i.e., axillary node involvement) to prescribe systemic chemotherapy or hormone therapy. Almost all patients included in the most recent studies (21,32,34,37) have received adjuvant systemic treatment with chemotherapy, hormone therapy, or both. Of the 59 patients treated at Institut Curie, 27 received adjuvant chemotherapy, with a regimen of cyclophosphamide, doxorubicin, and 5-fluorouracil. Patients who received chemotherapy were slightly younger and had more involved nodes than those who did not, but these differences were not statistically significant. Survival and metastases-free interval rates were not statistically different in the 27 patients who received chemotherapy and in the 32 patients who did not. This apparent lack of benefit from chemotherapy may be explained by the fact that in this particular group of patients, chemotherapy did not reverse the adverse prognostic influence of massive nodal involvement. Little is known about the effect of hormone therapy in these patients. Of 13 patients who received tamoxifen for at least 2 years in the Institut Curie series, only 1 developed distant metastases, 7 years after diagnosis. The numbers are too small to make significant statistical comparisons, but these results suggest that hormone treatment may be very effective and support its use, at least in patients who have high hormone receptor levels.

The common policy in most institutions is to give adjuvant systemic therapy to patients with involved axillary nodes. As suggested by the results of recent studies, the

outcome of occult breast cancers with axillary metastases seems similar to that of stage II breast cancer, and the prognostic factors are probably identical. Therefore, the administration of adjuvant systemic treatments including chemotherapy, endocrine treatment, or trastuzumab should be recommended to patients with occult breast cancer and axillary metastases, with the same indications criteria as for patients with stage II breast cancer.

MANAGEMENT SUMMARY

- Occult primary breast cancer presenting as an axillary lymph node is rare and should not be confused with ectopic breast cancer localized in the axillary tail of the breast.
- The heterogeneity of treatment and the limited number of patients studied in the published literature make it difficult to standardize treatment options.
- After the diagnosis of adenocarcinoma has been established by a biopsy of an isolated axillary mass, extensive workup evaluation is not necessary. A thorough clinical examination, bilateral mammograms, breast metastatic work-up, and tumor markers are sufficient to establish a high presumption of axillary metastases of mammary origin.
- Breast MRI should be used in all cases. An early contrast-enhancing image of the breast should be localized by sonography or mammography for biopsy or surgical excision. CT scan localization, or MRI localization if available, must be used if sonographic or mammographic localization is impossible.
- An axillary dissection is generally performed to provide additional prognostic information and to provide local control in the axilla.
- The breast should be treated. Breast-conserving therapy in patients with an occult breast primary tumor by whole breast irradiation to a dose of 50 to 55 Gy limits the risk for disease recurrence and is an alternative to mastectomy.
- Irradiation of the upper axilla and supraclavicular area, to a minimum dose of 45 Gy, is recommended in patients with more than three involved axillary nodes. In cases of patients with one to three nodes, the value of this irradiation is debated. The whole axilla should be irradiated in patients who did not undergo axillary node dissection.
- Recommendations for adjuvant systemic therapy based on estrogen receptor, progesterone receptor, and HER2 in patients with an occult primary should be similar to that for other patients with node-positive breast cancer.

SECTION X

Evaluation After Primary Therapy and Management of Recurrent Breast Cancer

CHAPTER 67

Surveillance of Patients following Primary Therapy

Robert W. Carlson

CHAPTER CONTENTS

The success of therapy for breast cancer results in an increasing number of breast cancer survivors being monitored for the development of recurrent disease. It is estimated that there are approximately 3 million breast cancer survivors in the United States alone. The magnitude of the follow-up of this large population requires efficient, timely, and cost effective monitoring. The optimal monitoring for recurrence of disease requires knowledge of the risk for recurrence, common sites of recurrence, accuracy of methods of detection of recurrence, and potential benefits and risks of detection of early disease recurrence.

ASSESSMENT FOR RISK OF RECURRENCE OF DISEASE

Assessment for risk of recurrence of disease may be performed by the integration of the anticipated natural history of a breast cancer based upon anatomic and biologic prognostic factors and the anticancer treatment delivered. The hazard rates for recurrence of disease have been studied retrospectively among 3,585 patients enrolled in seven large clinical trials (1). The peak for annual hazard for recurrence occurred in year 1 to 2 and then decreased consistently to 5 years, and then declined slowly through year 12. The hazard for recurrence was especially high for those with 4 or more involved axillary lymph nodes during the first 5 to 6 years of follow-up, but thereafter was similar to those with fewer nodes involved. The hazard for recurrence was higher in those women with estrogen receptor negative versus receptor positive breast cancer during the first 3 years of follow-up, and then similar or lower thereafter.

Long-term follow-up studies have documented that the most common sites of recurrent disease are local soft tissue, bone, lung, liver, and brain. Multiple sites are often involved at the time of detection of first recurrence, and almost always during the course of the metastatic disease. Tumors that are estrogen receptor positive, progesterone receptor positive, low or intermediate grade, and with low mitotic rate are more likely to metastasize to bone than viscera when compared to tumors without those. In contrast, menopausal status, tumor size, and nodal status do not impact the frequency of bone versus visceral site of metastatic disease. Further, many factors associated with overall prognosis at diagnosis of early breast cancer retain prognostic significance for survival following first diagnosis of metastatic breast cancer. Long-term survival after recurrent breast cancer is relatively unusual, and apparent cures of disease are uncommon except for patients with ipsilateral in-breast tumor recurrences (2).

The goals of surveillance are to detect recurrence at a time that allows initiation of therapy to improve survival and to maintain a high quality of life. There is little high-level evidence that these goals are achieved by any surveillance program.

THE CONTRALATERAL BREAST

Frequency of Contralateral Disease

The occurrence of breast cancer in the contralateral breast of women with a known history of breast cancer may represent either a new primary tumor or a metastasis from the originally diagnosed breast cancer. While the determination of a new primary versus a metastasis may be difficult, a contralateral breast cancer represents a new primary if the cancer is of a different histology (e.g., ductal vs. lobular) or is associated with an *in situ* component. Metachronous second primary breast cancers are more likely to be *in situ* cancer, small size, and node negative (3). The risk of a metachronous, contralateral, second primary breast cancer is generally estimated at 0.5% to 1.0% per year (3,4). Recent data suggests that the frequency of metachronous, contralateral, estrogen receptor positive second primary breast cancer is declining, probably because of the risk reduction provided by adjuvant endocrine therapies (5). Factors that increase the risk include a known *BRCA1* or *BRCA2* mutation, young age at first primary, family history of breast cancer, lobular histology for first primary breast cancer, and prior radiation exposure. Factors that decrease the risk include prior chemotherapy or endocrine therapy (6). While there are no randomized studies of screening mammography of the contralateral breast, contralateral second primary breast cancers in women undergoing routine screening mammography are smaller, and more likely to be *in situ* and node negative than those in women not undergoing routine mammography (7). The occurrence of metachronous contralateral breast cancer has modest impact on overall survival (7).

Screening for Contralateral Disease

Conceptually, the monitoring for a new primary breast cancer in the contralateral breast may be viewed as monitoring in a high risk for breast cancer population with an increased risk of competing mortality secondary to the initial primary breast cancer. In the general population of women age 40 and older, the use of screening mammography has been demonstrated to decrease breast cancer mortality. It is thus likely that routine screening mammography would decrease breast mortality from a second primary tumor, although the mortality rate for second primary breast cancers is low.

Breast magnetic resonance imaging (MRI) screening has high sensitivity, moderate specificity, and high cost as an adjunct to the performance of mammography. No randomized clinical trials of breast MRI as screening or surveillance are available in any clinical setting. Non-randomized trials in women without known breast cancer but at high risk of breast cancer document a higher detection rate of breast cancer with the use of breast MRI scanning (8). To date, no similar prospective trial has been reported in the follow-up of women following diagnosis of breast cancer. The American Cancer Society currently recommends screening MRI as an adjunct to screening mammography, based upon non-randomized screening trials and observational studies, in women with known *BRCA* mutation, who have a first degree relative with a known *BRCA* mutation, who have a lifetime risk of greater than 20% to 25% based upon family history, who had radiation exposure to the chest between age 10 and 30 years, who have known Li-Fraumeni syndrome themselves or in first degree relatives, or who have Cowden and Bannayan-Riley-Ruvalcaba syndromes themselves or in first-degree relatives (9). The American Cancer Society makes no recommendation for or against screening MRI in women with a personal history of breast cancer. A study of breast MRI screening in women at risk of breast cancer and with negative mammograms included 245 subjects with a personal history of breast cancer (10). Breast cancers were documented in 4% of the subjects with a prior history of breast cancer, and the positive predictive value of MRI recommended biopsy was 32%. A retrospective study of women screened by MRI who had a personal, but no family, history of breast cancer documented 17 cancers in 144 subjects (11). Ten of the 17 cancers were detected by MRI only. The positive predictive value of MRI was 39%. The non-randomized nature of all of these studies prohibits assessment of the impact of breast MRI screening on breast cancer mortality.

The value of clinical breast examination has not been adequately studied, although the performance of clinical breast examination is a generally accepted part of routine healthcare of the adult female. Breast self-examination was found to be of no advantage in early detection or mortality reduction in a large, randomized clinical trial in a population of factory workers in China (12).

Based on the increased risk of a second primary breast cancer in the contralateral breast, it appears prudent to perform regular clinical breast examinations and mammography as a routine part of surveillance programs. The role of breast MRI screening is yet to be defined, but would appear reasonable in those with very high contralateral risk. Such high risk patients are those with a known, or a high risk for, genetic mutation conferring risk for breast cancer or a prior history of thoracic radiation. For other populations, insufficient information exists to allow for specific recommendations regarding the use of screening MRI. The value of breast self-examination has not been demonstrated.

LOCOREGIONAL RECURRENCES

Most patients with a locoregional recurrence of breast cancer following either breast conserving therapy or mastectomy present with symptoms. Approximately 40% of isolated locoregional recurrences are detected during routine examinations in asymptomatic patients and a similar number are diagnosed outside of routine follow-up examinations in symptomatic or asymptomatic patients (13).

Ipsilateral Breast Tumor Recurrence

Ipsilateral breast tumor recurrence following breast conserving surgery is experienced by 5 years in approximately 7% of patients with whole breast irradiation and 26% of patients without whole breast irradiation (14). The addition of a radiation boost to the tumor bed decreases in-breast recurrence rates by approximately 41% compared with whole breast irradiation alone (15). Most recurrences occur in the prior tumor bed, and positive pathologic margins, younger age, higher grade tumor, larger tumor size, negative estrogen receptor status, and involvement of axillary lymph nodes have all been reported to increase the risk of ipsilateral breast tumor recurrence (14–16). Approximately 70% of ipsilateral breast tumor recurrences occur within the first 5 years of primary diagnosis (14,16). Breast recurrence during the first 5 years of follow-up is associated with a substantially worse overall prognosis than are in-breast recurrences that manifest later.

Detection of ipsilateral breast tumor recurrence is often difficult because of post-surgical, post-radiotherapy changes in the breast. The sensitivity of mammography for ipsilateral breast tumor recurrences is approximately 50% to 70% and ultrasonography 80% to 85%. Overall, approximately two thirds of local recurrences are detected by the patient or on clinical examination (17,18).Detailed reviews of studies of screening mammography in women with a personal

history of breast cancer generally document that patients diagnosed with mammography detected only in-breast recurrences have superior survival to those with symptomatic recurrences (19,20). These studies all suffer from being relatively small in sample size and are non-randomized. Thus, it is impossible to correct for confounding by lead-time and length-time biases.

Breast MRI scanning has high sensitivity for detecting in-breast recurrences, but is expensive and is associated with highly variable specificity.

Local-Regional Recurrence Postmastectomy

Local-regional recurrence following mastectomy is experienced by 5 years in approximately 6% of patients with postmastectomy regional irradiation and 23% of patients without postmastectomy irradiation (21). In the overview analysis, axillary lymph node status strongly predicted for absolute risk for local-regional recurrence (21). In women with axillary lymph node-negative disease, the 5-year local recurrence risk following surgery alone was 6%, and this was reduced to 2% with the use of local-regional irradiation. In women with axillary lymph node-positive disease, the 5-year local recurrence risk following surgery alone was 23% and this was reduced to 6% with the addition of local-regional irradiation. Increasing tumor grade, tumor size, and number of involved axillary lymph nodes increases the risk of local-regional recurrence.

Detection of local-regional recurrences following mastectomy with or without radiation is typically the result of either patient identification or of a routine clinical examination. Local-regional recurrences are rarely detected by radiographs or other screening studies.

Distant Recurrences

Well established prognostic factors allow the estimation of risk for development of systemic disease following treatment for stage 0, I, II, and III breast cancer. Known prognostic factors include histologic subtype of breast cancer, tumor grade, tumor size, involvement of skin or chest wall, extent of involvement of regional lymph nodes, hormone receptor status, *HER2* level of expression or amplification, and multigene array expression profile.

Breast cancer metastases occur in a generally predictable pattern, with synchronous multiple sites of recurrence being common. Bone is the most common site of disseminated disease, and represents approximately 40% of first recurrences. The most commonly involved bones are the spine, ribs, pelvis, skull, femur, and humerus. Breast cancer metastasis to bone distal to the elbow or knee is rare. Other common sites for metastatic disease include lung, liver, lymph nodes, and soft tissue. The site of first metastasis from breast cancer is influenced by estrogen receptor status (Table 67-1). Estrogen receptor-positive breast cancer is more likely to spread to bone, while receptor-negative breast cancer is more likely to spread to viscera and soft tissues and is associated with a higher rate of early recurrence (Table 67-1) (22,23). Even in those patients undergoing routine surveillance during follow-up, most recurrent disease is symptomatic at time of diagnosis (24,25).

Infiltrating lobular breast cancer has a propensity for recurrences in intra-abdominal and retroperitoneal sites including stomach, intestine, peritoneum, and ureter (often bilateral) (26).

Currently available treatment of recurrent or metastatic breast cancer is rarely curative, even when the recurrence is limited (2). Further, the amount of tumor burden in asymptomatic or minimally symptomatic patients does not predict disease response to systemic treatment, ability to palliate symptoms, or overall survival. Thus, there is no advantage to diagnosing asymptomatic, early, subclinical disease.

Routine Blood Tests

The routine performance of blood tests for alkaline phosphatase, aspartate aminotransferase, γ-glutamyl transferase, bilirubin, calcium, and creatinine was studied by the International Breast Cancer Study Group in 4,105 women

TABLE 67-1

Location of First Recurrence in Randomized Trials of Intensive versus Routine Surveillance

Type of Recurrence	*GIVIO Trial (24)*		*National Research Council Project on Breast Cancer (46)*	
	Intensive Monitoring (n = 201 Recurrences or Deaths)	*Control (n = 196 Recurrences or Deaths)*	*Intensive Monitoring (n = 219 Recurrences)*	*Control (n = 174 Recurrences)*
Local regional recurrence alone	32 (15.9%	36 (18.4%)	55 (25.1%)	49 (28.2%)
Contralateral breast alone	12 (11.4%)	13 (6.6%)	Not stated	Not stated
Distant metastases	127 (63.1%)	127 (64.8)	164 (75.9%)	125 (71.8%)
Bone	52 (25.9%)	55 (28.1%)	84 (38.3%)	53 (30.5%)
Liver	13 (6.5%)	12 (6.1%)		
Lung/pleura	24 (11.9%)	21 (10.7%)	28 (12.8%)	18 (10.3%)
Other sites	19 (9.4%)	27 (13.8%)	22 (10.0%	21 (12.1%)
Multiple sites	19 (9.4%)	12 (6.1%)	30 (13.7%)	33 (19.0%)
Second Primary (not breast)	8 (4.0%)	11 (5.6%)		
Death without recurrence	11 (5.5%)	9 (4.6%)		

with invasive breast cancer (27). At the time of analysis, 2,140 patients had experienced a relapse, 93 had a second non-breast primary tumor, and 111 had died without relapse during 10-years median follow-up. In this analysis, only alkaline phosphatase was abnormal in at least 20% of patients with recurrent disease, and was abnormal in 32% of patients with bone metastasis and 71% of patients with liver metastasis. Aspartate aminotransferase and γ-glutamyl transferase were elevated in 62% and 75% of patients with liver metastasis. Bilirubin, calcium, and creatinine were of no value in detecting recurrent disease. Thus, while alkaline phosphatase was the most reliable of the blood tests, it was of low sensitivity for bone or liver disease. In another study of 1,371 patients with node positive breast cancer, serial alkaline phosphatase determinations were found to have low sensitivity and specificity for bone recurrence (28). Thus, monitoring of routine blood tests as a part of breast cancer surveillance is not recommended.

Circulating Tumor Markers

Tests of serum carcinoembryonic antigen (CEA) and MUC-1 antigen (CA 15-3; CA27.29) have been proposed as tumor markers for the surveillance of breast cancer recurrence. Elevations in these antigens are common in patients with newly diagnosed breast cancer, and their levels are prognostic in some studies. Prospective and retrospective studies using these markers in breast cancer surveillance following primary treatment demonstrate that recurrences of breast cancer may be detected with low to modest sensitivity approximately 5 to 6 months prior to the detection of metastatic or recurrent disease by other methods (29). However, false positive elevations in these markers are common with associated risk of incorrectly diagnosing recurrence of disease, and no advantage in overall survival or quality of life has been demonstrated with the use of these markers. Guidelines generated by expert panels consistently recommend specifically against, or do not recommend, surveillance using any serum tumor marker test (30–32). Thus, the monitoring of circulating tumor markers, including those measuring CEA or MUC-1 antigen appears to be of no value and is not recommended in the surveillance of women following treatment for early stage breast cancer.

Bone Specific Monitoring

Bone pain is a common symptom of bone metastasis from breast cancer. However, many patients with bone pain do not have recurrent cancer, and up to 32% of patients with bone metastasis do not have pain (33,34).

Radionuclide bone scanning is, in general, a sensitive and moderately specific imaging modality for breast cancer metastatic to bone. The NSABP has reported on the benefit of 7,984 routine follow-up bone scans in 2,697 patients with node positive breast cancer as a part of NSABP B-09 (35). Scans were obtained at baseline, every six months for 3 years, and then annually. At the time of the analysis, 779 patients had experienced a recurrence, and 163 of these were in bone only. In 146 of the patients with bone recurrence, information about the presence or absence of symptoms was available. Ninety-five patients had the bone recurrence detected by routine scheduled bone scans, and 35 of these patients were asymptomatic. All 51 patients who had the bone recurrence documented by a nonroutine bone scan were symptomatic. At most, only 0.6% of the total number of bone scans was positive in the absence of symptoms.

In a study of 241 patients with node positive breast cancer, the use of serial bone scans detected 25 patients with bone metastasis, only 13 of whom were asymptomatic (36). In a study of 1,601 women with node positive breast cancer, 1,441 had a baseline and repeat bone scan at one year of follow-up (28). This study documented the inability of the one year bone scan to predict for the eventual development of bone recurrence. With a median of 4 years of follow-up, those women with a normal one year bone scan had a 6.9% risk for development of first relapse in bone, while those with a doubtful one year bone scan had an 11.2% chance of first relapse in bone. Abnormal, radiologically confirmed, one year bone scans were present in only 1.2% of all patients.

Recent studies have suggested that the use of whole body MRI scanning may be more sensitive and specific for the early detection of bone recurrence. However, the routine use of whole body MRI scanning is currently cost-prohibitive.

There is, thus, no evidence supporting the use of routine surveillance for bone recurrences in women with a history of early stage breast cancer.

Liver Specific Monitoring

Prospective study of intensive surveillance including liver ultrasonography and liver function tests versus minimal testing have found no difference in the cumulative rate of detection of breast cancer hepatic metastasis during any time interval up to 5 years (24).

No prospective studies testing the value of computed tomography of the liver as surveillance have been reported. Existing data from other surveillance studies predict that computed tomography surveillance would be neither efficacious nor cost effective. Thus, there is no evidence supporting the performance of liver specific monitoring in the surveillance of women with a history of early stage breast cancer.

Lung Specific Monitoring

Most patients with pulmonary recurrences of breast cancer present with symptoms referable to the chest. Studies addressing the use of routine screening chest radiographs have demonstrated very low rates of metastases detection in the asymptomatic patient. In a study of 241 patients with node positive breast cancer who underwent serial chest radiography the first two years following diagnosis, 3.4% were found to have asymptomatic pulmonary metastasis (36). In a prospective randomized trial of intensive versus spontaneous surveillance, the utility of chest radiographs was specifically assessed (37). Neither disease free nor overall survival was improved with the routine performance of chest radiographs. Thus, the use of chest radiography in the surveillance of women with early stage breast cancer is discouraged.

SECOND NON-BREAST CANCERS

Individuals with breast cancer have a risk of developing second malignancies from a variety of potential causes including those associated with genetic mutations such as the *BRCA1* and *BRCA 2* mutations, secondary cancer related to treatment with chemotherapy, radiation, and endocrine agents, and the usual wide variety of other cancers unrelated to breast cancer and its treatment. A population-based study of 525,527 women with primary breast cancer reported an increased incidence following breast cancer diagnosis of stomach, colorectal, non-melanoma skin, endometrial, ovarian, kidney, and thyroid cancers, melanoma, soft tissue sarcoma, and leukemia (38). Whether these increased risks were attributable to underlying susceptibility, treatment, surveillance, or other factors could not be assessed within the cohort.

Radiation Therapy Treated Patients

In the Early Breast Cancer Trialists' Collaborative Group analysis of patients with early breast cancer treated with radiation therapy, the occurrence of second malignancies including lung cancer, esophageal cancer, leukemia, and soft tissue sarcomas were found to be increased, although the absolute risk was small (14). The impact of radiation postmastectomy or post breast conserving therapy on second cancers was the subject of a single institution study of 16,705 women with breast cancer. At 10-years of follow-up, an excess of sarcomas (relative risk 7.46; 95% confidence intervals 1.02–54.52, p = .02.) and lung cancers (relative risk 3.09; 95% confidence intervals 1.12–8.53, p = .022) was observed. The absolute risk of a second primary sarcoma or lung cancer was, however, extremely low with 35 of 13,472 patients treated with radiation therapy experiencing a sarcoma and 58 experiencing lung cancer. Of the patients experiencing lung cancer, 52 occurred in patients with a history of tobacco use.

Chemotherapy Treated Patients

An analysis of 2,465 patients studied in consecutive adjuvant programs utilizing cyclophosphamide, methotrexate, and 5-fluorouracil (CMF) chemotherapy with or without doxorubicin found no excess second cancer risk at 15-years of follow-up (39). The Early Breast Cancer Trialists' Collaborative Group analysis of second cancers in patients with early breast cancer treated with poly-chemotherapy documented a decreased risk of contralateral breast cancer in women under the age of 50 years but no statistically significant difference in risk of any other second cancer (14). In an analysis of AC-based NSABP trials, the cumulative incidence of AML/MDS at 5 years was 0.21% (95% CI 0.11%–0.41%) with standard AC and increased to 1.01% (95% CI 0.63%–1.62%) with intensification of the cyclophosphamide (40).

Endocrine Treated Patients

The Early Breast Cancer Trialists' Collaborative Group analysis of second cancers in patients with early breast cancer treated with tamoxifen documented a decreased risk in contralateral breast cancer in women with a first breast cancer that was ER-positive or ER-unknown, and an increased risk of cancer of the uterus (14). The incidence of uterine cancer with tamoxifen was approximately 1.9 per 1,000 per year versus 0.6 per 1,000 per year without tamoxifen. There was no difference in second cancers at any other site. Similar rates of tamoxifen associated endometrial cancer have been documented by the NSABP (41). The increased risk of endometrial cancer associated with tamoxifen is limited to postmenopausal women, and no additional monitoring beyond routine gynecologic care is recommended (42). The vast majority of tamoxifen associated endometrial cancers are associated with symptoms of vaginal bleeding, bloody vaginal discharge, staining, or spotting. In the absence of these symptoms, routine gynecologic care is appropriate. In the presence of these symptoms, gynecologic evaluation to exclude the presence of benign or malignant endometrial pathology is appropriate.

Analysis of adjuvant endocrine therapy trials incorporating an aromatase inhibitor document a greater risk reduction for contralateral breast cancer than is achieved with tamoxifen alone. In the ATAC Trial, anastrozole compared to tamoxifen reduced the occurrence of contralateral breast cancer by 42% (95% CI 12%–62%; p = .01) and in the patients with receptor positive disease by 53% (95% CI 25%–71%; p = .001) (43). As the use of tamoxifen decreases the occurrence of contralateral breast cancer by approximately 50%, the use of an aromatase inhibitor would appear to decrease overall contralateral breast cancer by 70% to 80%, to contralateral rates of breast cancer not dissimilar to those of women without a history of breast cancer. Similar reductions in contralateral breast cancer have been observed in trials switching to an aromatase inhibitor after 2 to 3 years of tamoxifen or as extended adjuvant therapy (44,45).

There is thus no evidence that screening studies other than those recommended for general health maintenance (such as routine screening colonoscopy according to published guidelines) should be performed to detect second primary non-breast cancers in women under surveillance for recurrence breast cancer, other than routine gynecologic evaluation in women receiving endocrine therapy with tamoxifen.

PROSPECTIVE TRIALS OF SURVEILLANCE FOLLOWING BREAST CANCER TREATMENT

Several high quality multicenter randomized trials of follow-up strategies have been reported. The Gruppo Interdisciplinare perla Valutazione degli Interventi in Oncologia (GIVIO) investigators randomized 1,320 women with Stage I, II, and III primary breast cancer to an intensive surveillance program including physician visits; annual radionuclide bone scan, liver echography and mammography; bi-yearly chest radiographs; and alkaline phosphatase and γ-glutamyl transferase tests every 3 months versus the same frequency of physician visits and annual mammography alone (24). At a median follow-up of 71 months, there were no differences in deaths between the two groups (odds ratio = 1.12; 95% CI = 0.87–1.43) or in number of distant metastasis. The intense surveillance resulted in a less than 1 month difference in mean time to detection of a distant metastasis. Patterns of site of first recurrence were also similar between the two treatment groups (see Table 67-1). Even in the intense follow-up group, only 31% of recurrences were found in asymptomatic patients. Assessment of quality of life did not differ across multiple dimensions between the two treatment groups.

In another randomized trial performed by the National Research Council Project on Breast Cancer, 1,243 patients with non-metastatic invasive breast cancer were randomized to intensive surveillance with physical examination; radionuclide bone scan and chest radiography every 6 months; and mammography every year versus the control group who underwent physical examinations and mammography at the same intervals (46). Relapse free survival was inferior in the intensive follow-up group, presumably because of earlier diagnosis of recurrent disease, but there was no difference in overall survival (5-year mortality 18.6% in the intensive follow-up group versus 19.5% in the clinical follow-up group). Sites of recurrent disease were similar between the two groups (see Table 67-1). A more recent follow-up of this trial reported 10-year mortality of 34.8% with intensive follow-up compared with 31.5% in the control group (47). Survival analysis revealed a hazard ratio of 1.05 (95% CI 0.87–1.26).

In another study, 472 patients with localized breast cancer following primary treatment were randomized to receive follow-up visits either every three or six months and also randomized to receive routine blood counts, calcium, sedimentation rate, liver enzymes, and CA 15-3 at every visit, chest x-ray every six months, and liver ultrasound and bone scan every second year, or to no routine testing (37,48). At a median follow-up of 4.2 years, there were no significant

differences in number of recurrences detected, disease free survival, overall survival, number of patient initiated phone calls concerning breast cancer, or extra medical visits. Costs of care were specifically assessed, and the intensive surveillance increased follow-up costs by more than twofold.

In a trial of 196 women with breast cancer, the subjects were randomized to regular follow-up surveillance visits or to yearly visits at the time of mammography (49). The number of recurrences was too low at the time of the report for assessment. However, the vast majority of participants found their clinic visits reassuring and the majority wished to continue their follow-up with the specialist clinic. However, 25% of the regular follow-up group and 35% of the annual follow-up group preferred less frequent follow-up evaluations in the future.

A study randomized 296 women with breast cancer to specialist follow-up or to follow-up in generalist practices (50). No difference was observed for time to diagnosis of recurrence by practice setting, and most recurrences (69%) presented as interval events between scheduled visits. A separate study randomized 968 patients who were 9 to 15 months following diagnosis and at least 3 months following completion of adjuvant chemotherapy and radiotherapy to follow-up through a tertiary-care cancer center or to follow-up with their own primary care physician (51). The primary care physicians were provided with a one-page guideline that outlined recommended follow-up and diagnostic tests to investigate signs or symptoms suggestive of recurrent or new primary cancer. Patients were to be referred back to the cancer center if recurrence or new primary tumor developed. The primary endpoint of the study was recurrence related serious clinical events such as spinal cord compression, pathologic fracture, and hypercalcemia. Health related quality of life was a secondary endpoint. The results document equivalent rates of serious clinical events between cancer center versus primary care physician follow-up groups. Health related quality of life did not differ between the two treatment groups throughout the study period.

Studies using the Surveillance, Epidemiology, and End Results-Medicare data bases have evaluated the use of routine testing, including mammography, bone scans, tumor antigen tests, chest radiographs, and other chest/abdominal imaging (52,53). These analyses demonstrate that women seeing medical oncologists, radiation oncologists, or surgeons are more likely to undergo routine mammography than women seeing other specialists. Women with breast cancer being followed by medical oncologists are also more likely than those followed by other specialists to undergo testing including tumor antigen testing, chest radiographs, and chest/abdominal imaging, although the rates of utilization are falling most rapidly among medical oncologists. To what extent the differing utilization of testing among specialists reflects differing risk populations versus inappropriate routine testing could not be determined from the SEER-Medicare data base. A prospective study comparing follow-up surveillance by specialists versus primary care physicians found relatively modest rates of compliance with ASCO-recommended testing in both groups, but with higher compliance among the specialist group (54).

Patients are usually highly accepting of breast cancer surveillance performed by advanced practice nurses, especially if there are occasional visits with a physician. Limited data suggests that telephone follow-up performed by nursing may be medically adequate follow-up, although most patients strongly prefer face-to-face contact (55).

Thus, the optimal surveillance of women following treatment for breast cancer requires relatively little testing, and can be performed by an interested, informed primary care provider, specialist provider, or nurse. As the long-term treatment of women with breast cancer occurs, such as with the extended adjuvant therapies of hormone receptor positive disease, one of the major challenges of primary care follow-up is the need to keep the primary care provider up to date regarding changes in optimal practice.

OTHER CONSIDERATIONS

Patient Expectations of Surveillance

Despite the extensive data demonstrating limited value of routine testing, many patients expect routine follow-up from their physicians (56). To a substantial degree this is because patients have unrealistic expectations of tests and their healthcare provider to detect recurrent breast cancer and to implement treatment for recurrence of disease so that it impacts overall survival substantially. During the follow-up period, patients require education about the importance of self-reporting symptoms, and the limited value of routine blood tests and radiographic studies other than annual mammography.

Opportunity to Assist with Survivorship Issues

Medical visits focusing on surveillance for recurrence also allow the provider and patient the opportunity to explore other issues of concern. Issues or concerns relating to fatigue, anxiety, sexual dysfunction, bone health, cognitive dysfunction, exercise, maintenance of ideal body weight, nutrition, and others are common among breast cancer survivors. During routine surveillance visits, patients with identified issues or concerns may be provided access to appropriate resources. Alternatively, patients may be referred to a survivorship program for follow-up including breast cancer surveillance if the survivorship program has the appropriate expertise and resources.

RECOMMENDED SURVIELLANCE

The large number of patients alive without recurrence of disease following treatment of early stage breast cancer and the availability of multiple studies addressing surveillance for recurrence of disease presents an opportunity for the widespread application of evidence-based surveillance. Given the large number of women alive with a history of breast cancer, the use of evidence-based surveillance monitoring has a large economic impact. A number of professional organizations have evaluated the evidence relating to surveillance and issued recommendations for evidence-based follow-up. Recommendations from representative major organizations are outlined in Table 67-2. As can be seen, there is remarkable consistency among the recommendations.

The optimal surveillance for breast cancer recurrence involves routine follow-up history taking and physical examination, yearly mammography of any retained breast, and monitoring for treatment related endometrial carcinoma in patients treated with tamoxifen and bone health in women experiencing a treatment related menopause or receiving an aromatase inhibitor. The guidelines are very consistent in not recommending surveillance radiographs, blood counts, blood chemistries, tumor markers, radionuclide scans, etc. for the asymptomatic patient. Patients with symptoms, physical findings, or concerning abnormalities on follow-up mammography warrant a full, expeditious, symptom- or finding-directed evaluation.

TABLE 67-2

Comparison of Guideline Recommendations for Surveillance of Women Following Primary Therapy of Breast Cancer

	National Comprehensive Cancer Network (30)	*American Society of Clinical Oncology (32)*	*European Society of Medical Oncology (57)*	*Canadian Breast Cancer Initiative (31)*
History and physical examination	Every 4–6 mo for 5 y, then annually	Every 3–6 mo for 3 y, then every 6–12 mo for 2 y, then annually	Frequency not specified	According to individual patient's needs
Mammography	Every 12 mo	Every 12 mo	Every 12 mo	Every 12 mo
Breast self-exam		Monthly		If a woman wishes
Gynecologic assessment	Every 12 mo for women on tamoxifen if uterus present	Regular gynecologic follow-up		For women taking tamoxifen, important to ask about vaginal bleeding
Bone health assessment	Ongoing monitoring of bone health			Postmenopausal, premenopausal with risk factors for osteoporosis, or taking an aromatase inhibitor should have screening bone mineral density test Patients should be counseled on exercise and adequate intake of calcium and vitamin D. Osteoporosis treatment should include a bisphosphonate.
Encourage adherence to endocrine therapy	Ongoing			
Encourage active lifestyle and ideal BMI	Ongoing			

MANAGEMENT SUMMARY

- Breast cancer recurrences are most common in soft tissues, bone, lung, liver, and brain.
- Second primary breast cancers are common in women with a history of early breast cancer, and yearly mammography of the contralateral breast and the ipsilateral breast, if conserved, is appropriate.
- Ipsilateral in-breast recurrences following breast conserving therapy are usually found by the patient, on clinical examination, or by mammography.
- Periodic follow-up visits should include history taking and focused physical examination.
- Distant recurrences are uncommonly detected by routine surveillance studies in asymptomatic patients without physical findings.
- No high-level evidence supports the surveillance for breast cancer recurrence with routine chest x-rays, computed tomography, ultrasounds, MRI scans, bone scans, liver function tests, alkaline phosphatase, tumor markers, or blood counts. The use of any or all of these tests is, therefore, to be discouraged in surveillance for breast cancer recurrence. Patients who have symptoms or physical findings concerning recurrent disease should have a focused, expeditious evaluation appropriate for the organ system of concern.
- Women treated with tamoxifen should have a yearly gynecologic assessment, and postmenopausal women with vaginal spotting should be promptly evaluated for the presence of endometrial carcinoma.
- Women experiencing treatment related ovarian failure or who are treated with an aromatase inhibitor should have monitoring of bone health.

CHAPTER 68

Surgery for the Primary in Patients with Distant Metastases

Tari A. King

CHAPTER CONTENTS

The traditional dogma that surgery is reserved for the palliation of symptoms in stage IV breast cancer is being challenged by advances in breast cancer diagnosis and treatment. Widespread mammographic screening and increased awareness have resulted in fewer patients presenting with inoperable disease; improved imaging technologies have resulted in the detection of low-volume metastatic disease in patients who would have previously been classified as having early-stage disease; and improved efficacy of modern chemotherapy regimens, including the use of targeted hormonal and biologic therapies, has resulted in prolonged survival for women with metastatic disease. Thus, in modern breast cancer treatment, the goals of therapy for patients with metastatic disease often extend beyond palliation; however, the role of local treatment in this setting remains uncertain.

Although the mean survival for patients with metastatic breast cancer remains 18 to 24 months, the range of survival extends from a few months to many years, and reports of improved survival in the more-recent decades of treatment raises the possibility of cure for a select group of patients in the future. Andre et al. (1) reported survival rates over two time periods for 724 consecutive breast cancer patients presenting with metastatic disease at diagnosis; overall 3-year survival for patients treated from 1987 to 1993 was 27%, which increased to 44% for those treated from 1994 to 2000. Clinical characteristics were similar in the two time periods, suggesting that the survival trend was related to treatment advances that occurred after 1993. Giordano et al. (2) also demonstrated a trend toward improved survival with more-recent year of recurrence and treatment in a multivariate analysis of 834 women who developed recurrent breast cancer between 1974 and 2000. Each more-recent year of recurrence was associated with a 1% per year reduction in the risk of death. Neither of these two datasets included the benefits obtained from newer therapies, such as trastuzumab and other targeted therapies, yet both demonstrate that improvements in systemic therapy have resulted in demonstrable improvements in survival for patients with metastatic disease.

Targeted therapy with the monoclonal antibody trastuzumab has further improved both survival and quality of life in patients with *ERBB2* (formerly HER2/neu) positive metastatic breast cancer (3). Patient selection based on amplification of the *ERBB2* gene was critical to the success of this therapy and highlights the need to address breast cancer in biologically meaningful subtypes (see Chapter 29, *ERBB2* Testing: Assessment of Status for Targeted Therapies, and Chapter 50, Adjuvant Treatment of *ERBB2*-Positive Breast Cancer, for a detailed discussion). Whether or not this rationale can be applied to the role of local surgery in the setting of metastatic disease is now a matter of great interest and debate.

HISTORICAL PERSPECTIVE

Conventional wisdom suggests that surgical excision of the primary tumor is unlikely to offer the patient any survival advantage and therefore should be reserved for the palliation of symptoms. However, this approach stems from a time before modern advances in systemic treatments and supportive care. Patients with metastatic cancer were often debilitated, not considered fit for general anesthesia, and often had bulky tumors in the breast and axilla that required extensive surgical procedures for complete extirpation. Survival after the diagnosis of metastatic disease was often brief, leading to the desire to avoid unnecessary morbidity from surgery. In the modern era, this concern is largely outdated, as many patients will experience prolonged survival (4,5) and the morbidity of common surgical procedures for breast cancer is exceedingly low (6).

Other historical arguments against surgery have included the desire to follow easily measurable disease for response to therapy, and the fear that removal of the primary tumor would result in increased angiogenesis and growth of otherwise dormant metastatic disease (7,8). Animal models suggest that resection of the primary tumor may be accompanied by release of growth-enhancing factors and induction of temporary immunosuppression (9,10). Further, circulating antiangiogenic factors, such as angiostatin and endostatin, are felt to result directly or indirectly from the presence of the primary tumor, and function to at least partially control angiogenesis of existing dormant micrometastatic tumors (11). According to the angiogenesis concept, upon removal of the primary tumor, angiogenesis is switched on and dormant cells begin to grow. Although

this has been documented in the Lewis lung animal model (8), there are few data to support this theory in humans.

BREAST CANCER GROWTH AND METASTASIS

The growth mechanisms of breast cancer have important implications both biologically and clinically. The fundamental question that has been debated over the past century is whether breast cancer is a *local* disease that spreads in an orderly fashion and becomes systemic, or whether breast cancer is a *systemic* disease at its inception. These two opposing theories, classically referred to as the Halstead and Fisher paradigms, formed the basis for breast cancer treatment in the 20th Century. The increasing acceptance of the Fisher paradigm over Halstead's theory resulted in a shift away from more radical surgery to increasing use of systemic therapies in recent decades; however, the increasing body of evidence demonstrating that local control does impact survival suggests that the truth is likely in the middle. Breast cancer may be, but is not universally, systemic at its inception, and local-regional treatments are important.

At present, metastatic disease is largely incurable and remains so due to a limited understanding of the molecular mechanisms of metastasis. A variety of models suggesting that genetic alterations resulting in metastases are acquired over time are unstable and may overgrow the primary tumor have been proposed. Experimental evidence supporting these theories exist, but their relevance to metastatic breast cancer in humans is uncertain. In the genomic era, new concepts of metastatic dissemination have been proposed. The ability of gene expression profiles of human primary breast cancers to predict metastatic potential (12) suggests that the ability to metastasize is an early and perhaps inherent, genetically predetermined property of the primary tumor cell. Support for this concept includes the finding of similar gene expression profiles from pairs of human primary breast tumors and their distant metastases (13), as well as similar gene expression patterns between premalignant, preinvasive, and invasive breast cancers (14). Kang et al. (15) have proposed that within the population of tumor cells with metastatic capacity, subpopulations of cells also have a superimposed tissue-specific gene expression profile that predicts the site of metastasis. Mathematical models suggest that not only does this "escapee" cell have the capacity to seed distant sites, but it may also metastasize back to the primary tumor (self-seed), thereby contributing both to the ongoing growth and destruction at the site of primary disease, as well as to an ever-growing source of disseminating tumor cells (16). Within the context of metastatic breast cancer, this theory of self-seeding would strongly support complete excision of the primary tumor.

The analysis of human-disseminated cancer cells has led to another model, termed the *parallel evolution model*, which proposes that the dissemination of metastatic cancer cells occurs early and is independent of later changes that may be acquired in tumor cells at the primary site (17). This theory is based on the finding that disseminated tumor cells in the bone marrow of patients without metastatic disease do not share the same genomic abnormalities as cells from the primary tumor; however, in patients with known metastatic disease, these cells are similar to the primary tumor. This theory challenges the concept of clonal genomic evolution, yet the true biologic potential, and therefore clinical significance, of disseminated cells found in the bone marrow of patients with early-stage disease is unknown, and multimodal therapy, including surgery, remains standard care for these patients (18).

Finally, there is an growing body of evidence supporting the *cancer stem cell theory*. This theory proposes that rare cells with indefinite proliferative potential are responsible for the formation and growth of tumors (19), and have the exclusive potential to proliferate and form metastasis (20). Other areas of investigation that may contribute to the understanding of the role of local treatment in metastatic disease include the study of the tumor microenvironment and the immune system (16,21).

In contrast to the conventional model, the newer concepts of metastases all support removal of the primary tumor to reduce either self-seeding, tumor cell dissemination, or the population of native cancer stem cells, followed by effective systemic therapy. There is a biologic rationale that supports a proper evaluation of the role of surgery for the primary tumor in stage IV disease, and this question is increasingly important as outcomes in stage IV disease continue to improve with newer targeted systemic agents. The question also has wider implications than for the population of women who present with stage IV disease and an intact primary, such as for those women who present with a synchronous in-breast recurrence and distant metastases.

LOCAL CONTROL AND SURVIVAL

It is now well established that local control does impact survival in stage I to III breast cancer, and this is particularly evident in patients with positive nodes and those at higher risk of local relapse (22). If preventing local recurrence decreases the incidence of distant relapse in earlier-stage disease, a natural extension of this argument is to consider whether optimizing local control, by removal of the intact primary tumor, may benefit select patients with metastatic disease. In 2002 Khan et al. (23) first challenged the traditional thinking with a report of 16,023 patients presenting between 1990 and 1993 with stage IV disease as captured by the National Cancer Database (NCDB) of the American College of Surgeons. Surprisingly, 9,162 (57.2%) patients underwent either partial [3,513] or total mastectomy [5,649] in the setting of stage IV disease, and surgical removal of the primary tumor was associated with a 39% reduction in the risk of death. Adding further support to the argument for local control, women treated surgically with clear margins had a 3-year survival of 35%, as compared to 26% for those with positive margins, and 17% for those not having surgery ($p < .0001$). Additional studies, both population-based and single-institution series, examining survival outcomes relative to surgical resection or radiotherapy (24) of the intact primary tumor, have now reported remarkably similar results, with an observed reduction in the hazard of death ranging from 40% to 50% (23–41).

Since the first such publication by Khan et al., at least 19 retrospective studies have evaluated the role of local therapy for the primary tumor in patients presenting with *de novo* stage IV breast cancer. The six multi-institutional registry and population-based studies provide information on over 27,000 patients, 14,443 (52%) of whom underwent surgery for the primary tumor, with all but one study, which excluded patients who received systemic therapy before surgery (29) demonstrating an association between surgery and improved survival (Table 68-1). Similarly, the single-institution studies provide information on over 4,000 patients, 1,670 (41%) of whom underwent surgery for the primary tumor, with over half of the studies demonstrating a similar association between surgery and improved survival (Table 68-2).

However, nearly all of these studies also revealed that surgery for the primary tumor was more likely to be pursued in women who were younger, had fewer metastatic sites, and had bone-only or estrogen-receptor (ER) positive disease, leading some to question whether these results truly reflected a consistent benefit from local therapy or consistent bias in patient selection.

Efforts to address some of these potential biases have included a case-matched pair analysis using the tumor registries from two large hospitals (28) and a second matched analysis using the National Comprehensive Cancer Network (NCCN) Breast Cancer Outcomes Database (29). In the first study, Cady et al. (28) performed a matched pair analysis of 622 Massachusetts residents who presented with an intact primary tumor and metastatic disease from 1970 to 2002. Cases and controls were matched by age (±5 years), date of diagnosis (±5 years), location of metastases, ER status, and use of systemic therapy. Among the group as a whole, overall survival (OS) was better for the 234 (38%) of patients who had surgery ($p < .0001$), and when case matching was performed, association between surgery and improved survival persisted for all groups except those with visceral metastases ($p = .09$), which reflected a population of 100 women. In the second matched analysis, Dominici et al. sought to eliminate "response to systemic therapy" as a potential selection bias for surgery by including only those patients who received surgery first, followed by systemic therapy or systemic therapy alone. Among 1,048 patients in the NCCN Breast Cancer Outcomes Database diagnosed with stage IV breast cancer from 1997 to 2007, 609 were eligible for the study and 551 patients had data available for matching by age, ER status, HER2 status, and number of metastatic sites. Ultimately, 236 patients who received systemic therapy alone were matched to 54 patients who received surgery, and there was no difference in survival between the two groups (median 3.4 years no surgery vs. 3.5 years surgery), suggesting that extirpation of the tumor itself may not be responsible for the survival benefit demonstrated in other series. This study, however, is limited by the small number of patients having surgery, the lack of information regarding the indications for surgery or timing of surgery available in the database, as well as and greater use of surgery in earlier time periods, all of which may have biased the study toward improved survival in the patients treated in the later years.

Although the survival benefit is less consistent among the single-institution studies listed in Table 68-2, an advantage of single-institution series is their ability to provide greater detail regarding specifics of treatment, course of the disease, and other patient factors. The Washington University series included an adult comorbidity evaluation (ACE-27) score that categorized comorbid conditions as none, mild, moderate, and severe; they found that this score was not significantly predictive of survival in patients with metastatic breast cancer (30). They also included patients who underwent surgery at any point in their disease course, and in about half of the cases (53%), surgery was undertaken to palliate symptoms associated with the primary lesion. In contrast, 43% of patients were believed to undergo surgery in the setting of unknown metastatic disease, which was then discovered on subsequent staging examination performed within one month of surgery. In related reports from Northwestern Memorial Hospital (32) and Memorial Sloan-Kettering Cancer Center (MSKCC) (34), 26 of 47 (55%) and 34 of 69 (49%) women with stage IV breast cancer underwent surgery for the primary tumor prior to staging, respectively, suggesting a potential bias toward a lower burden of metastatic disease.

To assess the impact of potential *stage migration bias*, Bafford et al. (26) examined the survival for women diagnosed with stage IV breast cancer prior to surgery as compared to those diagnosed after surgery in their series of 61 patients and found that the benefit of surgery was only realized among patients operated on before the diagnosis of metastatic disease. This is in contrast, however, to series from Spain (37) and the Netherlands (45) which found no differences in overall survival based on the timing of surgery relative to the diagnosis of metastatic disease. Unfortunately, the frequency with which unsuspected metastatic disease is diagnosed after surgery is not ascertainable from population-based registries, yet this may partially account for the finding that younger patients with smaller tumors were more likely to undergo surgical resection in all reported series. Alternatively, surgery may be a surrogate for more aggressive therapy overall in select patients with metastatic disease.

Data from single-institution series can also be used to generate hypotheses about which subsets of patients may benefit from more aggressive local therapy. Fields et al. (30) found that women with bone-only metastatic disease lived longer than those with metastases at other sites, regardless of whether surgical resection was performed (adjusted HR 0.76; 95% CI 0.58–0.98). This is consistent with the known indolent course of osseous metastases and supports the findings from the stratified analysis of the Geneva Cancer Registry (38). Modern series that include patients treated in the era of molecularly targeted therapy also demonstrate that patients with ER, progesterone-receptor (PR), and/or HER2 positive disease have an improved OS (25,26,34). In the series from MSKCC, which was limited to patients treated in the time period following the introduction of trastuzumab for HER2 amplified disease (2000–2004), the association between surgical therapy of the primary tumor and improved OS was evident in patients with ER, PR, and/or HER2 amplified disease, but not for those with triple-negative disease, suggesting that the impact of local-regional control may vary by molecular subtype in the setting of stage IV disease just as it does in earlier-stage disease (35,42). Viewed in aggregate, all series reported over the last decade consistently demonstrate that about half of women presenting with *de novo* metastatic breast cancer undergo resection of the primary tumor, and the majority of the studies suggest that women undergoing surgery survive longer than those treated without resection. Although all available studies are retrospective and therefore inherently biased by the inability to control for patient selection and other treatment factors, a recent meta-analysis of 15 of the aforementioned studies, which included meta-regression to balance for number and type of metastatic sites, ER/HER2 status, age, use of radiotherapy, and systemic therapies, confirms the results of the individual series. Surgery of the primary tumor was an independent factor for improved survival in multivariate analysis, with an HR of 0.69 (0.63–0.77, $p < .00001$) (43). Further, the meta-regression analysis demonstrated that the survival benefit for surgery was independent of age, extent or site of metastatic disease, and HER2 status, but was most evident in the setting of multimodality care; the more treatment modalities that were offered to patients (systemic therapies and/or radiotherapy), the more the benefit of surgery emerged. Interestingly, populations with fewer ER positive breast cancer patients derived more benefit from surgery in this meta-analysis. While this may reflect the known indolent course of ER positive osseous metastases, these findings provide further evidence that the dogma to reserve surgery only for the palliation of symptoms in stage IV disease may be outdated in the era

of multidisciplinary care and molecularly targeted therapy, and support the rationale to address the role of local therapy for the primary tumor in stage IV disease according to biologically meaningful subtypes.

SURGERY FOR LOCAL CONTROL

In addition to the potential impact on survival, there are many other questions regarding the role of surgery for the primary tumor that remain unanswered. The rationale for surgery in the 50% of patients with stage IV breast cancer in all reported series is uncertain, but may have been related to "fear of advanced local-regional disease" or patient preference. The low morbidity of breast surgery compares favorably with toxicity profiles of many systemic therapy agents used in the metastatic setting, perhaps adding to the appeal of surgical local control. In a retrospective review of surgical practice patterns over a 15-year period at MSKCC (44), the frequency of mastectomy in the setting of any stage IV disease remained stable at 1.7% of all mastectomies performed, yet the indication for mastectomy as cited by the treating surgeon changed over time. The rate of traditional "toilet" mastectomy or mastectomy performed for "symptoms" of local disease decreased from 41% to 25% between the two time periods analyzed (1990–1995 and 2000–2005), while rates of "local control" mastectomy increased from 34% to 66%. Among 84 patients presenting with *de novo* stage IV disease from the same study, a more detailed review of treatment data demonstrated that the most frequent indication for surgery of the primary tumor was to "optimize local control" in the setting of a complete, good, or stable response of distant disease to systemic therapy. Surgery was performed for symptom control in 30 of 84 (36%) patients in this series presenting with *de novo* stage IV disease.

One cannot assume that the primary tumor will respond to systemic therapy in parallel with metastatic sites of disease, and progressive local disease may lead to impaired quality of life and the need for palliation. The true frequency with which unresected local disease becomes a "local control" problem or "symptom control" problem requiring surgery in the modern era is difficult to ascertain without prospective collection of patient information. Single-institution data range from a low of 9% (7 of 82 patients) undergoing palliation in the University of Texas MD Anderson Cancer Center (MDACC) series (25), to 36% in both the MSKCC dataset (44) and the Northwestern series (32), to 53% reported in the Washington University series (30). All of these figures are likely biased by the culture of the individual institution and the inherent inaccuracy of abstracting "subjective" information by retrospective chart review. Data regarding the frequency of recurrent local disease at time of death are also limited. In the MSKCC series, patients undergoing surgery for local control (n = 128) had an 11% incidence of death with recurrent local disease (median follow-up, 35 months), and patients undergoing surgery for palliation of symptoms (n = 49) had a 10% incidence of death with recurrent local disease (median follow-up, 29 months).

Perhaps the strongest evidence to date in favor of surgery for local control is that from Hazard et al. (32), who reported that surgery is strongly protective against uncontrolled chest-wall disease, and further, that a controlled chest wall mediates the survival benefit of surgical resection. In their report from Northwestern University, surgery was strongly protective against symptomatic chest wall disease in 47 patients with stage IV breast cancer undergoing surgery either at diagnosis or following response to systemic therapy, as compared to 64 patients managed either nonoperatively or with delayed (palliative) surgery (odds ratio [OR] 0.14, 95% CI 0.04–0.50, p = .002) (32). Ultimately, 23 of 64 patients (36%) required delayed local palliation. A Translational Breast Cancer Research Consortium prospective, multi-institutional registry study TBCRC 013 examining the role of surgery for the primary tumor in *de novo* stage IV disease has recently completed accrual and data presented at the 2013 San Antonio Breast Cancer Symposium demonstrated that the need for true surgical palliation of symptoms is infrequent in the modern era (45).

Additional support for the rationale of optimizing local control includes the identification of a larger population of patients with oligometastatic or low-volume metastatic disease, many of whom would have been treated aggressively for cure in the era before widespread magnetic resonance imaging (MRI) and positron emission tomography (PET). The natural history of this category of stage IV breast cancer is largely unknown, yet conceptually, they may not be very different from patients with earlier-stage disease who are found to harbor occult bone marrow micrometastases. Studies suggest that bone marrow micrometastases are present in up to 30% of stages I to III patients at the time of diagnosis and are associated with a poor OS and breast cancer disease-free survival (46), yet surgical treatment and adjuvant therapy are routinely performed in these patients, resulting in a significant number of long-term survivors. Hortobagyi (47) has also suggested that an aggressive multimodal approach that includes surgery produces long-term, disease-free survival or cure in a subset of patients with limited metastatic breast cancer. These long-term survivors with stage IV disease are typically young, with limited metastatic disease and excellent performance status (47,48).

An analogous situation is the breast cancer patient with a solitary recurrence or metastatic lesion that is resected surgically or treated with radiotherapy at curative doses, rendering them stage IV NED (no evidence of disease). Although this again represents a minority of patients with metastatic disease, a review by Singletary et al. (49) demonstrates that surgery combined with adjuvant therapy, compared with radiation or systemic therapy alone, can result in significantly better survival in select patients with metastatic disease to the lung, liver, brain, or sternum. Across the four disease sites (lung, liver, brain, bone), better patient outcomes after surgery were associated with good performance status, long disease-free interval after treatment of the primary tumor, complete resection of the tumor, and restriction of metastasis to single tumors or to a single site.

Additional theoretical advantages for removing the primary tumor include cessation of tumor-cell seeding into the circulation and decreasing the overall tumor burden. The level of circulating tumor cells (CTC) before treatment is an independent predictor of progression-free survival and OS in patients with metastatic breast cancer, and patients who experience a decrease in the level of CTC after the initiation of therapy have a better prognosis than those who do not (50). Whether or not these theories are valid in the setting of metastatic breast cancer with an intact primary is uncertain and awaits the results of ongoing randomized trials.

ADDITIONAL QUESTIONS AND THE VALUE OF RANDOMIZED TRIALS

The benefit for surgery of the primary tumor demonstrated by the meta-analyses (43) is consistent with a now well-established body of evidence that local therapy has an impact on survival in the setting of multimodality therapy for breast cancer patients with stage I to III disease (see Chapter TKTK for full discussion). However, the meta-analysis cannot determine

which type of surgery—mastectomy or lumpectomy—is better, and it cannot fully assess the role of radiotherapy or axillary surgery. Historically, surgery in stage IV disease was limited to palliation, hence the term *toilet mastectomy*; however, in the series from Rapiti et al. (38) and Khan et al. (23), 31% and 46% of all patients, respectively, had T1 and T2 tumors. Only 12% and 16% of all patients, respectively, had T3 tumors, suggesting that many primary tumors in patients with metastatic disease are amenable to treatment with lumpectomy, a procedure with very low morbidity, yet the role of radiotherapy in this setting is uncertain. Prospective randomized trials of breast conservation in early-stage disease provide consistent evidence that lumpectomy with negative margins *plus* radiation therapy are important in local control; however, in the metastatic setting, data regarding the use of regional radiotherapy are limited, and there are no guidelines for treatment.

The use of local radiation cannot be distinguished from radiation to metastatic sites in the National Cancer Database Study, and although most other series report that the use of radiation was higher in the surgery groups (Tables 68-1 and 68-2), only the Geneva Cancer Registry reported the lack of radiotherapy in women treated with lumpectomy to be independently associated with an increased hazard of death. Some authors have also suggested that radiotherapy to the primary site may be an acceptable alternative to surgery with potentially decreased morbidity (24,51). In the series by Le Scodan et al. (24), surgery was used in only 71 of 320 patients who received local-regional radiotherapy, and when compared to patients who received no local-regional therapy, radiotherapy was significantly associated with improved survival on multivariable analysis (HR 0.70, CI 0.58–0.85, $p < .001$). Confirmation of the role of radiotherapy following surgery in the setting of metastatic disease will be achieved only through randomized trials.

If removal of the primary tumor improves survival by reducing tumor burden, one might also assume that reduction of the tumor burden in the axillary nodes would be beneficial, yet it remains controversial as to whether there is a survival benefit for any patient with breast cancer who undergoes axillary dissection. This procedure continues to be performed, however, in stage II and III breast cancer, primarily for local control, and to obtain prognostic information and guide treatment. In the metastatic setting, neither Khan (23) nor Rapiti (38) were able to demonstrate a benefit for axillary dissection, although it has been suggested that this was likely due to the small number of axillary dissections performed and their correlation with excision to negative margins (52). In a report from MDACC (53), among the 82 patients who underwent surgical intervention at the primary site in combination with appropriate systemic therapy, including trastuzumab, patients who underwent axillary lymph node dissection demonstrated a trend toward improved OS on univariate analysis compared to patients who underwent sentinel lymph node biopsy alone or no axillary surgery (log rank test, $p = .051$). Axillary clearance is encouraged for patients with positive nodes in all but one of the ongoing randomized trials.

The timing of surgery, or how and when to integrate surgery into the multidisciplinary management of patients with stage IV breast cancer, is also relevant to the hypothesis that local therapy of the primary tumor is beneficial. If the tumor functions as a source of new metastatic deposits, treating it early in the course would intuitively seem to have greater benefit. Yet, the available data are limited and conflicting. In addition to the two series described above that assessed the timing of surgery relative to the diagnosis of metastatic disease (26,37), in the report from MDACC (53), patients having surgery 3.0 to 8.9 months after diagnosis or greater than 9.0 months after diagnosis had a longer metastatic progression-free survival that those having surgery within 3.0 months of diagnosis. There were several other significant differences between these surgical groups, such as use of chemotherapy or hormonal therapy alone, margin status, type of surgery, and indication for surgery, making it difficult to draw any meaningful conclusions. Yet, this study clearly suggests that delaying surgery until after primary systemic therapy, as is done in cases of locally advanced breast cancer, may be beneficial.

Prospective randomized trials designed to examine the role of local-regional treatment in patients with stage IV disease are now underway in five countries (Table 68-3). The first trial from Tata Memorial Hospital opened in 2005 with an accrual goal of 350 patients randomized to complete resection, including axillary surgery or no surgery following six cycles of chemotherapy. Preliminary results reported at the 2013 San Antonio Breast Cancer Symposium suggested no difference in overall survival between those who received surgery and those who did not; however, the authors stated concern over what appeared to be a shorter time to distant disease progression after surgery. A multicenter study initiated in Turkey in 2007, the Turkish Federation study (MF07-01) addresses the question of whether surgery before systemic therapy versus systemic therapy alone is associated with improved survival. In this trial, local-regional treatment could be mastectomy or lumpectomy followed by radiation therapy, with or without axillary dissection in patients with positive nodes. Early results from this trial were also presented at the 2013 San Antonio Breast Cancer Symposium, again showing no improvement in survival with surgery. However, as both of these studies were only presented in abstract form, additional information about the details of the patient populations and systemic therapies they received are needed to draw firm conclusions.

Similar to the Turkish Federation study, the Danish Breast Cancer Trialists Group recently opened the SUBMIT (Systemic therapy with or without up-front surgery of the primary tumor in breast cancer patients with distant metastases at initial presentation) study, with an accrual goal of 258 patients in each arm and an anticipated accrual time of 60 months.

Finally, the Eastern Cooperative Oncology Group trial in the United States (E2108) and the Japan Clinical Oncology Group Study (JCOG1017) trial, are both designed to address the role of surgery for the primary tumor in patients who are not refractory to upfront optimal systemic therapy. The choice of primary systemic therapy in both studies is made with consideration of biologic subtype (ER, HER2 status) and disease burden, and randomization to surgery or no surgery is performed after a predefined period of treatment. Complete resection with clear margins is required in both studies; however, the trials differ with respect to the role of axillary clearance and radiation therapy.

CLOSING REMARKS

New insights into cancer biology have led to an increased focus on biologic subtypes and targeted therapies, resulting in improvements in OS for patients with both early- and late-stage disease. A growing body of evidence suggesting that local treatment may have a greater influence on breast cancer survival than previously thought has now also led to the opening of several well-designed prospective trials to answer the question of whether local-regional treatment can further improve outcomes for patients with metastatic breast cancer. These trials raise intriguing questions, and in parallel with new biological concepts of breast cancer metastasis, challenge the traditional surgical approach to stage IV disease.

TABLE 68-3

Ongoing Randomized Trials Evaluating the Role of Surgery in Stage IV Breast Cancer

	Opened	*Accrual Goal*	*Eligibility*	*Stratification*	*Treatment Prerandomization*	*Local-Regional Therapy*	*Primary End Point*	*Secondary End Point*
Tata Memorial Hospital, India (55–57)	2005	350	M1 disease, resectable primary tumor	HR status, visceral vs. bony mets, no. of met sites	6 cycles chemotherapy	Complete resection including ALND + RT as indicated	OS	6-mo PFS
Turkish Federation (MF07-01) (58)	2007	271	M1 disease, resectable primary tumor	None	None	Complete resection, ALND if positive nodes, RT for all cases with BCS, PMRT per individual protocol	OS	PFS, QOL
Danish Breast Cancer Trialists Group (SUBMIT) (59)	2012	516	M1 disease, resectable primary tumor	Age, site of metastasis, HR status, HER2/neu status	None	Resection with clear margins, RT if margins not clear, ALND encouraged for positive nodes	2-yr survival	OS, QOL
Eastern Cooperative Oncology Group (ECOG E2108) (60)	2011	880 (assumes 616 randomized)	M1 disease, intact primary, stable disease or objective response to optimal systemic therapy	HR status, HER2/neu status, endocrine therapy, chemotherapy, number of metastatic organs	Optimal[a] therapy 4–6 mos	BCS or mastectomy, clear margins, ALND if positive nodes, RT for all cases with BCS, PMRT per individual protocol	OS	Local control QOL
Japan Clinical Oncology Group (JCOG 1017) (41)	2011	500 (assumes 410 randomized)	M1 disease, resectable primary tumor, no brain mets, stable disease or objective response to 3 cycles optimal therapy	ER status, HER2 status, metastatic site(s), institution	Optimal therapy[a] × 3 cycles	Complete resection of primary tumor, no axillary clearance, no RT	OS	Distant PFS, local PFS, need for palliation, adverse events[b]

[a]Optimal therapy defined according to ER and HER2 status, and sites/burden of metastatic disease; use of standard clinical guidelines encouraged.
[b]Includes adverse events of chemotherapy, operative morbidity, and serious adverse events.
HR, hazard ratio; ALND, axillary lymph node dissection; RT, radiation therapy; OS, overall survival; PFS, progression-free survival; BCS, breast-conserving surgery; PMRT, postmastectomy radiation therapy; QOL, quality of life; ER, estrogen receptor; BCT, breast-conserving treatment.

MANAGEMENT SUMMARY

- Survival in patients with metastatic breast cancer is improving due to more sensitive imaging modalities, resulting in an increased rate of diagnosis in asymptomatic patients with a low disease burden, and to improvements in systemic therapy.
- The role of surgery of the intact primary tumor on survival in patients with metastatic disease is uncertain. Multiple retrospective studies suggest a survival benefit, but selection bias in these studies prohibits firm conclusions. The available data suggest that local-regional treatment may be considered as part of a multimodality treatment in patients with favorable clinicopathologic characteristics, including young age, limited metastatic disease burden, and ER-positive tumors.
- Surgery is an effective means of maintaining local control on the chest wall during the patient's lifetime. Either mastectomy or lumpectomy are appropriate approaches when surgery is chosen. The data on axillary surgery are extremely limited, but if surgery is undertaken, removal of all gross disease seems prudent.
- The benefit of radiation therapy following surgery is uncertain, and decisions regarding its use should be made on a case-by-case basis.
- Formal randomized trials to examine the role of surgery in patients with *de novo* stage IV breast cancer are currently underway in five countries.

CHAPTER 69

Management of Local Regional Recurrences after Primary Breast Cancer Treatment

Meena S. Moran, Anees B. Chagpar, and
Erica L. Mayer

CHAPTER CONTENTS

INTRODUCTION

Contemporary treatments for early-stage breast cancer have minimized the risk of local-regional recurrence (LRR) to a cumulative frequency that is typically <1% per year (1,2). While multimodality advances in surgical approaches, radiation, and systemic therapy (chemotherapy, targeted drug therapy) all contribute to these low recurrence rates, the management of LRR remains challenging with limited data to guide subsequent treatment. The confirmation of a recurrent diagnosis may have widespread psychological and social implications for the patient, in addition to leading to loss of the conserved breast after breast conservation therapy (BCT), or causing uncomfortable and potentially difficult to control chest-wall disease after mastectomy. The care of each patient with LRR must be tailored to that individual's needs, using a multidisciplinary team approach. The treatment strategy delivered to each patient with LRR should include a combination of active therapy and symptom palliation, with the ultimate aim of ensuring that the patient's quality of life is maintained at an optimum level for as long as possible.

Initial clinical-pathologic features that lead to increased risk of LRR include number of involved lymph nodes, primary tumor size, and ultimate stage of disease. Other prognostic factors that may affect a patient's risk for LRR include margin status after definitive surgery, tumor grade, patient age, hormone receptor status, receipt of adjuvant radiation, receipt of systemic therapy, and possibly primary tumor oncogene expression. LRR is most often detected clinically after mastectomy, and radiographically after BCT. Signs and symptoms of LRR include palpable nodules or induration, skin ulceration or other suspicious skin changes, thickening of the breast/chest wall, and abnormally enlarged or hard lymph nodes (Fig. 69-1).

When a patient experiences a LRR, the disease can recur locally and/or regionally, with or without distant metastasis. A local recurrence is defined as recurrent cancer in the previously treated ipsilateral intact breast (BCT) or along the chest wall (postmastectomy). Regional recurrences, which generally occur in under 4% of patients (3), arise most often within the lymph nodes of the axilla or supraclavicular fossa and less frequently in the infraclavicular chain or internal mammary nodes. While distant metastasis from breast cancer can occur anywhere in the body, the most common sites include bone, liver, and lungs.

The overall prognosis after a LRR is related to the disease-free interval before recurrence, with early recurrences (≤2 years) carrying a worse overall prognosis than LRRs that occur later (4). Other factors affecting overall prognosis after LRR include the extent of local-regional disease, presence of metastatic disease, hormone receptor status and HER-2 status at the time of recurrence, and patient age. A significant portion of patients with LRR will present with simultaneous distant metastasis, but for those with isolated local recurrence, aggressive treatment can offer patients long-term survival. While the hazard ratios for LRR are highest in the first few years after diagnosis of breast cancer, there is a persistent rate of relapse beyond 15 years (5).

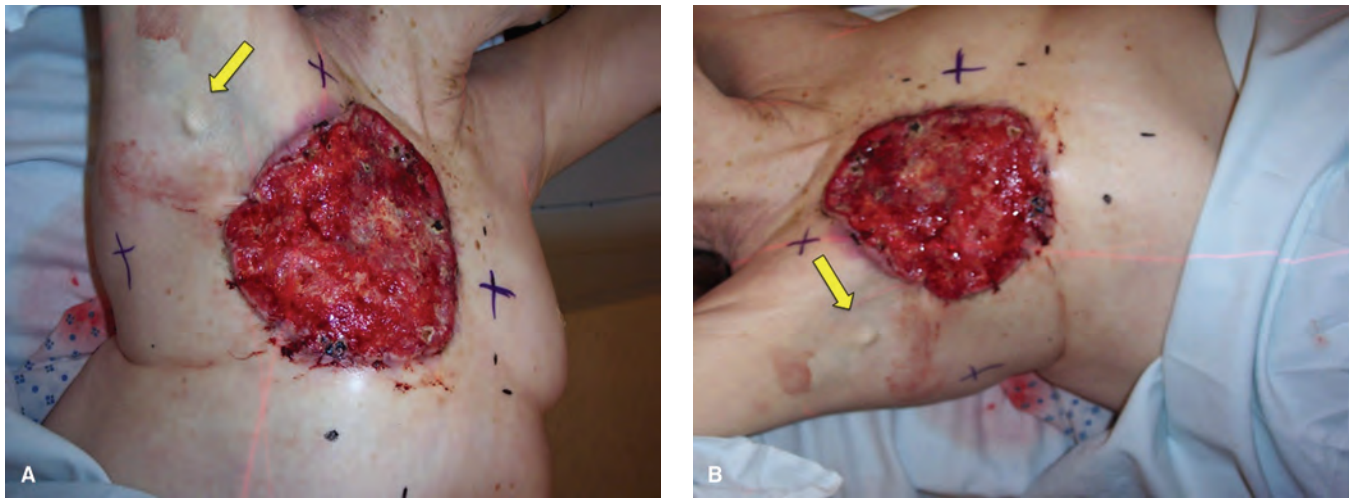

FIGURE 69-1 **(A)** and **(B)** An advanced CWR in a patient who was not a candidate for surgical resection due to her elderly age and poor performance status. The CWR was ulcerated at presentation and continued to grow despite chemotherapy. Only superficial debridement was performed. Note the arrow highlighting the large, fixed palpable lymph node in the axilla.

Thus, long-term follow-up for breast cancer patients at risk of LRR is warranted.

Because new primaries should theoretically have a prognosis independent of the primary breast cancer, attempts have been made to distinguish LRR as 'true recurrence' versus 'new primary' based on location/quadrant of the recurrence (i.e., whether the recurrence is in or near the quadrant of primary disease, or is distant from the primary tumor) and histopathologic features (Fig. 69-2). Additionally, radiation oncologists have further classified ipsilateral breast tumor recurrence (IBTR) as a 'marginal miss' if the recurrence is adjacent to, but not within, a previously radiated area. Retrospective series suggest that true recurrences have an earlier median time to presentation, are located near the lumpectomy cavity or scar, have histology similar to the primary tumor, and are characterized by a more aggressive natural history and a higher association with concurrent metastasis, earlier metastasis, and shorter survival (6,7). While earlier studies may have misclassified true recurrences versus new primaries, recent improvements in the classification of breast cancers and molecular analysis of clonal differences may help to distinguish patients with true recurrences who carry an overall worse prognosis (8). Nevertheless, given evidence suggesting the association of LRR with the development of distant failure and subsequent diminished overall survival (5), aggressive management of isolated LRR in a patient without documented distant metastasis is of paramount importance. Even for a patient with documented distant metastasis at the time of LRR, optimal local-regional therapy can significantly reduce the morbidity of uncontrolled LRR; however, the potential toxicity of local-regional treatment modalities needs to be weighed against possible benefits in quality of life.

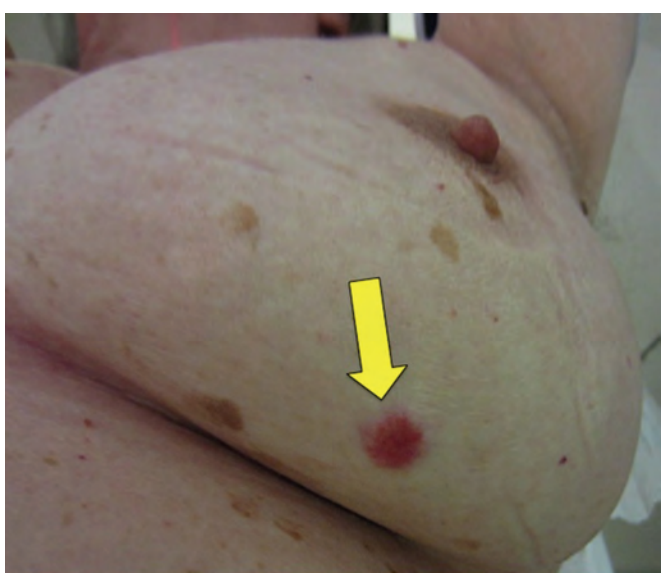

FIGURE 69-2 Ipsilateral breast tumor recurrence in a patient previously treated with breast conservation. Despite the patient's other skin lesions, the index of suspicion remained high, and a biopsy confirmed a local recurrence in the previously treated breast. The tumor recurrence was located in a separate quadrant remote from the primary tumor.

SCREENING AND EVALUATION FOR LRR

Routine surveillance for LRR after treatment for breast cancer should be conducted with regularly scheduled follow-up visits including a complete history/physical examination, yearly mammography (after BCT), and routine self-examination. Any additional work-up should generally be symptom-directed. To date, there are no data supporting the routine use of any diagnostic imaging (outside of breast imaging), laboratory testing, or tumor markers to detect recurrence in an asymptomatic breast cancer survivor.

Approximately one third of all IBTRs are found on surveillance mammography alone; the remainder are detected by physical examination with or without follow-up imaging (9). Most IBTR located close to the lumpectomy site tend to occur earlier than those remote from the primary tumor site (10), and tend to have the same mammographic appearance

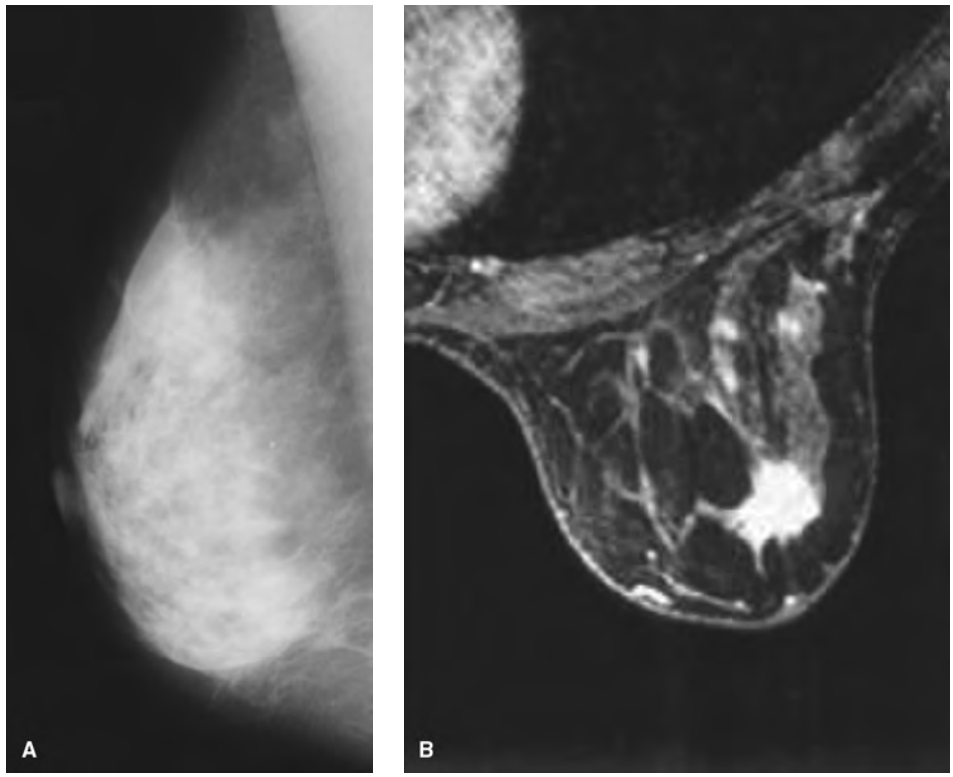

FIGURE 69-3 Imaging of an ipsilateral breast tumor recurrence in a patient previously treated with breast conserving surgery and radiation. Given the density of the breast and scar tissue, mammogram was unable to detect recurrence. MRI was more sensitive in discerning density and scar tissue from tumor.

as the primary tumor (11). Detection of IBTR by mammography alone can be challenging due to post-operative and post-radiation scar tissue development, but detection of IBTR is higher when recurrent tumors are associated with calcifications.

Breast MRI can also be utilized to screen for LRR (Fig. 69-3), though the evidence to support the benefit of its use, particularly to detect LRR, needs to be established. Sensitivity of MRI for detection of recurrence ranged from 75% to 100%, while specificity ranged from 66.6% to 100% (12). Both sensitivity and specificity increase when MRI is performed after a longer time interval from the original surgery, although long-term follow-up data supporting this observation is limited to approximately 3 years (12). Other conditions (such as fat necrosis, foreign body cysts, bony nodules, or unrelated second primary tumors) may resemble a LRR; thus, the area of concern should always be pathologically confirmed with a biopsy.

At the time of biopsy, molecular subtype and variations in hormonal receptor and HER-2 status of the LRR should be reevaluated, as discordance between the primary tumor and recurrent tumor will be important for systemic treatment-related decisions. There should be a relatively high level of suspicion for simultaneous distant metastasis when LRR are detected, and thus, a full metastatic workup is warranted, which may include CTs, MRIs, PET/CT, and/or bone scan. This workup should be performed to determine the extent of recurrent disease prior to rendering decisions regarding aggressive local-regional management. For breast-conserved patients, in addition to routine diagnostic mammography and ultrasound, a breast MRI may help to elucidate multifocal or more extensive disease, and may be able to differentiate recurrence from scar tissue, as invasive recurrence often enhances on MRI whereas scar tissue does not (12). While a chest x-ray is typically not beneficial, a CT scan may be particularly useful in the postmastectomy recurrence setting to determine the extent of disease in superficial tissue versus more extensive pectoralis muscle or transmural involvement, in differentiating between radiation-induced versus tumor-induced brachial plexopathy, and in determining presence of visceral metastasis or enlarged lymph nodes. For any patient with suspicion of metastatic disease, efforts should be made to confirm the metastasis histopathologically when technically feasible.

MANAGEMENT RESULTS

IBTR after BCT

A standard treatment for optimizing local control in the definitive setting for early stage breast cancer is breast conservation therapy, which typically includes breast conserving surgery followed by adjuvant radiation therapy (5). Definitive adjuvant radiation therapy generally entails a course of whole breast radiation therapy, typically 44 to 50 Gy in 1.8 to 2.0 Gy per fraction (standard fractionation), often followed by a 10–16 Gy boost dose to the lumpectomy cavity, which is delivered over 5 to 6.5 weeks. Alternatively, patients may receive hypofractionated radiation, which delivers biologically equivalent doses of radiation in 3 to 4 weeks and has been demonstrated to be as safe and efficacious as standard fractionation (13). Over the last several years, increasing numbers of women have been treated with partial breast radiation (typically

delivered twice daily over 1 week) as a faster alternative to conventionally fractionated whole breast radiation. While the existing data on definitive partial breast irradiation cohesively suggest excellent local-regional control comparable to that of whole breast radiation, prospective data with long-term outcomes and safety are lacking (14). Irrespectively, given the limited tolerance of normal tissue after these definitive doses of radiation to the breast, IBTRs occurring in previously radiated BCT patients are often treated with mastectomy, which is generally felt to be the standard management approach. For patients who have not been treated with radiation therapy as a component of their initial treatment, a repeat breast conservation procedure with excision of the recurrence followed by a course of radiation therapy can be considered. It remains uncertain whether mastectomy after IBTR improves outcomes compared with lesser surgery. A number of studies comparing mastectomy and breast conservation as treatment for IBTR are detailed in Table 69-1. Together, these studies suggest that the rates of recurrence are greater after a second local excision compared with mastectomy, but whether this ultimately translates to improved survival outcomes remains unclear (15).

Second attempts of breast conservation in previously radiated patients with small, histologically favorable local relapses have been reported. The initial experiences of salvaging an IBTR with a breast conserving approach utilized a wide local excision alone. In carefully selected patients with mobile tumors measuring less than 2 cm in size and favorable pathologic features, 5-year local control approaches nearly 80%, and is significantly better for patients in whom a negative margin was attained on the second local excision surgery (20). The published data cohesively suggests that with a second local excision without additional radiation therapy, local relapse rates range from approximately 20% to 50% as shown in Table 69-1.

Based on the observation that the risks of local relapse reported after a second breast conserving surgery approximates the risk of local relapse experienced after primary breast conserving surgery (~35%), there have been efforts in evaluating re-irradiation after second local excision for IBTR, with the hopes of decreasing the local relapse rates with a similar magnitude of benefit as seen in definitive settings (approximately two-thirds risk reduction). In previously radiated BCT patients, a repeat breast conserving approach should only be attempted if the patient is refusing salvage mastectomy, and re-irradiation should only be utilized on protocol where toxicity and efficacy can be monitored, documented, and reported.

With existing knowledge and expertise using partial-breast irradiation in the primary setting, various techniques to deliver a second repeated course of radiation for LRR have been investigated. Low-dose rate interstitial brachytherapy, which has the longest clinical experience for partial breast irradiation in the definitive setting (14), has been utilized in the hands of experienced clinicians to deliver a re-irradiation dose to the tissue surrounding the lumpectomy cavity. The rationale for re-irradiation with a partial breast technique is based on the hypothesis that focal treatment can eradicate microscopic disease while maintaining normal tissue tolerance, and thus have acceptable side effects. Various methods of re-irradiation of IBTR have been described; these include interstitial brachytherapy, where multiple interstitial catheters are inserted into the high-risk area (typically 1–2 cm surrounding the lumpectomy cavity). The catheters are after-loaded with low-dose-rate sources to deliver 30 to 55 Gy to the previously radiated breast (22). Furthermore, intra-operative radiation has been described to deliver a targeted x-ray to the IBTR resection cavity at the time of the resection surgery (23). Lastly, utilization of high dose-rate intraluminal brachytherapy (i.e., Mammosite®) (24) and external-beam partial breast techniques (25) for re-irradiation of the high-risk area after repeat BCT have also been reported. The results of published studies are shown in Table 69-2. For patients who received partial breast irradiation as part of their primary, definitive treatment who subsequently experience IBTR, the data to salvage these patients with a repeat breast conserving approach are very limited.

Factors to consider when evaluating a patient for re-irradiation after BCT include interval between initial radiation treatment and recurrence, anatomic considerations (such as close proximity to skin) that may preclude safe and cosmetically favorable delivery, and whether there is ample residual breast volume amenable to re-irradiation. It is important to note that because safe thresholds for normal breast tissue, skin, muscle, bone and subcutaneous tissue are not established in this setting and existing data are limited, all BCT patients being considered for a second breast conserving approach with re-irradiation should be treated on Institutional Review Board (IRB)-approved protocols with the informed consent of the patient.

Currently, a phase II national trial, RTOG 1014, is underway and will evaluate the adverse events associated with the use of a repeat breast conserving approach after IBTR. In this trial, patients who experience an IBTR less than 3 cm in size with a time interval of greater than one year from completion of their initial course of radiation will undergo a second

local excision followed by partial breast irradiation utilizing 3D-conformal external beam radiation techniques to deliver 45 Gy in 1.5 Gy fractions bid. The primary endpoint being evaluated is adverse effects after re-irradiation, with secondary endpoints including in-breast recurrence rates, mastectomy-free survival, overall survival, monitoring/correlating circulating tumor cells with relapse, and cosmesis (Fig. 69-4).

LRR after Mastectomy

Mastectomy in the definitive setting is associated with excellent local control in the majority of breast cancer patients. While breast conserving surgery is associated with greater odds of LRR than mastectomy (pooled OR: 1.561; 95% CI, 1.289–1.890), LRRs still occur in approximately 8.5% of mastectomy patients (31). Chest wall recurrences (CWRs) have been reported in up to 40% of patients depending on primary tumor characteristics and initial treatment (32).

The diagnosis of CWR, defined as a breast cancer recurrence in the skin, subcutaneous tissue, muscle, or underlying bone after mastectomy, requires a high index of suspicion. Many CWRs occur within two to three years after mastectomy, but can be detected more than 10 years after initial treatment occasionally. Careful surveillance of the chest wall after mastectomy is therefore required. LRRs after mastectomy are generally detected by physical

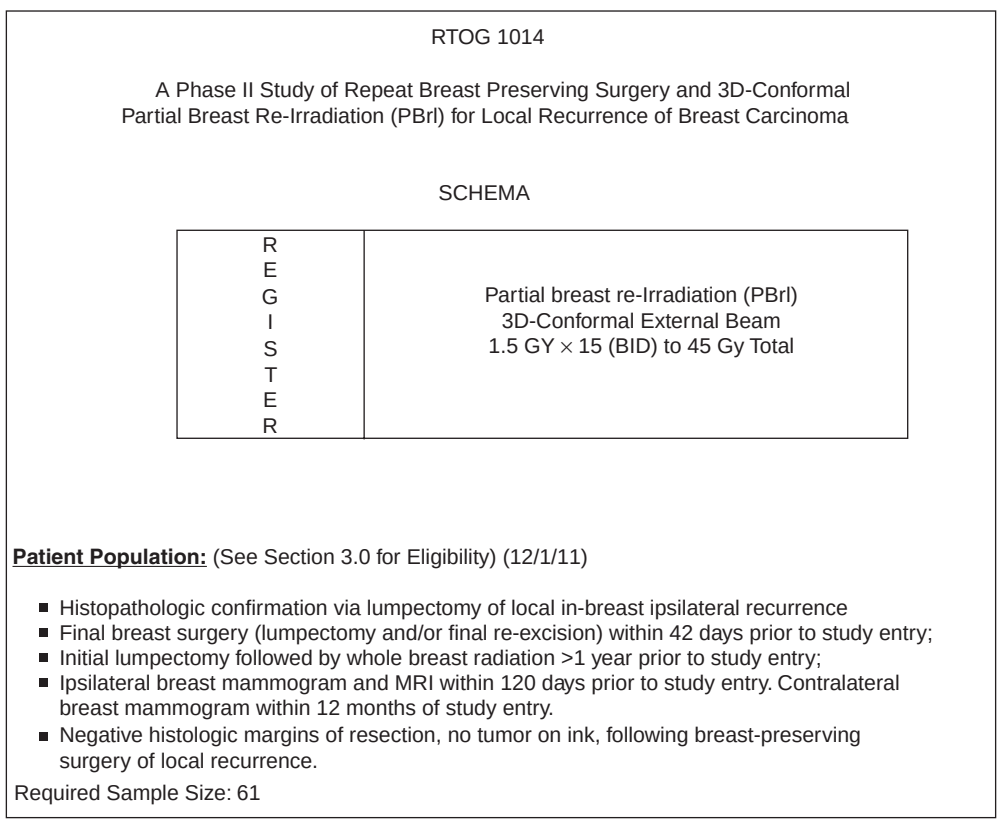

FIGURE 69-4 RTOG 1014: Study schema, patient eligibility, and target accrual.

examination, as imaging surveillance has not been shown to be particularly useful. The majority of CWRs present as asymptomatic nodule(s) in the skin or a slight erythematous rash. Often, this involves the previous mastectomy scar, and may be mistaken for foreign body granuloma, fat necrosis, or radiation-induced injury. Histologic confirmation is, therefore, required, and can be obtained with a punch biopsy.

While CWRs are often considered to be a harbinger of metastasis with an ominous prognosis, not all of these patients will fare poorly. Initial attention should be paid to evaluating for the presence of concomitant distant metastatic disease, which is present in up to a third of patients (4). Patients with a reasonable prognosis include those who: are without distant metastases, were node-negative at their initial cancer diagnosis, were disease-free for more than 24 months prior to their CWR, and are candidates for chest wall radiation therapy. In this more favorable subgroup, median overall survival is 141 months (10-year actuarial survival 75.4%), and more aggressive local-regional treatment may be warranted.

Additionally, outcomes are most favorable for those patients who are able to undergo complete surgical excision of the LRR followed by radiation therapy. Despite high response rates with the use of radiation therapy alone for CWR, 60% to 70% experience a second failure, thus surgical resection should be strongly considered for any patient with localized, recurrent disease. For patients in whom surgical resection is not feasible, radiation alone can provide meaningful palliation of localized symptoms, but is unlikely to provide a durable response or cure. Systemic therapy should be considered, either initially to decrease the burden of tumor prior to local-regional therapy, or after local-regional treatment.

CWR Following Mastectomy

If technically feasible, the standard of care for a CWR is surgical resection, which provides excellent local control, and is particularly useful in patients who have previously had radiation therapy or those in whom radiation therapy is contraindicated. For patients with isolated recurrences involving only the skin or the surgical scar, resection of the CWR is often straightforward. Resection with primary closure is generally feasible and can provide excellent local control. With more extensive disease, closure of the chest wall with either a skin graft or autologous flap may be needed, and preoperative consultation with a plastic surgeon is advised. Every attempt should be made to attain wide negative resection margins. For patients with deep CWR extending to underlying bony elements, the utility of resection of ribs and sternum remains controversial. Such extensive resections are often associated with significant morbidity, although some authors have reported reasonable long-term results of full-thickness resections in selected patients (Table 69-3).

In patients who have not received previous radiation therapy, definitive doses of adjuvant postmastectomy radiation therapy should be delivered to maximize local-regional control. The technique should be similar to that utilized in the postmastectomy setting, with tangential chest wall fields which are matched to the supraclavicular field anteriorly, and the use of a posterior axillary boost if indicated, based on the presentation of the recurrence, the individual patient's body contour, and the dose distribution obtained (41). Importantly, field size should always cover the entire chest wall (as opposed to a limited field encompassing just the local recurrence site) and regional lymph nodes, as limited treatment of the chest wall increases the risk of failure elsewhere on the chest wall and in the supraclavicular and axillary nodal basins. Typically, 50 Gy is delivered to the entire chest wall followed by a 10 Gy boost to the recurrence site, if feasible, and 46 to 50 Gy to the regional lymph nodes. A 0.5 cm to 1.0 cm bolus is placed over the entire chest wall to maximize skin dose, and can be utilized every other day during the course of chest wall irradiation or alternatively, for the first 20 Gy (10 fractions). Standard radiation fields are shown in Figure 69-5.

CWR Following Mastectomy with Reconstruction

It has been well demonstrated that reconstruction does not increase the incidence of CWR after mastectomy, nor does the incidence of CWR vary with the type of reconstruction (42). The majority of CWRs following skin-sparing mastectomy with reconstruction occur under the skin, and are easily palpable on clinical examination (42). While the length of time between mastectomy and finding a CWR may be slightly longer in patients who have had reconstruction, the prognosis between these patients and those who develop a CWR after a conventional mastectomy is not significantly different (43). Surveillance remains physical examination, and patients who present with a subcutaneous nodule should be treated with a high index of suspicion; punch biopsy may provide a histologic diagnosis.

Patients who present with a CWR following autologous reconstruction do not necessarily require complete removal of the reconstruction (43,44). In patients who have had transverse rectus abdominis myocutaneous (TRAM) or latissimus flap reconstruction, the CWR can often be resected with local flap rearrangement to preserve the breast mound. In patients who have had implant-based reconstruction, on the other hand, removal of the implant may be warranted in order to facilitate subsequent radiation therapy. Patients who have not previously received postmastectomy radiation should receive full doses of radiation therapy to the chest wall and regional lymph nodes after surgical resection of LRR to further diminish local regional relapse rates (as state earlier).

CHEST WALL RECURRENCE IN PREVIOUSLY IRRADIATED PATIENTS

In a patient who has been previously radiated, surgical resection of a CWR may be technically more challenging due to the added sequelae of radiation, but surgical resection should, nevertheless, be considered. Because the local control failure rates after postmastectomy CWR treated with a chest wall resection alone remain unacceptably high (approximately 33% at 5 years (45)), re-irradiation of the chest wall with curative intent has been utilized and seems

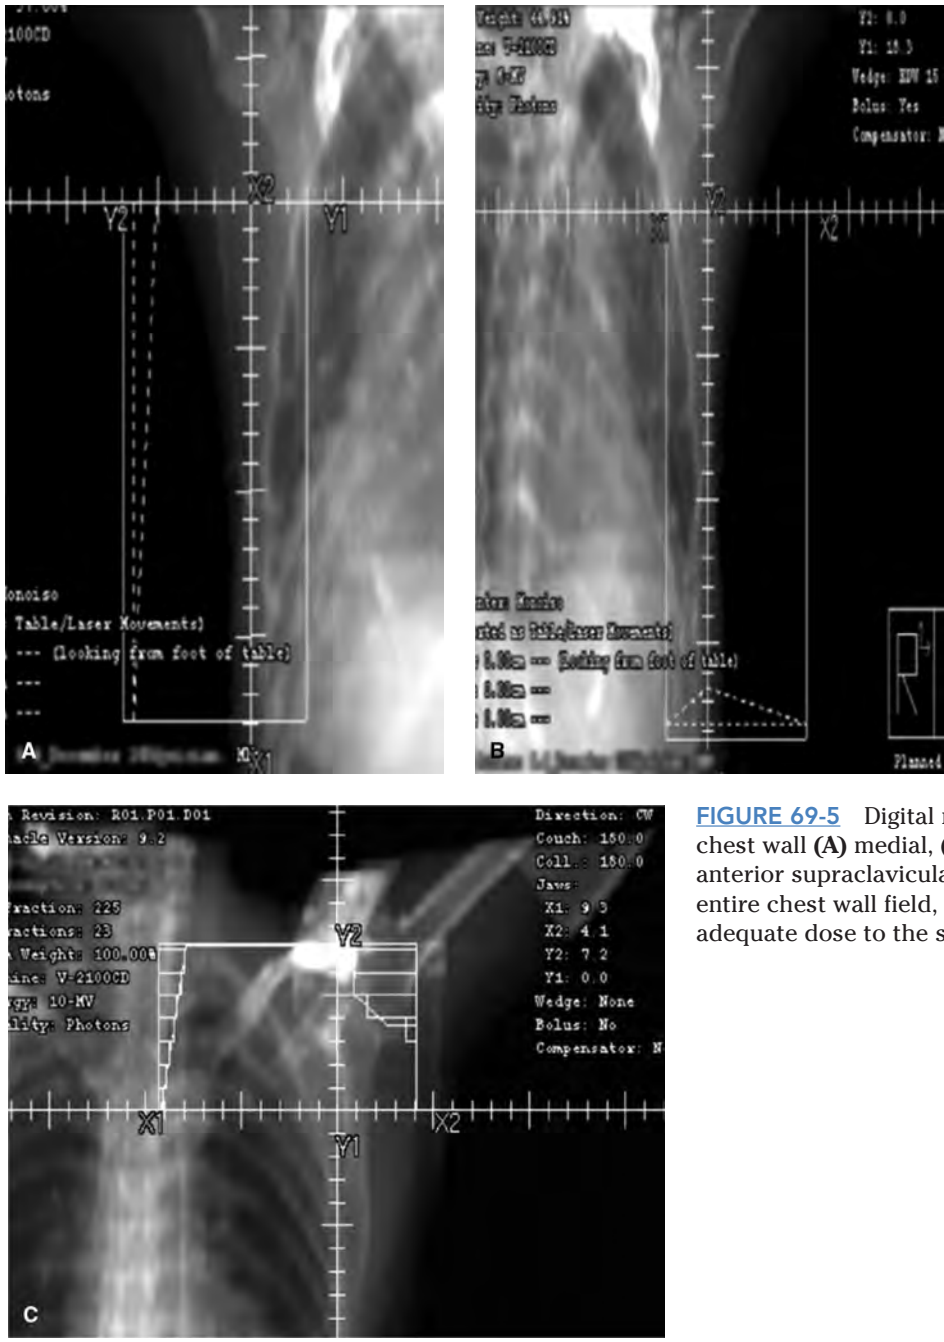

FIGURE 69-5 Digital reconstructed images of standard chest wall **(A)** medial, **(B)** lateral tangential fields, and **(C)** an anterior supraclavicular/axillary field. Bolus is placed on the entire chest wall field, irrespective of the disease, to ensure adequate dose to the skin.

to improve the prognosis of previously radiated women with CWR. In one recently published series of re-irradiation of the chest wall, no patients had treatment related death, brachial plexopathy, pericarditis, or higher than Grade II pneumonitis. While skin toxicity was elevated with the re-irradiation, (Grade III 7% at 1°RT course vs. 19% at re-irradiation), no patients developed Grade IV toxicity, suggesting that re-irradiation to the chest wall to definitive doses is relatively well tolerated with acceptable acute and late toxicity (46). Typically, doses of 40 to 50 Gy to the chest wall followed by a boost to the recurrence site utilizing electron beams are utilized (Fig. 69-6). In these cases, re-irradiation of the regional nodes is contraindicated. Radiation fields need to be tailored to encompass the gross disease with a 2–3-cm margin at a minimum, with particular attention to ensure that the brachial plexus dose does not exceed tolerance.

HYPERTHERMIA

Hyperthermia, or heating of the tumor beyond physiologic temperatures, has been evaluated for decades as a method for cytoreduction of superficial malignancies. Laboratory and *in vitro* data suggest a biologic rationale for hyperthermia, including a direct cytotoxic effect on the cycle in the S phase (a phase in the cell cycle with increased resistance to radiation), inhibition of sub-lethal damage repair, and improved intratumoral oxygen content (facilitating free radical-mediated cytotoxic damage from radiation). Fundamental differences in mechanisms of activity and resistance for hyperthermia and radiation support a rationale for concomitant delivery, theoretically providing a synergistically anti-tumor effect. Hyperthermia may also function as a radiosensitizer, allowing for lower total doses of radiation to

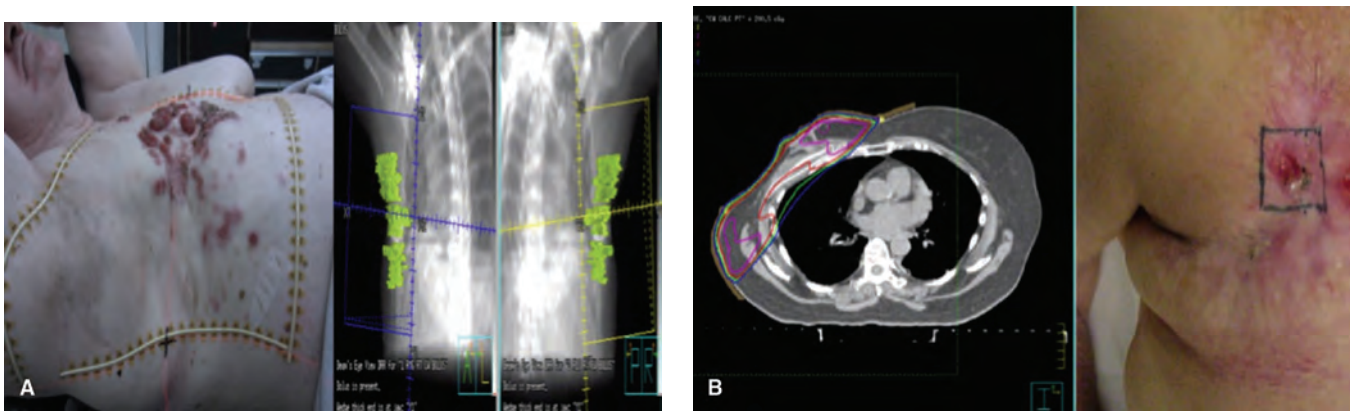

FIGURE 69-6 **(A)** Patient with CWR after mastectomy and postmastectomy radiation (previously received 50 Gy to the chest wall and regional nodes). **(B)** Digital reconstructions of the re-irradiation field volume that was targeting the CWR. This volume received 40 Gy. **(C)** Dosimetry plan showing an axial slice of the treatment plan, depicting the 95% (prescription) line in green covering the clinical target volume, which was achieved with mixed photon and electron beams with bolus. **(D)** Image of chest wall at the completion of 40 Gy. The two areas with residual disease were boosted with an additional 10 Gy each. The patient had a complete clinical response to treatment.

be therapeutic. Typically, hyperthermia involves heating the tumor bed to a temperature range of 40° to 45°, concomitant with delivery of radiation. Radiotherapeutic management of LRR presents specific challenges, including potential resistance to radiation, dose limitations in previously radiated patients, and poor vasculature (and thus poor oxygenation) after radiotherapy; hyperthermia may thus offer an additional modality with local cytotoxic benefit.

To date, it remains unclear whether the addition of hyperthermia to radiation for recurrent breast cancer is beneficial in improving long-term outcomes. While multiple randomized trails have been undertaken, many of these protocols included multiple tumor sites, and several of these studies have never been published in manuscript form. Furthermore, of the published data, heterogeneous patient populations, differences in eligibility and treatment protocols, and weaknesses in study design, adherence to protocol requirements, and selection of complete response as the primary endpoint assessed instead of local control, disease-free, or overall survival, have limited the ability to draw conclusions regarding the benefits of hyperthermia. In one series of 134 patients previously treated with radiation with recurrent breast cancers, re-irradiation with doses of 32 Gy delivered in 8 fractions with concurrent hyperthermia (and no chemotherapy) resulted in complete response (CR) rates of 71%; unfortunately, local disease free survival was not reported (47). The International Collaborative Hyperthermia Group (ICHG) conducted a meta-analysis of 5 randomized trials of re-irradiation of CWR with or without hyperthermia. The mean re-irradiation dose was 30 Gy in their cohort of 210 patients. Patients randomized to concurrent HT had a CR rate of 59%, whereas those randomized to re-irradiation alone had a CR rate of 41% ($p < .001$) (48). Despite this apparent benefit in the field treated with hyperthermia, three-fourths of these patients progressed outside of the radiation field following treatment, and there was no impact on survival with a median of 18 months with or without hyperthermia. Thus, while the use of hyperthermia may be an option in patients who have had previous radiation with limited additional options, additional controlled studies are needed to discern any long-term benefit.

REGIONAL NODAL RECURRENCE (AFTER BCT OR MASTECTOMY)

In addition to improving rates of IBTR and CWR, the use of multi-modality therapy in the definitive setting improves regional relapse rates, and thus the overall incidence of isolated regional nodal recurrences in the definitive setting is generally low (under 4%) (3). The manifestations of a regional lymph node relapse in most patients are usually minimal, most often presenting as an asymptomatic mass. Only a minority of patients will present with symptoms such as pain, arm edema, decreased range of motion or other physical impairments, or neurologic symptoms (49). In patients with symptoms suggestive of brachial plexopathy or arm edema without obvious lymphadenopathy, it may be difficult to distinguish clinically between tumor recurrence in the axilla or deep supraclavicular fossa and the effects of previous postoperative radiation treatment. The use of MRI may be helpful in this regard, as local enhancement with gadolinium suggests the presence of tumor, rather than radiation related fibrosis.

Regional lymph node recurrences generally confer a poor prognosis, and the risk of distant metastasis, whether simultaneously at the time of relapse or subsequently after salvage treatment, is high (>50%). Prognosis is related to the site of the disease, with supraclavicular, internal mammary, or multiple sites of nodal disease conferring a worse overall prognosis than axillary recurrences alone (50). Nevertheless, combined utilization of both surgical resection and radiation therapy confer higher disease-free and overall survival than using either modality alone, and thus, ideally, both modalities need to be considered.

AXILLARY AND SUPRACLAVICULAR RECURRENCES

The management of axillary recurrences is typically limited by the extent of disease and previous therapy that the patient has received. The surgical management of axillary recurrences has evolved, primarily due to the increased use

of sentinel lymph node (SLN) biopsy. In a patient who has an axillary regional recurrence after only SLN biopsy, a full level I/II axillary dissection is warranted. In a patient who has undergone a full axillary dissection (+/- axillary radiation), re-dissection is typically not a technically viable option, but axillary exploration and resection of gross disease may be considered for small, mobile, isolated recurrences. In contrast, the technical feasibility of performing a sentinel lymph node biopsy for IBTR, regardless of previous axillary sentinel node biopsy or dissection, has been demonstrated (51). In the re-operative setting, the sentinel node can be identified approximately 87% of the time when 10 or less lymph nodes were removed at original surgery (51). Repeat surgical assessment of the axilla may be particularly useful given the significant risk of concomitant IBTR and regional recurrence, and may prove to provide prognostic information useful in guiding management decisions for recurrences. Because of altered drainage patterns in these patients, particularly in those that have had 10 or more lymph nodes removed, clinicians should utilize a preoperative lymphoscintigram when considering repeat surgical axillary assessment (9).

For a patient who has an isolated nodal recurrence in a previously radiated field, regional re-irradiation with therapeutic doses is generally not considered safe, but limited field re-irradiation may be considered as a salvage option in patients unresponsive to systemic treatment or those with unresectable disease. Particularly for supraclavicular and axillary recurrences, utilization of standard external beam techniques would result in doses to the normal structures that are well beyond threshold. For example, with re-irradiation to the supraclavicular fossa or axilla, threshold doses to the brachial plexus would be exceeded, which could result in significantly debilitating and painful brachial plexopathy. While technological advancements in the delivery of radiation using intra-operative electron beam therapy have allowed for promising preliminary investigation of re-irradiation of the axilla (52), this technique warrants further investigation prior to its routine use. Furthermore, the requirements for an intra-operative linear accelerator and a dedicated, shielded operating room prohibit the widespread utilization of this technique in many radiation therapy centers.

There is ongoing debate as to whether supraclavicular lymph node involvement should be considered as local-regional disease or distant metastases, as overall, most are associated with a grave prognosis. Clearly, outcomes of regional relapses in the supraclavicular fossa are worse than those in the axilla (53). The largest and most recent series of supraclavicular recurrences comes from the Danish Breast Cancer Cooperative Group Database, reporting on 305 patients with an isolated supraclavicular recurrence with or without other local-regional metastases but no distant metastasis. Additional sites of synchronous local-regional disease were present in 38% of the patients. Nineteen percent had gross removal of the tumor, 33% had curative radiation, 26% had combined local-regional treatment and systemic therapy, and only 10% underwent surgery plus radiation. Combined local-regional and systemic therapy resulted in the highest rate of initial remission (67%) compared to either local-regional therapy alone (64%) or systemic therapy alone (40%), but the 5-year progression-free and overall survival were only 15% and 24% percent, respectively, with the only significant predictor of favorable outcomes on multivariate analysis being receipt of combined local-regional and systemic therapy (54). These data are consistent with other retrospective series suggesting that patients with isolated supraclavicular recurrences have long-term disease free survival ranging from 15% to 30% with the utilization of multi-modality therapies (55). Therefore, patients with isolated supraclavicular recurrences without distant metastasis should be considered for curative multimodality therapy whenever possible.

INTERNAL MAMMARY NODAL CHAIN RECURRENCES

Nodal recurrence in the internal mammary nodal (IMN) chain is rare, despite the fact that these nodes are the second lymph node drainage basin of breast cancer and are typically not intentionally treated after definitive surgery in most breast cancer patients (Fig. 69-7). With IMN recurrence rates ≤2% after definitive treatment (56), there are limited data on the effects of surgical resection, systemic therapy, and/or radiation therapy in this setting, with the existing published literature consisting of only a few small series and case reports. One of the largest series of IMN recurrences in breast cancer describes 133 patients with IMN failure after definitive treatment. The 5-year survival rate of patients with IMN recurrences was approximately 30% overall, while that for those with isolated IMN recurrence was generally higher, approximately 45% (57). The factors that were found to significantly correlate with improved disease-free survival rates after IMN recurrence on multivariate analysis included: no concurrent distant metastases (HR: 0.7, 95% CI, 0.4–0.9; p = .031), presence of endocrine therapy for ER/PR+ patients (HR: 0.2, 95% CI, 0.1–0.5; p = .001), and presence of radiotherapy delivered to the IMN area after recurrence (HR: 0.3, 95% CI, 0.1–0.9; p = .026). While surgical resection of an isolated IMN recurrence has been described utilizing various techniques and appears to be associated with a low mortality rate, the surgery itself is typically very extensive requiring en bloc resection of the recurrence, surrounding chest wall, ribs, sternum, and previously radiated areas and often requires reconstruction of the chest wall defect (58). One series reported

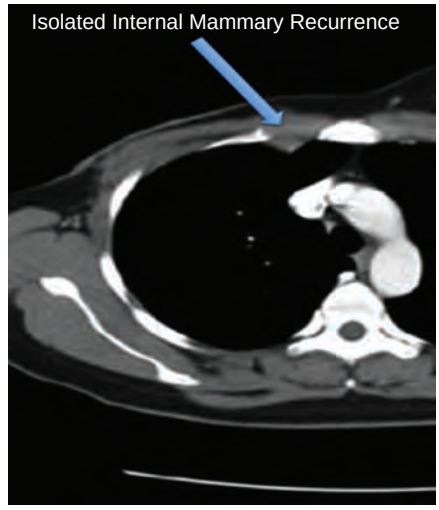

FIGURE 69-7 An isolated internal mammary recurrence 3 years after definitive treatment in a patient who underwent neoadjuvant chemotherapy, mastectomy, and axillary lymph node dissection for a triple negative clinical Stage IIIA (cT3c, N1c, M0) and pathologic Stage IIA (ypT2, ypN1) breast cancer. She received adjuvant postmastectomy radiation therapy: 50 Gy to the chest wall, a 10 Gy boost to the mastectomy scar, and 46 Gy to the supraclavicular fossa. The internal mammary radiation nodes were not intentionally included in her definitive treatment.

25 IMN recurrences treated with surgery, for which the en-bloc resection entailed a portion of the sternum, a mean of 3 (range 2–5) adjacent ribs, with the vast majority undergoing an omentoplasty for reconstruction of the chest wall. No post-operative deaths were reported, but 38% (11 patients) had adverse post-operative events which included 2 that required re-operation for necrosis of the omentum (n = 1) and overlying skin (n = 1) (59). More recently, a less invasive technique for treating IMN recurrence using a thoroscopic approach has been described (60). Because it remains unclear whether such extensive surgery provides a durable survival benefit compared with radiation therapy (+ systemic therapy) for IMN recurrences, for patients who have not previously received radiation, the mainstay of treatment for IMN recurrences is radiation therapy, typically to doses of 40 to 60 Gy.

SYSTEMIC THERAPY FOR LRR

Given the increased risk of distant failure after LRR, there is interest in whether systemic therapy can reduce the development of metastatic disease. Selection of systemic therapy for management of LRR presents challenges, as the benefit of additional, or a change in, systemic therapy after LRR is not well described by clinical trial data. Often decisions regarding systemic therapy for LRR become individualized based on tumor subtype, type of prior therapy if any, and interval since prior treatments.

Endocrine Therapy

For LRR confirmed to be hormone receptor (HR) positive, introduction of, or change in, endocrine therapy is generally considered. One prospective randomized trial has assessed the role of endocrine therapy use in the recurrent setting. The Swiss Group for Clinical Cancer Research (SAKK) trial 23/82 randomized 167 patients with LRR after mastectomy and "good risk" features (HR positive disease or disease-free interval >12 months with 3 or fewer nodules measuring 3 cm or smaller) to tamoxifen until relapse or observation (61). All patients underwent complete resection of disease and radiotherapy. The addition of tamoxifen improved median disease-free survival (DFS) from 2.7 to 6.5 years (p = .053), with notable improvement observed in postmenopausal patients. A benefit in overall survival was not observed. As prior adjuvant endocrine therapy was not utilized in this patient population, contemporary interpretation of this data is limited. However, given the good-risk profile of most endocrine agents, the risk-benefit balance favors use of highly effective, low-toxicity endocrine therapies in the setting of LRR.

Selection of the endocrine agent depends on prior and current exposures as well as menopausal status. In the setting of LRR during exposure to an endocrine agent, it is prudent to consider changing to an alternative endocrine agent. If the patient is already postmenopausal and was on an aromatase inhibitor, then change to tamoxifen could be considered. Alternatively, if premenopausal on tamoxifen, initiation of ovarian suppression and change to aromatase inhibitor can be discussed. The role of continuation of endocrine therapy in the setting of HR negative LRR after HR positive primary disease is not well understood.

Chemotherapy

The use of chemotherapy for LRR is frequently considered, yet not well established. Attempts to ascertain the value of offering chemotherapy for LRR through randomized trials have been complicated by limited accrual and trial design. Historic experiences include small trials evaluating the addition of actinomycin-D (n = 32) (62) and alpha-interferon (n = 32) (63). In addition to the endocrine question, the SAKK trial also offered chemotherapy to "poor risk" patients with LRR, and randomized 50 to observation versus chemotherapy (adriamycin, cyclophosphamide, vincristine) after excision and radiation. Unfortunately, this section of the trial was closed due to poor accrual and results were never formally published (64). Two ongoing European studies, the German GBSG GABG 6 and the French FNCLCC-FACS 03, aim to randomize patients with LRR after resection to observation versus polychemotherapy, but are not yet completed.

The most contemporary completed clinical trial to assess the role of adjuvant systemic therapy for LRR is the BIG 1-02/IBCSG 27-02/NSABP B-37 "CALOR" (Chemotherapy as Adjuvant for Locally Recurrent Breast Cancer) study (65). This trial enrolled patients with an isolated local and/or regional invasive recurrence after complete surgical resection, and randomized to subsequent chemotherapy of physician choice, or no chemotherapy (Fig. 69-8).

The CALOR protocol recommended at least 2 agents of chemotherapy for the duration of 3 to 6 months. Radiotherapy was recommended (and mandatory for those with involved margins) in both arms, endocrine therapy was mandatory for estrogen receptor positive disease, and trastuzumab was optional for HER2 positive disease. The primary endpoint of the study was disease free survival; initial goal accrual was close to a thousand patients; however, the trial was closed after 8 years due to low accrual after enrolling 162 patients. Results were presented at a median follow-up of 4 years.

The accrued study population included about 60% with prior breast conserving surgery, and 60% to 70% with prior adjuvant chemotherapy exposure. Over 50% had in-breast recurrence, with the rest recurring on scar/chest wall or in regional lymph nodes; over 60% of the recurrent tumors were estrogen receptor positive. In the treatment arm, most patients (69%) received polychemotherapy. Over 90% of estrogen receptor positive tumors received endocrine therapy, and less than 10% received trastuzumab. The primary analysis showed that the addition of chemotherapy led to a significant improvement in 5-year disease-free survival from 57% to 69% (HR 0.59, 95%, p = .0455), as well as an improvement in the secondary endpoint of 5-year overall survival, from 76% to 88% (HR 0.41, p = .02). Results remained significant for both disease-free and overall survival in multivariable Cox proportional hazards modeling controlling for location of recurrence, disease-free interval, estrogen receptor status, and prior chemotherapy. Significant benefit was seen in the pre-specified analysis of estrogen receptor negative disease (35% vs. 67%, HR 0.32, p = .007) but not for estrogen receptor positive disease (69% vs. 70%, HR 0.94, p = .87).

Given the results of the CALOR study, it is reasonable to offer chemotherapy following definitive surgical resection after LRR, particularly for estrogen receptor negative tumors.

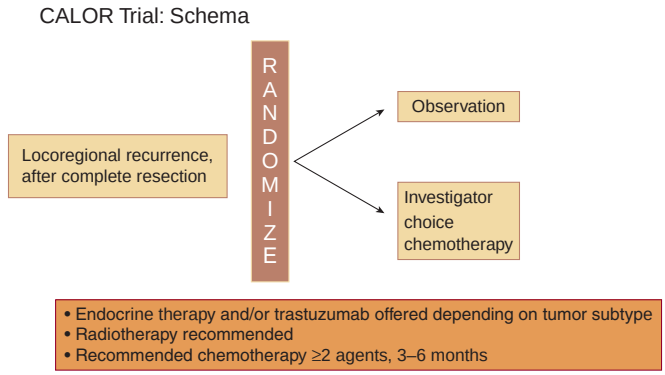

FIGURE 69-8 Schema of the BIG 1-02/IBCSG 27-02/NSABP B-37 CALOR study.

TABLE 69-4

Factors to Consider in Risk Assessment and Systemic Treatment Decision-Making for LRR of Breast Cancer

Disease-Related Factors	*Patient-Related factors*
Disease-free interval	Patient preferences
Previous therapeutic exposures and response	Pre-existing toxicities, performance status
Biological factors (hormone receptors, HER2)	Menopausal status
	Patient co-morbidities and biologic age

Adapted from Cardoso F, Fallowfield L, Costa A, et al. Locally recurrent or metastatic breast cancer: ESMO Clinical Practice Guidelines for diagnosis, treatment and follow-up. *Ann Oncol* 2011;22 (Suppl 6): vi25–30.

However, broad extrapolation may be restricted by limitations in trial design, as well as evolution in optimal adjuvant management at the time of primary diagnosis. In current situations of LRR, decisions regarding the role of additional chemotherapy remain quite personalized and reflect both disease- and patient-related factors (Table 69-4). Generally, in patients with a longer disease-free interval, who have not received both taxane and anthracycline previously, and who have tumor biology suggestive of chemosensitivity (e.g., HR negative, higher grade, etc.), consideration of a course of non-cross resistant chemotherapy should be considered (66). In situations presenting with a shorter disease-free interval since comprehensive adjuvant chemotherapy, or where disease is not thought to be chemosensitive (e.g., HR positive lower grade), the role of further chemotherapy is less certain.

Targeted Therapy

For individuals with HER2+ breast cancer with LRR who are trastuzumab naive, consideration of a course of trastuzumab and chemotherapy followed by extension of trastuzumab monotherapy is appropriate. Benefit from continuation of HER2-directed therapy has been observed after metastatic disease progression on trastuzumab (67); therefore, consideration of retreatment with trastuzumab-based therapy can be considered if previously received or if recurrence occurs while receiving trastuzumab. Partner chemotherapies typically include taxane or vinorelbine. Alternatively, consideration of treatment with an alternative HER2-directed agent, such as lapatinib, could be considered. At the time of writing, the use of other biologics approved in the metastatic setting, including everolimus, pertuzumab, and TDM1, is not appropriate in the setting of LRR; however, consideration of clinical trial enrollment is strongly encouraged.

Other Therapies for LRR

Photodynamic treatment (PDT) uses laser light in combination with a photosensitizing drug (a hematoporphyrin derivative) for the treatment of cancer. In small series that have utilized PDT for chest wall recurrences, the complete response rates have been highly variable (69). Most patients included in these series were heavily pretreated and often had extensive disease, although better results were noted for smaller nodular tumors or limited sites. PDT can cause pain and prolonged superficial skin necrosis, although surgical repair is rarely needed (70).

Additional local therapies investigated in small studies include intra-arterial regional chemotherapy, topical chemotherapy (Miltefosine), biologic response modifiers, and interferon (71–74).

TIMING OF TREATMENT

Systemic therapy in the absence of best efforts at surgical resection and radiotherapy is of limited value, and tends to be discouraged. Increasingly, if systemic therapy is planned for local-regional recurrence, providing therapy prior to planned surgical resection in a "neoadjuvant" fashion may be considered. Advantages of this strategy include not only downsizing a tumor and facilitating excision, especially if not operable at presentation, but also allowing *in vivo* observation of tumor sensitivity to the agent of choice. Careful multidisciplinary planning is crucial in the care of a patient with LRR.

GENOMIC TESTING

Genomic testing, using methods such as OncotypeDX, has become commonplace in treatment decision-making for stage 1 and 2 HR positive tumors (see Chapters 29 and 44). The role of commercial genomic testing in the setting of local-regional recurrence is unclear. As the OncotypeDX test was originally constructed and validated using tumor tissues naive to endocrine chemotherapies, the utility of the test in the setting of recurrent tumor is unknown. An analysis of OncotypeDX testing before and after receipt of neoadjuvant chemotherapy showed scores remained correlated, suggesting receipt of chemotherapy did not alter the expression levels measured in the testing algorithm (68). However, until further confirmatory data is available, or unless a local recurrence is thought to be a primary tumor, use of commercial genomic testing to guide systemic therapy in the setting of local-regional recurrence is not recommended.

SURVEILLANCE

Continued surveillance after local-regional recurrence should follow traditional paradigms for primary breast cancer (Chapter 67). Additional serologic or radiologic investigations are not recommended in the absence of worrisome symptoms.

MANAGEMENT SUMMARY

Local Recurrence after Breast-Conservation Treatment

- Local recurrence after breast-conservation treatment is most often detected by breast imaging. A biopsy should be performed to confirm the recurrence, with pathologic confirmation and determination of hormone receptor and HER2 status. Patients should undergo a metastatic workup to rule out distant metastasis.
- Mastectomy is the standard treatment.
- There are limited data utilizing a repeat breast conservation approach. The existing published data suggest that this approach is feasible in a patient refusing mastectomy, but with a substantially higher risk of subsequent local recurrence than with mastectomy. Patients treated with re-irradiation should ideally be treated on an Institutional Review Board (IRB)-approved protocol.

Local Recurrence after Mastectomy

- Local recurrence after mastectomy is most commonly detected by physical examination.
- The index of suspicion for recurrence should be high, and a biopsy is indicated for confirmation and marker studies.
- All patients who develop a chest wall recurrence (CWR) after mastectomy should undergo a full metastatic workup, as concomitant metastasis occur frequently.
- CWR should be considered for surgical excision followed by radiation therapy to optimize local control. The volume of radiation treatment should include the entire chest wall and appropriate nodal regions (depending on prior axillary surgery and current extent of disease). The area of CWR should receive a total dose of at least 60 Gy (including a boost to the recurrence site).
- Patients who present with a CWR following autologous reconstruction may not require reconstruction removal; the CWR can often be resected with local flap rearrangement to preserve the breast mound.
- If the local recurrence is not operable, systemic treatment should be considered to render the recurrence operable.
- For patients with a local recurrence after mastectomy and postmastectomy radiation therapy, there is no standard treatment. Re-irradiation to gross disease may be reasonable in a patient in whom surgery and system therapy are not options. Hyperthermia or photodynamic treatment may provide additional therapeutic options for these patients.

Regional Lymph Node Recurrence

- The diagnosis of a regional nodal recurrence needs to be confirmed by biopsy.
- Concomitant local relapse should be ruled out, and a full metastatic workup is indicated.
- If the regional recurrence is operable, surgical resection of the recurrence should be pursued.
- After surgical excision, the role of systemic treatment is not defined.
- In view of the wide variation in presentations of regional lymph node recurrence, the overall treatment program must be individualized based on site(s) of recurrence and prior treatment.

Systemic Therapy In LRR

- For recurrences that are found to be hormone receptor (HR) positive, introduction of, or change in, endocrine therapy should be considered.
- Based on the CALOR study, it is reasonable to offer chemotherapy following definitive local treatment after LRR, particularly for HR-negative tumors. The decisions regarding the role of additional chemotherapy need to be personalized to the individual patient.
- For patients who have HER2+ recurrences and are trastuzumab naive, a course of concomitant chemotherapy with trastuzumab followed by trastuzumab as monotherapy is appropriate. Alternatively, another HER2-directed agent, such as lapatinib, may be utilized in patients who have received trastuzumab.
- Systemic therapy may also be considered in the setting of an isolated recurrence in a "neoadjuvant" fashion to downsize the recurrence prior to resection.

CHAPTER 70

Treatment of Metastatic Breast Cancer: Endocrine

Stephen R.D. Johnston and Gaia Schiavon

CHAPTER CONTENTS

INTRODUCTION

The optimal management of patients with metastatic breast cancer (MBC) remains a challenge. Systemic drug treatments such as chemotherapy, endocrine therapy, biological targeted therapy, and supportive therapies, including bisphosphonates for bone disease, are the mainstay of care. The clinical decision as to which is the most appropriate treatment option is based on a number of patient- and disease-related factors (Table 70-1). Approximately two-thirds of human breast carcinomas express estrogen receptors (ER) and thus may be dependent on estrogen for their growth, and for patients in whom their breast cancer (either primary tumor or biopsy of accessible metastatic disease) is positive for ER and/or progesterone receptor (PgR), endocrine therapy is an important treatment option to consider that has minimal toxicity.

For patients with ER/PgR positive (+ve) breast cancer and an estimated low risk of rapid progression of their advanced disease (i.e., soft tissue and/or bone metastases as their dominant site, absence of life-threatening visceral involvement, disease-free interval greater than 2 years, limited sites of metastatic involvement), endocrine therapies can be very effective in the treatment of their advanced/metastatic disease. For example, locally advanced ER +ve disease within the breasts of elderly women is often slow growing and extremely hormone sensitive. Excellent clinical responses can be achieved with simple well-tolerated endocrine therapy such as the antiestrogen tamoxifen, albeit maximal response and tumor shrinkage may take between 6 and 9 months to occur (Fig. 70-1A,B). However, sites of visceral metastases such as the liver may also respond well to endocrine therapy provided appropriate selection of patients is undertaken. For example, postmenopausal patients with strongly ER/PgR+ve disease with a long treatment-free-interval of many years after completion of adjuvant tamoxifen may then develop metastatic disease within the liver but with a limited number of tumors and preserved organ function (i.e., normal liver function tests). They may lack any symptoms from their advanced disease and show good overall performance status. Such patients can have an excellent clinical response to endocrine therapy alone with, for example, aromatase inhibitors (AIs), which may last for 18 to 24 months before their disease progresses and patients require chemotherapy (Fig. 70-1C,D).

Although evidence from randomized trials directly comparing endocrine therapy to chemotherapy as initial first-line treatment for MBC is limited, a Cochrane review found no survival differences but more toxicity associated with initial chemotherapy (1). Therefore, appropriate selection of patients who are suitable for initial endocrine therapy is therefore crucially important in order to maximize the benefits from such treatments, in particular as long-term disease control for up to 18 months with minimal side effects is not uncommon. In this chapter the evidence for each of the current endocrine therapy options that are available for advanced disease in both post- and premenopausal women are reviewed in more detail, together with the emerging strategies that might be used in the future to further enhance their effectiveness. In particular, recent results from several key clinical trials of endocrine therapy (including those in combination with various targeted signaling inhibitors) will be discussed, along with the implications for the optimal sequence of endocrine therapies in advanced breast cancer.

However, one of the key factors that determine whether endocrine therapy will be an effective option for metastatic disease relates to prior exposure to adjuvant endocrine therapy and to the level of hormone receptor expression. These two factors are among the most important in determining a tumor's underlying endocrine sensitivity, and whether "intrinsic de-novo" or "acquired resistance" will influence the outcome and response to endocrine therapy in the metastatic setting. These issues will be addressed first, before reviewing the clinical data that are available with each of the various current endocrine treatments in first- and second-line settings and the future strategies that might be used to circumvent/prevent endocrine resistance.

TABLE 70-1

Clinical Parameters Utilized in Decision Making for Systemic Therapy Options in Advanced Breast Cancer

Patient Factors
Age
Menopausal status
Performance status
Severity and nature of symptoms
Presence/absence of visceral disease
Organ function (i.e., liver/renal/bone marrow function)
Disease and Treatment-Related Factors
Tumor biology (ER/PgR status; HER2 status)
Dominant site of disease (i.e., bone/soft tissue vs. visceral metastases)
Number of sites of metastases (tumor burden)
Prior adjuvant systemic therapies
Duration of treatment-free period (i.e., sensitive vs. resistant disease)

IMPLICATIONS OF PRIOR ADJUVANT THERAPY AND ER EXPRESSION

Impact of Adjuvant Endocrine Therapy

The use of adjuvant endocrine therapy has significantly improved survival of women diagnosed with ER+ve early stage breast cancer (2). Until recently tamoxifen had been the gold standard of adjuvant endocrine therapy for ER+ve breast cancer. Tamoxifen is a nonsteroidal ER antagonist that inhibits breast cancer growth by competitive antagonism of estrogen at the receptor site. However, its actions are complex due to partial estrogenic agonist effects that in some tissues (i.e., bone) can be beneficial (3) but in others may be harmful, increasing the risk of thrombo-embolism and uterine cancer (4).

The results of the most recent Early Breast Cancer Trialists Collaborative Group overview involving over 21,000 women has shown that tamoxifen for about 5 years reduces the risk of death by around one-third in the first 15 years (RR 0.71) (2). The proportional risk reduction was not significantly affected by age, the use of chemotherapy, nodal status, or expression of PgR, with the absolute benefit relating to absolute risk of recurrence. Despite the significant clinical benefit from tamoxifen in early breast cancer and its impact on improving overall survival (OS), a significant annual hazard rate for recurrence persists in ER+ve breast cancer, with over half the recurrences occurring after 5 years of therapy has completed (2). This raises the issue of whether tamoxifen can be used again in MBC if it has already been given in the adjuvant setting.

In the recent past, AIs have demonstrated superior risk reduction over tamoxifen in postmenopausal early breast cancer. In the ATAC (Arimidex, tamoxifen, Alone or in Combination) trial, anastrozole was compared with tamoxifen and with the combination of the two drugs and was shown to be superior to both in terms of disease-free survival (DFS) (hazard ratio [HR] 0.86, 95% CI, 0.78–0.95; p = .003) in hormone-receptor-positive patients at a median follow up of 120 months (5). Similarly, the BIG 1-98 trial letrozole was significantly better than tamoxifen in terms of both DFS (HR 0.82, 95% CI, 0.74–0.92) and OS (HR 0.79, 95% CI, 0.69–0.90). (6) There have also been several trials that have reported a benefit in risk reduction with the use of adjuvant AIs given after an initial 2 to 3 years of tamoxifen versus tamoxifen for 5 years. While the use of adjuvant AIs in postmenopausal breast cancer has further improved outcomes, for those who still subsequently relapse, this has created new challenges to determine the most appropriate endocrine therapy strategies to utilize in women with metastatic disease.

Initial sensitivity to adjuvant therapy in early breast cancer can be an important predictor for the likelihood of response to further endocrine therapy in the metastatic setting. Some patients relapse very early while taking their adjuvant endocrine therapy. These tumors might be expected to have intrinsic "de-novo" endocrine resistance. Alternatively, some patients may relapse at the end, or shortly after completing adjuvant endocrine therapy, and as such could have developed "acquired" resistance, which may still allow response to alternative endocrine therapies. Alternatively, patients may relapse at a much later time point many years following completion of their adjuvant endocrine therapy (late relapse), and cancer cells in this situation may have retained full endocrine sensitivity. Thus the time point for relapse from diagnosis (disease-free interval) and also from prior adjuvant therapy (treatment-free interval) both might determine the response to further endocrine therapy in the metastatic setting (Fig. 70-2).

Change in Receptor Expression in MBC

It is well recognized that the level of ER expression in breast cancer cells determines the extent of endocrine sensitivity, and therefore the magnitude of benefit that can be obtained from adjuvant endocrine therapy. In the EBCTCG tamoxifen overview, highly ER+ve disease (≥200 fmol/mg as measured by ligand-binding assay) was associated with the greatest benefit with a hazard rate ratio for breast cancer mortality with tamoxifen of 0.53, while those women with the lowest but still measurable ER levels (<9 fmol/mg) did not derive any benefit from adjuvant tamoxifen (2). Utilizing more modern immuno-histochemistry (IHC) assays to measure ER, it was initially thought that tumors where only 1% of cells stained positive for ER by could benefit from adjuvant tamoxifen (7,8). However, more recent molecular studies have categorized different subtypes of ER+ve breast cancer that may better relate to likely hormone sensitivity and suggest that very few of the ER weak tumors (i.e., those with only 1% to 9% cells ER+ve) show a similar molecular feature to those strongly ER+ve tumors (9). Likewise, tumors that are ER negative (-ve) but express PgR may have a low expectation of clinical benefit from endocrine therapy. As such the primary breast tumor's level of ER expression (and possibly its molecular subtype) could predict the benefit from endocrine therapy for tumors that recur at loco-regional or distant sites many years later.

Increasingly, it has become important to establish whether the receptor status in the tumor changes during progression from early breast cancer to regional or metastatic recurrence, because this itself may be the most important factor in determining the likelihood of response to further endocrine therapy. Several studies comparing receptor expression between paired biopsies have showed that receptor expression may change, with either a reduction or loss of ER expression in up to 35% of tumors and gain of the human epidermal growth factor receptor 2 (HER2) expression in up to 10% of ER+ve breast cancers (Table 70-2) (10–13). Either or both of these phenotypes is known to account for acquired endocrine resistance, but may still allow response to alternative endocrine therapy strategies as illustrated

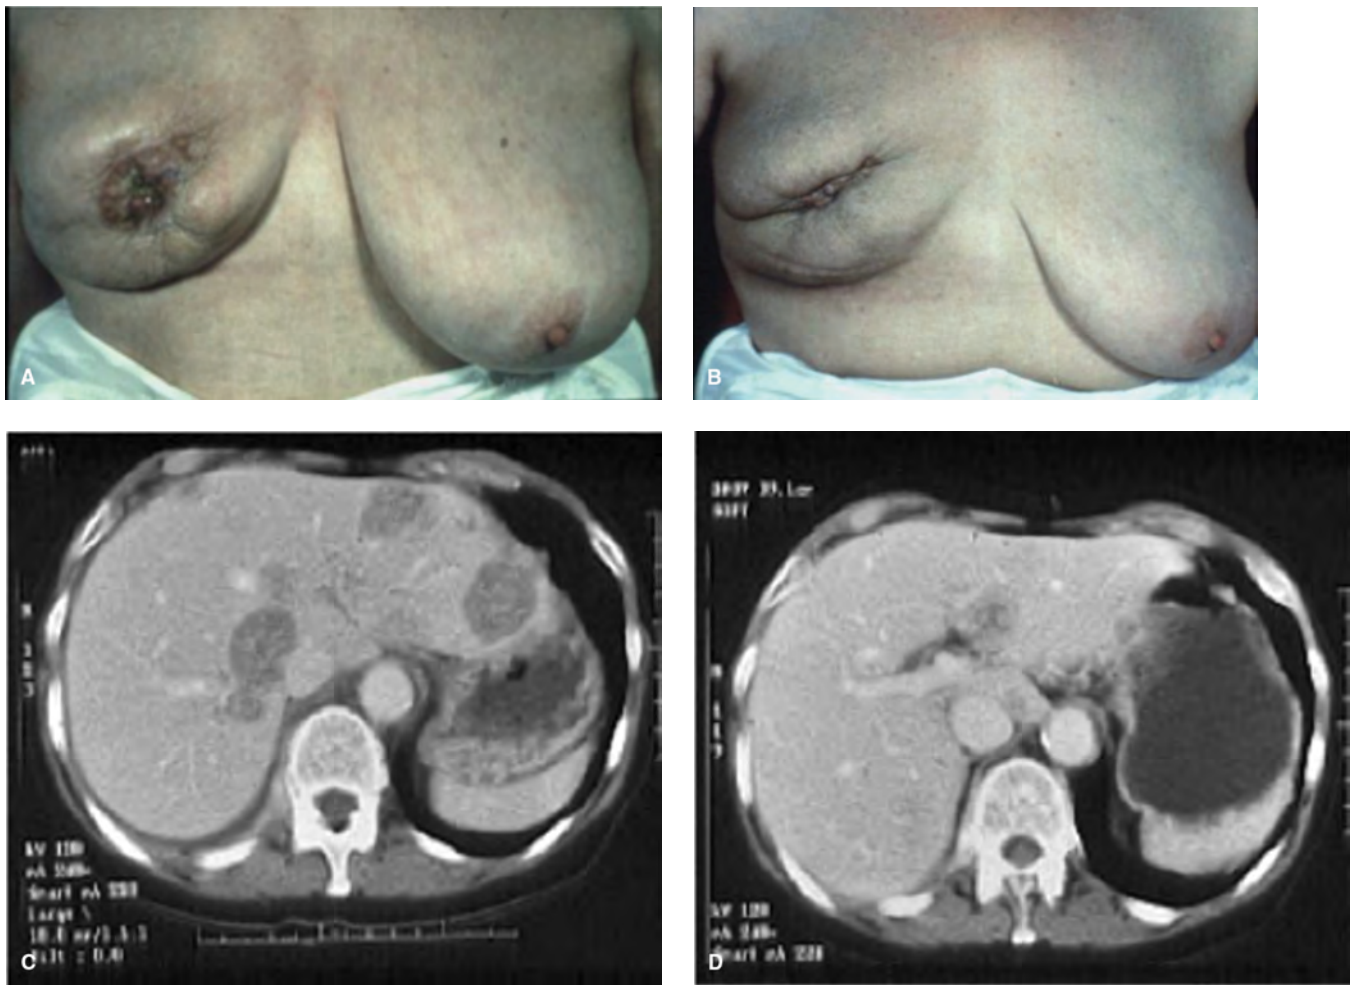

FIGURE 70-1 **(A)** An elderly woman with a locally advanced ER positive (+ve) slow growing right breast cancer at the time of diagnosis prior starting systemic treatment. **(B)** Excellent response with significant tumor shrinkage after 6 months of endocrine therapy (tamoxifen). **(C and D)** Transaxial scan CT images of a patient with limited number of lesions and preserved organ function at baseline (C) and after aromatase inhibitor-based therapy (D) showing partial response.

below due to partial non-cross resistance between different endocrine treatments.

As such, re-biopsies taken from sites of metastatic disease whenever clinically appropriate and feasible are increasingly recommended in order to plan appropriate systemic further therapy, in particular whether an endocrine approach will be effective option. This has been emphasized in the recent 2012 International Consensus Guidelines for the treatment of advanced disease, recognizing the importance of first- and second-line endocrine therapy as preferential options for patients with potentially endocrine-responsive MBC (14). The options available to these patients are discussed in the next two sections.

FIRST-LINE ENDOCRINE THERAPY OPTIONS FOR POSTMENOPAUSAL MBC

Tamoxifen

Historically, the selective estrogen receptor modifier (SERM) tamoxifen was the standard first-line treatment option for hormone receptor-positive MBC in postmenopausal patients, especially in those presenting with advanced disease or in whom adjuvant endocrine therapy had not been given. In 86 clinical studies involving 5,353 patients, the objective response rate (ORR including complete response [CR] + partial response [PR]) of 34% was observed, with an additional 19% of patients achieving stable disease (SD) for at least 6 months (15). A median duration of response up to 24 months was observed. Response rates (RR) tended to increase with age, with a 27% response in patients younger than 50 years compared with 43% in those over 70. Tamoxifen was generally well tolerated with a low incidence of serious side effects, including a low but significantly increased incidence of endometrial cancer and thromboembolic events due to its partial estrogenic agonist effects (16).

Tamoxifen was compared with many other endocrine therapies (high-dose estrogens, megestrol acetate (MA), oophorectomy, and other SERMs) in randomized trials, and although these trials are small and lacking statistical power by modern standards, tamoxifen was consistently shown to be at least as effective or better, and often with a better toxicity profile (17–30). However, the majority of women with

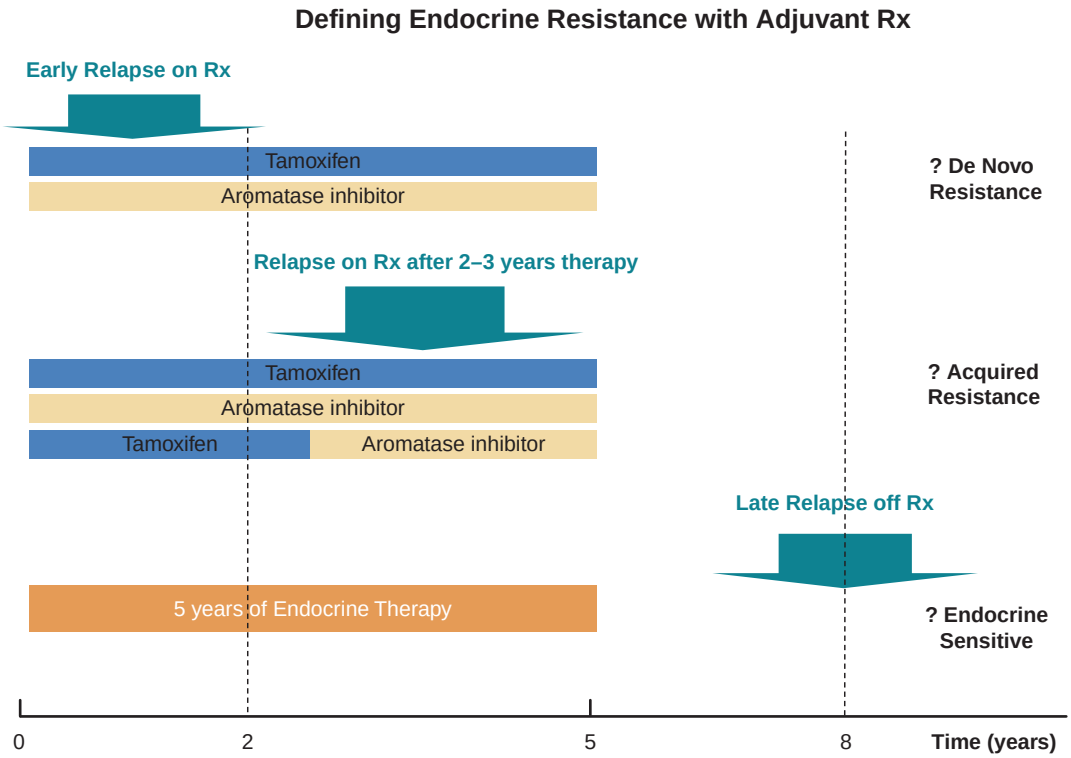

FIGURE 70-2 Conventional definitions of endocrine sensitivity/resistance to adjuvant endocrine therapy. The time-point for relapse from diagnosis (disease-free interval) and also from prior adjuvant therapy (treatment-free interval) both might determine the response to further endocrine therapy in the metastatic setting.

ER +ve breast cancer have already been treated with tamoxifen in the adjuvant setting, and while in the past tamoxifen therapy was often used again if there was a treatment-free period of several years, nowadays alternative endocrine approaches that deprive tumors of circulating estrogens are utilized in preference as first-line therapy.

Aromatase Inhibitors

From the mid 1990s, the potent third-generation oral AIs become the standard first-line treatment option for postmenopausal patients with ER +ve advanced/metastatic breast cancer. Estrogens are normally synthesized in the ovary in premenopausal women; following menopause, mean plasma estradiol (E2) levels fall from about 400–600 pmol/L to around 25–50 pmol/L. These residual estrogens come solely from peripheral aromatase conversion particularly in subcutaneous fat, and plasma E2 levels correlate with body mass index in postmenopausal women (31). The oral AIs anastrozole (Arimidex™), letrozole (Femara™), and exemestane (Aromasin™) all reduce serum estrogen levels in postmenopausal women by preventing the conversion of adrenal androgens into oestrogens (Fig. 70-3). Anastrozole and letrozole are third-generation nonsteroidal AIs that have similar pharmacokinetics with half-lives of approximately 48 hours, allowing a once-daily schedule (32,33). Exemestane is a steroidal aromatase inactivator with a half-life of 27 hours (Fig. 70-3) (34). All three compounds are orally active, and based on the clinical trials outlined below (Table 70-3) these drugs were licensed and approved as first-line endocrine treatment for postmenopausal women with ER+ve advanced breast cancer.

The first published data came from two parallel multicenter double-blind randomized controlled trials in which

anastrozole was compared with tamoxifen as first-line therapy in ER+ve breast cancer. The North American study in 353 women showed that anastrozole significantly prolonged the time to disease progression from 5.6 to 11.1 months (p = .005)(35), while in the larger global trial in 668 patients no difference was found between the treatments in terms of median time to progression (TTP) (8.2 months vs. 8.3 months), response rate (RR) (33% both arms), or clinical benefit rate (CBR) (36). The explanation for the different results may have involved a higher proportion of patients with unknown ER status in the second trial, and a subsequent combined analysis of women with just ER+ve disease from both trials confirmed a significant improvement in disease-free survival (8.5 months vs. 7.0 months) in favor of anastrozole (37). Short-term side effects such as hot flashes, vaginal dryness, and headaches were infrequent and similar in both trials in comparison with tamoxifen.

AI, aromatase inhibitors; CBR, clinical benefit rate; HD, high dose (500 mg i.m. at day 0 + 500 mg at days 14 and 28, thereafter 500 mg monthly until progression); LD, loading dose regimen (500 mg on day 0, 250 mg on days 14, 28, and 250 mg every 28 days thereafter); mo, months; n, number; ORR, objective response rate; OS, overall survival; Tam, tamoxifen; PFS, progression-free survival; TTP, time to progression.

The largest single trial was conducted with letrozole in comparison with tamoxifen in over 900 women with advanced breast cancer. Patients treated with letrozole had a significantly higher ORR, CBR, and prolonged TTP (Table 70-3) (38). Of particular note in this trial, nearly 20% patients had received prior tamoxifen in the adjuvant setting, although it had ceased a median of 3 years prior to development of metastatic disease—in this subgroup, retreatment with tamoxifen had a low response rate of 8% compared with a 32% response rate with letrozole. The improvements in clinical efficacy for letrozole resulted in an early improvement in survival during the first 2 years, although with longer follow-up this difference was lost (39). The explanation for this may relate to the high number (>50%) of patients who prospectively crossed over to the alternate treatment at the time of progression, because significantly more patients benefited from second-line letrozole after progression on tamoxifen than from second-line tamoxifen after letrozole.

Likewise, a European study in 383 patients compared the efficacy and tolerability of the steroidal aromatase inactivator exemestane with tamoxifen as first-line therapy (40). After a median follow-up of 29 months, there was an improvement in progression-free survival (PFS), together with a higher objective response rate with exemestane than tamoxifen (Table 70-3). A subsequent meta-analysis of 6 phase III prospective randomized clinical trials involving 2,787 women treated with second- or third-generation AI versus tamoxifen confirmed a significant advantage in ORR, TTP, and clinical benefit (CB = OR + SD), favoring AIs over tamoxifen (41). However, no difference was found in overall survival. Tamoxifen was associated with a significantly higher incidence of thromboembolic events and vaginal bleeding than the AIs. While some of the smaller trials were not always conducted with the academic rigor of large trials, they all consistently showed small but significant efficacy advantages of the AIs over tamoxifen.

All three drugs (anastrozole, letrozole, exemestane) are thus approved as first-line endocrine therapy options for postmenopausal women with ER+ve advanced breast cancer. It is not clear that one drug is significantly better than any other when direct comparisons have been made, although letrozole achieved greater aromatase inhibition than anastrozole in a crossover pharmaco-dynamic trial (42). Current clinical evidence suggests that there are unlikely to be major direct clinical differences between the different AIs in MBC (43). While there are no comparative data for exemestane with anastrozole or letrozole, further clinical responses have been reported for both exemestane and the second-generation steroidal inhibitor formestane in patients relapsing after anastrozole, letrozole, or the other nonsteroidal inhibitors, suggesting some partial non-cross resistance between the two types of inhibitors (44,45). In clinical practice, this has meant that exemestane is often used as a second-line option after prior first-line letrozole or anastrozole, as discussed further below.

Fulvestrant (alone or in combination with AI) as First-Line Therapy

Most postmenopausal women with metastatic ER+ve breast cancer have already received either an AI or tamoxifen in the adjuvant setting. Thus, the current clinical challenge is to establish an optimal first-line endocrine therapy for MBC given prior adjuvant endocrine therapy exposure. The ER down-regulator fulvestrant (Faslodex™) is a novel type of antagonist that, unlike tamoxifen, has no known agonist effects (46,47). Fulvestrant binds to the ER, but due to its steroidal structure and long side-chain, it induces a different conformational shape with the receptor to that achieved by the nonsteroidal antiestrogen tamoxifen. Because of this, fulvestrant prevents ER dimerisation and leads to the rapid degradation of the fulvestrant–ER complex, producing the loss of cellular ER (Fig. 70-4) (48). It has been shown that due to its unique mechanism of action, fulvestrant delays the emergence of acquired resistance compared with tamoxifen in an MCF-7 hormone-sensitive xenograft model (49), and that the lack of agonist effects means fulvestrant does not support the growth of tumors that became resistant to, and subsequently stimulated by, tamoxifen (50).

Early clinical studies showed that fulvestrant at the initially approved dose of 250 mg monthly by intramuscular injection (i.m.) had similar efficacy to tamoxifen as first-line treatment of hormone receptor MBC, with a median TTP of 6.8 and 8.3 months respectively (HR 1.18, 95% CI, 0.98–1.44; $p = .088$) and ORRs of 31.6% and 33.9% respectively (51). Given the widespread use of prior tamoxifen as adjuvant therapy, two separate phase III first-line trials compared fulvestrant with the AI anastrozole in postmenopausal women with locally advanced or metastatic breast carcinoma who had progressed after prior endocrine therapy (97% with tamoxifen, 56% as adjuvant therapy) (52,53). These trials were prospectively designed to allow combined analysis of data, and at a median follow-up of 15.1 months fulvestrant was at least as effective as anastrozole in terms of median time to progression (5.5 months vs. 4.1 months, respectively) and objective response (19% vs. 17%, respectively) (54). A subsequent survival analysis after a median follow-up of 27 months showed no significant difference in the median time to death between fulvestrant and anastrozole (27.4 months vs. 27.7 months, respectively) (55).

While these early first-line studies suggested that fulvestrant 250 mg was as effective as either tamoxifen or anastrozole in the first-line setting, more recent first-line studies with fulvestrant have investigated either different loading dose (LD) schedules (LD = 500 mg on day 1, then 250 mg on days 14, 28, and monthly thereafter) or a high dose (HD) schedule (HD = 500 mg on days 1, 14, 28, and monthly thereafter). A phase II trial (FIRST) compared fulvestrant HD with anastrozole as first-line treatment and showed a significantly longer TTP with HD fulvestrant (median TTP not reached versus 12.5 months; HR 0.63; 95% CI, 0.39–1.00; $p = .049$) (56). As discussed later, a randomized comparison of HD versus LD fulvestrant in the second-line setting (CONFIRM trial) has confirmed the better efficacy for the 500 mg HD schedule (57), resulting in an amendment to fulvestrant's new drug approval in 2010.

Preclinical evidence from two separate xenograft models suggested that fulvestrant could be significantly more effective when given in a low estrogen environment by combining it with an AI (58,59). Two randomized phase III trials tested the combination of anastrozole with fulvestrant (LD) versus anastrozole alone as first-line therapy in postmenopausal MBC patients (Table 70-3). SWOG S0226 demonstrated that fulvestrant plus anastrozole significantly improved median PFS (15.0 months vs. 13.5 months) and median OS (47.7 months vs. 41.3 months) compared to anastrozole alone (60). Safety and tolerability were similar between the two treatment arms. Conversely, the FACT trial reported no difference in the median PFS or median OS between the combination and the anastrozole arm (61). The main difference between these two trials was the proportion of endocrine therapy-naïve patients, 60% and 33% in the SWOG and FACT trial, respectively. Indeed, in an unplanned subgroup analysis of the endocrine-naïve subgroup in the SWOG trial, a significantly higher benefit was observed in the combination arm (median PFS 17.0 months versus 12.6 months), not observed in the smaller number of endocrine-naïve patients in the FACT trial. On the basis of this result, a currently active first-line phase III trial (FALCON, NCT01602380) is establishing whether fulvestrant (HD) and anastrozole is better than anastrozole alone in truly endocrine-therapy-naïve patients.

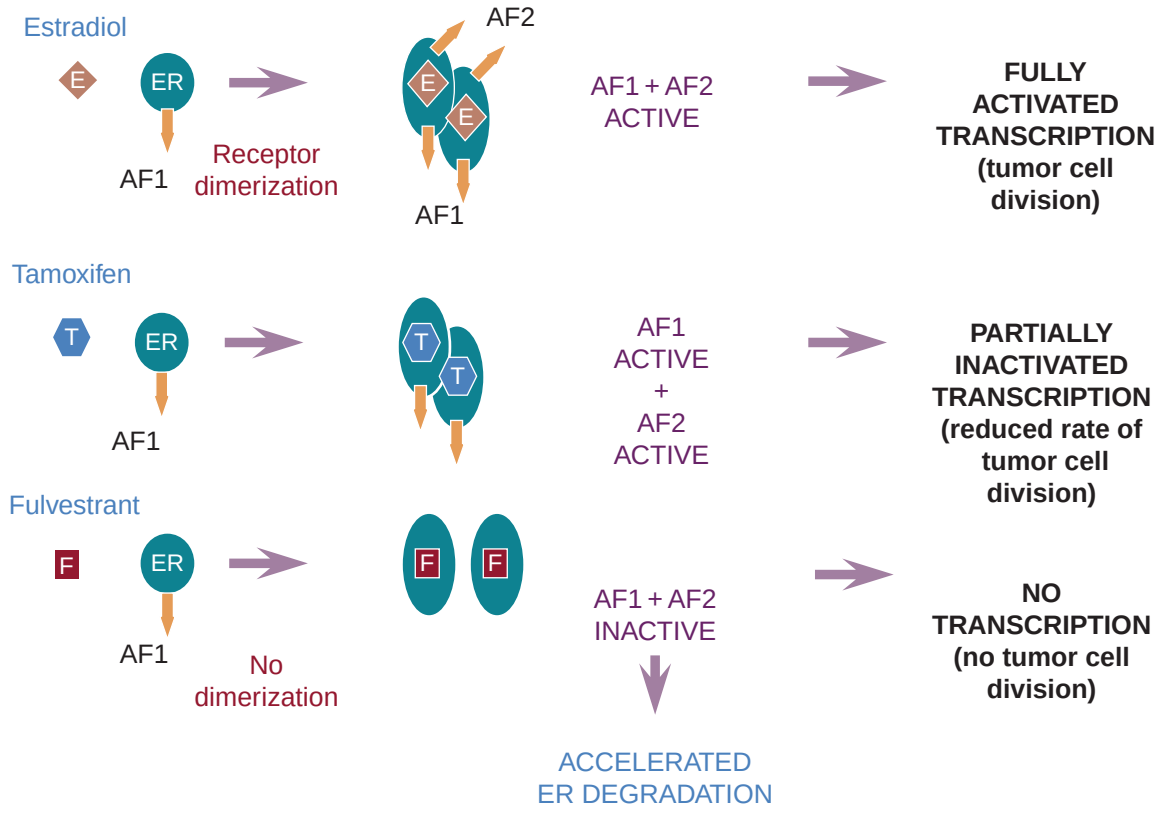

FIGURE 70-4 Diagram summarizing the different "mechanisms of action" of estradiol, tamoxifen, and fulvestrant via the estrogen receptor (ER) leading to different effects in transcription and ultimately tumor cell division.

To date, therefore, the nonsteroidal AIs remain the most effective first-line endocrine option for the majority of postmenopausal patients with MBC. In those with endocrine-sensitive disease, including those who are endocrine-therapy naïve, expected TTP are of the order between 10 to 15 months (Table 70-3). However, the influence of prior adjuvant endocrine therapy remains an important variable in the likelihood of success. While resistance to AIs inevitably develops, it does not preclude further endocrine responses, and effective second-line options are required for these patients.

SECOND-LINE/SEQUENTIAL ENDOCRINE THERAPY FOR POSTMENOPAUSAL MBC

Historically in the 1980s-1990s, tamoxifen was used as a first-line treatment for MBC followed by alternative endocrine therapies in the second-line setting such as the progestin megestrol acetate or the first-generation AI aminoglutethimide. When the third-generation AIs were first investigated as second-line therapy for postmenopausal women progressing after prior tamoxifen, in several RCTs they were shown to be superior in efficacy and/or side effects in this setting (Table 70-4) (62–69). However, given their subsequent improved efficacy in the first-line setting versus tamoxifen as discussed above, from 2001 onward the nonsteroidal AIs letrozole or anastrozole became the standard first-line therapy. Thus, it became important to know what the optimal endocrine therapy was in the second-line MBC setting following prior AI therapy, and in particular whether tamoxifen could be used, how effective the partially non-cross steroidal aromatase inactivator exemestane was, and what was the role of fulvestrant following prior AI therapy. The evidence for each is discussed below.

Tamoxifen

There are limited trials that have assessed the efficacy of tamoxifen after prior adjuvant AI therapy, and few prospective data show efficacy for tamoxifen where disease had progressed on a nonsteroidal AI (i.e., anastrozole or letrozole). The largest available data come from the letrozole versus tamoxifen study where over 50% of the patients prospectively crossed over to the alternative treatment at the time of progression (39). Median OS from the cross-over data was 19 months for patients who crossed to second-line tamoxifen from their AI, compared with 31 months for patients who crossed to second-line letrozole from tamoxifen. The only other data come from retrospective questionnaire data from the combined analysis of the two international phase III anastrozole versus tamoxifen TARGET trials. This analysis suggested that of 119 patients who went on the receive tamoxifen following progression on anastrozole, 58 patients (49%) derived clinical benefit and 12 patients (10%) had an objective response (70). A subsequent double-blind cross-over study by the Swiss centers in the TARGET Trial (SAKK 21/95 sub-trial) further investigated the clinical impact of the sequence anastrozole followed by tamoxifen and reported that 8/16 (50%) derived clinical benefit from tamoxifen (71).

A more contemporary source of data for the efficacy of tamoxifen after prior AI therapy (often in the adjuvant setting) has come from the phase II randomized TAMRAD study testing tamoxifen plus the mTOR inhibitor everolimus (RAD001) (n = 54) versus tamoxifen alone (n = 57) in postmenopausal patients with ER+ve MBC (72). Patients in

[a]P vs MA (or AG).

the tamoxifen-alone arm had an ORR of 13%, a CBR of 42%, a median TTP of 4.5 months, and a median OS of 32.9 months. These limited data show that tamoxifen may have clinical benefit in almost 50% of patients relapsing on or after an AI, but relatively few obtain an objective response. Further details of this trial are described below.

Thus, tamoxifen may have some limited efficacy as second-line therapy after an AI although data are sparse to confidently determine the optimal sequence. However, preclinical studies (discussed later) suggest that tamoxifen may be an agonist in cells resistance to long-term estrogen deprivation, and that more effective endocrine/signaling strategies may exist for use following failure of first-line aromatase inhibitor therapy.

Exemestane

Steroidal AIs such as exemestane have an androgen structure and compete with the aromatase substrate androstenedione. They inactivate aromatase by irreversibly binding to its catalytic site, and additional aromatase must be produced before estrogen biosynthesis can resume. Early data suggested a lack of cross-resistance between steroidal AIs and nonsteroidal AIs and that steroidal AIs may be an option in nonsteroidal AI-resistant disease (73). In a phase II, open-label, multinational trial, 24% of patients overall achieved clinical benefit with exemestane following either aminoglutethimide (n = 136) or nonsteroidal AI treatment (n = 105) (45). The ORR and CBR were 8% and 27%, respectively, for patients who received prior aminoglutethimide, with 5% and 20%, respectively, for those who had previously received nonsteroidal AIs.

A separate retrospective analysis of 96 patients receiving exemestane, most of whom had received prior nonsteroidal AIs, reported that 39% experienced clinical benefit with exemestane (74). Lack of cross-resistance between exemestane and nonsteroidal AIs (NSAIs) was also reported in an open-label, exploratory trial comparing sequential treatment with exemestane and NSAIs in MBC (75). Exemestane showed activity in patients after relapse or lack of response to letrozole/anastrozole with an ORR of 8.7%, a CBR of 43.5%, a median TTP of 5.1 months, and a median OS 27.2 of months. As such, exemestane became a standard second-line treatment option for postmenopausal MBC after failure of first-line nonsteroidal AI therapy. As discussed below, exemestane was chosen as the control arm for two large phase III trials that assessed the steroidal antiestrogen fulvestrant in patients no longer responding to a NSAI.

Fulvestrant

Early clinical data with fulvestrant in advanced breast cancer following resistance to AIs came from several phase II studies that showed that fulvestrant 250 mg monthly produced clinical benefit in 20% to 52% patients who had received, and had progressed on, prior treatment with tamoxifen and a nonsteroidal AI (76–80). These results suggested that in addition to being effective after prior tamoxifen, disease progression after nonsteroidal AIs may not preclude subsequent treatment with fulvestrant. Two phase III studies have compared fulvestrant with exemestane, which is a recognized standard of care in this setting (Table 70-4).

The Evaluation of Faslodex versus Exemestane Clinical Trial (EFECT) compared the efficacy of fulvestrant 250 mg using the loading dose (LD) schedule versus exemestane in 693 patients in whom the disease had progressed on treatment with nonsteroidal AIs. Both therapies were equally effective and well tolerated, with a median TTP of 3.7 months for both arms and similar CBR (31.5% for exemestane and 32.2% for fulvestrant) (81). To note, 60% of patients had received at least two prior lines of endocrine therapy.

Given the pre-clinical data that suggested that the efficacy of fulvestrant, especially in the setting of endocrine resistance (i.e., post tamoxifen or AIs), may be more effective in a low background estrogen environment, this hypothesis was recently tested in a large UK phase III trial (82). The primary aim of the Study of Faslodex versus Exemestane with/without Arimidex (SoFEA) trial was to compare progression-free survival in patients who have progressed on a nonsteroidal AI following evidence of a prior endocrine response. In total, 736 patients with prior response to a NSAI in locally advanced/metastatic disease for more than 6 months (82%), or as adjuvant therapy for more than 12 months (18%) were enrolled in this partially blinded placebo-controlled study that compared fulvestrant (LD) plus continued anastrozole (n = 243), fulvestrant plus placebo (n = 231), or exemestane (n = 249). There was no significant difference in ORR, CBR, and OS (Table 70-4), and the median PFS was 4.4, 4.8, and 3.4 months, respectively. A longer PFS was positively correlated with duration of prior AI therapy, but no interaction with treatment was observed. These results confirmed the findings of EFECT trial in this setting, and a planned meta-analysis of the two studies confirmed no difference in efficacy between exemestane and fulvestrant (LD) (83).

Given the early data in the first-line setting suggesting that fulvestrant may be more effective if given in a high dose (HD) schedule, fulvestrant 250 mg monthly versus 500 mg monthly was compared in 736 patients with ER+ve MBC progressing after prior endocrine therapy in the CONFIRM trial (57). The objective response rates were similar in both arms (Table 70-4), although fulvestrant HD was associated with a significantly prolonged PFS compared to fulvestrant 250 mg (6.5 vs. 5.5 months, respectively; HR 0.80, 95% CI, 0.68–0.94; $p = .006$). The toxicity profile for both doses is similar, and fulvestrant HD has now become the approved dose for use in the United States and Europe. A final analysis showed a median OS of 26.4 versus 22.3 months in fulvestrant HD and 250 mg, respectively (HR 0.81, 95% CI, 0.69–0.96; $p = .016$), indicating that fulvestrant 500 mg is associated with a clinically relevant 4.1 month difference in median OS and 19% reduction in risk of death compared with fulvestrant 250 mg (84).

Progestins

Progesterone derivatives such as medroxyprogesterone (MPA) and megestrol acetate (MA) represent one choice of endocrine therapy in the treatment of MBC, although their exact mechanism of antitumor action is unclear (85). They suppress adrenal steroid synthesis and ER levels, altering tumor hormone metabolism and leading to consequent tumor cells death (85,86). Progestins have been demonstrated to have similar efficacy to tamoxifen (87,88), and therefore can represent a useful option in some patients, but they are associated with such significant side effects as weight gain, fluid retention, vaginal bleeding, and risk of thromboembolic events (89,90). Progestins may also act through the glucocorticoid receptor, androgen receptor, or progesterone receptor, and this activity seems to be maintained in patients resistant to steroidal AIs (86,90).

Anastrozole and exemestane have been shown to be marginally superior to MA in terms of survival in more recent randomized clinical trials (Table 70-4), but pooled analysis of nine phase III RCTs comparing AIs (both steroidal and nonsteroidal) versus MA in second-line for patients with MBC did not find any significant difference in terms of ORR and TTP (91). Unfortunately, the activity of MA after steroidal AIs failure has not been systematically studied because trials comparing steroidal AIs with MA have not employed a cross-over design (90).

Estrogens

In the 1940s, Haddow described the efficacy of the synthetic estrogen diethylstilbestrol (DES) in the treatment of breast cancer (92), discussing the paradox that certain organic compounds can both induce cancer and be used as antitumor therapy (93). The evidence of efficacy was restricted to postmenopausal women and suggested that the menopause-induced decline in estrogen levels may sensitize breast cancer cells to DES (94). To note, some patients have been treated with intermittent therapy, with repeated regressions upon reintroduction of DES (95). In the early 1980s a trial demonstrated no statistically significant difference in efficacy of tamoxifen and DES and tamoxifen became the preferred agent in view of its better toxicity profile (17).

On the basis of the antitumor effect of DES described above, it has been hypothesized that estrogen deprivation during AIs therapy paradoxically sensitize ER+ve breast cancer cells to low-dose estradiol therapy. In a phase II trial, 66 postmenopausal MBC patients treated with an AI with PFS (≥24 weeks) or relapse (after ≥2 years) of adjuvant AI use were randomized to low-dosage estradiol (6 mg, a level similar to that found in premenopausal women) versus 30 mg of oral estradiol (a level similar to that found in pregnant women) (96). A daily dose of 6 mg of estradiol provided a similar CBR as 30 mg (29% and 28%, respectively), with fewer serious adverse events (18% vs. 34% ≥ grade 3 toxicities). At disease progression, 7 patients with estradiol-sensitive disease were re-treated with AIs whose 2 had PR and 1 had SD, suggesting resensitization to estrogen deprivation. Therefore, the efficacy of 6 mg estradiol should be further examined in phase III clinical trials in MBC women with acquired resistance to AIs.

Abiraterone

AIs are structurally related to the natural substrate androstenedione, and they decrease circulating estrogen levels in postmenopausal women without affecting adrenal biosynthesis of corticosteroids, aldosterone, or other enzymes in the steroidogenic pathway. As cytochrome P450 (CYP)17 is upstream from aromatase in the steroid synthesis pathway, theoretically abiraterone acetate (AA), an irreversible inhibitor of cytochrome P450 (CYP)17, should be able to inhibit more completely the sex steroid synthesis (Fig. 70-5). In a phase I trial, AA demonstrated antitumor activity with manageable side effects, including hypokalemia and fluid retention (97). A currently ongoing randomized phase II trial, BCA2001, is comparing AA (plus low-dose prednisone)

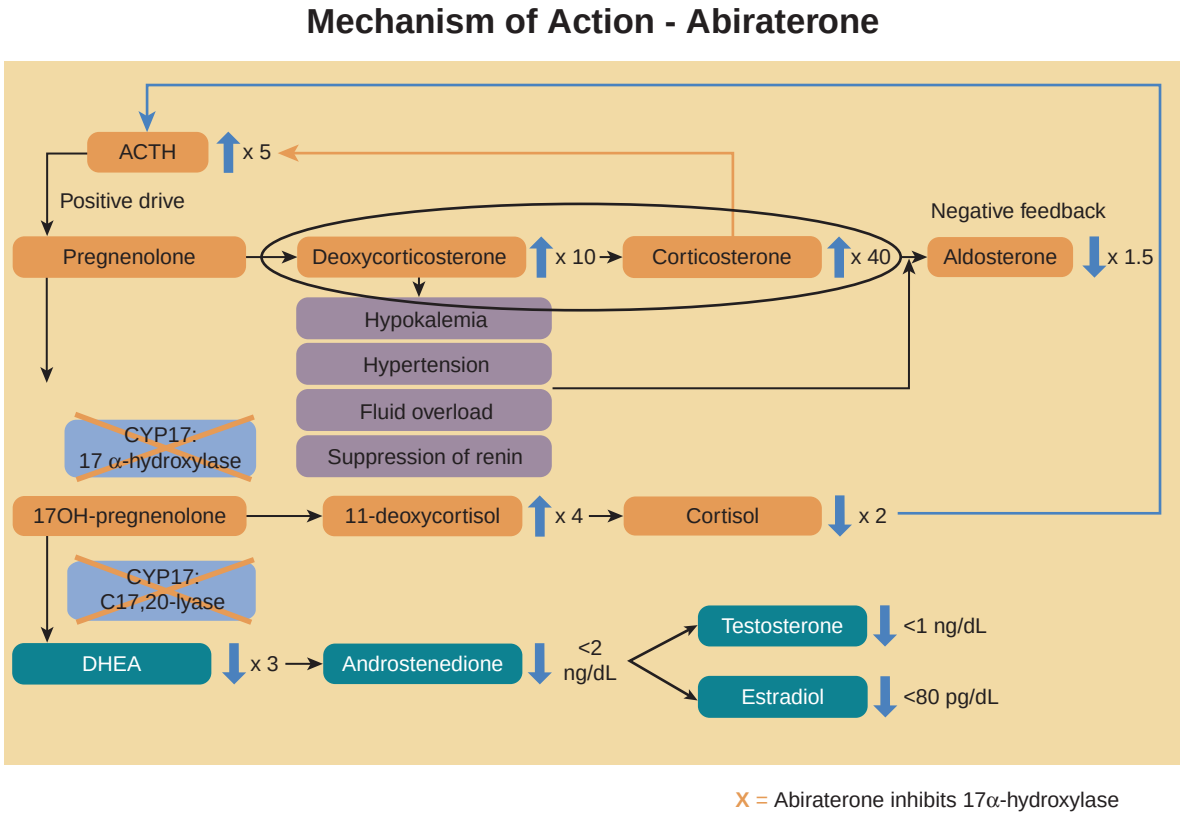

FIGURE 70-5 Mechanism of action of abiraterone acetate (AA), an irreversible inhibitor of cytochrome P450 (CYP)17, in the sex steroid synthesis pathway. (Modified with permission from Attard G, et al. *JCO* 2008;26:4563–4571.)

with or without exemestane versus exemestane alone (98). The hypothesis is that AA would reduce the production of adrenal androgens that may be converted to estrogens and would further suppress the production of estrogens peripherally by the addition of an AI (98). The BCA2001 study will evaluate whether ER signaling remains important to breast cancer growth in the setting of AI failure in postmenopausal women with ER+ve MBC. This study will also determine whether continued aromatase inhibition, through the use of exemestane, is required to maximally suppress estrogen biosynthesis when AA is used.

COMBINATION OF ENDOCRINE AND TARGETED THERAPIES

While there have been significant improvements in the efficacy of endocrine therapy for breast cancer, especially following the introduction of AIs (99), a major clinical issue with all endocrine therapies including estrogen deprivation is either primary lack of endocrine response in the tumor (de-novo resistance) or the subsequent failure of therapy following an initial endocrine response in the tumor (acquired resistance) (100). Understanding the basis for this resistance in advanced breast cancer is an important issue in helping determine what will be the most effective therapy options for the clinic.

Understanding Resistance to Aromatase Inhibitors

In the past much research has concentrated on mechanisms of resistance to tamoxifen. However, recent progress has been made in elucidating the basis for acquired resistance to long-term estrogen deprivation that may provide helpful clues as to prevention of resistance to AIs. It is now known that acquired (or secondary) endocrine resistance develops as consequence of a series of complex adaptive changes occurring in breast cancer cells during the selective pressure of long-term endocrine treatment (101). Activation of various pathways including PI3K/Akt/mTOR, EGFR/HER2, and FGFR leads to endocrine resistance in pre-clinical models, and increasing evidence suggests that targeting these could be a valid strategy to reverse resistance to endocrine therapy.

Laboratory research with ER+ve breast cancer cells into the mechanisms of resistance to long-term estrogen deprivation (LTED) has demonstrated that various growth factor pathways and oncogenes involved in the signal transduction cascade become activated and utilized by breast cancer cells to bypass normal endocrine responsiveness (102). Pre-clinical data indicate that exposure to LTED (analogous to that caused by AIs) and the subsequent development of acquired resistance is associated with adaptive increases in ER gene expression and intercellular signaling, resulting in hypersensitivity to low estradiol levels (103-106). There is evidence for increased "cross-talk" between various growth factor receptor signaling pathways and ER at the time of relapse on LTED (Fig. 70-6), with ER becoming activated and super-sensitized by a number of different intracellular kinases, including mitogen-activated protein kinases (MAPKs), epidermal growth factor receptor (EGFR) and HER2 / HER3 signaling, and the insulin-like growth factor (IGF)/AKT pathway (106-109). In cells that become resistant to long-term estrogen deprivation (LTED-R), ER-mediated gene transcription is

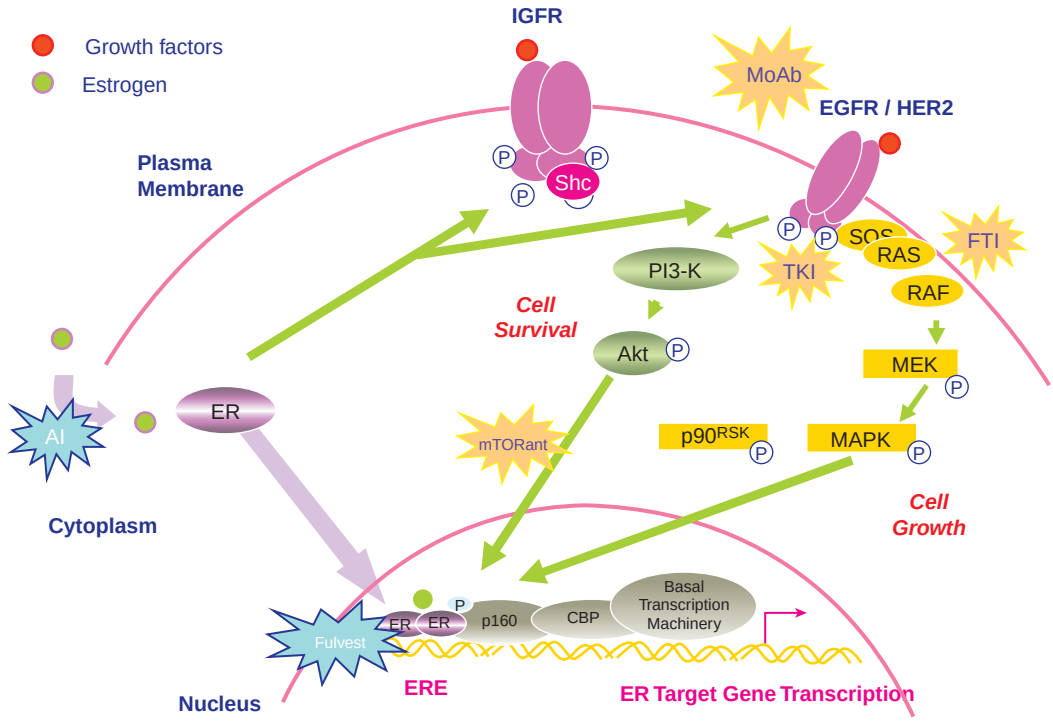

FIGURE 70-6 Cross-talk between various growth factor receptor signaling pathways and ER at the time of relapse on long-term estrogen deprivation (LTED), with ER becoming activated and super-sensitized by a number of different intracellular kinases, including mitogen-activated protein kinases (MAPKs), epidermal growth factor receptor (EGFR) and HER2/HER3 signalling, and the insulin-like growth factor (IGF)/AKT pathway. In cells that become resistant to LTED (LTED-R), ER-mediated gene transcription is enhanced 10-fold in these cells, but can be abrogated by a number of different approaches to interrupt upstream signalling including the EGFR tyrosine kinase inhibitor (TKI) gefitinib, MEK inhibitors, and the ER down-regulator fulvestrant that degrades ER protein.

enhanced 10-fold in these cells, but can be abrogated by a number of different approaches to interrupt upstream signaling including the EGFR tyrosine kinase inhibitor (TKI) gefitinib, MEK inhibitors, and the ER down-regulator fulvestrant, which degrades ER protein (104).

The ER can become involved with the PI3K/Akt/mTOR pathway in breast cancer cells, with both genomic and non-genomic "cross talk" between this signaling pathway and ER. Due to its role in cell survival, there is evidence that the pathway becomes activated in acquired hormone-resistant breast cancer and accounts for survival of cells despite the presence of continued endocrine blockade. Breast cancer cell lines with activated Akt (e.g., via loss of the regulatory PTEN tumor suppressor gene) have been shown to be especially sensitive to mTOR antagonism. Pre-clinical models of ER+ve hormone-sensitive and resistant breast cancer have been used to examine the effects of combining mTOR antagonists with endocrine therapy (110,111). Boulay et al. demonstrated that the estrogen-dependent growth of both wild-type MCF-7 and aromatase-expressing (MCF-7/Aro) breast cancer cells could be inhibited in a dose-dependent manner by the mTOR antagonist everolimus, suggesting that mTOR signaling is required for the estrogen-dependent proliferation of these cells (111). In subsequent experiments with the MCF-7/Aro cells, both the AI letrozole and the mTOR inhibitor everolimus inhibited androstenedione-induced cell proliferation. However, the combination of letrozole and everolimus produced maximal growth inhibition, with clear evidence for additive/synergistic effects. In particular increased activity of the letrozole-everolimus combination correlated with a greater effect on G1 progression and a significant decrease in cell viability and apoptosis.

Likewise, a separate group have shown that MCF-7 cells expressing a constitutively active Akt were able to proliferate under reduced estrogen conditions and were resistant to the growth inhibitory effects of tamoxifen, both *in vitro* as well as *in vivo* in xenograft models (110). However, co-treatment with temsirolimus inhibited mTOR activity and restored sensitivity to tamoxifen, primarily through induction of apoptosis, thus suggesting that Akt-induced tamoxifen resistance may in part be mediated by signaling through the mTOR pathway. These laboratory data therefore support a strategy for targeting a downstream element of the pathway such as mTOR, which has been shown to restore endocrine sensitivity in both cell lines and xenograft models and thus provides a rationale for combining endocrine therapy with mTOR inhibition. The main clinical issue is whether this benefit is confined to tumors that have developed endocrine resistance, or whether this could be an effective first-line treatment options that improves the efficacy of aromatase inhibition.

Thus, it would appear that the ER remains an integral part of signaling even following failure of AIs and that a possible successful approach could involve the use of various signal transduction inhibitors to abrogate activation of ER signaling (Fig. 70-6). As discussed below, clinical evidence is now emerging that such drugs may be more effective when

given in combination with endocrine therapy in an attempt to delay or reverse endocrine resistance.

Combinations with mTOR Antagonists

One of the first clinical studies to demonstrate a benefit for an endocrine-mTOR inhibitor combination was a randomized phase II study in 270 postmenopausal women with ER+ve primary operable breast cancer that evaluated the benefit of adding everolimus (10 mg/day) or placebo to neoadjuvant letrozole (2.5 mg/day) for 16 weeks preoperatively (112). The primary endpoint of the study was tumor response, with significantly greater response rates for the addition of everolimus to letrozole by both clinical (68.1% vs. 59.1%) and radiological assessments. A significantly greater reduction in cell proliferation measured by change in Ki-67 was seen in the letrozole/everolimus combination arm compared to letrozole, and associative correlative studies were also conducted to determine those tumors most likely to respond to combined mTOR antagonism and aromatase inhibition. Interestingly, specific mutations in PIK3CA were found to be associated with a greater likelihood of an anti-proliferative response to the combination of letrozole plus everolimus. In particular mutations in the allosteric helical domain of exon 9 were associated with a poor anti-proliferative response to letrozole alone but a good response to letrozole plus everolimus. This particular PIK3CA mutation has been associated with a worse prognosis in breast cancer, and a greater likelihood of response to the combination would support a role for the PI3K/Akt/mTOR pathway in endocrine resistance.

There have been two important studies in the metastatic setting that have evaluated the addition of everolimus to endocrine therapy for postmenopausal women with ER+ve MBC who have already received prior endocrine therapy (Table 70-5). Tamoxifen plus everolimus was compared with tamoxifen alone in patients with AI-resistant MBC in the small randomized phase II study TAMRAD (Tamoxifen plus Everolimus) (72). The combination therapy showed an improvement in TTP (8.6 months vs. 4.5 months), 6-month CBR (61% vs. 42%), and median overall survival compared with tamoxifen alone. Importantly, the trial design included stratification according to type of resistance to previous treatment with AIs, with primary resistance being defined as disease progression developing either during/within 6 months of completion of adjuvant AI therapy or within 6 months of starting AI therapy for MBC, while acquired secondary resistance was defined as those relapsing >6 months after stopping adjuvant AIs or responding for ≥6 months to AIs in the metastatic setting. An exploratory subgroup analysis showed that the greatest clinical benefit from the combination arm occurred in patients with acquired secondary resistance.

These clinical data from TAMRAD would support the hypothesis that tumors that initially respond and then develop resistance to AIs may utilize the PI3K/Akt/mTOR pathway and that this combined approach should be most effective in those patients with ER+ve advanced disease that progresses during or recurs after NSAI therapy (113). This was confirmed in the Breast Cancer Trials of Everolimus-2 (BOLERO-2) study, a large randomized phase III trial that assigned 724 postmenopausal patients with ER+ve MBC in a 2:1 ratio to either exemestane alone or the combination of exemestane and everolimus (114). All patients had progressed on a NSAI, and importantly 84% of them had demonstrated prior hormone-sensitive disease defined as "at least 24 months of endocrine therapy before recurrence in the adjuvant setting, or a response or stabilization for at least 24 weeks of endocrine therapy for advanced disease" (114). Furthermore, nearly 60% of patients had also received an antiestrogen (tamoxifen or fulvestrant), and approximately 80% had received their AI for MBC—as such, the study was predominantly one of second-line endocrine therapy in patients with evidence or prior endocrine sensitivity before developing acquired secondary resistance to their NSAI. In BOLERO-2 there was a statistically significant and clinically relevant improvement in PFS for the combination (median 7.8 months vs. 3.2 months, HR = 0.45; p <.0001) (115). The clinical benefit was primarily due to better control of the disease, although there was a significant improvement in tumor response rates from only 0.4% in the exemestane-alone group to 9.5% in the everolimus/exemestane group (p = .001)(114). OS results are expected to be mature in 2014. An increased incidence of side effects including stomatitis, fatigue, rash, diarrhea, non-infectious pneumonitis, and hyperglycemia was observed in both trials for the addition of everolimus, albeit the majority were grade 1 or 2 in severity (72,114). Given that many of these toxicities are not

observed with endocrine therapy alone, this may impact on treatment feasibility in clinical practice. However, the magnitude of benefit in PFS led to the approval of everolimus in combination with exemestane in the United States and Europe during 2012 as a new treatment option for ER+ve MBC previously treated with an AI.

A key question remains as to whether the combination of an mTOR inhibitor with endocrine therapy will only be effective for endocrine-resistant breast cancer, or whether this is a new option for endocrine-sensitive MBC in the first-line setting that could substantially delay or prevent endocrine resistance developing. A large first-line phase III study (HORIZON) has recently reported the efficacy of the oral mTOR antagonist temsirolimus (30 mg orally for 5 days every 2 weeks) in combination with letrozole versus letrozole/placebo in 1,112 patients with AI-naïve ER+ advanced breast cancer (Table 70-5) (116). In contrast to BOLERO-2, the population in this larger study was mainly totally endocrine therapy naïve (approximately 60%) and had received no prior AI therapy for locally advanced/metastatic disease. Temsirolimus had previously shown some efficacy using an iv formulation in heavily pretreated MBC (117), and in a small 3-arm randomized phase II study in combination with letrozole (118).

However, in HORIZON there was no improvement in PFS overall (median 9 months, HR = 0.90; p = .25) or in the 40% patient subset that had received prior adjuvant endocrine therapy. Toxicities such as rash, diarrhea, stomatitis, and asthenia were greater for the combination, and the study was terminated by the Independent Data Monitoring Committee after the second interim analysis. These data suggest that as first-line therapy the combination may not be any better than an AI alone.

Thus, it is becoming clear that improving endocrine therapy by the addition of an mTOR antagonist is not that simple (119). The significant efficacy for the combination of everolimus and exemestane in those patients refractory to prior AI therapy is a major advance in providing greater clinical benefit compared with the use of just further endocrine therapy alone for these patients, which may spare the use of palliative chemotherapy for a period of time. The up-regulation of the PI3K/Akt/mTOR pathways during the acquisition of resistance to long-term estrogen deprivation was already evident from pre-clinical studies and has now been confirmed in both the TAMRAD and BOLERO-2 trials. As for identifying untreated ER+ve MBC patients who would benefit from the combination in the first-line setting, this appears much trickier—it is possible that some ER+ve tumors are inherently primed to respond to the combination, as shown with the PIK3CA mutations in the neoadjuvant study. However, to date there is no proven biomarker that can be used as a true indicator of mTOR activation to identify patients with tumors dependent on this pathway, other than the clinical development of acquired secondary resistance to nsAI therapy, which is where this therapy should be used.

Combinations with EGFR / HER2 Therapies

Results from various pre-clinical studies of acquired endocrine resistance in ER+ breast cancer have consistently demonstrated that a functional ER signalling pathway persists that often cross-talks with enhanced peptide growth-factor-receptor signalling pathways (104,120). The clinical implication of these experimental data were that a combined approach utilizing hormonal agents combined with growth-factor-receptor targeted therapies could enhance efficacy and delay/prevent the emergence of endocrine resistance. In particular, a number of trials have been conducted with either the HER2 monoclonal antibody trastuzumab or the EGFR/HER2 tyrosine kinase inhibitors (TKIs) gefitinib, erlotinib, or lapatinib in combination with endocrine therapy (121). While some of these trials have included patients with established hormonal resistance where activated growth factor pathways may be operative, many of the trials were conducted in the first-line ER+ve hormone-sensitive setting in combination with an AI. In patients with established endocrine resistance, it was hoped that combined therapy could be more effective than another endocrine therapy, while in the first-line setting the expectation was that combined therapy might delay the time to disease progression by blocking a key resistance mechanism in ER+ve breast cancer cells (i.e., peptide growth factor signalling) from the outset.

Gefitinib and erlotinib are both small-molecule tyrosine kinase inhibitors of the ATP binding site of the epidermal growth factor receptor (EGFR) and have been shown to delay the development of tamoxifen resistance in vitro (122). Phase II monotherapy studies of gefitinib in unselected patients with advanced breast cancer were disappointing, and the only trial to report a reasonable number of responses included patients with ER+ve tamoxifen-resistant breast cancer (123), the setting in which pre-clinical models had shown the best evidence of activity for gefitinib. Subsequently, two small phase II studies explored the potential benefit for combining either gefitinib or erlotinib with an AI in unselected patients with ER+ve advanced breast cancer, but neither study showed significant clinical efficacy (124,125).

Two randomized phase II studies of HER family targeting have been reported to date in the first-line advanced breast cancer setting (Table 70-6). A double-blind placebo-controlled phase II trial of tamoxifen with/without gefitinib was conducted in 290 patients as first-line endocrine therapy in postmenopausal women with ER+ve metastatic breast cancer (126). This study set out to prove the pre-clinical concept that combination therapy could delay the onset of acquired resistance to endocrine therapy, as demonstrated both in xenograft models *in vivo* (120,127). The patient's disease was either endocrine naïve or had developed greater than a year after completion of adjuvant tamoxifen (Stratum 1, n = 206), or had developed during or after AI therapy (Stratum 2, n = 84). In the endocrine-naïve patients (Stratum 1) there was a numerical increase in progression-free survival from 8.8 to 10.9 months (HR 0.84, 95% CI, 0.59–1.18; p = .31), which met the predefined criterion of a 5% improvement in PFS. Patients who had been pre-exposed to AIs did not gain any benefit from the combination, suggesting that difference in patient populations is crucial in selecting an appropriate populations to test in these studies.

A second randomized trial of gefitinib and anastrozole versus anastrazole alone in a similar first-line patient population of women with ER+ve advanced breast cancer reported a significant prolongation of progression-free survival from a median of 8.2 months with anastrozole to 14.6 months with the combination (HR 0.55, 95% CI, 0.32–0.94) (128). Although the number of patients in this second study was only 93, a subsequent combined analysis suggested that the benefit for the combination was seen exclusively in those patients who were endocrine therapy naïve and had not received any prior endocrine therapy in the adjuvant setting. On the basis of these results, a prospective multicenter study (MINT, NCT 01151215) was set up with a novel tyrosine kinase inhibitor AZD8931, a potent inhibitor of EGFR, HER2, and HER3, to test the hypothesis that combined therapy of growth factor blockade together with anastrozole could delay time to progression compared with anastrozole alone in endocrine-therapy-naïve metastatic breast cancer. This study will be the definitive test of this concept.

[a]Statistically significant difference.

Likewise, targeting HER2 in hormone receptor positive breast cancer has been explored as a means of improving endocrine responsiveness. This may involve re-expression of silenced ER as outlined in pre-clinical data (129). Indeed, clinical evidence exists that trastuzumab can restore both ER expression and endocrine responsiveness in a series of 10 patients with ER-ve HER2+ve advanced breast cancer who had serial biopsies during trastuzumab therapy (130). A phase II clinical trial of letrozole and the monoclonal antibody trastuzumab in patients with ER+ve/HER2+ve MBC revealed that the combination was well tolerated and had a CBR of 50% (131). Subsequently, a randomized phase II trial in 207 patients with known ER+ve/HER2+ve MBC (TAnDEM) reported a doubling of PFS with the addition of trastuzumab over anastrozole alone (4.8 months vs. 2.4 months; $p = .0016$), although there was no significant impact on OS (Table 70-6) (132). A small phase II study (eLEcTRA) showed a similar potential benefit for the addition of trastuzumab to letrozole as first-line treatment in ER+ve/HER2+ve MBC (133).

Subsequently, lapatinib, a potent oral tyrosine kinase inhibitor of both EGFR and HER2, has been explored in combination with endocrine therapy based on *in vitro* data have demonstrated that estrogen deprivation significantly enhances the anti-proliferative effects of lapatinib in HER2 amplified breast cancer cell lines (134). Likewise, preclinical evidence suggested that lapatinib could significantly enhance sensitivity to tamoxifen in cell lines with acquired tamoxifen resistance (135). Results from a phase III trial of 1,286 patients with metastatic ER+ breast cancer who were randomized to receive either letrozole alone or letrozole combined with lapatinib were recently reported (136). In patients with known ER+ve/HER2+ve tumors (n = 219), the addition of lapatinib to letrozole significantly reduced the risk of progression (HR 0.71, 95%CI, 0.53–0.96; $p = 0.019$), improving the median PFS from 3.0 months for letrozole to 8.2 months for the combination (Table 70-6). The clinical benefit was also significantly greater for the combination (48% vs. 29%; $p = .003$), and the combination became an approved treatment option in the United States and Europe from 2010 for ER+ HER2+ MBC in situations when chemotherapy was not indicated.

In the EGF30008 trial there were an additional 952 patients with ER+ve/HER2–ve tumors, where the hypothesis was that any development of acquired resistance to letrozole due to adaptive EGFR or HER2 up-regulation might be prevented/delayed by the combination. However, in the ER+ve/HER2–ve population overall there was no improvement in PFS, although potential benefit from the addition of lapatinib may exist for those subset of patients that relapsed during adjuvant tamoxifen therapy. This result is consistent with previous data relating to tamoxifen sensitizing to HER2 up-regulation in some cases, but also implies that in endocrine sensitive disease co-blockade of HER2 with estrogen deprivation from the outset cannot delay resistance. As such, combined endocrine therapy and growth factor targeting in only indicated for MBC that is proven to have both ER and HER2 amplification, and further research is indicated in the first-line setting in ER+ve/HER2–ve MBC to see whether combined therapy can further improve the efficacy of endocrine therapy—the first-line MINT study in endocrine naïve MBC will be the definitive test of this concept in clinical practice.

ENDOCRINE THERAPY FOR PREMENOPAUSAL PATIENTS WITH METASTATIC BREAST CANCER

For women with ER+ve MBC who are still premenopausal when they develop advanced disease, the available endocrine therapy options include ovarian ablation (via surgery, radiotherapy, or luteinizing hormone-releasing hormone analogues [LHRHa]), tamoxifen, or a combination of ovarian ablation with tamoxifen or with an AI (Fig. 70-7). While oophorectomy and ovarian irradiation induce permanent ovarian ablation, the most widely used method involves using an LHRHa to induce a potentially reversible medical ovarian ablation. Goserelin (Zoladex™) is the most widely used LHRHa in ER+ve advanced disease and is administered as a 3.6 mg subcutaneous monthly depot injection. The most common side effects are those of estrogen suppression, including hot flushes and less frequently reduced libido, vaginal dryness, headache. The local injection is well tolerated. A pooled analysis of several phase II studies that included 228 pre- and perimenopausal women with advanced breast cancer showed that 36% had an objective response to goserelin, with an additional 50% showing stabilization of their disease (137). The median duration of response was

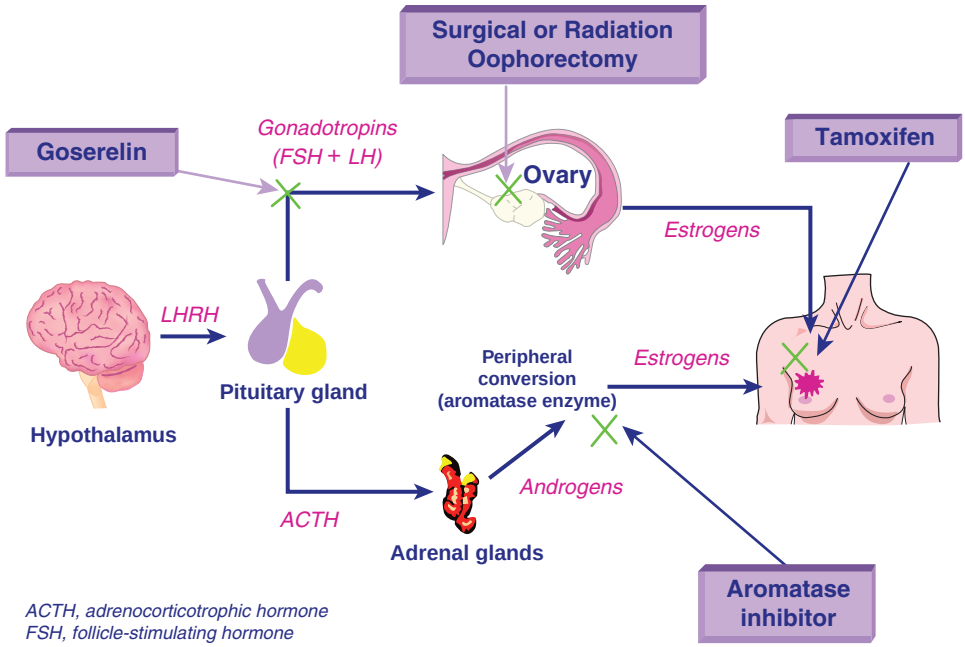

FIGURE 70-7 Available endocrine therapy options for women with ER+ve MBC developing advanced disease when they are still premenopausal: ovarian ablation (via surgery, radiotherapy, or luteinizing hormone-releasing hormone analogues [LHRHa]), tamoxifen, or a combination of ovarian ablation with tamoxifen or with an aromatase inhibitor (AI).

10 months, with an overall survival of 26 months. These results were comparable to previously published data with either tamoxifen or surgical oophorectomy in this group of premenopausal patients with advanced disease (25).

Combined therapy of goserelin plus tamoxifen has been compared with goserelin alone as first-line endocrine therapy in 318 pre- and perimenopausal women with advanced breast cancer (138). In this study objectives response rates were statistically similar (38% for goserelin + tamoxifen, 31% for goserelin), but there was a significant improvement in median TTP (6.5 months vs. 5.3 months). OS was similar (32 vs. 29 months), and there was no difference in tolerability for the combination. In another trial 161 premenopausal patients with advanced breast cancer were randomly assigned to treatment with the LHRHa buserelin, tamoxifen, or both (139). Combined treatment with buserelin and tamoxifen was superior to treatment with buserelin or tamoxifen alone by ORR (48% vs. 34% and 28%, respectively), median PFS (9.7 months vs. 6.3 months and 5.6 months, respectively, $p = 0.03$), and OS (3.7 years vs. 2.5 years and 2.9 years, respectively; $p = .01$).

Subsequently, there was a meta-analysis of four randomized trials of LHRHa + tamoxifen versus LHRHa alone, and significant benefits were found for the combination in terms of improved ORR (39% vs. 30%; $p = .03$), median PFS (8.7 months vs. 5.4 months, HR 1.31, $p < .001$), and most importantly OS (34.8 months vs. 30.0 months; $p = .02$) (140). Thus, standard practice is now to recommend LHRHa plus tamoxifen as first-line endocrine therapy in hormone-sensitive advanced breast cancer. Of note, some caveats need to be considered because there was no formal cross-over of patients who received the LHRH agonist alone to tamoxifen as second-line therapy in three of the four studies, and there was no detailed collection of toxicity or quality of life data (141). In a nonrandomized controlled study, fulvestrant 250 mg has also been combined with goserelin 3.6 mg every four weeks, with a CBR of 58% in 26 premenopausal patients (142).

Several unanswered questions remain in the endocrine therapy of premenopausal patients. In particular, it is unclear whether complete estrogen suppression using LHRHa and an AI will be superior to using LHRHa + tamoxifen as first-line endocrine therapy for advanced disease. Given the superiority of AI over tamoxifen in postmenopausal women, it is not unreasonable to suppose that LHRHa + AI could further enhance endocrine responsiveness over LHRHa + tamoxifen; however, there are no randomized data yet to answer this, and there are concerns that the hormonal toxicities of maximal estrogen blockade might outweigh the benefits. Likewise, it is unclear whether sequential estrogen suppression might not be a better long-term strategy compared with maximal estrogen suppression up front. In the past, further clinical benefit has been reported for premenopausal women with advanced breast cancer initially treated with goserelin, and then at progression given an AI combined with goserelin (143).

New randomized trials will be required to see if a sequential approach of LHRHa alone or LHRHa + tamoxifen followed by switch at progression to LHRHa + AI would produce overall greater disease control and improved survival than using LHRHa + AI up front. Unfortunately, the relatively small number of suitable patients for such trials makes them difficult to undertake, and answers to these clinical questions are unlikely to occur quickly.

NEW COMBINED STRATEGIES TO OVERCOME ENDOCRINE RESISTANCE

The emergence of endocrine resistance during prolonged therapy is complex, and it is unlikely that any single mechanism is operative. While the EGFR/HER2 and mTOR pathways have been studied extensively, numerous other signaling pathways may also be implicated. Both pre-clinical and early phase clinical research is now trying to identify various other strategies to overcome endocrine resistance, based on the availability of targeted therapeutics that can be combined with endocrine therapy. Some of the key areas are discussed below, together with a list of current randomized trials that are investigating various signal transduction inhibitors in combination with endocrine therapy in ER+ve advanced breast cancer (Table 70-7).

TABLE 70-7

Randomized Clinical Trials Investigating Signal Transduction Inhibitors (STIs) Plus Endocrine Agents in MBC

Target	*Agent*	*Stage and Study Number*	*Estimated Enrollment (n pts)*
PI3K/AKT/mTOR	XL147 (inhibitor of PI3K) or XL765 (dual inhibitor of PI3K and mTOR) Plus Letrozole	Phase I/II (NCT01082068)	99
	GDC-0941 + Fulvestrant or GDC-0980 + Fulvestrant or Placebo + Fulvestrant	Phase II (NCT01437566)	270
	BKM120 (pan-PI3K inhibitor) Plus Fulvestrant versus Placebo Plus Fulvestrant	Phase III (NCT01633060)	615
	MK-2206 (Akt inhibitor) Plus Anastrozole, or Letrozole, or Exemestane, or Fulvestrant	Phase I (NCT01344031)	54
Histone deacetylase (HDAC)	Entinostat (SNDX-275) Plus Exemestane versus Placebo Plus Exemestane	Phase II (NCT00676663)[149]	125
Vascular endothelial growth factor/ angiogenesis	Bevacizumab Plus Tamoxifen or Letrozole versus Tamoxifen or Letrozole alone	Phase III (NCT00601900)	502
	Bevacizumab Plus Letrozole or Fulvestrant versus Letrozole or Fulvestrant alone	Phase III (NCT00545077)[155]	378
	BMS-690514 (inhibitor of EGFR, HER2, and VEGF receptor kinases) Plus Letrozole versus Lapatinib Plus Letrozole	Phase II (NCT01068704)	140
Proteasome (NF-kB pathway)	Bortezomib plus Fulvestrant versus Fulvestrant alone	Phase II (NCT01142401)	118
Src kinase	Dasatinib Plus Fulvestrant versus Fulvestrant Alone	Phase II (NCT00754325)[166]	100
	Dasatinib Plus Exemestane versus Exemestane Alone	Phase II (NCT00767520)[167]	157
Fibroblast growth factor receptor (FGFR)	AZD4547 Plus Fulvestrant versus Fulvestrant Alone	Phase I/II (NCT01202591)	120
Insulin-like growth factor type I (IGF-I)	MEDI-573 (dual Dual IGF-I/II-neutralizing antibody) Plus AI versus AI Alone	Phase Ib/II (NCT01446159)	193
	BMS-754807 Plus Letrozole versus BMS-754807 Alone	Phase II (NCT01225172)	59
	MM-121 Plus Exemestane versus Exemestane Alone	Phase II (NCT01151046)	130
Cyclin dependent kinase (CDK) 4/6	PD-0332991 Plus Letrozole versus Letrozole alone	Phase I/II (NCT00721409)[174]	177
	PD-0332991 Plus Letrozole versus Placebo Plus Letrozole	Phase III (NCT01740427)	450
Epidermal growth factor family and HER2	Lapatinib or Trastuzumab or Both Plus AI	Phase III (NCT01160211)	525
	Pertuzumab Plus Trastuzumab Plus AI versus Trastuzumab Plus AI	Phase II (NCT01491737)	250

AI, aromatase inhibitor; HER2, human epidermal growth factor receptor 2; mTOR, mammalian target of rapamycin; n, number; PI3K, phosphatidylinositol-3-kinase; pts, patients.

Agents Targeting PI3K/AKT/mTOR Pathway

Several other drugs that target the PI3K/AKT pathway upstream of mTOR are currently being tested in phase I/II trials in patients with advanced ER+ve breast cancer in the hope that they may prove more specific and effective than current mTOR inhibitors. These include pan- or isoform-specific PI3K inhibitors, dual PI3K/mTOR inhibitors, and AKT inhibitors (Table 70-8) (101). For example, BKM120 is a potent oral pan-PI3K inhibitor that when given either continuously or intermittently in combination with letrozole in a phase I study has been demonstrated to be safe, with evidence of anti-tumor efficacy as assessed by FDG-PET scans (144). The combination of BKM120 with fulvestrant has also been investigated (145), and a randomized phase III study of BKM120 with fulvestrant in patients with HR+ve/HER2–ve locally advanced/metastatic breast cancer who have progressed

TABLE 70-8

Novel Agents Targeting PI3K/AKT/mTOR Pathway under Investigation

Target(s)	*Drug*	*Pharmaceutical Company*
PI3Kα	BYL719	Novartis
PI3Kα	GDC-0032	Genentech
PI3Kα	MLN-1117	Millenium
PI3Kd	CAL-101	Calistoga
Pan-PI3K	XL-147	Exelixis/Sanofi
Pan-PI3K	BKM120	Novartis
Pan-PI3K	GDC-0941	Genentech
Pan-PI3K	PKI-587	Pfizer
PI3K/mTOR	XL-765	Exelixis/Sanofi
PI3K/mTOR	BEZ235	Novartis
PI3K/mTOR	GDC-0980	Genentech
PI3K/mTOR	PF-4691502	Pfizer
TORC1/2	MLN-128	Millenium
TORC1/2	OSI-027	OSI Pharma
TORC1/2	AZD2014	AstraZeneca
AKT (catalytic)	AZD5363	AstraZeneca
AKT (allosteric)	MK-2206	Merck
AKT (catalytic)	GDC-0068	Genentech

after prior AI therapy (BELLE-2, NCT01610284) is recruiting a second-line patient population very similar to that in the BOLERO-2 trial. Given the likely increased use of everolimus in combination with exemestane in the second-line setting, a further trial will assess the role of BKM-120 with fulvestrant in patients who have progressed on or after mTOR inhibitors (BELLE-3) (NCT01633060).

Another approach is to develop drugs that target PI3K and mTOR together, and two pharmaceutical companies have set up studies comparing these dual inhibitors with pan-inhibitors of PI3K, both in combination with endocrine therapy versus endocrine therapy alone. For example, either XL147 (inhibitor of PI3K) or XL765 (dual inhibitor of PI3K and mTOR) are being combined with letrozole in a phase I/II trial (NCT01082068) in ER+ve advanced breast cancer. Likewise, FERGI is a multicenter, international, randomized, double-blinded, placebo-controlled phase II trial recruiting patients with advanced or MBC who have previously received treatment with an AI, randomized to receive either GDC-0941 (pan PI3K inhibitor) + fulvestrant or GDC-0980 (dual inhibitor of PI3K and mTOR) + fulvestrant, or placebo + fulvestrant (NCT01437566).

Whether these dual targeted drugs are more effective than pan-isoform PI3K inhibitors remains to be seen, together with early assessments of toxicities. Other therapeutics have been developed to target Akt (Table 70-8), which is an important regulator of the pathway, and a phase I trial of MK2206 in combination with anastrozole, letrozole, exemestane, or fulvestrant is currently recruiting postmenopausal women with ER+ve metastatic breast cancer (NCT01344031).

Histone Deacetylase Inhibitors (HDACI)

Another possible approach to reverse hormone resistance is the use of histone deacetylase inhibitors (HDACI) to resensitize breast cancer cells to hormone manipulation (146,147). It has been shown that in some breast cancers, expression of ER can be repressed/lost by epigenetic modifications such as methylation and histone deacetylation, and this could be a mechanism for endocrine resistance. Entinostat is an HDACI that has been shown to increase expression of both ER and the enzyme aromatase in a dose-dependent manner both *in vitro* and *in vivo*, which then sensitized breast cancer cells to estrogen and subsequent inhibition by the AI letrozole (148). Furthermore, in xenograft experiments the combination of letrozole plus entinostat was significantly more effective at inhibiting xenograft growth than either therapy alone. In a randomized phase II trial (ENCORE 301, NCT00676663), entinostat in combination with exemestane was compared to exemestane/placebo in patients who had received prior hormonal therapy (149). This trial showed prolongation of median PFS (4.3 months vs. 2.3 months) and extension of OS benefit (26.9 months vs. 19.8 months), and a randomized phase III trial is being planned. Similarly, a phase II study testing vorinostat and tamoxifen in 43 patients with ER+ve MBC progressing on endocrine therapy showed a ORR of 19% and a median response duration of 10.3 months (150). Correlative studies suggest that HDAC2 expression could be a predictive biomarker, and that histone hyperacetylation may be a valid pharmaco-dynamic marker for the efficacy of this combination.

Anti-angiogenic Agents

Pre-clinical data (151) and retrospective clinical data (152) suggest that high vascular endothelial growth factor (VEGF) levels in breast tumors are associated with a decreased response to endocrine therapy. Because several phase II studies had suggested the feasibility and activity of the combination of bevacizumab with endocrine agents (153,154), a randomized phase III study (LEA) was conducted to test the hypothesis that anti-VEGF treatment with bevacizumab could prevent resistance to hormone therapy (either letrozole 2.5 mg/day or fulvestrant 250 mg/4 weeks) given as first-line therapy in endocrine responsive advanced breast cancer (155). The PFS was better with the combination of bevacizumab plus endocrine therapy than with endocrine monotherapy (18.4 months vs. 13.8 months), but this was not statistically significant. The combination had a significantly higher incidence of hematologic and non-hematologic toxicities and does not appear to be a promising approach to enhance first-line therapy. The absence of a robust positive effect in the LEA trial together with negative data from the BEATRICE trial in women with triple-negative disease question the efficacy of angiogenesis inhibition in breast cancer (156). Results from another ongoing randomized phase III trial of endocrine therapy alone or endocrine therapy plus bevacizumab for women with hormone receptor-positive advanced breast cancer are also awaited (NCT00601900).

Growth factors and hormones are involved in the regulation of breast cancer cell proliferation, which requires activation of MAPK via Ras and Raf (157). Sorafenib is an oral multikinase inhibitor that inhibits tumor growth by acting on the tumor cells and tumor vasculature cells in preclinical models of human cancer, including breast cancer (158). It targets the MAPK pathway at the level of Raf kinase, induces tumor cell apoptosis, and potently inhibits VEGFR-1, VEGFR-2, VEGFR-3, and platelet-derived growth factor receptor (PDGFR)-β tyrosine kinase autophosphorylation (159). This suggested that sorafenib may be of potential benefit in the treatment of breast cancer, especially in patients who are resistant to hormone therapy. The rationale for evaluating the use of sorafenib in combination with hormonal therapies in patients with breast cancer in this setting has been investigated in a study of the combination of anastrozole and sorafenib in women with MBC where the combination demonstrated a 23% CBR in 35 patients with hormone receptor positive, AI-resistant MBC, which may be attributable to the restoration of sensitivity to AIs (160).

Another inhibitor of angiogenesis is BMS-690514, which is a potent and selective inhibitor of epidermal growth factor receptor (EGFR), HER2, and HER4, as well as the VEGF receptor kinases. When BMS-690514 was tested in a panel of breast tumor cell lines, there was a clear demarcation between cell lines that were sensitive and those that were resistant. Overexpression of HER2 seemed to be sufficient to predispose breast tumor cell lines to inhibition by BMS-690514, again underscoring its intrinsic potency to that receptor target (161). An open-label randomized, parallel, two-arm phase II study comparing BMS-690514 plus letrozole with lapatinib + letrozole in recurrent/metastatic breast cancer patients who are hormone receptor positive despite HER2 status and who relapsed while receiving or after completing adjuvant antiendocrine therapy has been recently completed and results are awaited (NCT01068704).

Proteasome Inhibitors

Several groups have now demonstrated that the PI3K/Akt pathway provides cancer cell survival signals, in part through activation of the nuclear factor kappa B (NF-κB) transcription factor, and that Akt activation of NF-κB may be an important mechanism in the development of tamoxifen-resistant breast cancer (162,163). Bortezomib is a proteasome inhibitor that blocks the NF-κB pathway. It was tested in a phase II study in combination with endocrine treatment (164). Despite effective target inhibition that was demonstrated in peripheral blood mononuclear cells and tumor samples, no objective anti-tumor responses were observed. Addition of a proteasome inhibitor to anti-hormonal therapy resulted in 22% CBR in a limited number of patients with endocrine resistant and progressive MBC. A randomized phase II study of fulvestrant versus fulvestrant in combination with bortezomib in women with ER+ve MBC is currently recruiting (NCT01142401) (Table 70-7).

Agents Targeting Src Kinase

Results from pre-clinical studies showed that the ER-Src kinase axis plays an important role in promoting hormonal resistance by proto-oncogenes such as HER2, PELP1, and that blocking this axis prevents the development of hormonal independence in vivo (165). Since PELP1, HER2, and Src kinase are commonly deregulated in breast cancers, combination therapies of Src inhibitors with endocrine agents may have better therapeutic effect by delaying the development of hormonal resistance. Dasatinib is a potent, broad-spectrum ATP-competitive inhibitor of Src tyrosine kinase. However, the addition of dasatinib to fulvestrant in a randomized phase II study in ER+ postmenopausal MBC patients who had progressed after a NSAI did not improve PFS, CBR, or OS (166). Similarly, 157 patients were randomized in a double-blind phase II trial (CA180-261) to receive dasatinib (100 mg daily) or matched placebo in combination with exemestane (25 mg daily). While the PFS difference was not significant in overall study population, a higher CBR in the dasatinib arm and higher PFS in patients with symptomatic bone metastasis (HR = 0.68) suggested that dasatinib may have efficacy in a subset of patients. The safety profile was consistent with previous dasatinib experience; AEs, including pleural effusion and diarrhea, were more common with dasatinib as compared with placebo (167).

Agents Targeting FGFR Pathway

Several studies have shown that the fibroblast growth factor receptor-1 gene (*FGFR1*) is amplified in approximately 10% of all breast cancers, correlating with increased *FGFR1* mRNA or protein expression (169). Amplification of *FGFR1* is uncommon in HER2-positive tumors, but is enriched in up to 20% of ER+ve breast cancers. Amplification and overexpression of *FGFR1* may be a major contributor to poor prognosis in luminal-type B breast cancers, driving anchorage-independent proliferation and endocrine therapy resistance (169). AZD4547 is a potent selective inhibitor of *FGFR-1, 2* and *3* receptor tyrosine kinases (enzyme and cellular phosphorylation endpoints) and has a significantly lower potency for inhibition of IGF1R and KDR (168). The co-administration of an FGFR inhibitor and exemestane has the potential to improve outcome for patients with aggressive disease or resistance to endocrine therapy. Therefore, GLOW is a randomized double-blind phase IIa study (with phase I combination safety run-in) designed to assess the safety and efficacy of AZD4547 in combination with exemestane versus exemestane alone in ER+ve breast cancer patients with FGFR1 Polysomy or Gene Amplification who have failed treatment with one prior endocrine therapy (adjuvant or first-line metastatic) (NCT01202591).

Agents Targeting Insulin-like Growth Factor Type I (IGF-I)

The role of the insulin-like growth factor (IGF) system in endocrine-resistant breast cancer has been studied, and inhibitors of this pathway are currently in clinical trials in ER+ve patients who have progressed on prior endocrine therapy. Early reports show no benefit for addition of IGF1R inhibitors to endocrine therapy in this setting, although pre-clinical research examining the effectiveness of IGF1R inhibitors in vitro by generating tamoxifen-resistant (TamR) cells shows that cells selected for tamoxifen resistance *in vitro* may have down-regulated IGF1R, making antibodies directed against this receptor ineffective (170). MEDI-573 is a dual-targeting human antibody that neutralizes IGF-I/-II ligands and inhibits insulin-like growth factor receptor 1 (IGF1R) and insulin receptor-A (IR-A) signaling pathways that play a role in breast and other epithelial cancers. By sparing insulin receptor-B (IR-B) and its hybrid receptors, MEDI-573 is expected to achieve antitumor activity without perturbing glucose homeostasis and has showed acceptable safety and favorable PK profiles without significant changes in glucose levels (171). A biomarker-rich phase Ib/II study of MEDI-573 with an AI in patients with advanced ER+ve breast cancer is ongoing (NCT01446159). Likewise, BMS-754807 is a small-molecule dual-kinase inhibitor targeting IGFIR and IR, and a phase II study of BMS-754807 combined with letrozole or BMS-754807 alone in hormone receptor-positive breast cancer subjects with acquired resistance to non-steroidal AIs (NCT01225172) is ongoing.

Inhibitor of Cyclin-dependent Kinase (CDK) 4/6

Modulating the cell cycle has always been an attractive therapeutic target in cancer, and previously published data have suggested that CDK 4/6 inhibition may play a key role in the treatment of subsets of breast cancers (172,173). PD 0332991 is a novel oral selective inhibitor of cyclin-dependent kinase (CDK) 4/6, which prevents cellular DNA synthesis by blocking cell cycle progression from G1 to S phase. Recently, it was reported that the combination of PD 0332991 and letrozole significantly improved median PFS in a randomized phase II study in patients with advanced ER+ve breast cancer, including those with identified cyclin D1 amplification and/or p16 loss in whom CDK 4/6 inhibition is expected to be most effective (174). In the first part of this two-part phase II study, 66 postmenopausal women with ER+ve MBC were randomly assigned to either the combination of PD 0332991 and letrozole or to letrozole alone. The second part of the study involved 99 patients with ER+ve

cancers possessing certain genomic alterations, specifically cyclin D1 amplification and/or p16 loss. A progression-free survival of 26.1 months was observed for patients in the combination arm versus 7.5 months for patients treated with letrozole alone. In patients with measurable disease, an improved response rate was seen (45% vs. 31%), and the toxicity profile for the combination was favorable with the most common adverse events being (uncomplicated) neutropenia, leukopenia, anemia, and fatigue.

On the basis of this extremely promising result, a randomized, multicenter, double-blind first-line study of PD-0332991 plus letrozole versus letrozole/placebo in postmenopausal women with ER+ve/HER-ve MBC who have not received any prior systemic anti-cancer treatment for advanced disease will open to recruitment soon (NCT01740427). As such, CDK 4/6 inhibition seems a very promising approach to enhance endocrine response in ER+ve endocrine sensitive breast cancer that could potentially produce that quantum leap in response to first-line endocrine therapy that to date has eluded this area of clinical research in ER+ve advanced breast cancer.

CONCLUSION

Enormous progress in endocrine therapy for ER+ve metastatic breast cancer has been made over the last three decades, as illustrated in this chapter. Tamoxifen is perhaps the best original example in oncology of a biologically targeted therapy, and it has subsequently had a major impact on improving survival in ER+ve early breast cancer. In the late 1990s the introduction of the third-generation AIs as first-line therapy for postmenopausal advanced disease heralded the next major improvement (Table 70-3), such that objective tumor response rates of >30% with progression-free intervals of 10 to 15 months and overall survival in excess of 3 years are now to be expected with endocrine therapy in this setting. This allows patients significant clinical benefit before the need for cytotoxic chemotherapy, allowing them to maintain a good quality of life with minimal toxicities from therapy. In the second-line setting, other endocrine therapies can still be effective, especially if good benefit was seen in the first-line setting, but as discussed above objective response rates are often <10% with progression-free intervals of only 3 to 4 months and overall survival less than 2 years (Table 70-4). More effective treatments following AIs are urgently needed.

Understanding the biology of ER+ve breast cancer and the mechanisms of resistance has been central to any attempts to improve further upon the current level of clinical efficacy achieved with various endocrine therapies in the advanced breast cancer setting. Undoubtedly, the recent significant efficacy for the combination of the mTOR antagonist everolimus and exemestane in those patients refractory to prior AI therapy is a major advance in providing greater clinical benefit compared with the use of just further endocrine therapy alone for these patients, which may spare the use of palliative chemotherapy for a period of time. This option is likely to become a new standard of care in the second-line setting for postmenopausal women with ER+ve advanced breast cancer who have been previously treated with a nonsteroidal AI. As indicated above, numerous other targeted approaches are also under investigation to see if they could be effective options in this second-line setting, and some may prove successful as it is unlikely that the mTOR pathway is the only relevant resistance mechanism.

Whether combinations of any signaling therapeutics and endocrine therapy will become a future option for the first-line hormone-sensitive setting is less clear. To date, any co-treatment of unselected hormone-sensitive ER+ve MBC with a given drug combination in the hope of delaying endocrine resistance and improving the benefit already obtained with first-line AI therapy does not appear to work. The challenge in daily clinical practice is to identify the relevant pathways that are operative in individual patients with ER+ve MBC, and in future all clinical studies in ER+ve advanced breast cancer should make a greater effort to enrich their trial population with the most appropriate patients. Genomic profiling in ER+ve breast cancer may help identify those more likely to develop resistance to endocrine therapy, or indeed the pathways that these tumors are most likely to utilize as escape mechanisms, which in turn may guide appropriate selection of target therapies to add in at the time of relapse. Selection of these ER+ve subgroups for future combination strategies may in turn yield answers faster than treating a more heterogeneous and unselected group of patients with ER+ve advanced breast cancer.

MANAGEMENT SUMMARY

- All patients with ER+ve metastatic disease should be considered for a trial of endocrine therapy, and sequential endocrine therapy should be given until the patient no longer responds.
- For patients with ER/PgR +ve breast cancer and a low risk of rapid progression of their advanced disease, endocrine therapy can be very effective in the treatment of their advanced/metastatic disease.
- The treatment-free interval since prior adjuvant endocrine therapy, together with quantitative levels of hormone receptors, determine the likelihood of benefit from further endocrine therapy in the metastatic setting.
- At the time of relapse, the majority of tumor cells retain estrogen receptor (ER), although levels of expression may fall and other signaling pathways that cross-talk with ER may be functional.
- For postmenopausal women with ER/PgR +ve advanced/metastatic breast cancer, aromatase inhibitors (AIs) are the treatment of choice—in the first-line setting, these therapies can give 10 to 15 months median progression free survival, depending on whether there has been exposure to prior adjuvant endocrine therapy.
- There is no proven benefit to combination endocrine therapy in postmenopausal patients with metastatic disease, although one trial in largely previously untreated patients did show a significant advantage for the combination of fulvestrant 500 mg plus an AI.
- In premenopausal advanced breast cancer, combined ovarian suppression and tamoxifen is more effective than either therapy alone. There are no data to show whether ovarian suppression and an AI is superior, and to date this is reserved as a second-line treatment option.
- Sequential endocrine therapy with other agents such as fulvestrant or exemestane can be effective in postmenopausal patients who have demonstrated prior endocrine responsiveness in the advanced setting, although response rates are low and overall the median progression free survival is only 3 to 5 months.

- The combination of the steroidal aromatase inactivator exemestane with the mTOR antagonist everolimus has become a new treatment option following progression on nonsteroidal AI, due to enhanced efficacy compared with exemestane alone. Additional toxicities need to be considered, and there is no role for this combination in the first-line endocrine naive setting.
- There is no proven role for the combination of growth factor receptor inhibitors and endocrine therapy in ER+ve/HER2-ve breast cancer.
- In postmenopausal women with known ER+ve/HER2+ve metastatic breast cancer, the combination of AIs and HER2 targeted therapy is an approved combination, and is more effective than endocrine therapy alone for those patients who do not require immediate chemotherapy.
- Improving outcomes for those patients with acquired endocrine resistance is an urgent issue. Ongoing research studies are investigating numerous different signaling inhibitors in combination with endocrine therapy based on pre-clinical evidence that these strategies could overcome endocrine resistance.

CHAPTER 71

Treatment of Metastatic Breast Cancer: Chemotherapy

Sing-Huang Tan and Antonio C. Wolff

CHAPTER CONTENTS

INTRODUCTION

In 2013, the United States had an estimated 232,340 new cases of breast cancer and 39,620 breast cancer-related deaths occurred in women (1). Survival has continually improved over the last six decades (1). In many developing countries, the incidence of breast cancer is rising sharply due to changes in lifestyle, reproductive factors and increased life expectancy (2). More than half of incident cases occur in the developing world, with the percentage of deaths in these countries double that in high-income countries (2). The treatment of advanced breast cancer is often more resource intensive and associated with worse outcomes, further taxing patient populations that may have fewer resources.

Access to screening programs has resulted in a higher proportion of women being diagnosed with earlier stages of disease which are imminently curable. However, approximately 6% to 10% of breast cancers are metastatic at presentation and systemic recurrence occurs in about 30% of early breast cancer cases, many beyond the first 5 years (3,4). Metastatic breast cancer (MBC) patients have a median survival of 2 to 3 years. Patients have a diverse clinical behavior driven by histological and molecular subtype (and increasingly by therapy) though historically fewer than 5% survive beyond 10 to 15 years (5–7). Patients with very limited disease, particularly if limited to soft tissue and/or bone, were the ones most likely to have long periods of progression-free survival (6). Newer therapies, particularly those targeting the estrogen receptor (ER) and the human epidermal growth factor receptor 2 (HER2) may have favorably altered the natural history of these breast cancer phenotypes (8).

CARE OF PATIENTS WITH METASTATIC DISEASE

MBC is by definition an incurable disease and most patients with metastatic disease will likely die from their disease. At the same time, the growing number of therapeutic options has changed the outcome for many patients, particularly for those with ER-positive and/or HER2-positive disease whose treatment backbone will center around the use of anti-estrogens and HER2-targeted therapies, respectively. Despite the lack of therapies targeting specific pathways, it is now well accepted that not all triple-negative breast cancers (TNBC) are the same, and there is a growing understanding that this nomenclature encompasses a spectrum of tumors with diverse clinical behavior (9). Patients with TNBC often will have durable and clinically meaningful

responses to conventional chemotherapy regimens, often given as single agents, and many are able to have prolonged progression-free survival (PFS) intervals.

Goals of Therapy

It is critical for patients and their doctors to establish early on the overall goals of therapy, which will primarily center around symptom control, prevention of complications, and in many cases prolongation of overall survival (OS). It is strongly recommended that members of the health team (especially physicians) discuss early on with patients and their family members and caregivers, including preliminarily when to discontinue chemotherapy and focus primarily on symptom management. Multidisciplinary care is key, and should include pain management, nutritional and psychosocial support, family therapy, and other medical specialists as needed. As discussed in greater detail in other chapters of this book, patients should be referred early on for a palliative care evaluation.

Disease Monitoring

A growing body of evidence suggests a role for maintenance chemotherapy in patients with MBC (10). It is often simple to assess if patients are benefiting from systemic therapy or not. At the same time, there is great interest in identifying early on if the treatment started will help them or not. Tumor markers like CA27.29/CA15-3 and CEA are often used to monitor disease status, but oncologists are strongly discouraged from making therapy changes exclusively based on a test result, especially if patients are clinically stable without worsening of symptoms or evident disease progression by imaging studies. Enumeration of circulating tumor cells (CTCs) has been a topic of great interest, and a commercial assay has been available since the mid-2000s based on evidence suggesting an early prognostic role for progression-free and OS in patients starting a new systemic regimen (11). Unfortunately, the enumeration assay detects circulating tumor cells in only 30% of patients with MBC. A recently completed trial (SWOG S0500, NCT00382018) is now examining whether treatment decision-making to continue or change therapy based on blood levels of CTCs in women with MBC lead to an improved clinical outcome (clinical utility).

In the meantime, more specific measures of circulating tumor DNA are now being tested with potential implications for surveillance in the adjuvant setting, monitoring of disease in the metastatic setting, and characterization of disease biology. Proof of concept studies have now shown that these assays are feasible, albeit costly if dependent on whole-genome sequencing approaches, and must now be prospectively tested (12,13). Other groups have tested more selective approaches that targeted the detection of circulating tumor DNA of more commonly observed somatic genomic abnormalities like mutations in PIK3CA (14).

Patients with Small Volume of Metastatic Disease

Improvements in staging imaging studies have also caused stage migration and a growing number of patients are now diagnosed with limited or oligometastatic disease (15). These patients, specially those presenting with locally advanced disease and small volume isolated systemic metastases may often benefit from combine modality therapy, including surgery and radiation therapy for local control and/or for resection of focal sites of systemic disease. The role of systemic therapy for patients who become free of macroscopic disease with no evidence of disease (NED) remains controversial.

In late 2012, investigators reported on the role of chemotherapy as adjuvant therapy for patients with locally recurrent breast cancer (the CALOR trial, NCT00074152). Unfortunately, the study was closed due to slow accrual after 162 eligible patients were randomized to ER and/or HER2-targeted therapy, with or without chemotherapy, but after 8 years of follow-up, a 5-year improvement in OS (88% vs. 76%) favored those also given chemotherapy. There was also a striking difference in disease-free survival (DFS) rate between the ER-negative population who received chemotherapy and those who did not (67% vs. 35%), but this was less pronounced in the ER-positive population (70% vs. 69%), suggesting that the majority of benefit was in ER-negative tumors. In view of the challenge of mounting a definitive study, the data suggest that combined multimodality therapy is a reasonable approach for a select group of patients.

PRINCIPLES OF CHEMOTHERAPY

Breast cancer is generally considered to be a chemosensitive disease. The short term aims of chemotherapy in MBC are to increase response rates and maximize symptom control; the medium term end points are to anticipate complications and extend PFS; and the long term goals are to attempt to improve OS while minimizing therapy toxicity or disruption of quality of life (QOL). Chemotherapy treatment is individualized based on disease and patient-related factors such as endocrine responsiveness and HER2 expression, tumor-related symptoms, disease-free interval, extent and sites of metastatic disease, organ function, comorbidities, age, and performance status. Treatment-related issues such as drug efficacy, side effect profile, previous systemic therapy, quality of life considerations, costs, and patient preferences have also to be taken into account. Tailoring chemotherapy options is made complex by a myriad of tumor and patient-related factors that must be considered, the large number of chemotherapy regimens available without specific predictive markers of benefit, and the likelihood of disease progression that will force patients to go through a sequence of treatment regimens. Therefore, early on it is critical to discuss with patients and their caregivers the overall goals of therapy, the limitations of existing regimens, the concept of palliative care, and limitations of active therapy.

Prospective trials comparing chemotherapy to best supportive care have not been pursued to a greater extent due to the number of therapy options with clinical efficacy in the adjuvant and advanced settings. Although there have been numerous trials in MBC, the higher response rates and longer PFS seen in certain regimens over others have not translated into survival benefits in most trials in part due to tumor biology, small sample sizes, study designs allowing crossover to the investigational agent, and the increasing availability of newer more efficacious therapeutic regimens.

Endocrine therapy must be the initial consideration in ER-positive MBC with a less aggressive phenotype, such as those with a long disease-free interval and predominantly bone and soft-tissue disease. Chemotherapy is meant for ER-negative disease or ER-positive disease that has become endocrine-resistant or that displays higher risk features such as the often discussed but infrequently observed visceral crisis and/or a short disease-free interval. Visceral crises are uncommon but could be defined as presence of symptomatic lymphangitic lung metastases, bone marrow replacement, carcinomatous meningitis, or symptomatic liver metastases (16). Small volume lung or liver metastases (especially if minimally symptomatic) must not be considered a definitive indication for chemotherapy if endocrine therapy is suitable.

A meta-analysis of published and unpublished trials comparing endocrine therapy or chemotherapy treatment in advanced breast cancer revealed no significant difference in OS (hazard ratio [HR] 0.94, 95% confidence interval [CI], 0.79–1.12, p = .5) (17). Notably, over 50% of women in these trials had visceral disease, which is often seen as an indicator for chemotherapy use. A pooled estimate of reported response rates (8 trials; n = 817) showed a significant advantage for chemotherapy over endocrine therapy (relative risk [RR] 1.25, 95% CI, 1.01–1.54, p = .04), but the two largest trials showed results in opposite directions with a significant test for heterogeneity (p = .0018), thus questioning this observation (18,19). Six of the seven fully published trials reported increased toxicity with chemotherapy, in particular nausea, vomiting, and alopecia. The shortcomings of these analyses were that the trials were from 1963 to 1995, and contained ER-negative or unknown tumors. These trials used endocrine agents which are not commonly used as first-line choices today and also had outdated chemotherapy regimens. Hence, the role of more contemporary chemotherapy agents in comparison to endocrine therapy remains uncertain. Clinical trials have failed to show a survival benefit of combined chemo endocrine therapy over either modality used separately (20).

Biopsy of metastatic sites of disease is always encouraged as this may impact subsequent treatment decisions, first to confirm the development of metastatic disease and second to retest ER and HER2, especially for tumors that may have tested negative when first diagnosed but the clinical behavior (e.g., long DFS) might suggest otherwise. Discordance in receptor results may occur due to tumor heterogeneity missed by the limited tissue sampling of a needle biopsy, limited reproducibility and concordance of assays especially when testing of the primary tumor and metastatic sites done years apart, or true biologic change over time (21,22).

Single versus Combination Chemotherapy

The active classes of chemotherapy drugs are the anthracyclines, taxanes, vinca alkaloids, antimetabolites, alkylating agents, epothilones, and other antimicrotubule agents such as eribulin. Randomized trials comparing combination versus sequential single agent chemotherapy have shown combination regimens give better response rates and tumor time to progression (TTP) or PFS, but survival benefit tend to be observed in studies that did not allow crossover from the single-agent arm to the new investigational drug upon progression (see Table 71-1). Well-defined comparisons of combination versus the same agents used in sequence (a registration strategy less favored by the pharmaceutical industry) are unavailable, hence the true impact on survival outcomes is not known.

In an early systemic review of 15 trials (n = 2,442) comparing polychemotherapy to single agents in MBC treatment, the complete and partial responses for polychemotherapy were significantly better than that associated with single agents (20). Survival data from 12 trials (n = 1,986) also favored polychemotherapy regimens (HR 0.82, 95% CI, 0.75–0.90), translating into an 18% reduction in risk of death (20). The limitations of this meta-analysis were its usage of published material instead of individualized patient data, trials from the pretaxane era consisting of outdated regimens, small sample sizes, poorly designed studies, heterogeneity of patients and their previous treatments, and a lack of data on exposure to adjuvant therapy, and prior treatment for metastatic disease. Its modest total number of patients (n = 996) only slightly exceeded that of an important randomized ECOG study comparing combination versus sequential single-agent therapy which is discussed later (23).

A Cochrane meta-analysis of 43 trials consisting of 9,742 women of whom 55% were receiving first-line chemotherapy for metastatic disease showed a statistically significant advantage for the combination regimens in terms of OS (HR 0.88; p < .00001), TTP (HR 0.78; p < .00001), and response rates (RR 1.29; p < .0001) (24). They were however associated with more leukopenia, nausea, vomiting, and alopecia.

Clinical trial designs have incorporated comparisons of (i) a particular agent versus combination regimens consisting of completely different agents, or (ii) a particular drug versus a regimen containing that same drug in addition to other agents. With regards to the first trial design, taxanes as single agents have shown superiority in terms of survival over older regimens such as cyclophosphamide/methotrexate/5-fluorouracil/prednisone (CMFP) or mitomycin/vinblastine (25,26). Capecitabine was reported to have comparable TTP and OS compared with intravenous (IV) cyclophosphamide/methotrexate/5-fluorouracil (CMF) (27). As for study design (2), the seminal Eastern Cooperative Oncology Group (ECOG) trial E1193 assigned 739 patients with MBC to doxorubicin alone, paclitaxel alone, or the combination, with crossover allowed for the single agent therapy arms (23). Combination therapy demonstrated significantly higher complete and partial responses compared to the single-agent doxorubicin or paclitaxel arms (47% vs. 36% vs. 34%), and median time-to-treatment failure (TTF) (8 months vs. 5.8 months vs. 6 months), although median survivals were similar (22 months vs. 18.9 months vs. 22.2 months). Responses were seen in 20% of patients crossing from doxorubicin to paclitaxel and 22% of patients crossing from paclitaxel to doxorubicin (p = not significant). Global QOL measurements from on-study to week 16 were similar in all three groups. While this is the largest randomized trial to address this issue, it remains a relatively small study with limited statistical power.

Other trials of similar design comparing concomitant epirubicin and paclitaxel versus sequential therapy in MBC (28), or capecitabine and taxanes in sequence or combination (29), did not show a survival benefit. Other combinations such as vinorelbine/doxorubicin and gemcitabine/vinorelbine have found no difference in OS between the combinations versus single agents doxorubicin or vinorelbine respectively (30,31). Two important trials have demonstrated a survival benefit of taxane-containing combinations over the taxane itself and will be discussed in detail later in the chapter (32,33). One of them showed that the docetaxel/capecitabine combination had significantly superior RRs, TTP, and OS over single-agent docetaxel, while the other showed that the gemcitabine/paclitaxel regimen had superior RRs, TTP, and OS compared to paclitaxel, although there was a lack of a planned crossover design in both studies.

In general, sequential single agents have a more favorable toxicity profile and a better QOL without compromising crucial end points such as OS and TTP. Hence, sequential therapy is useful in the metastatic setting where efficacy should be balanced with a good QOL. This sequential single-agent strategy is also useful in patients with less aggressive disease, those who are older, or with a poorer performance status. However, in cases where rapid tumor shrinkage is needed due to symptomatic disease, combination therapy is preferred.

Intermittent versus Continuous Chemotherapy

The issue of chemotherapy duration in the metastatic setting remains an unresolved issue. Several randomized trials have attempted to address the potential benefits of continuous chemotherapy versus chemotherapy for a fixed

number of cycles, and then resumption only upon disease progression. Trial designs have varied with regards to the maintenance treatment with some continuing the same chemotherapeutic agents while others have utilized different regimens (see Table 71-2). However, earlier studies in the pretaxane era comparing shorter versus longer chemotherapy durations were hampered by insufficient sample sizes, chemotherapy drugs considered obsolete, nonstandard chemotherapy schedules, and limited durations in the control arms. More recent trials with newer agents have been carried out. A recent meta-analysis of 11 randomized controlled trials (RCTs) (n = 2,269) demonstrated that longer first-line chemotherapy had a marginally improved OS (HR 0.91, 95% CI, 0.84–0.99; p = .046) and substantially longer PFS (HR 0.64, 95% CI, 0.55–0.76; p < .001) (34). No statistically significant variation in effects on OS and PFS were seen when trials were stratified according to timing of randomization, study design, number of cycles in the control arm, and concomitant endocrine therapy. Lengthening PFS is considered clinically beneficial as this may improve QOL by delaying symptoms of progressive disease that may be perceived as valuable by the patient. Unfortunately, only the study by Coates et al. (35) in this meta-analysis evaluated this issue, reporting that QOL was indeed better in the extended chemotherapy arm. Shortcomings of this analysis were lack of individualized patient data, no quality control on original records and analyses, limitation of subgroup analyses to those only on trial, moderate number of trials and sample numbers, outdated chemotherapeutic agents, and heterogeneity of study designs, chemotherapy regimens and publication status. There were three studies in the meta-analysis which included more recent agents like paclitaxel and liposomal doxorubicin, none of which demonstrated a survival benefit with maintenance therapy as well (36–38). In the Spanish Breast Cancer Research Group (GEICAM) 2001–01 study, patients without disease progression after three cycles of doxorubicin followed by three cycles of docetaxel were randomized to pegylated liposomal doxorubicin (PLD) for six cycles or to observation (38). PLD significantly prolonged the primary end point of TTP by 3.3 months compared to observation although OS was not significantly prolonged. PLD toxicities were manageable with up to 5% experiencing fatigue, mucositis, and palmar-plantar erythrodysesthesia.

OS seems not to be influenced by continuing chemotherapy indefinitely, with the benefit primarily in PFS. Thus, patients who need to stop treatment due to drug-related toxicities can be reassured that this is not detrimental to their survival. In those who have symptomatic disease and

remain responsive to chemotherapy, continuing therapy can be a favorable option to prolong time to disease progression. In clinical practice, no predefined number of courses of chemotherapy must be delivered, and factors such as treatment tolerability and disease response in terms of disease stabilization as opposed to tumor shrinkage must be taken into account. If the patient shows improvement after two to three cycles, then the same regimen is continued for another two to three cycles before further reassessment. The duration of treatment in patients who have stable disease or who continue to respond is controversial. Although there is limited evidence for maintenance chemotherapy long-term, chemotherapy can be continued beyond six to eight cycles for PFS benefit, and only ceased upon disease progression or intolerable toxicities. Endocrine therapy could be used as maintenance therapy in ER-positive disease, or the patient closely monitored for recurrence without any systemic therapy if ER-negative disease and a therapy holiday is being considered. However, the targeted therapy such as trastuzumab should be continued if HER2-positive disease, either alone or with endocrine therapy in endocrine responsive disease. For those who progress while on one line of treatment or during the chemotherapy-free period, they are generally switched to an alternative agent or regimen based upon their performance status, previous chemotherapy exposure, and potential for further treatment response.

Chemotherapy Scheduling

The impact of chemotherapy scheduling has been less well studied. The Norton-Simon hypothesis derived from clinical and laboratory observations states that "therapy results in a rate of regression in tumor volume that is proportional to the rate of growth that would be expected for an unperturbed tumor of that size" (39). This hypothesis has led to the dose-dense approach to breast cancer chemotherapy, thus short circuiting the Gompertzian growth curve before tumor regrowth achieves its mathematically greatest gains. This has been illustrated by the Cancer and Leukemia Group-B (CALGB) 9741 adjuvant trial, which confirmed the clinical efficacy in terms of DFS and OS of a dose-dense 2-weekly schedule of sequential doxorubicin/cyclophosphamide and paclitaxel for four cycles each with colony stimulating support over an identical regimen but administered in a 3-weekly fashion (40). The use of dose-density as strictly defined has not been shown to be effective in the metastatic setting.

Weekly scheduling attempts to maximize frequency and cumulative doses with a more favorable toxicity profile. A weekly scheduling at a lower chemotherapy dose with regards to taxanes has been shown to be superior to the 3-weekly regimen. In the CALGB 9840 trial, a higher response rate and TTP favoring weekly paclitaxel over the 3-weekly schedule has been demonstrated (41).

Oral CMF (cyclophosphamide for 14 days, methotrexate and 5-FU on days 1 and 8) every 28 days has been shown to be better than IV CMF every 3 weeks with respect to response rates (48% vs. 29%; $p = .003$) and OS (17 months vs. 12 months; $p = .016$) possibly due to scheduling leading to a higher dose intensity achieved (42).

Trials exploring other scheduling approaches such as theoretically non-cross-resistant agents utilized in a sequential fashion, or adding on additional different agents have not shown any remarkable clinical significance (43–45). In summary, the trials in general do not demonstrate any major survival benefit from using dose-dense chemotherapy, sequential non-cross resistant regimens or "intensified" regimens whereby new agents are added on, and appear to support simpler single-agent regimens to minimize therapy-related toxicities. At the same time, weekly regimens (e.g., paclitaxel) or even daily regimens (e.g., oral etoposide) appear to be more efficacious with less side effects.

CHEMOTHERAPY OPTIONS (SINGLE AGENT AND COMBINATIONS)

In view of the lack of specific biomarkers that predict differential responsiveness to conventional chemotherapy regimens according to the established phenotypes, the regimens discussed below in principle equally apply to patients with TNBC and those with ER-positive/HER2-negative disease that has become endocrine-resistant. Later in this chapter we discuss strategies that may potentially apply more specifically to TNBC, especially in tumors that might have basal-like features.

Meaningful improvements in survival have been seen with the advent of newer therapeutic options and better supportive medical care. Median OS is about 18 to 24 months, with a range of a few months to many years, according to tumor subtype as well as sites and burden of metastatic disease. Several favorable prognostic factors include ER-positivity, a longer relapse-free interval of more than 2 years and metastases involving the chest wall, bones, or lymph nodes. Weight loss, poor performance status, elevated serum lactate dehydrogenase, and less than 35 years old are poor prognostic factors.

The goals of treatment are alleviation of symptoms, prolongation of survival, and improvement in QOL. OS in MBC trials is the gold standard although this end point requires prolonged follow-up and is now frequently diluted by increasingly more effective subsequent treatment options.

There is no standardized treatment regimen sequence to be utilized in MBC although anthracyclines and taxanes are the mainstay of initial treatment. Eighty reports of 63 trials were identified from the Cochrane Breast Cancer Group (CBCG) and abstracts from the American Society of Clinical Oncology (ASCO) annual scientific meeting (2000–2007) (46). There was little evidence from trials reported from 2000 to 2007 that major survival differences existed between many commonly employed chemotherapy regimens.

Combination chemotherapy versus sequential single agent use depends on disease characteristics and patient-related factors. For those with rapidly progressive symptomatic disease or a visceral crisis, combination therapy would be the preferred choice particularly in the first-line setting. Once disease stability is achieved (usually six to eight cycles), a switch to maintenance therapy should be considered. In the absence of rapid clinical progression or life-threatening visceral metastases, sequential single agent chemotherapy is recommended for most patients with low risk disease such as no multi-organ involvement and a longer disease-free interval, with consideration also given to endocrine therapy to this group if ER-positive. Single-agent therapy given in weekly schedules is also preferable for those with visceral impairment or bone marrow suppression due to metastatic disease where dose-reduced single agents may attempt to control the disease at first. For those with asymptomatic or minimally symptomatic disease and/or without visceral involvement, endocrine therapy can be used upfront. If PFS is short or the disease becomes more symptomatic, then switch of treatment to chemotherapy may be considered before another line of endocrine therapy.

Single-Agent Chemotherapy

Single agents include anthracyclines, taxanes, antimetabolites and other microtubule inhibitors. Response rates range

from 25% to 45% and PFS 5 months to 8 as first-line therapy; 15% to 30% and 2 months to 5 respectively as second-line therapy; and 0% to 2% and 1 to 4 months respectively as third-line therapy (47). From fourth-line therapy and beyond, data are scant, although chemotherapy is often continued with further lines of treatment. While worth considering in patients with good performance status and whose disease might have responded to earlier lines of chemotherapy, there is little or no evidence to support pursuing this in patients with poor performance status or whose disease is refractory to earlier lines of therapy. Rather, palliative care measures aiming at reducing symptoms and improving QOL should take primacy over a simple switch to another chemotherapy drug.

Lack of response to first-line chemotherapy treatment or a short progression-free period portends a poorer response to subsequent lines of treatment. The drug of choice for first-line therapy would depend on the disease-free interval since the end of adjuvant chemotherapy. Those whose disease recurs in <12 months would reflect a degree of resistance to the previous regimen. Sequential single agents may have lower response rates but also lower toxicities and no compromise in survival.

Anthracyclines

Since their introduction in the 1980s, anthracyclines have remained one of the most active agents for breast cancer. In an overview of randomized trials, inclusion of anthracyclines—such as doxorubicin—were found to confer a benefit in RR, TTF, and OS over nonanthracycline containing regimens (48). Anthracyclines have response rates of 35% to 50% for those who are anthracycline-naïve, or those who develop metastases after 12 months after anthracycline-based adjuvant therapy (23,30,49), but their efficacy in those with an anthracycline-free interval of <12 months is uncertain. Common dosing schedules are doxorubicin 60–75 mg/m^2 3-weekly or 20 mg/m^2 weekly; or epirubicin 75–100 mg/m^2 3-weekly or 20–30 mg/m^2 weekly. The risk of congestive heart failure is dose-related and rises from about 5% at a cumulative doxorubicin dose of 400 mg/m^2 to 16% at cumulative doses of more than 500 mg/m^2 (50). The use of anthracyclines in the metastatic setting is limited by acute toxicities such as nausea, vomiting, myelotoxicity, alopecia, and long-term issues such as leukemogenic risks and cardiotoxicity.

Liposome-encapsulated and PLD have comparable efficacy to doxorubicin but with reduced cardiotoxicity. Women with MBC who were randomized to receive either first-line PLD 50 mg/m^2 every 4 weeks or doxorubicin 60 mg/m^2 every 3 weeks showed comparable objective RR (33% vs. 38%), PFS (6.9 months vs. 7.8 months) and OS (21 months vs. 22 months), but there was significantly higher risk of cardiotoxicity with doxorubicin (RR = 3.16, 95% CI, 1.58–6.31; $p < .001$) (51). PLD caused less alopecia (20% vs. 66%), nausea (37% vs. 53%), vomiting (19% vs. 31%), and neutropenia (4% vs. 10%), but had more palmar-plantar erythrodysesthesia (48% vs. 2%), stomatitis (22% vs. 15%), mucositis (23% vs. 13%), and infusion reactions (13% vs. 3%).

Using PLD as salvage therapy has been shown to have comparable efficacy to that of common salvage regimens such as vinorelbine in taxane-refractory MBC (52). In women whose disease progressed after first or second-line taxane-containing chemotherapy for MBC, PLD 50 mg/m^2 every 28 days compared to vinorelbine 30 mg/m^2 weekly or mitomycin 10 mg/m^2 on day 1 every 28 days plus vinblastine 5 mg/m^2 on days 1, 14, 28, 42 every 6 to 8 weeks demonstrated similar PFS (HR 1.26; $p = .11$) and OS (HR 1.05; $p = .71$) (52). In anthracycline-naive patients, PLD had a significantly longer PFS compared to the comparator arms (HR 2.4; $p = .01$), although those patients on PLD had more palmar-plantar erythrodysesthesia (37% vs. <1%) and stomatitis. These results suggest that liposomal doxorubicin may offer an alternative therapeutic option for those who are at increased cardiac risk such as elderly patients, those who have cardiac risk factors, and those previously exposed to anthracyclines.

In patients previously treated with adjuvant anthracyclines, the combination of liposomal doxorubicin with docetaxel compared to docetaxel alone showed an improved RR and PFS but not OS (53). However, this combination was not granted regulatory approval because of excessive palmar-plantar erythrodysesthesia. Nonetheless, rechallenging patients with liposomal doxorubicin either singly or in combination with other agents remains an option for those previously treated with adjuvant anthracyclines if more than 12 months have elapsed since their completion (54).

Anthracycline Combinations

Data have shown that anthracycline-based regimens have improved response rates and PFS compared to regimens that do not contain doxorubicin (20,48,49), with some showing a survival benefit (48). Anthracycline-based combination regimens like doxorubicin/cyclophosphamide (AC), epirubicin/cyclophosphamide (EC), cyclophosphamide/doxorubicin/5-FU (FAC or CAF), or 5-FU/epirubicin/cyclophosphamide (FEC) are more active than single-agent anthracyclines but also have more toxicities, mainly myelosuppression, gastrointestinal toxicity, cardiotoxicity, and alopecia. They have not demonstrated a survival benefit over monotherapy. For example, the French Epirubicin Study Group comparing first-line epirubicin 75 mg/m^2 alone with fluorouracil 500 mg/m^2, epirubicin 50 mg/m^2, cyclophosphamide 500 mg/m^2 (FEC 50), and 5-FU 500 mg/m^2, epirubicin 75 mg/m^2, cyclophosphamide 500 mg/m^2 (FEC 75) as first-line treatment for advanced breast cancer patients found superior response rates for the combination regimen compared to single-agent therapy (FEC 50 [44.6%] and FEC 75 [44.7%] vs. epirubicin [30.6%] [$p = .04$ and $p = .0006$]) (55). The epirubicin alone group showed better tolerability than the two combination groups, which did not differ significantly. PFS and OS were not significantly different among the three groups but more early relapses occurred in the epirubicin and FEC 50 groups.

Another randomized prospective study comparing sequential monotherapy versus sequential combination regimens as first and second-line therapies: weekly epirubicin (E) 20 mg/m^2 until progression or until cumulative dose of 1,000 mg/m^2 followed by mitomycin (M) 8 mg/m^2 every 4 weeks (n = 153) versus combination cyclophosphamide 500 mg/m^2, epirubicin 60 mg/m^2, and fluorouracil 500 mg/m^2 every three weeks (CEF) followed by mitomycin 8 mg/m^2 plus vinblastine (V) 6 mg/m^2 every 4 weeks (n = 150) found higher objective response rates for the anthracycline regimens (CEF 55%, E 48%, M 16%, MV 7%) (56). Between the two anthracycline regimens, the combination gave longer response durations (CEF 12 months vs. E 10.5 months) but there was no difference in PFS or OS between the two treatment arms. Toxicities were less and QOL was better in the single-agent arm.

Rechallenging with Anthracyclines/Liposomal Doxorubicin

Rechallenging with anthracycline-based chemotherapy up to cumulative doses of doxorubicin 450–550 mg/m^2 and epirubicin 800–900 mg/m^2 is acceptable. Retrospective studies

have examined the feasibility of rechallenging with anthracyclines in the first-line setting for patients who have been exposed to anthracyclines in the adjuvant setting (57–60). All studies had a similar schema comprising a chemo-naive group, others who had received CMF or CMF-like regimens, or anthracyclines. There was a trend towards a worse clinical outcome (response rates and survival) for those with prior adjuvant chemotherapy, and this was statistically significant in two studies (58,59). However, there was no difference between CMF and anthracycline-based adjuvant regimens with regards to impact on first-line anthracycline therapy outcomes.

A small randomized phase III study compared rechallenging with epirubicin/docetaxel versus docetaxel alone as first-line chemotherapy in patients exposed to adjuvant or neoadjuvant epirubicin, and found similar antitumor efficacy in the two arms with more leukopenia, nausea and stomatitis in the epirubicin/docetaxel arm (61). Hence, the use if anthracyclines as first-line treatment for those already exposed to adjuvant anthracyclines is generally not recommended. In this case, taxane-based therapy is usually considered instead.

Liposomal doxorubicin is active in MBC patients who have been previously treated with conventional anthracyclines, with an overall clinical benefit rate of 24% (62). In a study conducted on behalf of the Spanish Breast Cancer Research Group, patients who did not have progression after three cycles of doxorubicin 75 mg/m^2 followed by three cycles of docetaxel 100 mg/m^2 administered 3-weekly were then randomized to liposomal doxorubicin 40 mg/m^2 once every 28 days for six cycles or observation (38). At a median follow-up of 20 months, liposomal doxorubicin significantly improved TTP (8.4 months vs. 5.1 months; HR = 0.54; p = .0002) compared to the control arm, although OS was not significantly prolonged (24.8 months vs. 22 months, HR = 0.86; p = .44). Liposomal doxorubicin was well tolerated with only 5% experiencing grade 3 or 4 fatigue, mucositis or palmar-plantar erythrodysesthesia. Hematologic toxicities were slightly greater with 12% experiencing neutropenia but only two with febrile neutropenia. However, non-cross-resistance between conventional and liposomal doxorubicin and the appropriateness of treating patients who have progressed on conventional doxorubicin with liposomal doxorubicin cannot be assessed from this study.

Data pooled from two prospective randomized phase III clinical trials comparing non-PLD or conventional doxorubicin combined with cyclophosphamide or liposomal doxorubicin versus conventional doxorubicin as monotherapy in patients previously treated with anthracyclines revealed significant differences for overall RR and median TTP in favor of liposomal doxorubicin, although there was no difference in OS (63–65). Moreover, there was less cardiotoxicity for the liposomal doxorubicin formulation.

In summary, data suggest that a greater benefit is achieved when rechallenging with non-PLD than conventional doxorubicin, either as monotherapy or in combination with other agents. Hence, patients who were exposed to adjuvant anthracyclines may remain responsive to liposomal formulations of anthracyclines.

Epirubicin versus Doxorubicin

In order to compare the efficacy of epirubicin to doxorubicin in the treatment of MBC, 13 randomized controlled trials (11 published reports and 2 reports in abstract form) were reviewed (66). No significant differences in response rates or median survival were observed at equal doses of epirubicin and doxorubicin. Although higher RRs were observed for higher epirubicin doses, this did not translate into a survival advantage. However, epirubicin was associated with less nausea, vomiting, neutropenia, and cardiotoxicity. A recent meta-analysis however failed to demonstrate a significant difference in congestive heart failure (CHF) risk between epirubicin and doxorubicin, although there was a suggestion of a lower rate of clinical heart failure for patients treated with epirubicin (67).

Taxanes

Until the development of taxanes in the 1990s, treatment options were much more limited. In a systematic review of taxane-containing chemotherapy compared with nontaxane regimens, taxane-based regimens showed a higher RR (odds ratio [OR] 1.34; p < .001), TTP (HR 0.92; p = .02), and OS (HR 0.93; p = .05), although there was significant heterogeneity in the trials, partially due to varying efficacy of the comparator regimens (68). The conclusion was that taxane-containing regimens were more effective than some, but not all nontaxane regimens. Taxanes have been studied in two main groups of patients; those who are anthracycline-naive and those who have been anthracycline pretreated.

Anthracycline-Naive Patients

In the TAX 303 phase III study evaluating docetaxel 100 mg/m^2 versus doxorubicin 75 mg/m^2 every 3 weeks for a maximum of seven cycles in MBC patients who had previous alkylating agent chemotherapy, docetaxel was significantly better than doxorubicin in terms of RR (48% vs. 33%; p = .008), even in those with poor prognostic factors such as visceral metastases and resistance to prior chemotherapy (69). Median TTP was longer in the docetaxel (26 weeks vs. 21 weeks) although the difference was not significant, and median OS was similar in the two groups (15 months vs. 14 months). Febrile neutropenia was more prevalent in the doxorubicin group, including cardiotoxicity, nausea, vomiting and stomatitis, whereas there was more diarrhea, neuropathy, fluid retention, skin and nail changes with docetaxel.

In an European Organisation for Research and Treatment of Cancer (EORTC) study (n = 331) for MBC comparing first-line doxorubicin 75 mg/m^2 with paclitaxel 200 mg/m^2 both once every 3 weeks, with a crossover design incorporated, doxorubicin was significantly better than paclitaxel for objective response rates (41% vs. 25%; p = .003), median PFS (7.5 months vs. 3.9 months; p < .001), but not in OS (18.3 months vs. 15.6 months; p = .38) (49). At crossover to doxorubicin or paclitaxel during second-line therapy, response rates were 30% and 16%, respectively. The doxorubicin arm was more toxic than paclitaxel in terms of hematologic, gastrointestinal, and cardiac side effects, but counterbalanced by better symptom control. There was no difference in QOL between the two treatment groups.

In the ECOG trial described previously, first-line paclitaxel 175 mg/m^2 versus doxorubicin 60 mg/m^2 produced equivalent outcomes in terms of RRs, TTF, and median survival, although this may be attributable to the lower dose of doxorubicin at 60 mg/m^2 used (23).

Paclitaxel 200 mg/m^2 every 3 weeks when compared to oral CMF plus prednisone (CMFP) every 28 days in untreated patients with MBC, had a significantly longer OS after adjustment for prognostic factors without a difference in overall response rate (ORR) and TTP (25). CMFP had more leukopenia, thrombocytopenia, nausea, and vomiting, but overall QOL assessments were similar in the two treatment arms. However, the dose of paclitaxel used in practice is usually 175 mg/m^2 as higher doses have greater toxicities but have not demonstrated a better efficacy (70).

In conclusion, the evidence does not indicate a clear superiority of an anthracycline or taxane in anthracycline-naive patients, and either agent can be used as first-line therapy after taking into account previous adjuvant therapy exposure, tolerability, and side effect profile.

Anthracycline Pretreated Patients

Taxanes have been compared to older nonanthracycline regimens in MBC patients with prior anthracycline exposure and found to be superior in terms of ORR, TTP, and OS in some instances. Docetaxel 100 mg/m^2 every 3 weeks compared to methotrexate/fluorouracil after anthracycline failure in advanced breast cancer had a significantly higher ORR (42% vs. 21%) and median TTP (6.3 months vs. 3 months), but no significant difference in OS although notably crossover was allowed upon progression (71). The same dose of docetaxel has also been shown to be significantly better to mitomycin plus vinblastine in MBC progressing after previous anthracycline therapy in terms of RR (30% vs. 11.6%; $p < .0001$), median TTP (19 weeks vs. 11 week; $p = .001$) and OS (11.4 months vs. 8.7 months; $p = .0097$) (26). Docetaxel 100 mg/m^2 every 3 weeks was found to be equivalent in terms of TTP and OS when compared to a regimen of vinorelbine and continuous infusional fluorouracil in MBC patients who had been exposed to anthracyclines in the adjuvant, neoadjuvant, or palliative setting (72).

Paclitaxel monotherapy is also active in those who have been exposed to anthracyclines. Paclitaxel 175 mg/m^2 every 3 weeks was found to be inferior to 3-weekly cisplatin/oral etoposide in patients with advanced breast cancer pretreated with anthracyclines (73). The cisplatin/etoposide arm was superior to paclitaxel with respect to RR (36.3% vs. 22.2%; $p = .038$), TTP (5.5 months vs. 3.9 months; $p = .003$), and median OS (14 months vs. 9.5 months; $p = .039$).

In the TAX-311 multicenter open-label phase III study (n = 449) comparing docetaxel 100 mg/m^2 versus paclitaxel 175 mg/m^2 in patients with advanced breast cancer that had progressed after an anthracycline-containing chemotherapy regimen, docetaxel demonstrated significantly superior median OS (15.4 months vs. 12.7 months, HR 1.41; $p = .03$) and TTP (5.7 months vs. 3.6 months, HR 1.64; $p < .0001$), with a higher ORR which did not reach statistical significance (32% vs. 25%; $p = .10$) (74). Both hematologic and nonhematologic toxicities were greater for docetaxel but QOL scores were not significantly different between the groups over time. Another trial directly comparing second-line docetaxel 100 mg/m^2 or paclitaxel 175 mg/m^2 after failure of anthracyclines, confirmed that TTP and OS were significantly better for docetaxel (75).

Inference from the available data suggests that docetaxel may be superior to 3-weekly paclitaxel. However, docetaxel maintenance therapy is often limited by hematologic toxicities, peripheral neuropathy, fatigue, nail changes, and fluid retention. Notably, docetaxel has not been compared to the more commonly used weekly paclitaxel schedule, which has demonstrated a survival advantage over the 3-weekly regimen.

In the CALGB 9840 trial for MBC patients who had received up to one line of prior chemotherapy in the metastatic setting, weekly paclitaxel was compared to 3-weekly paclitaxel 175 mg/m^2 (41). Owing to a 30% incidence of grade 3 sensory neuropathy, the starting dose of weekly paclitaxel was amended from 100 mg/m^2 to 80 mg/m^2. The weekly regimen was superior to the 3-weekly regimen in terms of RR (42% vs. 29%; $p = .0004$), TTP (9 months vs. 5 months; $p < .0001$), and OS (24 months vs. 12 months; $p = .0092$). The statistical validity may have been reduced by inclusion of 158 patients who received paclitaxel 175 mg/m^2 from the CALGB 9342 study evaluating three doses of single-agent paclitaxel (76). Although grade 3 or more neutropenia was more frequent with the 3-weekly compared to weekly regimen (15% vs. 9%), febrile neutropenia requiring hospitalization remained infrequent in both arms (4% vs. 3%). Grade 3 neuropathy was a treatment-limiting toxicity more common with the weekly regimen (24% vs. 12%; $p = .0003$).

These results were confirmed by the Anglo–Celtic study, which showed a better response rate for the weekly paclitaxel 90 mg/m^2 for 12 cycles compared to 3-weekly paclitaxel 175 mg/m^2 for four cycles (42% vs. 27%; $p = .002$) (77). Although the TTP was not significantly different, it was thought that the mismatch in treatment duration may have accounted for this.

A meta-analysis of randomized controlled trials comparing weekly and 3-weekly taxanes in advanced breast cancer reported that weekly paclitaxel 80–100 mg/m^2 had an OS survival benefit over 3-weekly paclitaxel 175 mg/m^2 therapy (5 studies, 1,471 patients, HR 0.78, 95% CI, 0.67–0.89; $p = .001$), but with worse sensory neuropathy (78). In contrast, no difference between weekly docetaxel 35–40 mg/m^2 and 3-weekly docetaxel 100 mg/m^2 was reported for ORR, PFS, and OS, the only advantage being significantly less neutropenia or neutropenic fever in the weekly docetaxel schedule. On the contrary, nail changes and epiphora were significantly lower in the 3-weekly docetaxel schedule. Limitations of this meta-analysis were small sample sizes with none of the trials designed to measure OS as a primary end point, lack of individualized patient data with only published trials used, and considerable heterogeneity in design, modes of treatment, and response rates.

Docetaxel 100 mg/m^2 as approved for MBC treatment in the U.S. and Europe is not a tolerable dose in Asian patients due to increased toxicities. In a study examining three different doses of second-line docetaxel at 60 mg/m^2, 75 mg/m^2 and 100 mg/m^2 for at least six cycles in pretreated MBC patients, significantly higher ORRs (22.1% vs. 23.3% vs. 36%; $p = .007$) and TTP (13.7, 13.9, 18.6 weeks; $p = .014$) were obtained with higher doses in the assessable population, but there was no difference in OS in the intent-to-treat population at a median follow-up of 30 months (79). About 80% of patients were exposed to prior anthracyclines in each arm. Most hematologic and nonhematologic toxicities were related to increasing doses, including those of febrile neutropenia rates (4.7% vs. 7.4% vs. 14.1%). Hence, lower doses of docetaxel must be considered for those who are more frail or who have tolerability issues. As a consequence, in clinical practice we usually use weekly paclitaxel 80 mg/m^2 or 3-weekly docetaxel 60–100 mg/m^2.

Cross-resistance between the Taxanes

There is evidence of an incomplete cross-resistance between paclitaxel and docetaxel, since modest responses are still seen in those exposed to the alternate taxane (80,81). However, using a taxane after progression on the other may be best reserved for patients who relapse more than 12 months after adjuvant taxane-containing therapy or who had previous clinical response to taxanes with a reasonable time lapse of at least a year. In a small retrospective study (n = 44) of patients with docetaxel-resistant MBC, paclitaxel 80 mg/m^2 weekly obtained objective responses in 14 of 44 women (31.8%, 95% CI, 17.5–46.1), seven of which had primary resistance to docetaxel (82). The median duration of response and time to progression were 6.1 months and 5 months respectively (82). In another larger retrospective study of weekly paclitaxel 80 mg/m^2 in 82 patients with docetaxel-resistant MBC, the patients were classified into those with primary or secondary resistance (short interval ≤120 days, long interval >120 days) (83). The response rate

to paclitaxel for those with primary docetaxel resistance (n = 24) was 8.3%, and those with secondary resistance (n = 58) was 24.1% (short interval [n = 39] 17.9%, long interval [*n* = 19] 36.8%), the differences in response rates being statistically significant (p = .0247). Conversely, docetaxel every 3 weeks was reported to have a response rate of about 18% to 25% in paclitaxel-refractory MBC (81,84).

The data suggest that treatment with an alternative taxane can result in objective responses. Studies support the notion that there is only partial cross-resistance between paclitaxel and docetaxel. However, it should be noted that there was wide variation in extent of prior anthracycline and/or taxane exposure in these studies, as well as the dose and schedule of taxanes used.

Nab-paclitaxel

Nab-paclitaxel is a Cremophor-free, albumin-bound formulation designed to distribute into tumor tissue more rapidly and at higher concentrations than conventional paclitaxel, thus possibly improving drug delivery and reducing toxicity. It is FDA-approved for MBC as monotherapy after failure of anthracycline-based combination chemotherapy for MBC, or after relapse within 6 months of adjuvant anthracyclines. It allows higher doses of paclitaxel infusion, over a shorter duration of 30 minutes, with no need for antihistamine or corticosteroid premedications.

It has been compared to docetaxel and paclitaxel, both as 3-weekly regimens. In a phase III trial comparing 3-weekly nab-paclitaxel 260 mg/m^2 without premedication versus paclitaxel 175 mg/m^2 with premedication in women with MBC (majority of whom had ≤1 prior MBC chemotherapy regimen not including a taxane) (85), nab-paclitaxel had significantly superior RRs (33% vs. 19%; p = .001) and TTP (23.0 weeks vs. 16.9 weeks, HR = 0.75; p = .006) compared with standard paclitaxel, but no difference in OS. OS was significantly longer in the subgroup who received nab-paclitaxel compared with paclitaxel as second-line or greater therapy (56.4 weeks vs. 46.7 weeks, HR 0.73; p = .024). Grade 4 neutropenia was significantly lower for nab-paclitaxel compared with standard paclitaxel (9% vs. 22%, respectively; p < .001) despite a 49% higher paclitaxel dose. Grade 3 sensory neuropathy was more common with nab-paclitaxel (10% vs. 2%, respectively; p < .001), lasting for a median of 22 days. No hypersensitivity reactions occurred with nab-paclitaxel despite the absence of premedication.

In another phase II trial (n = 302) comparing first-line nab-paclitaxel 300 mg/m^2 3-weekly, 100 mg/m^2 weekly or 150 mg/m^2 weekly, versus docetaxel 100 mg/m^2 3-weekly, there was a significant prolongation of PFS (>5 months) in patients receiving nab-paclitaxel 150 mg/m^2 weekly compared with docetaxel 100 mg/m^2 q3w (86). Nab-paclitaxel 150 mg/m^2 weekly showed a significantly longer PFS than docetaxel by independent radiologist assessment (12.9 months vs. 7.5 months, respectively; p = .0065). Both 150 mg/m^2 (49%) and 100 mg/m^2 (45%) weekly of nab-paclitaxel demonstrated a higher ORR than docetaxel (35%), but this did not reach statistical significance. Nab-paclitaxel 3-weekly versus docetaxel was not different for PFS or ORR. Disease control rate (stable disease ≥16 weeks or confirmed overall complete or partial response) was significantly higher for patients receiving either dose of weekly nab-paclitaxel compared with docetaxel, but survival data were not mature at the point of this publication. Grade 3 or 4 fatigue, neutropenia, and febrile neutropenia were less frequent in the nab-paclitaxel arms, whereas the frequency and grade of peripheral neuropathy were similar in all arms.

Nab-paclitaxel has also shown activity, albeit limited, in taxane-resistant MBC patients (87), with a tolerable toxicity profile of only about 17% grade 1 or 2 sensory neuropathy in taxane-pretreated MBC patients (88). In general, nab-paclitaxel demonstrated better response rates and PFS compared to 3-weekly paclitaxel or docetaxel. However, nab-paclitaxel (and ixabepilone) failed to demonstrate superior efficacy compared to standard weekly paclitaxel in the three-arm phase III open-label randomized trial CALGB 40502/NCCTG N063H study (NCT00785291) comparing the three therapies given in a weekly fashion with bevacizumab (which became optional subsequently) as first-line for metastatic breast cancer patients (89). The PFS for ixabepilone was found to be significantly inferior to paclitaxel, while nab-paclitaxel was not superior to paclitaxel. There was no difference in OS for all treatment arms and unfortunately the investigational arms were more toxic (e.g., peripheral neuropathy) than the conventional weekly paclitaxel arm.

The higher cost of nab-paclitaxel may compare favorably to the cost of docetaxel (90). However, the lack of meaningful clinical efficacy when compared to conventional paclitaxel suggest that the extra cost associated with the use of nab-paclitaxel can only be justified in patients who cannot tolerate use of steroids needed in most patients treated with paclitaxel.

Anthracyclines versus Taxanes

In a meta-analysis of individualized patient data on three single-agent trials comparing taxanes with anthracyclines (n = 919), taxanes fared significantly worse for PFS (5.1 months vs. 7.2 months, HR1.19; p = .011), although response rates for taxanes versus anthracyclines (38% vs. 33%; p = .08), and survival (19.5 months vs. 18.6 months, HR 1.01; p = .9) were similar (91).

Single-agent anthracyclines may be used for first-line therapy of MBC if the patient is anthracycline-naive. Re-using anthracyclines in the metastatic setting after adjuvant exposure is not usually preferred due to the presence of dose-limiting cardiotoxicity and the availability of multiple other drug options. A taxane may also be used as first-line treatment for those who are taxane-naive or who have an adjuvant taxane-free interval of more than 12 months. In the latter scenario, an alternative taxane (docetaxel or paclitaxel) to that used in the adjuvant setting may be preferred. Both are reasonable options in the first-line setting with neither being definitively superior to the other. Resistance to anthracyclines and taxanes has been defined as disease recurrence occurring within 6 to 12 months of an adjuvant, neoadjuvant or first-line metastatic regimen or while on active treatment.

Anthracycline Combined with Taxanes

It is not clear if the combination of the two most active agents anthracyclines and taxanes are more beneficial compared to sequential use of these agents in the treatment of MBC. This has been compared in several phase III studies evaluating a paclitaxel-based or docetaxel-based combination (23,92).

ECOG 1193 trial compared doxorubicin 60 mg/m^2, paclitaxel 175 mg/m^2 over 24 hours, and the combination of doxorubicin 50 mg/m^2 followed 3 hours later by paclitaxel 150 mg/m^2 over 24 hours, the latter plus granulocyte colony-stimulating factor, as first-line therapy in 739 women with MBC (23). Although complete and partial responses, and PFS were significantly higher in the combination arm compared to either the doxorubicin or paclitaxel arms, there was no significant difference in median OS as well as QOL measurements. Cardiac toxicity was equivalent in patients receiving single-agent doxorubicin and combination therapy perhaps due to the dose and administration schedule of the combination arm.

A Spanish Breast Cancer Research Group (GEICAM-9903) phase III study evaluated three cycles of doxorubicin 75 mg/m^2 followed by three cycles of docetaxel 100 mg/m^2, both every 21 days or six cycles of the combination doxorubicin 50 mg/m^2 and docetaxel 75 mg/m^2 every 21 days, to determine if sequential therapy could reduce the incidence of hematological toxicity especially febrile neutropenia (primary end point) while maintaining antitumoral activity (secondary end point) (92). Febrile neutropenia was significantly less common in the sequential compared to the combination arm (29.3% vs. 47.8%), and so were other toxicities like asthenia, diarrhea, and fever. There were no significant differences between the sequential versus the combination arms in terms of ORRs (61% vs. 51%), median duration of response (8.7 months vs. 7.6 months), median TTP (10.5 months vs. 9.2 months), and median OS (22.3 months vs. 21.8 months).

The ERASME 3 study compared docetaxel/doxorubicin or paclitaxel/doxorubicin every 3 weeks for four cycles followed by docetaxel or paclitaxel respectively for four cycles as first-line therapy in MBC (93). At a median follow-up of 50.2 months, there was no significant difference in QOL scores (measured after the first four cycles), ORR, PFS, and OS between the two treatment arms. However, hematologic toxicity and asthenia were significantly increased in the docetaxel arm and neuropathy in the paclitaxel arm.

The therapeutic benefit of anthracycline/taxane combinations compared to nontaxane anthracycline combinations has been studied as first-line therapy in several studies (94–99). Only a few studies have demonstrated an OS advantage for the anthracycline/taxane combination over anthracycline-based regimens (97,99). An Eastern European phase III trial of doxorubicin 50 mg/m^2 followed 24 hours later by paclitaxel 220 mg/m^2 over 3 hours versus 5-FU 500 mg/m^2 IV, doxorubicin 50 mg/m^2 IV, and cyclophosphamide 500 mg/m^2 (FAC) showed an overall RR (68% vs. 55%; p = .032), median TTP (8.3 vs. 6.2 months; p = .034), and OS (23.3 vs. 18.3 months; p = .013) significantly in favor of the doxorubicin/paclitaxel arm (97). The percentages of second-line therapy were similar in both arms except that taxane use was more prevalent in the FAC arm (24% vs. 2%). The grade 4 neutropenia rate was significantly higher in the doxorubicin/paclitaxel arm (89% vs. 65%; p < .001), although the incidences of fever, infection, and cardiotoxicity were low. QOL measurements were similar in the two arms.

In another Dutch study (n = 216), first-line doxorubicin 50 mg/m^2 followed one hour later by docetaxel 75 mg/m^2 compared with FAC showed a significantly higher objective RR (58% vs. 37%; p = .003), TTP (8 vs. 6.6 mo; p = .004), and OS (22.6 vs. 16.2 mo; p = .019) (99). Although febrile neutropenia rates were significantly higher in the doxorubicin/docetaxel arm (33% vs. 9%; p < .001), with two toxic deaths, the congestive heart failure rate was similarly low in both arms (3% vs. 6%). Additional taxanes as second-line therapy was administered to 67% and 23% of patients in the FAC and doxorubicin/docetaxel arms respectively. It should be noted that OS was not a primary study end point, there was a small sample size and the survival on the anthracycline-based arm was particularly poor.

An EORTC study looked at combinations of doxorubicin/paclitaxel versus doxorubicin/cyclophosphamide did not reveal any benefit in terms of RR, PFS, and OS although there was a significantly increased febrile neutropenia rate in the doxorubicin/paclitaxel arm (32% vs. 9%) (95). The doxorubicin/docetaxel combination was also compared to AC in the TAX 306 multicenter, multinational randomized phase III trial (n = 429) and showed a significantly higher RR (59%, CR 10%, PR 49%) than for those taking AC (47%, CR 7%, PR 39% [p = .009]) and TTP (37.3 vs. 31.9 weeks; p = .014), but no OS benefit and similar QOL measurements (98). Some 29% in the AC group received additional treatment with docetaxel compared with only 6% in the doxorubicin/docetaxel group. There was also a higher febrile neutropenia rate in the doxorubicin/docetaxel arm (33% vs. 10%; p < .001), although cardiotoxicity was similarly low in both arms (CHF 3% in doxorubicin/docetaxel and 4% in the AC arms).

In a phase III study comparing 3-weekly docetaxel/doxorubicin/cyclophosphamide (TAC) (75/50/500 mg/m^2) to FAC (500/50/500 mg/m^2) as first-line in MBC, TAC demonstrated a significantly higher RR (55% vs. 44%; p = .02), but there were no improvements in TTP or OS compared with FAC (94). A significantly higher incidence of grade 3 and 4 hematologic and nonhematologic toxicities, including more cardiotoxicity, was found in the TAC arm. A higher percentage in the FAC group received crossover docetaxel treatment than the TAC group (38% vs. 11%).

In a U.K.-driven trial assessing the combination of epirubicin/paclitaxel versus epirubicin/cyclophosphamide, a significantly better response rate (65% vs. 55%; p = .015) for the epirubicin/paclitaxel arm was demonstrated, although there were no differences in TTP and OS (96). Comparing epirubicin/docetaxel versus epirubicin/cyclophosphamide also did not yield any differences in the efficacy end points of ORR, PFS, and OS in a German study (100).

Two pooled analyses have not found an OS advantage for the anthracycline/taxane combination although there was a better response rate and TTP (91,101).

In a combined pooled analysis and literature-based meta-analysis of seven phase III prospective randomized trials (three published and found abstracts; n = 2,805), a significant difference was found in favor of anthracycline/taxane combinations over standard anthracycline regimens for ORR (RR 1.21; p < .001), a borderline significance for TTP (RR 1.10; p = .05), but no significant OS difference (101). The neutropenia and febrile neutropenia rates were significantly higher in the anthracycline/taxane arms. This analysis has been hampered by incomplete and non-definitive abstract data, heterogeneity in median follow-up which could have affected survival analysis, and a lack of individualized patient data.

In another analysis consisting of individualized patient data collected on eight randomized combination trials (n = 3,034), there was a significant benefit of anthracycline/taxane combinations over nontaxane anthracycline-based regimens, in terms of response rate and PFS, with no significant difference in OS (91).

On the basis of these results, anthracycline/taxane combinations should not routinely replace anthracycline-based regimens in clinical practice. There was limited statistical power in these trials to detect an OS benefit. Meta-analyses confirmed a better response rate and PFS, but not OS. The disappointing results of the anthracycline/taxane combinations are not completely unexpected as there is no preclinical evidence of synergy between them and both have overlapping and limiting hematological toxicities. These regimens should be reserved for only those patients with good performance status and life-threatening disease.

Other Taxane Combinations

After progression on anthracyclines, taxane combinations may sometimes be used if a higher response rate is required. Certain combinations have shown a survival benefit compared to single-agent taxanes such as docetaxel/capecitabine and paclitaxel/gemcitabine (32,33). However, there was no planned crossover in the studies, a third arm with single-agent capecitabine or gemcitabine were missing, and these combinations have been associated with increased toxicities.

Based on data from these trials, the FDA approved both combination regimens for treatment of MBC pretreated with anthracyclines: the capecitabine/docetaxel combination indicated for anthracycline and/or taxane-failed disease and the gemcitabine/paclitaxel combination as first-line therapy after failure of prior anthracycline-based adjuvant chemotherapy.

The capecitabine/docetaxel combination capitalizes on the synergistic antitumor activity of these two drugs observed in xenograft models (102). Capecitabine generates 5-FU preferentially in tumor tissue mimicking continuous 5-FU infusion, this tumor selectivity achieved because of the higher activity of thymidine phosphorylase in human tumor tissue compared with healthy tissue (103,104). Docetaxel also causes upregulation of thymidine phosphorylase and Bcl-2 downregulation (105). Both drugs also capitalize on their nonoverlapping toxicities as docetaxel is myelosuppressive, but capecitabine has a low incidence of myelosuppression. An international phase III trial of 511 patients with unresectable locally advanced or metastatic disease previously exposed to anthracyclines in the neoadjuvant, adjuvant or metastatic setting were randomized to capecitabine 1,250 mg/m^2 twice daily for 14 out of 21 days and docetaxel 75 mg/m^2 on day 1 every 21 days (n = 255) compared to docetaxel 100 mg/m^2 every 21 days (n = 256) (32). In addition, more than 90% of patients had received previous alkylating agents and 5-FU had been administered to about three-quarters of patients. The capecitabine/docetaxel arm demonstrated superior TTP (HR 0.652; p = .0001, 6.1 months vs. 4.2 months), OS (HR 0.775; p = .0126, 14.5 months vs. 11.5 months), and objective tumor response (42% vs. 30%; p = .006). Of note, approximately 30% of patients in each arm were ER-negative which indicates activity of the treatment in this subgroup. More grade 3 adverse events (AEs) in the capecitabine/docetaxel arm necessitated treatment interruption or dose reduction (71% vs. 49%), due largely to hand-foot syndrome. The frequency of grade 3/4 neutropenia and neutropenic fever was 24% versus 28% in the combination versus docetaxel arms. Approximately 65% patients in the combination arm required dose reduction of capecitabine alone (4%), docetaxel alone (10%), or both drugs (51%) for AEs, while only 36% required dose reduction for the docetaxel arm. Myalgia, arthralgia, neutropenic fever and sepsis were more common with docetaxel, while hand-foot syndrome, diarrhea and stomatitis were more frequent with docetaxel/capecitabine, although there was no significant difference in QOL scores. A high proportion of patients received post-study treatment in both arms (70% and 63% in combination and single-agent docetaxel arms respectively), with similar proportions in each arm receiving post-study 5-FU, vinorelbine, anthracyclines, trastuzumab and paclitaxel. Post-study docetaxel was administered in 20% and 7% of the combination and single-agent docetaxel arm respectively; and the use of post-study capecitabine was more common in the monotherapy compared to the combination arm (27% vs. 4%). As no crossover was planned and only a small proportion of patients on docetaxel subsequently received capecitabine, no definitive conclusions can be made regarding the relative merits of combination over sequential single-agent therapy (106). Lower doses of capecitabine and docetaxel may retain the efficacy while reducing the concomitant toxic effects as has been suggested by a retrospective analysis of this trial (107), which is important to consider when dealing with otherwise incurable disease and a primary goal of palliation.

Of interest, in a Mexican Oncology Study Group (MOSG) randomized phase III trial evaluating sequential capecitabine followed by a taxane versus combination capecitabine/paclitaxel or capecitabine/docetaxel, the response rate was higher for the combination arms, but there was a lack of PFS or OS benefit (29). On the contrary, another trial having a similar design of sequential docetaxel followed by capecitabine on progression versus combination capecitabine/docetaxel, but using different capecitabine doses and drug sequence, reported a higher ORR, TTP, and OS for the combination arm (108).

A randomized multicenter phase III trial by the AGO Breast Cancer Study Group was designed to show noninferiority of capecitabine/paclitaxel (XP) to epirubicin/paclitaxel (EP) as first-line in MBC with the primary end point PFS showing equivalence (12.3 months vs. 11.8 months,; p not significant), and the secondary end points of response rates and OS being comparable (109). The toxicity was relatively low for XP compared to other nonanthracycline containing combination therapies, with febrile neutropenia in only one patient and skin toxicities in five patients. Four patients stopped treatment for gastrointestinal reasons in the XP arm. This suggests that XP is an efficacious and more tolerable regimen compared to capecitabine/docetaxel.

A phase III global study which supported the approval of gemcitabine in MBC compared the efficacy of gemcitabine 1,250 mg/m^2 on days 1 and 8 plus paclitaxel 175 mg/m^2 on day 1 (GT) (n = 266) to paclitaxel 175 mg/m^2 on day 1 (n = 263) in 21-day cycles for patients who had relapsed after neoadjuvant or adjuvant anthracyclines (33). The GT arm was significantly better in terms of median OS (18.6 months vs. 15.8 months; p = .0489), TTP (6.14 months vs. 3.98 months; p = .0002) and ORR (41.4% vs. 26.2%; p = .0002). Grade 3 and 4 neutropenia (47.9% vs. 11.5%), febrile neutropenia (5% vs. 1.2%) and grades 2 to 4 fatigue and neuropathy were increased in the GT arm. As there was no preplanned crossover design and only 15.6% of patients on paclitaxel received subsequent gemcitabine as post-study treatment, there are no definite conclusions regarding the advantage of the combination over sequential therapy. As the standard comparator arm consisted of 3-weekly paclitaxel, there can also be no conclusions drawn regarding the superiority of the combination over other paclitaxel schedules such as weekly regimens which have been used more commonly nowadays. Notably, there is no evidence of synergy between gemcitabine and paclitaxel preclinically.

In a phase III trial, gemcitabine 1,000 mg/m^2 days 1,8/docetaxel 75 mg/m^2 on day 1 (GD) every 21 days was compared to capecitabine 1,250 mg/m^2 twice daily every 21 days/docetaxel 75 mg/m^2 (CD); one prior anthracycline regimen in the neoadjuvant, adjuvant, or first-line metastatic setting being required (110). No differences were found in PFS (8.05 months vs. 7.98 months; p = .121), ORR (32% both arms), and OS (19.29 months vs. 21.45 months; p = .983), although TTF was longer in the GD arm (4.24 months vs. 4.07 months; p = .059). Post-study treatment was administered in 71% and 73% of patients in the GD and CD arms respectively. Hematologic toxicities were similar between the arms except for grade 3 and 4 leukopenia (78% vs. 66%; p = .025). Erythropoietin and granulocyte colony-stimulating factor were administered to 18% and 30% of patients, respectively, in the GD arm and to7% and 25%, in the CD arm, with more patients in the GD arm requiring transfusions (17% vs. 7%; p = .0051). Several nonhematologic grades 3 to 4 toxicities were significantly higher in the CD arm that included diarrhea (8% vs. 18%; p = .009), hand-foot syndrome (0% vs. 26%; p < .001), and mucositis (4% vs. 15%; p < .001). Fewer patients in the GD arm discontinued treatment as a result of drug-related AEs (13% vs. 27%, respectively; p = .002), which could be related to the high doses of both drugs used in the capecitabine/docetaxel arm.

In another more recent phase III trial of GD versus CD with planned crossover to the alternate single agent (capecitabine or gemcitabine) on progression, the two combination arms

had similar efficacy and toxicities consistent with prior clinical experience (111). Exploratory analysis suggested that the GD to C crossover sequence may provide a benefit in TTP and OS compared to the CD to G arm although this was not significant.

In a phase III Central European Cooperative Oncology Group (CECOG) trial of MBC patients who had one prior anthracycline regimen in either early or late stage disease, randomized to 21-day schedules of either 8 cycles of combination gemcitabine 1,000 mg/m^2 days 1 and 8/docetaxel 75 mg/m^2 on day 8 or sequential docetaxel 100 mg/m^2 for 4 cycles followed by gemcitabine 1,250 mg/m^2 on days 1 and 8, there was no significant difference in TTP, ORR, response duration, and OS (112). A significantly larger proportion of patients in the sequential arm experienced greater leukopenia (68% vs. 29%; $p < .001$), neutropenia (83% vs. 49%; $p < .001$), but significantly more in the combination arm experienced anemia ($p = .003$). The increased neutropenia seen contrarily in the sequential arm was due to the use of docetaxel 100 mg/m^2 without granulocyte colony stimulating factor (GCSF) support.

However, weekly paclitaxel has been found to have significantly greater OS compared with docetaxel/gemcitabine. In a Hellenic Cooperative Oncology Group study ($n = 416$), patients were randomized to first-line paclitaxel 175 mg/m^2/carboplatin AUC6 (PCb) 3-weekly for six cycles, docetaxel 75 mg/m^2 on day 8/gemcitabine 1,000 mg/m^2 on days 1, 8 (GDoc) 3-weekly for six cycles or weekly paclitaxel 80 mg/m^2 for 12 weeks (Pw) (113). Those who had HER2-positive disease were allowed trastuzumab. The primary end point OS was superior for the weekly paclitaxel group compared to the other two groups (median survival: Pw 41 months vs. PCb 29.9 months vs. GDoc 26.9 months; $p = .037$), while there was no significant difference in TTP. In multivariate Cox model analysis adjusting for performance status (PS 1 vs. 0), the survival difference was statistically significant in favor of Pw compared with PCb for PS 1 patients, while the survival advantage for Pw over GDoc was not affected by PS. Those in the GDoc arm experienced more hematologic toxicities, while those in the paclitaxel containing arms had more sensory neuropathy. Febrile neutropenia occurred rarely in all three arms. Severe mucositis and alopecia were more prevalent in the GDoc and PCb arms compared to the Pw arm. The weekly paclitaxel arm was well-tolerated in all age groups, which suggests that it is a safe regimen for the older patient population. QOL was comparable in all treatment groups while weekly paclitaxel had the greatest cost effectiveness.

Although the above combinations have shown effective clinical responses, they are not often used due to associated toxicities, and the equivalent efficacies of sequential agents.

Capecitabine

Capecitabine is the first oral fluoropyrimidine approved by the FDA for MBC patients after failure of anthracyclines and taxanes. It has excellent tolerability with limited alopecia and bone marrow suppression. It received accelerated approval based on an ORR of 25.6% in a single arm trial in 162 patients with refractory breast cancer (114). Capecitabine 1,250 mg/m^2 twice daily for 14 days every 21 days has RRs of about 30% in first-line therapy (27) and about 15% to 30% in anthracycline and taxane pretreated patients (115–118). The lower dose capecitabine 1,000 mg/m^2 twice daily has a superior therapeutic index and comparable efficacy, and may help in alleviating the side effects such as palmar-plantar erythrodysesthesia, diarrhea, and nausea (119,120). Other schedules have also been attempted with reduced toxicity and apparent similar efficacy; such as, fixed, lower starting doses, or shorter week on/week off schedules (121,122).

Gemcitabine

Gemcitabine is a nucleoside metabolic inhibitor that targets DNA synthesis indicated for first-line treatment of MBC in combination with paclitaxel after failure of prior anthracycline-containing adjuvant chemotherapy, unless anthracyclines were clinically contraindicated (33).

As a single agent, gemcitabine is well-tolerated and results in objective ORRs of about 14% to 24% in the first-line setting and 12% to 30% in anthracycline and/or taxane pretreated patients (123–125). Thrombocytopenia can be dose-limiting especially in those who have been heavily pretreated. In a randomized phase III study comparing first-line gemcitabine 1,200 mg/m^2 or epirubicin 35 mg/m^2 on days 1, 8, and 15 of a 28-day cycle in anthracycline-naive MBC patients ≥60 years (median 68 years), epirubicin (n = 199) compared to gemcitabine (n = 198) demonstrated statistically significant superiority in TTP (6.1 months vs. 3.4 months; $p = .0001$) and overall survival (19.1 months vs. 11.8 months; $p = .0004$) (126). The ORRs for epirubicin versus gemcitabine was 40.3% and 16.4% in 186 and 183 evaluable patients respectively ($p < .001$). Common hematological grade 3 and 4 toxicities for gemcitabine versus epirubicin were neutropenia (25.3% and 17.9%), leukopenia (14.3% and 19.3%), and thrombocytopenia (9% vs. 1.5%). This confirms the greater efficacy of anthracyclines in the first-line setting but also illustrates that gemcitabine is an active drug in older population. In clinical practice, gemcitabine as a single agent or in combination with carboplatin is often used as subsequent salvage therapy in MBC after anthracyclines and taxanes have failed.

Vinorelbine

Vinorelbine is a vinca alkaloid which interferes with microtubule assembly, inducing cell cycle arrest at mitosis. Single agent weekly vinorelbine 30 mg/m^2 has objective RRs of about 15% to 40% depending on whether it is used as first-line, or in heavily pretreated patients (31,127,128). Single agent oral vinorelbine has shown ORR of 26% to 42% depending on line of treatment in several phase II trials (129–131). Vinorelbine is a good option for the older population and its main side effects are neutropenia, peripheral neuropathy, constipation, and less commonly paralytic ileus, with alopecia being rare. In clinical practice, its main use is reserved usually for the second or third-line settings after anthracyclines and/or taxanes have been utilized.

Phase III trials of IV vinorelbine/5-FU compared to docetaxel in anthracycline pretreated patients or IV vinorelbine/doxorubicin versus doxorubicin failed to show any benefit of the combination arms over their comparison monotherapy arms (30,72).

In the pivotal study of 64 patients with locally advanced or MBC (61% had visceral disease and 73% had at least 2 organs involved), oral vinorelbine given on a weekly basis for 8 weeks (60 mg/m^2 for first 3 cycles, then 80 mg/m^2 subsequently) resulted in a 31% response rate (24.1% PR, 6.9% CR), median PFS 17.4 weeks, and a safety profile comparable with intravenous vinorelbine (132).

Oral vinorelbine combined with capecitabine is an active combination which has been found to have comparable efficacy to the intravenous equivalent. Its toxicities are predictable and manageable, with a low rate of alopecia which may be viewed favorably by patients. In a pivotal phase II study evaluating this combination of 3-weekly oral vinorelbine 80 mg/m^2 (after cycle 1 at 60 mg/m^2) on days 1 and 8, plus capecitabine 1,000 mg/m^2 (750 mg/m^2 if ≥65 years) twice daily on days 1 to 14 as first-line therapy in women with HER2-negative MBC, the objective RR was 51% (complete response 4%), the clinical benefit rate was 63% (response or

SD for ≥6 months), median duration of response 7.2 months, median PFS 8.4 months, and median OS 29.2 months, with similar efficacy in those with visceral metastases (133). The toxicities were predictable and manageable with the main grade 3 and 4 toxicity being neutropenia (49%); two patients experiencing febrile neutropenia and three patients having a neutropenic infection (including one septic death). A particularly low rate of alopecia (9%) was observed.

This regimen was also evaluated in those resistant or refractory to anthracyclines and taxanes in two phase II studies (134). The study by Jones et al. consisting of 40 patients (75% refractory/resistant to anthracyclines/taxanes) receiving oral vinorelbine 60 mg/m^2 on days 1, 8, and 15 plus capecitabine 1,000 mg/m^2 bid on days 1 through 14 every 3 weeks, showed a RR 23.5%, median PFS 3.4 months, and median OS 11.3 months (134). In another small Italian phase II study (n = 38) administering oral vinorelbine 60 mg/m^2 on days 1 and 8 plus capecitabine 1,000 mg/m^2 bid on days 2 to 7, 9 to 16 every 3 weeks in MBC patients refractory to anthracyclines and taxanes, there was a RR of 39%, a median TTP 4.5 months, median duration of response 7 months and median OS 10 months (135).

Of interest, a randomized 3-arm phase II study of HER2-negative MBC patients previously exposed to neo- or adjuvant anthracyclines, comparing oral vinorelbine 80 mg/m^2 (after the first cycle at 60 mg/m^2) on days 1 and 8 plus capecitabine 1,000 mg/m^2 bid on days 1 through 14 every 21 days, the same drugs alternating every 3 cycles, and docetaxel 75 mg/m^2 plus capecitabine 1,000 mg/m^2 bid on days 1 to 14 every 3 weeks, showed a similar efficacy (RR, OFS, OS) for the combination arms, while the all oral combination induced less neutropenia, infection, hand-foot syndrome, fatigue/asthenia, and alopecia, and the docetaxel/capecitabine combination less gastrointestinal toxicity (136). The third arm evaluating sequential therapy was inferior although this could have been due to the higher prevalence of visceral disease in this arm.

In a retrospective observational study comprising patients from 13 centers and 7 countries between 2006 and 2008 (n = 216) who had received oral vinorelbine alone (54%) or in combination with capecitabine (46%) either as first (56%) or second-line (44%), disease control was achieved in 77% of patients; 74% as single-agent, 81% in combination, 82% in first-line, 71% in second-line (137). Median PFS was 9.7 months and 6.6 months in first- and second-line therapy respectively. These oral regimens were described by caregivers as convenient (81%), well-tolerated (84%), and had a good compliance by patients (76%). Because data from every-day practice matched that obtained from previous clinical trials in efficacy and tolerability, this is an attractive oral formulation to use.

The combination of alternating intravenous and oral vinorelbine has been combined with other agents such as epirubicin or docetaxel in phase II trials in the first-line setting, using an intravenous schedule on day 1 and an oral schedule on either day 8 or 15, with promising ORR of about 50% (138,139). Other chemotherapy agents have been evaluated via phase I and II trials in combination with oral vinorelbine, such as gemcitabine (140), paclitaxel (141), docetaxel (142), liposomal doxorubicin (143), and temozolomide (144), although none have been used commonly in clinical practice. Both oral and IV vinorelbine formulations have been used in treatment of MBC and have similar efficacy.

Vinflunine

Vinflunine is a novel microtubule inhibitor of the vinca alkaloid family which has shown activity in a phase II trial of anthracycline and taxane pretreated MBC patients with an ORR of 14%, median PFS of 2.6 months and a median OS of 11.4 months (145). In another phase II study of vinflunine used as second line treatment after anthracycline/taxane therapy, the ORR was 30%, median duration of response was 4.8 months, median PFS was 3.7 months, and OS 14.3 months (146). Several phase III trials have been set up in view of these promising phase II results.

CMF

CMF remains a viable option for MBC treatment but is often used later in the treatment sequence after the more commonly used agents such as anthracyclines, taxanes, capecitabine, vinorelbine, and gemcitabine. Although first-line CEF (cyclophosphamide 400 mg/m^2, epirubicin 50 mg/m^2, and fluorouracil 500 mg/m^2 on days 1 and 8) has demonstrated higher response rates (57% vs. 46%; p = .01), longer TTP (8.9 months vs. 6.3 months; p = .0064), and TTF (6.2 months vs. 5 months; p = .01) compared with IV CMF (cyclophosphamide 500 mg/m^2, methotrexate 40 mg/m^2, and fluorouracil 600 mg/m^2 on days 1 and 8), OS (20.1 months vs. 18.2 months;, p = .23) was reported to be similar (147). In practice, oral CMF is used more commonly and has been shown to be superior to the equivalent IV formulation (42).

Other Combinations

Various other combinations have shown activity in pretreated MBC in phase II or phase III studies. These include gemcitabine/cisplatin (RR 30% to 50%) (148–150), gemcitabine/vinorelbine (RR 30% to 40%) (31,151), and gemcitabine/epirubicin/paclitaxel (RR 62%) (152). Cisplatin has been combined with vinorelbine in patients previously treated with anthracyclines and docetaxel with a RR of about 50% (153). Other platinum combinations include cisplatin/docetaxel in anthracycline-resistant advanced breast cancer (RR 36%) (154), carboplatin/paclitaxel as first-line therapy (RR 41%) (155), cisplatin/capecitabine in anthracycline and taxane pretreated patients (RR 36%) (156), or cisplatin/oral etoposide in anthracycline pretreated patients (RR 36%) (73). Less common combinations of vinorelbine with doxorubicin or epirubicin have also shown promising activity (30,157). None of these regimens have shown an OS advantage over other more traditional regimens or single agents (30,152,157,158).

Ixabepilone

Increased use of anthracyclines and taxanes in the neo- or adjuvant settings limits treatment options for patients upon relapse. Nonanthracycline, nontaxane combinations have higher response rates but have not shown a survival benefit over single agents and other combination treatment regimens, hence the necessity for new drug developments.

Epothilones are naturally occurring macrolide antibiotics derived from the myxobacterium *Sorangium cellulosum*. Ixabepilone is an epothilone, belonging to a class of nontaxane tubulin polymerizing agents that have activity in taxane-resistant patients. It is approved by the United States FDA as monotherapy for patients who have tumors which are resistant to anthracyclines, taxanes, and capecitabine and in combination with capecitabine for MBC or locally advanced breast cancer resistant to anthracyclines and taxanes, or for those who are taxane resistant and further anthracyclines are contraindicated. It has however been refused marketing authorization by the European Medicines Agency (EMA) Committee for Medicinal Products for Human Use in 2008 due to its marginal benefits and concerning side effects such as significant peripheral neuropathy.

In a pivotal multicenter phase II study, patients with tumor progression after anthracyclines, taxanes, and capecitabine were given ixabepilone 40 mg/m^2 once every 21 days (159). In this heavily pretreated population (n = 113, 88% had received at least two prior lines), ORR was 11.5% and 18.3% in independent and investigator-related assessments. Median duration of response, PFS and OS were 5.7 months, 3.1 months, and 8.6 months respectively, 50% of which achieved SD. Grade 3 and 4 toxicities included peripheral sensory neuropathy (14%), fatigue/asthenia (13%), myalgia (8%), and stomatitis/mucositis (6%); with resolution of peripheral sensory neuropathy after a median of 5.4 weeks. In a separate phase II study of patients with MBC exposed to taxanes in the adjuvant, neoadjuvant or metastatic setting, the RR of 22% was slightly better, the main side effects being neutropenia, febrile neutropenia, fatigue, and diarrhea (160).

In a pivotal phase III registration trial (BMS 046), ixabepilone 40 mg/m^2 on day 1 plus capecitabine 1,000 mg/m^2 twice a day for 14 days every 21 days versus capecitabine 1,250 mg/m^2 for 14 days every 21 days in 752 women with locally advanced or MBC pretreated with or resistant to an anthracycline and resistant to a taxane demonstrated prolonged PFS (5.8 months vs. 4.2 months), a 25% reduction in risk of disease progression (HR 0.75; p = .0003), and increased response rates (35% vs. 14%; p < .0001) for the combination arm, but not OS (161,162). However, there was a clinically meaningful increase in OS in KPS 70–80 patients receiving combination therapy (HR 0.75; 95%CI 0.58–0.98) in a later analysis of OS (163). Majority of patients (65%) had ≥3 metastatic sites, and nearly half had received ≥2 prior regimens. Grade 3 and 4 toxicities were more frequent in the combination arm such as sensory neuropathy (21% vs. 0), fatigue (9% vs. 3%), and neutropenia (68% vs. 11%), as well as death related to toxicity especially in those with ≥ grade 2 liver dysfunction (3% vs. 1%). This study did not incorporate a crossover design from monotherapy capecitabine to ixabepilone, limiting interpretation of the optimal use of combination compared to sequential single-agent therapy.

In a larger confirmatory phase III study (BMS 048) using identical comparison arms of ixabepilone/capecitabine versus capecitabine, in 1,221 women with MBC previously treated with anthracyclines and taxanes but not necessarily resistant to them (about 25% and 74% of patients in both arms respectively received prior anthracyclines and taxanes) there were increased response rates (43% vs. 29%; p < .0001) and PFS (6.2 months vs. 4.2 months, HR 0.79; p = .0005) in the ixabepilone/capecitabine arm, but no significant difference in OS (16.4 months vs. 15.6 months, HR 0.90; p = .1162), although on adjusting for prognostic factors (i.e., performance status, age, number of organ sites, visceral disease, and ER status), an OS benefit was observed (HR 0.85; p = .0231) (163a). Of note, nearly a quarter of those in the ixabepilone-containing arm experienced grade 3 and 4 reversible peripheral neuropathy. The patients in BMS 046 all met strict resistance criteria in the pretreatment phase, whereas only half of the population in BMS 048 met the resistance criteria stipulated in BMS 046. A preplanned subset analysis of patients with TNBC suggested activity of this combination for this subgroup in terms of PFS (164). The data suggest a clinical benefit associated with addition of ixabepilone to capecitabine in TNBCs that had progressed after prior anthracycline and a taxane therapy as outlined below in the TNBC section. The combination of ixabepilone and capecitabine appears moderately well-tolerated with minimal overlapping toxicities. However, ixabepilone and its combinations are best reserved for patients with aggressive disease and limited treatment options.

However, in the previously described CALGB 40502/NCCTG N063H trial, the ixabepilone arm was closed early after the first interim analysis when the comparison of ixabepilone to paclitaxel crossed the futility boundary (89).

Eribulin

Eribulin mesylate is a structurally simplified, synthetic analog of halichondrin B, derived from the marine sponge *Halichondria okadai*. It is a nontaxane microtubule inhibitor with a unique end-poisoning mechanism by binding to the microtubule ends or inducing tubulin aggregates, which compete with soluble tubulin for addition to the growing ends of the microtubule (165). Specifically, eribulin sequesters alpha and beta tubulin into nonfunctional aggregates, causing a decreased ability for polymerization, an irreversible mitotic block, and cell cycle arrest at the G2/M phase with resulting apoptosis (166).

A phase III open-label Eisai Metastatic Breast Cancer Study Assessing Physician's Choice Versus E7389 (EMBRACE) trial randomized 762 women with locally recurrent or metastatic breast cancer in a 2:1 fashion to eribulin mesilate (1~4 mg/m^2 on days 1 and 8 of a 21-day cycle) or treatment of physician's choice (TPC) (167). Approximately 96% on the TPC arm received chemotherapy including vinorelbine (25%), gemcitabine (19%), capecitabine (18%), taxanes (15%), anthracyclines (10%), and other chemotherapies (10%) representing practical clinical decisions at that time (2006–2008), with only 4% receiving hormonal therapy. Nine patients received hormonal therapy and none received biologic therapy or best supportive care only. Patients had received two to five previous lines of chemotherapy (≥2 for advanced disease), including an anthracycline and a taxane, unless contraindicated. A median of four chemotherapy regimens were administered in both arms, 16% were HER-positive, about 25% were triple-negative and 50% had more than two organs involved. The primary end point median survival was significantly longer for eribulin compared to TPC (13.1 months vs. 10.6 months, HR 0.81; p = .041) and so was objective response rates (12% vs. 5%; p = .002). However, eribulin was not significantly different from TPC for median PFS (3.7 months vs. 2.2 months, HR 0.87; p = .137). The most common AEs in both groups for all grades were fatigue or asthenia (270 [54%] of 503 patients on eribulin and 98 [40%] of 247 patients on TPC), neutropenia (260 [52%] patients receiving eribulin and 73 [30%] of those on TPC), and nausea (174 [35%] of patients on eribulin and 70 [28%] of those on TPC). Peripheral neuropathy was the most common AE (35%, grade 3/4 approximately 8%) which led to discontinuation of eribulin in 5% of patients. A predefined exploratory subgroup analysis also demonstrated significant improvement in favor of eribulin for estrogen receptor, progesterone receptor, HER2, triple-negativity, number of organs involved, sites of disease, and prior capecitabine therapy (168). EMBRACE has been the only phase III study in MBC to define OS as the primary end point and meet it with a clear 3 month survival benefit. Furthermore, no study in MBC has included such a heavily pretreated population. The results of this study led to the FDA regulatory approval of eribulin in 2010 as third-line treatment of MBC after anthracycline and taxane failure in the adjuvant or metastatic setting, and at least two prior lines of metastatic chemotherapy regimens. Eribulin is a CYP3A4 substrate, and although phase II trials prohibited use of drugs metabolized by CYP3A4 and anticoagulant therapy, details of the EMBRACE study regarding use of CYP3A inhibitors were not described. Results are being awaited for a phase III E301 study for MBC in which eribulin

is being compared to capecitabine as second-line therapy, the primary objectives being to assess OS and PFS (169).

Platinums

Cisplatin and carboplatin have limited activity as single agents in MBC treatment. However, they have been combined with many different cytotoxics in the first- and second-line setting with some success. In the first-line setting, platinum agents with taxanes or vinorelbine have achieved RRs of up to 60% (170). In pretreated MBC patients, platinums with taxanes, vinorelbine or gemcitabine have yielded RRs of 40% to 50%. Cisplatin has demonstrable activity as a single agent as first-line therapy in MBC (171). The Translational Breast Cancer Research Consortium recently reported on encouraging preliminary results of trial TBCRC 009 (NCT00483223) with single-agent carboplatin and cisplatin in patients with TNBC and no more than one prior chemotherapy regimens for MBC. The role of platinum agents along or in combination with inhibitors of the enzyme poly ADP ribose polymerase (PARP) is an area of active research, especially among TNBC patients who also carry germline mutations in *BRCA1* or *BRCA2*.

Newer Agents

Several newer agents are in development and undergoing early phase clinical trial testing. Novel taxoids such as larotaxel, cabazitaxel and tesetaxel which may have activity in taxane resistant patients are undergoing phase II trials (172–175). Etirinotecan pegol (NKTR-102) is a topoisomerase I inhibitor-polymer conjugate that has shown activity in anthracycline-taxane and anthracycline-taxane plus capecitabine pretreated MBC including those with triple-negative disease (176). Liposomal cisplatin is a nontoxic form of cisplatin and its combination with vinorelbine in the first-line treatment of MBC resulted in a 53% response rate, a clinical benefit response of 90% and TTP of 8 months (177). Side effects included nausea and vomiting (14%), anemia (11%), and neutropenia (44%), but there were no neuropathy or nephrotoxicity events.

Summary on Chemotherapy Options (Single Agent and Combinations)

Sequential single agents may have lower response rates but also less toxicity and no compromise on OS when compared to combination chemotherapy. They are most appropriate for frail or elderly patients, or those with more indolent tumors. Anthracyclines and taxanes are the most active agents and are usually utilized alternately as first or second-line regimens for metastatic disease, depending on previous chemotherapy exposure in the adjuvant setting. However, with the wider use of anthracyclines and taxanes in the adjuvant and neoadjuvant setting, alternative agents need to be sought. Other active agents which are used include vinorelbine, gemcitabine, eribulin, and ixabepilone. Oral capecitabine is also a convenient oral formulation with a tolerable side effect profile. However regional differences in fluoropyrimidine tolerability exist, with more toxicities reported in the U.S. compared to Asian and European populations (178). This could be due to a possibly higher dietary folate intake in the U.S. or intrinsic genetic polymorphisms.

Combination therapy with its attendant higher response rates and better TTP may be more appropriate for symptomatic patients or for those with a visceral crisis, but at the cost of greater toxicity. In addition, its higher response rates do not translate into a superior survival outcome. A further disadvantage is that upon tumor progression, the disease is presumed to be resistant to both agents thus reducing the number of active agents available for use subsequently.

Although regulatory approvals consider OS as the gold standard, few phase III trials have the ability to detect OS differences especially in the first-line setting. Crossovers or subsequent therapies with newer more effective agents may attenuate OS differences. Few studies in the past have incorporated a crossover plan in their analysis and those that did failed to show an improvement in TTP or OS.

The recommendation is to use combination therapy for more aggressive disease and bulky visceral involvement, especially for those patients with a good performance status and minimal comorbidities. None of the combination regimens are established as standard first-line agents. Anthracyclines and taxanes-based combinations are the most commonly used although the former is limited by cumulative cardiotoxicity depending on prior exposure. Common anthracycline regimens include doxorubicin/cyclophosphamide, epirubicin/cyclophosphamide, doxorubicin/cyclophosphamide/fluorouracil, or epirubicin/cyclophosphamide/fluorouracil. Anthracycline/taxane combinations are not often used due to their significant hematologic toxicity and the lack of survival advantage over sequential single agents and other drug combinations. These other active combinations include the more commonly used anthracycline combinations, platinum/taxane, platinum/gemcitabine and platinum/vinorelbine regimens, cyclophosphamide/methotrexate/5-FU or others like capecitabine/docetaxel, gemcitabine/paclitaxel and ixabepilone/capecitabine which are less commonly utilized.

TRIPLE-NEGATIVE DISEASE

TNBC accounts for 6% to 28% of breast cancers (179). It possesses distinct epidemiological, histological, and clinical behavior features. Its prevalence is significantly higher among premenopausal women of African American or Hispanic descent, occurs at a younger age, and has a poorer survival when compared to other breast cancer subtypes (180,181). The risk factors are younger age (<26 years) at first full-term pregnancy, higher parity, absence of (or shorter duration of) breast-feeding, lower number of breast-fed children, younger age at menarche, use of medications to suppress lactation and high BMI (181,182). TNBCs are known to have an early recurrence peak within the first 3 years after diagnosis followed by a sharp decrease in subsequent years with virtually no relapse after 8 years (183). In a retrospective analysis, a greater proportion of TNBCs had visceral metastases as the site of first recurrence within the first 5 years compared to other subtypes of breast cancer (HR 4.0, 95% CI, 2.7–5.9; $p < .0001$) (184). However with longer follow-up, the subset of patients with ER-positive breast cancer (proliferative subset) had the same incidence of visceral metastases as TNBC (185). It seems to have a predilection for the lung and brain and less for the bone, which may be due to its propensity for hematogenous rather than lymphatic spread (186).

Triple-negative metastatic disease has a shorter median survival of 7 to 13 months with a limited duration of response to successive lines of chemotherapy of about 12 weeks to first-line, 9 weeks to second-line, and 4 weeks to third-line therapy (187). The poor prognosis of TNBC is independent of tumor grade, lymph node status, tumor size, and treatment (188). The majority of TNBCs are invasive ductal carcinomas; the less common histological subtypes include medullary, adenoid cystic, and metaplastic cancers. TNBCs can include other molecular subtypes that are difficult to characterize using standard markers available in clinical practice, such as claudin-low tumors, the interferon-rich, and the normal-breast-like subgroup (189). The risks for

TNBCs as a whole cannot be generalized to certain subtypes which may have inherently more favorable outcomes such as adenoid cystic or medullary carcinomas (190,191).

The definition of TNBC hinges on IHC-based negativity of estrogen, progesterone, and HER2 receptors. About 65% to 85% of TNBCs are of the basal-like subtype, the remaining of which includes a subset of poorly differentiated, highly proliferative breast cancer phenotype. Some 23% of basal-like cancers do not have the triple-negative (TN) phenotype, while about 30% of TNBC lack a basal phenotype (192). Basal-like breast cancers have no standard panel of IHC markers limiting their applicability in clinical practice. While IHC markers like ER/PR/HER2-negativity, presence of CK5/6, CK14, CK17, EGFR, and C-kit cave been used to try to identify the basal subtype, the reconciliation between phenotypes described based on microarray studies and those able to be defined using standard IHC assays in clinic remain suboptimal (193). Consequently, while most TNBCs appear to have a worse clinical outcome, despite greater initial responsiveness to chemotherapy, it remains not possible in most cases in usual clinical practice to identify the small subset of patients who on occasion present with a more indolent course.

Platinums

Treatment of TNBC is challenging due to the lack of standardized therapies. Approximately 70% to 90% of *BRCA1*-associated tumors have a TN and/or basal phenotype (194). In vitro studies of *BRCA1*-associated breast cancers have shown sensitivity to mitomycin-C (195), and platinum drugs (196); agents that cause interstrand cross-links, etoposide and bleomycin that cause double-strand breaks, whereas resistance to mitotic-spindle poisons such as taxanes and vinca alkaloids have been reported (197).

Small studies that did not select patients for triple-negativity showed single-agent platinum activity of 42% to 54% in MBC, but response rates were even lower at 0% to 9% for those who were pretreated (198). Platinum agents bind directly to DNA, forming DNA adducts leading to inter- and intra-strand crosslinks and resulting double-strand breaks (199). The *BRCA1* gene maintains genomic stability by promoting repair of these DNA double-strand breaks, particularly at the arrested replications forks (200). In preclinical models, cells with *BRCA1* mutations are unable to repair platinum-induced DNA damage and are thus postulated to be more susceptible to these agents (201). Two percent of breast cancers may be *BRCA1*-positive, whereas it may be as high as 10% with TNBCs (202). In addition to decreased *BRCA1* expression conferring subsets of TNBCs with more sensitivity to platinum agents, epigenetic alterations in *BRCA1* may also demonstrate this increased sensitivity (203).

The activity of platinum agents in *BRCA1*-mutant TNBCs is best observed in the neoadjuvant setting. High pathologic complete response rates of 70% to 90% have been observed when using cisplatin monotherapy for *BRCA1* mutants in several small neoadjuvant studies (204–206). A retrospective analysis of the clinical outcomes in Korean patients with metastatic breast cancer who received platinum-containing chemotherapy as first- or second-line treatment, focusing on the TN phenotype, found that the ORR of the TN phenotype was 38.8% and the disease control rate was 67.2%, which did not show statistical difference from those of other phenotypes (207). However, TN group showed shorter OS after platinum-containing chemotherapy (p = .005) than other phenotypes of breast cancers. Furthermore, OS from the relapse of TN group was poorer than others (p = .002).

A smaller French retrospective analysis (n = 143) of MBC patients treated with platinum-based chemotherapy reported a higher response rate for the TN subgroup versus the non-TNBC group (33.3% vs. 22%), but there was no difference in PFS and OS (208). A small retrospective study (n = 36) specifically examining cisplatin/gemcitabine chemotherapy in MBC (17 TNBC, 19 non-TNBC) reported a higher median PFS (5.3 months vs. 1.7 months; p = .058) for the TN subgroup, with a reduction of 47% in rate of progression for the TN compared to the non-TN patients (HR 0.53; p = .071) after adjusting for age, race, and menopause status (209).

A small trial (n = 15) using cisplatin in MBC patients who had received between zero and two chemotherapy regimens including prior anthracycline exposure, reported impressive response rates of 72% (CR 46%, PR 26%) (210). Sirohi et al. examined patients from a prospectively maintained breast unit database treated with platinum-based chemotherapy in the neoadjuvant, adjuvant and metastatic setting (211). . The regimen administered in the advanced setting was mitomycin/vinblastine/cisplatin or carboplatin. The ORR (CR + PR) was higher for TN metastatic patients (41% [14 of 34, 95% CI, 25%–58%] versus 31% (38 of 121, 95% CI, 23%–40%; p = .3), the median PFS was significantly longer (6 months vs. 4 months; p = .05) although OS was not significantly different (11 months vs. 7 months; p = .1) (211). However, the superior RR was not confirmed in another retrospective study consisting of a TN MBC patient population receiving platinum/taxane chemotherapy, although the time to death and OS were similarly poorer (212).

Currently, there is no clear indication as to whether platinums demonstrate superiority compared to other chemotherapeutic agents in an unselected TN population. There is insufficient data to recommend its use over standard regimens in early lines of chemotherapy, except perhaps in *BRCA* mutation carriers. A U.K.-driven phase III TNBC trial for metastatic TNBCs comparing carboplatin versus docetaxel with crossover at progression should shed further light on the efficacy of platinums in this breast cancer subtype (NCT00532727). Potential biomarkers have been identified but have not gained clinical utility. A nonrandomized phase II study designed to evaluate carboplatin or ciplatin as first- or second-line therapy in metastatic TNBC and to also study the expression of p63/p73 as biomarkers of response has been done (213). Preliminary results have shown an overall RR rate of 30.2% including four complete responses. The median PFS was about 3 months and about a third remained on study for more than 6 mos.

Taxanes

The efficacy of taxanes in TNBCs has been demonstrated in the adjuvant setting in both retrospective and prospective trials (214,215). Hence, there is much interest in their specific use in the metastatic setting. In an exploratory retrospective subset analysis of the CALGB 9342 trial which tested three doses of paclitaxel 170 mg/m^2, 210 mg/m^2 and 250 mg/m^2 in MBC, the triple-negative tumors (n = 44) were not found to differ significantly in terms of RRs and TTF from other tumor subtypes (n = 92), although the OS was significantly reduced (8.7 months vs. 12.9 months; p = .008) (216). There have been some data suggesting resistance of *BRCA1* mutation carriers to docetaxel such as a retrospective study of 175 patients with MBC treated with docetaxel-based regimens and demonstrating 19 patients with primary resistance, of which five were *BRCA1* mutation carriers and were TN (217). A U.K.-based *BRCA*-trial similar to the TN trial comparing first-line carboplatin and docetaxel in MBC patients who are *BRCA* carriers is also underway and will be able to answer the question of whether *BRCA* mutations confer resistance to docetaxel.

Nab-paclitaxel may represent a more effective TN treatment option. Paclitaxel-albumin-bound particles were demonstrated to have a higher efficacy, less toxicity, shorter infusion schedules, and higher intracellular drug delivery across endothelial cells compared to paclitaxel (85). Caveolin-1 encodes a protein which is a component of the caveolar membranes responsible for transcytosis of nab-paclitaxel into tumor cells. Caveolin-1 was strongly associated with high grade tumors, ER-negativity, and expression of basal cytokeratins, p63 and p-cadherin. CAV1 and CAV2 expression is also significantly associated with the basal-like phenotype (218). However, the evidence comparing it against paclitaxel remain scarce.

Antitubulin Agents

Ixabepilone is a novel class of agents that bind to β-tubulin, promoting microtubule stabilization, and causing cell cycle arrest in the G2/M phase and apoptosis (219). It can overcome or circumvent primary mechanisms of resistance to taxanes such as MDR P-glycoprotein or mutations in the class III isoform of β-tubulin (220). A pooled analysis (n = 1,973) of two large phase III clinical trials comparing ixabepilone/capecitabine with capecitabine in patients with MBC either resistant to (BMS 046) or pretreated with anthracyclines and taxanes (BMS 048) demonstrated increases in PFS in the combination compared to capecitabine arm (4.2 months vs. 1.7 months) and ORR (31% vs. 15%), with a trend to improved OS (10.3 months vs. 9 months) in the TN population (n = 443) (221). Although the ORR and PFS for the capecitabine arm in the overall population was 25% and 4.2 months respectively, the TNBC subgroup showed only a 15% ORR and 1.7 months PFS in those receiving capecitabine only.

EGFR Inhibitors

Currently, studies are focusing on the role of cytotoxics in combination with targeted therapies. TNBCs and basal-like breast cancers express EGFR in up to 72%, although activating mutations are rare (222). EGFR monoclonal antibody inhibitors have been explored given the relatively high expression of EGFR in this setting but have yet to gain a foothold in the therapeutic armamentarium.

Cetuximab has low activity as a single agent and shows only modest efficacy with chemotherapy. Cetuximab/carboplatin versus cetuximab alone has shown objective response rates of 18% versus 6%, and clinical benefit response rates (partial response or stable disease for ≥6 months) of 27% versus 10% in the Translational Breast Cancer Research Consortium (TBCRC) 001 multicenter randomized phase II study (n = 102) (223). The combination was deemed worthy of further evaluation. However notably, this was essentially a comparison of an anti-EGFR drug with or without carboplatin. The treatment effects could have been a reflection of the lack of a platinum rather than the presence of cetuximab per se.

A larger phase II study BALI-1 (n = 173) compared cisplatin/cetuximab versus cisplatin with conversion to cetuximab/cisplatin upon progression in TN MBCs who received less than one prior chemotherapy regimen (224). The best ORR was 20% (95% CI, 13.1%–28.5%; p = .5 for testing ORR >20%), with cetuximab/cisplatin and 10.3% (95% CI, 3.9%–21.2%), with cisplatin (OR 2.126, 95% CI, 0.809–5.591; p = .11). The median PFS was improved with the addition of cetuximab (3.7 months vs. 1.5 months, HR 0.675; p = .032), although it did not meet prespecified end points for significance. Grade 3 and 4 AEs occurring in more than 5% of patients in either arm included acne-like rash, neutropenia, fatigue, and dyspnea. In a subset of the U.S. Oncology 225200 trial, carboplatin/irinotecan and/or cetuximab (n = 78) showed a higher ORR (49% vs. 30%) but minimal difference in PFS (5.1 months vs. 4.7 months) with the cetuximab-containing arm (225).

The combination of ixabepilone with or without cetuximab as first-line treatment for TN locally advanced or MBC is currently being investigated in a randomized phase II trial (NCT00633464). Other EGFR inhibitors are also being evaluated in TNBCs such as panitumumab (NCT00894504) and erlotinib (NCT00739063), the latter trial being terminated because of poor accrual.

The evidence for EGFR playing a crucial role in TNBC oncogenesis has not been strong so far. Perhaps multiple downstream and parallel signaling pathways after EGFR activation may require multitargeted therapeutics. Samples from patients enrolled in two trials outlined above are currently being used to evaluate biomarkers of response (223,225,226).

PARP Inhibitors

PARPs constitute a large family of 18 proteins, in which PARP1, the founding member, and PARP2 activity are involved in single-stranded DNA base excision repair and replication fork repair by homologous recombination (227,228). PARP1 is also involved in histone modification and chromatin remodeling, allowing access of DNA repair proteins to the necessary sites (229). DNA repair is done via homologous recombination in normal cells, a process in which *BRCA* is integral. Cells that are deficient in *BRCA1* or *BRCA2* are more dependent on PARP1 to maintain genomic stability and hence the inhibition of PARP is potentially lethal.

PARP inhibition is likely to be highly specific for tumors that are deficient in *BRCA1* or *BRCA2* (230,231), while adding chemotherapy to PARP inhibitors may improve the efficacy in non-*BRCA* forms of TNBCs (232). In a proof-of-concept clinical trial, olaparib was shown to be effective in *BRCA1* and *BRCA2* mutation carriers, with almost doubling of the ORR at the oral 400 mg bid compared to the 100 mg bid dose (41% vs. 22%), prolongation of the median PFS (5.7 months vs. 3.8 months) with well-tolerated side effects of nausea, vomiting, fatigue, and anemia, although 30% required dose reductions or delays (233). Olaparib 200 mg bid was reported to be too myelosuppressive when used together with weekly paclitaxel 90 mg/m^2 for 3 out of 4 weeks despite growth factor support (234).

Iniparib is not a bona fide PARP inhibitor (235). It has been proposed to act via nonselective modification of various proteins by nonspecific adducts which alters stability, activity, and/or localization of the proteins resulting in a cellular insult capable of inducing various cellular responses including apoptosis, stress, cell-cycle perturbation, or DNA damage (235). An open-label phase II study (n = 123) compared carboplatin (C) AUC2 on days 1 and 8, and gemcitabine (G) 1,000 mg/m^2 on days 1 and 8, with or without iniparib (I) 5.6 mg/kg on days 1, 4, 8, 11 administered in 21-day cycles, in patients with metastatic TNBC who had received not more than two prior lines of treatment for metastatic disease (236). They found that the primary objective clinical benefit response (CR/PR/SD for ≥6 months) improved from 34% to 56% (p = .01) (236). Additional end points also improved such as overall response (52% vs. 32%; p = .02), median PFS (5.9 months vs. 3.6 months, HR 0.59; p = .01) and OS (12.3 months vs. 7.7 months, HR 0.57; p = .01). There was no significant difference in side effects such as neutropenia, thrombocytopenia, anemia, fatigue, and increased alanine aminotransferase between the groups. However, this was not confirmed in a larger phase III study (n = 519) with a similar TN patient population which did not meet the prespecified criteria for the co-primary end points of PFS (HR 0.79; p = .027) and OS (HR 0.88;

p = .28) (237). Some 152 of 258 GC pts (59%) crossed over to receive GCI following disease progression. Exploratory analysis showed that PFS and OS benefit was restricted to the prespecified stratification subgroup receiving the treatment in the second- and third-line setting compared to the first-line setting. This could be hypothesized to be due to the imbalance in baseline characteristics, increased disease severity for the first-line therapy subgroup, and exposure to taxanes in the first-line setting which could have caused increased susceptibility to DNA damaging agents thereafter. In multivariate analysis, the difference in treatment effects between the two exploratory first-line versus second-line and third-line subgroups were less pronounced. The toxicity profile was similar to that in the phase II study. We have a relatively limited knowledge of the mechanism of action of iniparib currently which compounds the issue.

The oral PARP1 inhibitor veliparib (ABT-888) is another drug that has shown some activity in *BRCA1* and *BRCA2* mutation carriers when given in combination with temozolomide, the main toxicity observed being thrombocytopenia managed by dose reduction (238). The ORR observed was 37.5%, the clinical benefit rate was 62.5% and the median PFS was 5.5 months in *BRCA*-carriers (as compared to 1.8 months in noncarriers).

Although PARP inhibitors have demonstrated impressive results in the treatment of *BRCA*-associated breast cancers, its effectiveness in the population of TNBCs without *BRCA* mutations is still lacking. An intriguing issue is whether PARP inhibitors are also beneficial in other non-triple negative subtypes. Genomic instability and defects in DNA repair mechanisms are not only restricted to TNBCs (239). A higher PARP expression has been detected in non-TN subtypes and linked to increased pathologic complete response rates to neoadjuvant taxane-anthracyclines regimens (240). Homologous DNA recombination impairment caused by PTEN deficiency has also been reported to cause increased susceptibility to PARP inhibition both *in vitro* and *in vivo* (241), and PTEN mutation or loss is present in about 50% of breast cancers (242). PARP inhibitors lack robust biomarkers to guide their usage apart from *BRCA* mutations. We have yet to refine their use with optimal chemotherapy regimens. More translational work will need to be done in this area to evaluate their clinical utility.

Src Inhibitors

Expression of the tyrosine kinase c-Src is frequently increased in breast cancer and promotes cellular motility and invasion (243). Current data on single-agent dasatinib, a dual abl/Src kinase inhibitor reports poor ORR 4.7% in heavily pretreated TNBCs, with a median PFS of 8.3 weeks (95% CI, 7.3–15.3) (244).

Androgen Receptor Targets

A subset of ER-negative tumors with paradoxical expression of genes known to be either direct targets of ER, responsive to estrogen, or typically expressed in ER-positive breast cancers was identified (245). *In vitro* studies demonstrated a proliferative response to androgens in an androgen receptor (AR) dependent and ER-independent manner (245). This particular subset of breast cancers could potentially be targeted by inhibitors of the androgen signaling pathway. In clinical practice, about 10% of TNBC patients have AR-positivity, which would represent about 2% of the entire breast cancer cohort assuming a TNBC rate of 20% (246). Hence, this drug would potentially cater only to a very small group of patients. A phase II feasibility study is currently underway (NCT00468715) evaluating the utility of bicalutamide, a nonsteroidal anti-androgen, in ER/PR-negative and AR-positive MBC patients.

Summary on Treatment in Triple-Negative Disease

Chemotherapy remains the backbone of treatment for TNBCs due to the lack of specific targeted therapies. In the St. Gallen 2011 and NCCN (version 3.2012) guidelines, there were no specific recommendations on the type of agents to use in unselected TNBCs (247). There are also no specific drug recommendations in this subpopulation by ASCO or ESMO to date. The profile of disease aggressiveness, young age, visceral metastases, and TN status seems to favor combination over single-agent chemotherapy. Anthracyclines (i.e., doxorubicin, epirubicin, and PLD) and taxanes (i.e., paclitaxel, docetaxel, and albumin-bound paclitaxel) remain important agents in this setting as in ER-positive breast cancers. However, in patients with visceral relapse within one year after anthracycline/taxane chemotherapy, other alternative agents should be used. These include the antimetabolites (i.e., capecitabine and gemcitabine) and microtubule inhibitors and/or stabilizers (i.e., vinorelbine, eribulin, and ixabepilone). Combination regimens that have activity include carboplatin/gemcitabine, platinum/vinorelbine, ixabepilone/capecitabine, capecitabine/vinorelbine, paclitaxel/gemcitabine, and docetaxel/capecitabine. As there is no standard first-line agent or regimen, therapy should be individualized for each patient and enrollment into clinical trials is encouraged. Although they demonstrate a better response to chemotherapy compared to ER-positive subtypes, the ultimate prognosis remains poor. Research into other modalities of treatment involving various tyrosine kinase inhibitors and inhibitors of FGFR receptors, mTOR, PI3K and MEK are ongoing.

CHEMOTHERAPY AFTER LOCAL THERAPY IN OLIGOMETASTATIC DISEASE

Oligometastatic disease is characterized by solitary or a few detectable metastatic lesions limited to a single organ such as the lung, liver, or bone. This population of more favorable stage IV disease is estimated to be present in about 1% to 10% of newly diagnosed MBC patients (248). For such individuals, combined local and systemic therapies with surgery, radiotherapy, regional, and systemic chemotherapy may result in long-term survival.

Assessment of the suitability of such treatment modalities depends on the biology of the tumor such as its disease-free interval, its extent of disease involvement, the feasibility of complete resection of the metastases, the performance status of the patient and the potential risks involved. Patients being considered for these more aggressive local treatment options should undergo a thorough restaging evaluation.

Local treatment options in isolated breast cancer metastases most commonly refer to resection, although other less common options such as radiotherapy, radiofrequency ablation or cryotherapy have been used. Resection of isolated metastases can also aid in diagnosing a possible new second primary or re-assessing the ER or cerbB2 status.

Isolated lung metastases occur in 10% to 20% of MBCs (249). The International Registry of Lung Metastases which has the largest dataset reports that in 467 breast cancer patients, complete lung metastasectomy was possible in 84% and led to a median survival of 37 months (5-year OS 38%; 10-year OS 22%) (250). Good prognostic factors included a disease-free interval of more than 36 months, single metastases and completeness of resection.

Approximately 5% of patients have metastases confined to the liver with no extrahepatic disease (251). The resection of liver metastases in breast cancer is much less recognized, with median survival ranging from 14.5 months to 63 months and 5-year OS 14% to 61% (252). In a recent systematic review of 19 studies consisting of 553 patients who had undergone hepatectomy for liver metastases, the median survival was 40 months with a 5-year survival of 40% (253). Other alternative local therapies such as radiofrequency ablation or transarterial chemoembolization have only limited data (254,255).

There is a very limited role for resection of bony sites, and this distribution is usually associated with an indolent course and good response to systemic agents such as endocrine therapy if ER-positive. The first treatment choice for bone metastases which are not at risk of a fracture is systemic therapy.

Many patients in various studies have been treated with some form of systemic therapy either prior to or after local therapy, and there is some evidence albeit limited that this results in delayed relapse or improved survival (248,256,257). It is not clear if these highly selected patients had a better tumor biology and would have had a good outcome either way. The largest dataset for chemotherapy after local treatment consisting of either surgery or irradiation for single metastatic disease comes from the MD Anderson Cancer Center where a series of three doxorubicin-based chemotherapy trials (n = 259) and a docetaxel-based trial (n = 26) comprising of 285 stage IV NED patients altogether were evaluated retrospectively (248). For the doxorubicin-based trials, the median follow-up was 87 months and the 20-year DFS and OS reached 26% for both which demonstrated that long-term survival was achievable in selected cases. The first isolated recurrence was locoregional in 80% of cases, but of the 53 patients that had an initial distant site of recurrence 23% achieved long-term disease control. Median follow-up for the docetaxel trial was 44 months and the 5-year DFS and OS were 34% and 59% respectively. At recurrence, 54% had distant site involvement and this subgroup has less favorable results with the six deaths at the last follow-up all involving distant recurrences. The historical control group utilized in this study showed a 5-year DFS and OS rate of 7% and 36% respectively, although it had its shortcomings such as a higher number of ER-unknown status patients and a lack of c-erbB2 testing.

The overall data suggest that after local treatment of limited locally recurrent or metastatic disease, followed by "adjuvant" systemic treatment, survival time can surpass the normally expected median survival of 2 to 3 years for MBC. However, available data are mostly retrospective with relatively small patient numbers, the reported data often refer to a highly select group of patients with favorable prognostic factors and no randomized trials have been done comparing them to surgically untreated patients. Patients who are suitable for this therapeutic strategy may only represent 1% to 3% of the total MBC population. Hence clinical trials with adequate statistical power are difficult to achieve but much needed supporting the rationale of a more aggressive multidisciplinary approach for these patients. The necessity of chemotherapy after isolated locoregional recurrence has been treated by surgery or radiotherapy is currently being investigated in a joint study by the International Breast Cancer Study Group (IBCSG), the National Surgical Adjuvant Breast and Bowel Project (NSABP), and the Breast International Group (BIG) (258).

Bevacizumab

Bevacizumab is a recombinant humanized monoclonal antibody derived by incorporating ~7% murine VEGF-binding sequences into a human IgG framework (259). It inhibits VEGF-induced endothelial cell proliferation and migration resulting in slower tumor growth. It also decreases interstitial fluid pressure in tumors, improving drug delivery and penetration. Its accelerated FDA approval for breast cancer in 2008 was supported by the observed PFS benefit demonstrated in the interim analysis of the E2100 trial comparing first-line bevacizumab/paclitaxel versus paclitaxel (260). However, there was a requirement for verification of bevacizumab effect on PFS and OS from other trials like Avastin and Docetaxel (AVADO) and Regimens in Bevacizumab for Breast Oncology (RIBBOn)-1.

The pivotal phase III E2100 trial (n = 722) enrolled locally recurrent or MBC patients, majority of which had HER2-negative disease (96%), to receive paclitaxel 90 mg/m^2 weekly on days 1, 8, and 15 +/– bevacizumab 10 mg/kg on days 1 and 15 in 4-week cycles until PD (260). Those who had HER2-positive disease were required to have received trastuzumab. Patients who had received taxane-based adjuvant therapy (about 17% and 15% in the combination and taxane-only arms respectively) were required to have had a disease-free interval of at least 12 months after completion of taxane therapy. There was a significantly longer PFS in the combination arm (11.8 months vs. 5.9 months, HR 0.60; $p < .001$), and an increased ORR (36.9% vs. 21.2%; $p < .001$). The OS rate, however, was similar in the two arms (median 26.7 vs. 25.2 months, HR 0.88; $p = .16$). Stratification factors included disease-free interval (≤24 months vs. >24 months), number of metastatic sites (<3 vs. ≥3), previous adjuvant chemotherapy (yes vs. no), and ER status (positive vs. negative vs. unknown). A benefit in PFS was seen irrespective of the predefined subgroups. The HR for PFS in the TN subgroup was 0.53 which was comparable to that of the overall study population which was 0.6. Notably, those negative for ER and PR (majority of whom were HER2-negative, <2% in each arm were HER2-positive) had a PFS of only 4.6 months on paclitaxel alone as compared to 8 months for those who were ER/PR-positive which reflects the intrinsic poor prognosis of ER-negative disease. The addition of bevacizumab had little effect on the frequency or severity of expected paclitaxel-related toxic effects. Grade 3 or 4 neuropathy (23.5% vs. 17.7%; $p = .05$), hypertension (14.8% vs. 0; $p < .001$), proteinuria (3.5% vs. 0; $p < .001$), headache (2.2% vs. 0%; $p < .001$), cerebrovascular ischemia (1.9% vs. 0%; $p = .02$), infection (9.3% vs. 2.9%; $p < .001$), and fatigue (9.1% vs. 4.9%; $p = .04$) were more frequent in the combination group. The increased incidence of peripheral sensory neuropathy in the combination arm was reflective of the longer duration and increased cumulative dose of paclitaxel. A criticism was the lack of an independent radiological review and hence 649 (89.9%) of the patients had at least one image submitted for review after the study was completed upon the request of the FDA (261). The results were confirmed with a 52% lower risk of progression or death, and an improvement in PFS (11.3 months vs. 5.8 months) which was similar to that in the study. There were no significant differences in QOL between the groups.

The results of the AVADO and RIBBOn-1 trials confirmed those of E2100, albeit at a lower magnitude. The AVADO trial (n = 736) was a three-armed placebo-controlled study testing docetaxel 100 mg/m^2 for nine 3-weekly cycles with or without bevacizumab at two doses of 7.5 mg/kg or 15 mg/kg every 3 weeks (262). Those exposed to adjuvant taxanes (bevacizumab 15 mg/kg 17%, bevacizumab 7.5 mg/kg 15%, placebo 15%) had to have a lapse of at least 12 months before. At a median follow-up of 25 months, the median PFS (primary end point) for bevacizumab 7.5 mg/kg versus placebo was 9 months versus 8.1 months respectively (HR 0.8; $p = .045$), and for bevacizumab 15 mg/mg versus placebo arms, a significant difference of 10 months versus 8.1 months

(HR 0.67; $p < .001$) in stratified analysis. Response rates were also higher in the bevacizumb-containing arms compared to placebo (placebo 46%, bevacizumab 7.5 mg/kg 55% [$p = .07$]; bevacizumab 15 mg/kg 64% [$p < .001$]). The trial was not powered to detect a survival difference and because crossover to bevacizumab upon progression was allowed, it is unlikely that a survival benefit will be seen. The trial was also not designed to detect a statistically significant difference between the two bevacizumab-containing arms. The combination of bevacizumab with docetaxel had no major impact on the toxicity profile of docetaxel. Most AEs occurred at similar incidence in both bevacizumab arms, although epistaxis, hypertension, and proteinuria were more frequent in the bevacizumab 15 mg/kg arm. The double-blinded placebo-controlled nature of the AVADO study was likely to have reduced reporting bias compared to the E2100 study which had higher incidences of hypertension and proteinuria. Patients treated in the combination arm reported better QOL scores. A subanalysis of those ≥65 years old revealed a similar magnitude of benefit to the overall study population and bevacizumab was found to be well-tolerated (263). Notably, the ORR in the docetaxel arm (46%) was almost double that in the paclitaxel arm (21%) of E2100 and bevacizumab benefit may have been lessened in the presence of a more active agent. Prolonged weekly paclitaxel is tolerated for longer periods compared to 3-weekly docetaxel, leading to discontinuation at 4.9 months for the docetaxel control arm and 5.1 months for the paclitaxel control arm in the E2100 study. For the combination arm, weekly paclitaxel was discontinued at 7.1 months for the E2100 trial and docetaxel was discontinued at 5.1 months and 5.5 months in the lower and higher dose bevacizumab arms of the AVADO study. Hence, in general weekly paclitaxel is easier to administer.

In the RIBBOn-1 trial, chemotherapy agents by physician choice (capecitabine 2,000 mg/m^2 for 14 days, nab-paclitxel 260 mg/m^2, docetaxel 75 mg/m^2 or 100 mg/m^2, or doxorubicin or epirubicin combinations) in combination with bevacizumab or placebo as first-line MBC treatment were evaluated in 1,237 patients randomized in a 2:1 ratio (264). The primary objective median PFS was longer for each bevacizumab combination (capecitabine cohort: increased from 5.7 months to 8.6 months, HR 0.69; $p < .001$, and taxane/anthracycline cohort: increased from 8.0 months to 9.2 months, HR 0.64; $p < .001$), with a superior ORR for the group treated with bevacizumab. There was no significant difference in OS. Approximately 70% of patients received another study treatment after discontinuation of study treatment, with about 50% of patients treated with placebo plus chemotherapy crossing over to the bevacizumab combination therapy at time of first progression.

A meta-analysis of the above three trials in the first-line setting showed a PFS hazard ratio of 0.64 (95%CI 0.57–0.71) and an OS hazard ratio of 0.97 (95%CI 0.86–1.08), with similar outcomes for the TN population (265). Of note, the crossover to bevacizumab-containing regimens on tumor progression may have masked the effect on OS.

An analysis of the known AEs in the E2100, AVADO, and RIBBOn-1 studies found that hypertension ranged from 2.8% to 16% for the bevacizumab-containing arms and 0% to 2% for the placebo arms (266). With the exception of hypertension, bevacizumab-related grade 3–5 adverse effects occurred in <5% of patients (266).

The Phase IV Avastin THErapy for advaNced breAst cancer (ATHENA) trial (n = 2,251) in HER2-negative locally recurrent or MBC or HER2-positive disease progressing after trastuzumab therapy assessed the efficacy and safety of bevacizumab with taxane (68%) or other nonanthracycline chemotherapy according to the physicians' standard of care (267). The most frequent grade ≥3 AE was neutropenia (5.4%). Grade ≥3 AEs previously associated with bevacizumab included hypertension (4.4%), arterial/venous thromboembolism (3.2%), proteinuria (1.7%), and bleeding (1.4%). Median TTP was 9.5 months (95% CI 9.1–9.9). The TTP was more favorable when bevacizumab was combined with taxanes (11 months) compared with nontaxane drugs like capecitabine or vinorelbine (7 months for both). An analysis of those ≥70 years old (median OS 20.3 months, 1-year OS 68%) and in the TN cohort (median OS 18.3 months, 1-year OS 60%) showed that the combination of bevacizumab with first-line chemotherapy was active and feasible (268). An updated analysis (median follow-up 20.1 months; n = 2,264) showed that the median TTP was 9.7 months (95% CI, 9.4–10.1 months), median OS was 25.2 months (95% CI, 24.0–26.3 months), and 1-year survival 72.7% in the overall population in the ATHENA trial (269).

Bevacizumab has also been studied as second-line therapy and beyond. The RIBBOn-2 phase III trial (n = 684) assessed the efficacy and safety of second-line bevacizumab 10 mg/kg every 2 weeks or 15 mg/kg every 3 weeks, in combination with nonanthracycline-based chemotherapy in HER2-negative MBC (270). Patients were randomly assigned 2:1 to chemotherapy (i.e., capecitabine, docetaxel, paclitaxel, nab-paclitaxel, vinorelbine, or gemcitabine) plus bevacizumab or chemotherapy plus placebo; the primary end point being PFS. The PFS was superior with bevacizumab (7.2 months vs. 5.1 months, HR 0.78; $p = .0072$), with an increased ORR (39.5% vs. 29.6%; $p = .0193$), with no statistically significant difference in OS. The safety profile was comparable with other studies. The most common grade 3 AEs related to bevacizumab treatment were hypertension (9.0%) and proteinuria (3.1%), resulting in higher rates of discontinuation in the bevacizumab arm compared with placebo (13.3% vs. 7.2%).

The AVF2119 study examined its role in women with heavily pretreated MBC (271). The subjects were refractory to both an anthracycline and a taxane in either the metastatic or adjuvant settings, and had received at least one, but no more than two, prior chemotherapy regimens for metastatic disease. Some 462 patients received bevacizumab 15 mg/kg every 3 weeks plus capecitabine 2,500 mg/m^2 in two divided doses for 2 of every 3 weeks or capecitabine monotherapy. About 80% in each arm received one to two prior chemotherapy regimens for MBC, and about 26% and 20% were HER2-positive in the bevacizumab-containing and capecitabine only arms respectively. The PFS (primary end point; 4.86 months vs. 4.17 months, HR 0.98; $p = .857$) and OS (15.1 months vs. 14.5 months) were statistically similar, although ORR was significantly higher in the combination arm (19.8% vs. 9.1%; $p = .001$). There were no differences between side effects like diarrhea, hand-foot syndrome, thromboembolic events, or serious bleeds, although hypertension was more common with bevacizumab. The widely accepted explanation for this lack of observed benefit was the more heterogenous patient population and the late disease stage when there would be more numerous and redundant dysregulated angiogenic pathways. It is also possible that capecitabine may have been continued for a longer period on the RIBBOn trials due to the lower dose of capecitabine utilized although we do not have comparative data from the AVF2119g and RIBBOn-2 studies.

Nonetheless in November 2011, the FDA revoked the licensed indication of bevacizumab to treat MBC as the magnitude of PFS from the E2100 was not reproduced in confirmatory studies (AVADO, RIBBOn-1), no study demonstrated an improved OS advantage, and the benefit-to-risk ratio did not favor bevacizumab taking into account its toxicity

profile such as hypertension, hemorrhage, and GI perforation. The addition of bevacizumab to paclitaxel in MBC patients is also expensive given the clinical benefit in terms of quality-adjusted life years (QALYs) gained (272).

Currently several randomized phase III trials in the first-line HER2-negative MBC setting are ongoing in Europe including the TURANDOT (NCT00600340) study which has completed recruitment looking at capecitabine plus bevacizumab versus paclitaxel plus bevacizumab, an issue unanswered by the RIBBOn-1 study.

Preclinical studies have shown that long-term suppression of a single proangiogenic pathway like VEGF can lead to a "tumor escape" phenomenon whereby there is increased expression of alternative proangiogenic proteins such as bFGF or PIGF (273). However, a provocative theory of accelerated disease progression on cessation of bevacizumab causing the observed lack of OS advantage has not been borne out in a pooled analysis of five placebo-controlled clinical trials consisting of 4,205 patients with breast (AVADO trial), pancreatic, colorectal, and pancreatic cancers (274). The impact of first-line treatment on OS may also have been diluted by crossover to bevacizumab and other subsequent efficacious lines of therapy making it a less useful objective in an era of increasingly effective systemic treatment options. Indeed, the greatest benefit appears to be when bevacizumab is administered early on in the treatment of MBC such as the first-line setting.

So far, trials have been performed in otherwise unselected HER2-negative patients, perhaps obscuring a relatively responsive patient subset. We need a more rational patient selection including discovery and validation of tumor and patient-related biomarkers of response or resistance, so as to improve therapeutic responses and cost effectiveness.

CHEMOTHERAPY IN OLDER PATIENTS

Cancer care in older patients is further discussed in Chapter 84. Older patients are more likely to have a reduced life expectancy, less tolerance to physiologic stress, comorbidities, impaired organ function, reduced cognition and functional status, and sometimes inadequate social support which make chemotherapy administration in this patient group more challenging. While the population of older breast cancer patients is projected to increase substantially within the next two decades, data on chemotherapy for this group of patients with MBC remains scarce. Based on data collected from 2003 through 2007, 40% of patients with newly diagnosed breast cancer were ≥65 years, 20% were ≥75 years and 5% were ≥85 years; the median age of death from breast cancer being 68 years (275). There is no exact age cut-off that defines patients as "older" but physicians have arbitrarily often selected an age cut-off of 65. However, chronological age does not give always give an accurate reflection of the functional reserve and performance status of a patient. Knowledge of age appropriate treatments in this subgroup of patients is important because they may experience complications due to alterations in drug pharmacokinetics, polypharmacy and potential drug interactions, poor compliance with medications and need for dose reductions which may compromise efficacy. The important physiological alterations which affect drug delivery in this age group are altered body composition, decreased gastrointestinal tract absorption, altered liver metabolism of drugs, decreased renal function, lower bone marrow regeneration capacity, cardiac and other comorbidities, and a decline in neurological function (276). Based on current data, there is no specific regimen recommended as optimal for older patients but sequential single agents are still the best approach to preserve QOL and minimize toxicity.

Older age does not modify the survival benefit of chemotherapy in MBC (277), although toxicities such as myelosuppression, cardiotoxicity, mucositis, and diarrhea may be more pronounced. Doxorubicin monotherapy has been used in older patients with MBC although a decreased clearance has been found (278). Doxorubicin-induced cardiotoxicity is a definite concern in this population. The risk of anthracycline-induced cardiomyopathy is increased in those >70 years (279), although some retrospective data have shown that cardiopulmonary deaths were not more common in those >65 compared to those 50 to 64 (50). PLD at 60 m/m^2 6-weekly or 50 mg/m^2 4-weekly has been shown to have a reduced cardiotoxic effect and equivalent antitumor efficacy in this age group as in younger patients, although there was a reportedly higher incidence of hematological toxicity, anorexia, asthenia, and stomatitis with the 6-weekly schedule (280). No difference in toxicity was observed between the age groups with the 4-weekly schedule. The clearance of epirubicin in multi-agent regimens is decreased in elderly women, although weekly epirubicin 25 mg/m^2 has been studied in older patients and those with a poorer performance status and found to be active and well tolerated (281).

Weekly taxanes have been studied in older breast cancer population and have shown good activity and tolerability with reduced myelosuppression. Weekly paclitaxel 80 mg/m^2 had reportedly comparable efficacy and toxicity in older (≥65 years) and younger patients (<65 years), although the younger group were more heavily pretreated (282). The clearance of paclitaxel is diminished in elderly patients (283), but this does not seem to be the case for docetaxel, although neutropenia is more pronounced (284,285). Weekly docetaxel has been used as first or second-line therapy with RRs of about 30% to 35% (286,287). Fatigue appears to be the main limiting factor for both taxanes (285,288). Care must be taken as there is a potential for excess glucocorticoid toxicity. Nab-paclitaxel does not require glucocorticoid premedication but is much more costly and has potential neurologic toxicity.

The relative unpredictability and sometimes severe toxicity of the fluoropyrimidines remains a concern in this age group. Continuous IV 5-FU has decreased clearance in older patients but is seldom used in MBC. Oral formulations are ideal for these patients as these may minimize discomfort, shorten hospital visits, and have a smaller impact on activities of daily living. As such, the prodrug capecitabine remains an attractive option for older patients owing to its ease of administration, although compliance has to be emphasized. The standard capecitabine 2,500 mg/m^2 dose was observed to result in toxic deaths due to grade 4 diarrhea, but its lower dose at 2,000 mg/m^2 is a feasible alternative with equivalent efficacy (289). Care must be taken to monitor renal function when using this drug in this population. In a randomized phase II trial comparing capecitabine 1,225 mg/m^2 twice a day to IV CMF in women ≥55 years, capecitabine was better than CMF for RR (30% vs. 16%) and median TTP (4.1 months vs. 3 months), although survival was similar (19.6 months vs. 17.2 months) (27). The study was prematurely closed because of the superior clinical benefit with capecitabine. The median age of patients receiving capecitabine was 69 years and that for CMF was 70 years. Capecitabine side effects were mainly hand-foot syndrome and diarrhea, with 16% of patients necessitating stopping treatment because of toxicities, while CMF side effects were mainly gastrointestinal.

Vinorelbine is a viable well-tolerated option in older patients and has shown objective responses in 30% to 38% of patients (290–292). with a stable disease rate of 33% to 38% (291,292). Neutropenia and constipation appear to be

the most significant toxicities. Apart from its IV formulation, it also comes in oral tablets which eases administration in this population.

Gemcitabine monotherapy remains a viable and well-tolerated option for treatment of MBC in this population. However, a randomized phase III study studying the efficacy of first-line gemcitabine 1,200 mg/m^2 to epirubicin 35 mg/m^2 both given weekly in women aged ≥60 years (median 68 years) with MBC revealed that epirubicin was significantly better than gemcitabine with respect to RR (40.3% and 16.4%; $p < .001$), TTP (6.1 months and 3.4 months; $p = .0001$), and OS (19.1 and 11.8 months; $p = .0004$) (126). Neutropenia and thrombocytopenia were more common in the gemcitabine group. In the epirubicin group, about 17% of patients had

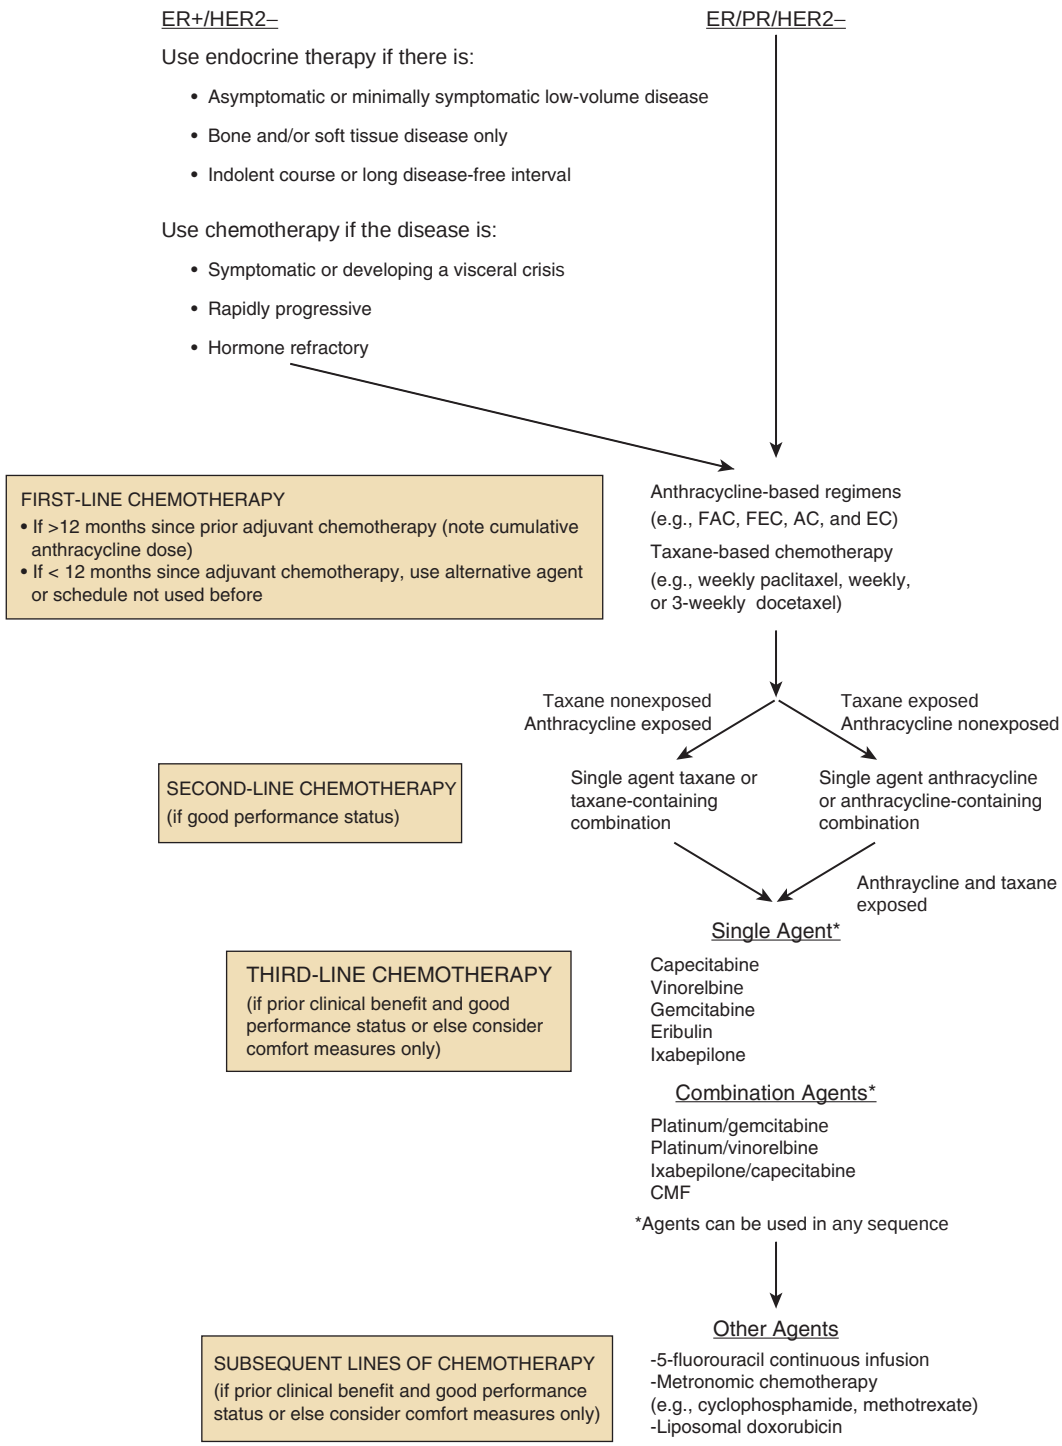

FIGURE 71-1 Decision algorithm for patients with ER/PR-positive, ERBB2-negative and triple-negative phenotypes. AC, doxorubicin, cyclophosphamide; EC, epirubicin, cyclophosphamide; ER, estrogen receptor; FAC, 5-fluorouracil, doxorubicin, cyclophosphamide; FEC, 5-fluurouracil, epirubicin, cyclophosphamide; CMF, cyclophosphamide, methotrexate, 5-fluorouracil; PR, progesterone receptor.

at least 10% decline in LVEF values from baseline. For those ≥70 years, mucositis and pulmonary toxicity occurred more frequently in the epirubicin and gemcitabine arms respectively. Of the 28 deaths, three were considered possibly or probably related to gemcitabine treatment.

For combination regimens, most studies have limitations such as small sample sizes, retrospective analyses and poor study design. A case-comparison study of patients with MBC in five clinical trials of the Piedmont Oncology Association comparing patients ≥70 years (n = 70), those aged 50 to 69 years (n = 60), and those younger than 40 years (n = 40) concluded that women aged ≥70 years or older were similar to their younger counterparts with respect to RRs, TTP, OS and toxicities (293). However, a 25% dose reduction for those ≥65 years was carried out for the first cycle in three of the five protocols.

The CMF dose has been reduced for those ≥65 years whereby the cyclophosphamide and methotrexate doses were modified based on creatinine clearance, and age was not found to affect the response rates in elderly patients using this modified CMF dose as compared to younger patients using standard dose CMF, although OS was worse in those >80 years (294).

In an older retrospective study of 1,011 patients treated between 1973 and 1984, doxorubicin-based combinations were found to yield a lower response rate, although TTP and OS were similar between those ≥65 years and 50 to 64 years (279). Notably, the hematologic toxicities were comparable between the two groups, but the dose intensity was lower for the older age compared to the younger patients. The toxicity and efficacy of the fluorouracil/epirubicin/cyclophosphamide combination was comparable in patients with MBC older or younger than 70 years (n = 20 each) in a retrospective study which studied chemotherapy-induced toxicity and therapeutic response of several different types advanced cancers (295). The oral vinorelbine/capecitabine combination as described above is an attractive option for elderly patients. The vinorelbine/gemcitabine combination has been shown to have serious toxicities (296).

Consensus opinion from the ASCO guidelines on the use of GCSF recommend using primary prophylaxis with CSF for patients aged >65 years even with regimens with febrile neutropenia rates of <20% (297). The use of primary prophylactic GCSF in those ≥65 years has been studied in the subanalysis of the NeuCup (Neulasta versus current practice neutropenia management) breast cancer trial and was found to reduce febrile neutropenia rates, febrile neutropenia-related hospitalizations, and dose reductions (298). However, chemotherapy dose-reduction in the palliative setting is potentially a simpler option that might circumvent the need for colony-stimulating support. The use of erythropoiesis-stimulating agents (ESAs) has been shown to result in increased mortality in a study of women receiving first-line chemotherapy for MBC (299). The increased mortality was due to breast cancer-related deaths as well as thrombotic/vascular events.

For elderly patients without life threatening or rapidly progressive disease, endocrine therapy is preferable. Chemotherapy can be considered once the tumor becomes endocrine refractory or as first line if the disease is very symptomatic or rapidly progressive.

IMMUNOTHERAPY TRIALS

Breast carcinomas are often infiltrated by inflammatory cells like macrophages and T lymphocytes. These inflammatory cells mediators represent an immune response against antigens expressed in cancer cells, and various studies have evaluated the expression of immune metagenes that may offer prognostic information in advanced disease (300). Vaccine-based studies have been explored for many years. In 2012, trials of monoclonal antibodies targeting antiprogrammed death receptors and ligands (PD-1 and PD-L1) were reported, and showed substantial antitumor activity in various solid tumors by modulating immune checkpoints via interference with inhibitory receptors on immune effector cells or their ligands (301,302). Trials are now exploring the clinical activity of these various antibody drugs against tumors that preferentially express the PD-1 ligand (PD-L1), including breast cancer.

CONCLUSION

A number of therapeutic advances have been made in the chemotherapy treatment of MBC in recent years. The advent of newer agents such as the epothilones and eribulin has enhanced our armamentarium of therapeutic options. However several unanswered questions still remain such as the optimal duration of chemotherapy, especially when combined with targeted therapy, the use of genetic profiling in personalising chemotherapy choices, and the identification of more effective treatment strategies for triple negative tumors. The choice of therapy for any particular patient is a complex individualized decision taking into account disease and patient-related characteristics. However with advancements in drug development, the natural history of MBC resembles more often that of a chronic disease process for which survival prolongation while preserving a reasonable QOL are goals of treatment. With a growing body of evidence for new agents and regimens, it is hoped that these may be expected to translate into improved patient outcomes in MBC.

MANAGEMENT SUMMARY (SEE FIG. 71-1)

- Upon clinical suspicion of metastatic disease, a full staging should be done with a CT scan of the thorax, abdomen, and pelvis; plus a bone scan; and imaging of the brain should there be any symptoms suggestive of brain metastases.
- Biopsy of a metastatic site should be considered whenever possible especially if it is easily accessible, to re-evaluate the ER, PR, and HER2-status.
- Consideration of the type of systemic therapy (endocrine therapy versus chemotherapy) should take into account tumor and patient-related factors such as ER-status, disease pace, extent and distribution, severity of symptoms, disease-free interval since previous adjuvant therapy, comorbidities, performance status, costs, and patient preferences. If the disease is HER2-positive, then anti-HER2 therapy should be used either in combination with chemotherapy (preferentially not with an anthracycline) or with endocrine therapy.
- Chemotherapy is the only option at present for those who have ER-negative disease, those who have progressed on hormonal therapy, and if there is extensive visceral disease, especially if it is symptomatic necessitating rapid therapeutic response. Anthracyclines and taxanes are the two most effective agents as first-line therapy although due consideration should be taken

regarding previous adjuvant therapy exposure as these drugs are almost invariably used as chemotherapy in the adjuvant setting.

- Combination therapy will yield higher response rates but is more toxic. Hence, sequential single agents may be as efficacious and certainly less toxic.
- The choice of second and subsequent lines of therapies should be made after careful consideration of disease and patient-related factors in association with the benefits and risks, although there is no standard approach to drug sequence. However, if disease recurrence occurs within less than 12 months of using a particular drug, a different class of agents is generally preferred.
- Disease response is monitored via a thorough history and physical examination, tumor markers if necessary, and imaging studies.
- Chemotherapy is generally given for at least six to eight cycles if there is disease response. There is no established total duration for chemotherapy although it can be maintained if there is continued clinical response with minimal drug toxicities. Due consideration should be given for chemotherapy drug holidays, especially if there are therapy-related toxicities. If the disease is ER-positive, endocrine therapy can be utilized as a form of maintenance systemic therapy after a course of chemotherapy upon disease stabilization.

CHAPTER 72

Treatment of HER2-overexpressing Metastatic Breast Cancer

Shruti Sheth, Sumanta Kumar Pal, and Mark D. Pegram

CHAPTER CONTENTS

INTRODUCTION

In 2013, it is estimated that 232,340 new cases of breast cancer will be diagnosed in females, and 2,240 in males, with a combined mortality of 40,030 (1). Of the new cases, approximately 6% will have *de novo* metastatic disease at the time of initial presentation (2). Additionally, a substantial proportion of those patients diagnosed with early-stage disease will go on to develop metastatic breast cancer (MBC) despite advances in locoregional and systemic adjuvant and neoadjuvant therapies (3). Whereas traditional cytotoxic chemotherapy (and endocrine manipulation for ER-positive disease) has been the mainstay of treatment for these patients, targeted therapeutics directed against human epidermal growth factor receptor 2 (HER2/ERBB2) emerging over the past 15 years have significantly improved outcomes for this subset of patients with MBC (4).

The receptor tyrosine kinase HER2 is a member of the ERBB family of transmembrane receptors, including HER1 (ERBB1, or EGFR), HER3 (ERBB3), and HER4 (ERBB4) (5). The ERBB family of receptors possesses a wide range of biological activities relating to malignant phenotypes, including cell proliferation, invasion, migration, angiogenesis, and cell survival. With the exception of HER2, ERBB family receptors undergo a conformational change in the ectodomain as a consequence of binding to as many as a dozen soluble ERBB ligands. This conformational change exposes a β-hairpin loop dimerization domain that facilitates EGFR, HER3, and HER4 to undergo homo- or heterodimerization (6). Dimerization leads to structural (allosteric) activation of intracellular kinase domains, with subsequent activation of a number of signal transduction cascades, including Ras-mitogen-activated protein kinase (Ras-MAPK), phosphatidyl 3' kinase-protein kinase B (PI3K-PKB/Akt), and phospholipase C-protein kinase C (PLC-PKC) pathways (7). By contrast, HER2 does not bind to any of the soluble ERBB-family ligands, and analysis of the crystal structure of the HER2 ectodomain demonstrates that the dimerization domain is natively exposed in an open conformation, suggesting that this transmembrane receptor species remains constitutively poised for dimerization (8). This unique structural property has been offered as a rationale for enhanced mitogenesis seen with increased HER2 expression levels, such as those observed in HER2-amplified tumors and in preclinical models of enforced HER2 overexpression in breast and ovarian cell line and xenograft models (9). Indeed, clinical data defining the role of HER2 in association with an aggressive tumor phenotype has served as the impetus for the development of HER2-targeted therapies. Given that as many as 20% of breast cancer patients harbor tumors with HER2 gene amplification, the clinical impact of such therapies will remain relevant for the foreseeable future (10).

HUMANIZED ANTI-HER2 MONOCLONAL ANTIBODIES AS THERAPY FOR HER2-POSITIVE MBC

Development of Trastuzumab

Initially, several murine monoclonal antibodies with anti-proliferative activity specifically against HER2-overexpressing human cancer cell lines were identified and characterized (11,12). The complementarity-determining regions from one

of the most potent of these murine monoclonal antibodies were subsequently fused into a human IgG_1 framework, resulting in a humanized HER2-directed monoclonal antibody, trastuzumab (13). Preclinical studies of trastuzumab demonstrated that following the humanization procedure, the activity of the antibody against HER2-overexpressing cancer cell lines and xenografts was retained, particularly when used in combination with other cytotoxic therapeutics (14). Numerous studies have been conducted that focused on the mechanisms of trastuzumab-related anti-tumor activity. Several plausible hypotheses have been suggested to account for the clinical activity of trastuzumab. Resolution of the crystal structure of trastuzumab complexed with HER2 has led to identification of a trastuzumab-binding epitope in the juxtamembrane region (subdomain IV) of the HER2 ectodomain. It is possible that this juxtamembrane binding generates steric alteration of HER2 dimers to the extent that intracellular tyrosine kinase domains cannot efficiently interact and activate (8). Moreover, modification of key cell cycle regulators (i.e., increased levels of p27, a Cdk2 inhibitor) subsequent to trastuzumab binding have been observed (15). Studies additionally suggest that inhibition of HER2 ectodomain cleavage by metalloproteinases may serve as a mechanism of trastuzumab activity, because the truncated p95 fragment generated from cleavage retains intracellular kinase activity (16,17). Alternatively, preclinical data support stimulation of antibody-dependent cellular cytotoxicity (ADCC) as an important mediator of trastuzumab's mechanism(s) of action (18,19).

Single-Agent Trastuzumab for Metastatic Breast Cancer

Pilot clinical trials suggested only modest activity of single-agent trastuzumab in the setting of heavily pretreated MBC with HER2-overexpression (20). Subsequently, a much larger study in a pretreated MBC population explored a dosing regimen including a loading dose of 4 mg/kg followed by 2 mg/kg weekly maintenance therapy. In a total of 213 treated patients, 8 CRs and 22 PRs were observed (ORR 15%). The median duration of response was 9.1 months, and median overall survival (OS) was 13 months (21). Clinically significant cardiac dysfunction was noted in 4.7% of patients, comprised of congestive heart failure (CHF), cardiomyopathy, or a decrease in ejection fraction (>10%). These observed cardiac adverse events, along with events reported in a concurrent trial of trastuzumab in combination with chemotherapy, prompted further examination of potential risk factors for trastuzumab-associated cardiac toxicity (22). In a preliminary review of trastuzumab-related cardiac adverse events, 9 of 10 patients with cardiac events had prior anthracycline therapy, and additionally had at least one risk factor for anthracycline-induced cardiomyopathy (including cumulative doxorubicin dose greater than 400 mg/m^2, radiotherapy to the left chest, age greater than 70 years, and history of hypertension) (22). Consequently, there is a "boxed warning" concerning trastuzumab-associated cardiotoxicity in the trastuzumab prescribing information, and periodic serial assessment of left ventricular ejection fraction (LVEF) by echocardiography, or by technetium (Tc-99m) stannous pyrophosphate multi-gated acquisition (MUGA) scan, is recommended as clinically indicated.

Whereas the previous two studies assessed a heavily pretreated population of metastatic HER2-positive patients, a separate trial assessed the use of trastuzumab as first-line monotherapy for HER2-overexpressing MBC. A total of 114 women were randomized to receive one of two trastuzumab dosing regimens: (i) a loading dose of 4 mg/kg followed by 2 mg/kg weekly, or (ii) a loading dose of 8 mg/kg followed by 4 mg/kg weekly. Among 111 assessable patients, 7 CRs and 23 PRs were observed (ORR 26%). Reports of cardiac dysfunction in the previously noted trials (21,22) led to an evaluation of cardiac events in this trial. Only two patients (2%) were noted to have clinically significant cardiac dysfunction, requiring no intervention other than discontinuation of trastuzumab. Of note, variations in trastuzumab dosing did not lead to significant differences in clinical endpoints. Median OS was 25.8 months and 22.9 in those who received 4 mg/kg and 2 mg/kg, respectively (23). In summary, although trastuzumab is most commonly integrated in combination with chemotherapeutics in the clinic, and although the above data sets were generated prior to the adjuvant trastuzumab era, it is important to remember that the antibody has significant clinical activity as a single agent and may offer an important treatment consideration for patients who may not be suitable candidates for chemotherapy-based regimens.

Preclinical Rationale for Trastuzumab in Combination with Cytotoxic Therapy

As previously noted, initial studies of trastuzumab in cell lines suggested optimum efficacy of the antibody when combined with cytotoxic therapy (11). Initially, these experiments specifically assessed the combination of trastuzumab and the DNA-damaging agent cisplatin. Further preclinical studies have assessed several distinct classes of chemotherapeutics in combination with trastuzumab against a panel of four HER2-overexpressing breast cancer cell lines (SKBR3, BT-474, MDA-MB 361, and MDA-MB 453) and confirmed *in vivo* in HER2 overexpressing xenograft models.

Based on work done in cell lines, the efficacy of trastuzumab-based combinations using *in vivo* xenograft models were explored (24). Synergy has been observed using the combinations of trastuzumab with alkylating agents, platinum analogues, topoisomerase II inhibitors, and ionizing radiation. Additive interactions were observed with the combination of trastuzumab with taxanes and anthracyclines (25). Results of these experiments helped to inform and prioritize the design and conduct of subsequent clinical trials of trastuzumab in combination with cytotoxic chemotherapy (see Table 72-1).

Pivotal Trial of Trastuzumab with Chemotherapy

A pivotal phase III registration trial of trastuzumab and cytotoxic chemotherapy randomized patients to receive either standard chemotherapy alone or standard chemotherapy plus trastuzumab as first-line therapy for HER2-positive metastatic disease. HER2-overexpressors were defined as those possessing IHC scores of 2+ or 3+, using the same murine monoclonal antibody upon which trastuzumab was based, as the primary detection antibody. In this trial, patients were stratified according to their prior adjuvant treatment. Patients who had not previously received adjuvant therapy with an anthracycline received doxorubicin or epirubicin and cyclophosphamide with or without trastuzumab, whereas in those patients who had previously received adjuvant anthracycline, a regimen of paclitaxel alone or paclitaxel in combination with trastuzumab was utilized. Trastuzumab was administered at a loading dose of 4 mg/kg, followed by a maintenance dose of 2 mg/kg weekly, until the observation of disease progression. Compared to nonrecipients of trastuzumab (n = 234), patients who received trastuzumab (n = 235) had a significantly longer time to disease progression (7.4 months vs. 4.6 months, $p < .001$), a higher rate of objective response (50% vs. 32%, $p < .001$),

TABLE 72-1

Key Trials of Trastuzumab Therapy and Associated Response Rates

Author	*Year*	*Study Type*	*N*	*1st Line?*	*Regimen*	*RR*
Phase II Studies						
Single Agent Therapy						
Baselga et al.	1999	Phase II	43	No	Trastzumab 250 mg loading followed by 100 mg/wk × 10 wks	12%
Cobleigh et al.	1999	Phase II	213	No	Trastuzumab 4 mg/kg loading followed by 2 mg/kg/wk	15%
Vogel et al.	2002	Randomized phase II	111	Yes	Trastzumab 4 mg/kg loading followed by 2 mg/kg/wk, or Trastzumab 8 mg/kg loading followed by 4 mg/kg/wk, or	26%
Paclitaxel and Trastuzumab						
Leyland-Jones et al.	2003	Phase II	32	No	Paclitaxel 175 mg/m^2 q3wks with trastzumab 8 mg/kg loading followed by 6 mg/kg q3wks	59%
Gasparini et al.	2007	Randomized phase II	118	Yes	Paclitaxel 80 mg/m^2/wk alone or with trastzumab 4 mg/kg loading followed by 2 mg/kg qwk	75%*
Gori et al.	2004	Phase II	25	No	Paclitaxel 60–90 mg/m^2/wk with trastzumab 4 mg/kg loading followed by 2 mg/kg qwk	56%
Seidman et al.	2001	Phase II	88	No	Paclitaxel 90 mg/m^2/wk with trastzumab 4 mg/kg loading followed by 2 mg/kg qwk	61%
Docetaxel and Trastuzumab						
Esteva et al.	2002	Phase II	30	Yes**	Docetaxel 35 mg/m^2/wk with trastzumab 2 mg/kg/wk for 3 out of 4 wks/cycle	63%
Tedesco et al.	2004	Phase II	26	Yes**	Docetaxel 35 mg/m^2/wk for 6 wks followed by 2 wks rest with trastzumab 4 mg/kg loading followed by 2 mg/kg qwk	50%
Raff et al.	2004	Randomized phase II	17	No	Docetaxel 35 or 40 mg/m^2/wk for 3 wk, then 1 wk off, with trastzumab 4 mg/kg loading (day 1) followed by 2 mg/kg qwk (days 8 and 15) of a 28-d cycle	59%
Montemurro et al.	2004	Phase II	42	No	Docetaxel 75 mg/m^2 q3wks × 6 with trastzumab 4 mg/kg loading followed by 2 mg/kg qwk	67%
Marty et al.	2005	Randomized phase II	186	Yes	Docetaxel 75 mg/m^2 q3wks alone or with trastzumab 4 mg/kg loading followed by 2 mg/kg qwk	61%*
Vinorelbine/trastuzumab						
Burstein et al.	2001	Phase II	40	No	Vinorelbine 25 mg/m^2/wk with trastzumab 4 mg/kg loading followed by 2 mg/kg qwk	75%
Jahanzeb et al.	2002	Phase II	40	Yes	Vinorelbine 30 mg/m^2/wk with trastzumab 4 mg/kg loading followed by 2 mg/kg qwk	78%
Burstein et al.	2003	Phase II	54	Yes	Vinorelbine 25 mg/m^2/wk with trastzumab 4 mg/kg loading followed by 2 mg/kg qwk	68%
Chan et al.	2006	Phase II	62	Yes	Vinorelbine 30 mg/m^2/wk with trastzumab 4 mg/kg loading followed by 2 mg/kg qwk	63%
De Maio et al.	2007	Phase II	40	No	Vinorelbine 30 mg/m^2/wk on days 1 and 8 of a 3-wk cycle with trastzumab 8 mg/kg loading followed by 6 mg/kg qwk	50%
Papaldo et al.	2006	Phase II (two-arm)	68	Yes	Vinorelbine 25 mg/m^2/wk alone or with trastzumab 4 mg/kg loading followed by 2 mg/kg qwk	51%
Capecitabine and Trastuzumab						
Schaller et al.	2007	Phase II	27	No	Capecitabine 1,250 mg/m^2 bid for 14 d in a 21-d cycle given with trastzumab 4 mg/kg loading followed by 2 mg/kg qwk	45%
Bartsch et al.	2007	Phase II	40	No	Capecitabine 1,250 mg/m^2 bid for 14 d in a 21-d cycle given trastzumab 8 mg/kg loading followed by 6 mg/kg q3wks	20%
Yamamoto et al.	2008	Phase II	56	No	Capecitabine 1,657 mg/m^2 bid for 14 d in a 21-d cycle given with trastzumab 4 mg/kg loading followed by 2 mg/kg qwk	50%

TABLE 72-1 *(Continued)*

Key Trials of Trastuzumab Therapy and Associated Response Rates

Author	*Year*	*Study Type*	*N*	*1st Line?*	*Regimen*	*RR*
Cisplatin and Trastuzumab						
Pegram et al.	1998	Phase II	39	No	Cisplatin 75 mg/m^2 on days 1, 29, and 57 with trastuzumab 250 mg loading followed by 100 mg/wk for 9 wks	24%
Gemcitabine and Trastuzumab						
Bartsch et al.	2008	Phase II	26	No	Gemcitabine 1250 mg/m^2 on days 1 and 8 of a 3-wk cycle with trastzumab 8 mg/kg loading followed by 6 mg/kg q3wks	19%
Three Drug Regimens						
Perez et al.	2005	Phase II	43	Yes	Paclitaxel 200 mg/m^2 q3wks and carboplatin (AUC 6 mg/mL) q3wks with trastzumab 8 mg/kg loading followed by 6 mg/kg q3wks	65%
			48	Yes	Paclitaxel 80 mg/m^2/wk given with carboplatin (AUC 2 mg/mL) every 3 out of 4 wks with trastzumab 4 mg/kg loading followed by 2 mg/kg qwk	81%
Pegram et al.	2004	Phase II	59	Yes**	Docetaxel 75 mg/m^2 q3wks with carboplatin (AUC 6 mg/mL) q3wks with trastzumab 4 mg/kg loading followed by 2 mg/kg qwk	58%
			62	Yes	Paclitaxel 75 mg/m^2 q3wks with carboplatin (AUC 6 mg/mL) q3wks with trastzumab 4 mg/kg loading followed by 2 mg/kg qwk	79%
Miller et al.	2001	Phase II	42	Yes	Gemcitabine 1,250 mg/m^2 on days 1 and 8 and paclitaxel 175 mg/m^2 on day 1 of a 3-wk cycle with trastzumab 4 mg/kg loading followed by 2 mg/kg qwk	67%
Stemmler et al.	2005	Phase II	20	No	Gemcitabine 750 mg/m^2 with cisplatin 30 mg/m^2 on days 1 and 8 of a 3-wk cycle with trastzumab 4 mg/kg loading followed by 2 mg/kg qwk	40%
Phase III Studies						
Slamon et al.	2001	Phase III	469	No	Trastuzumab 4 mg/kg loading followed by 2 mg/ kg/wk	32%
					Taxane or anthracycline with cyclophosphamide given with trastuzumab 4 mg/kg loading followed by 2 mg/kg/wk	50%
Robert et al.	2006	Phase III	196	Yes	Paclitaxel 200 mg/m^2 q3wks alone with trastzumab 4 mg/kg loading followed by 2 mg/kg qwk	36%
					Paclitaxel 200 mg/m^2 q3wks with carboplatin (AUC 6 mg/mL) q3wks with trastzumab 4 mg/kg loading followed by 2 mg/kg qwk	57%
Burstein et al.	2007	Phase III	81	Yes	Vinorelbine 25 mg/m^2/wk with trastzumab 4 mg/kg loading followed by 2 mg/kg qwk, or	51%
					Docetaxel/Paclitaxel, investigator preference, with trastzumab 4 mg/kg loading followed by 2 mg/kg qwk	40%
Pegram et al.	2007	Phase III	263	Yes	Docetaxel 100 mg/m^2 q3wks with trastzumab 4 mg/kg loading followed by 2 mg/kg qwk	73%
					Docetaxel 75 mg/m^2 q3wks with carboplatin (AUC 6 mg/mL) q3wks with trastzumab 4 mg/kg loading followed by 2 mg/kg qwk	73%

*Indicates RR for trastuzumab containing arm.
**indicates first- and second-line treatment included.

a longer mean duration of response (9.1 months vs. 6.1 months, $p < .001$) and prolonged median OS (25.1 months vs. 20.3 months, $p = .046$) (4). Along with the trastuzumab monotherapy noted above, these data supported regulatory approval of trastuzumab for the treatment of HER2-positive MBC by the U.S. Food and Drug Administration in 1998.

In addition to providing strong support for the combination of trastuzumab with cytotoxic chemotherapy, the study also provided important insights related to cardiac toxicity. Of 63 patients who experienced symptomatic or asymptomatic cardiac dysfunction in this study, 39 patients had received the combination of anthracycline, cyclophosphamide, and

trastuzumab. A much lower rate of cardiac dysfunction was observed in the remaining groups, with an incidence of 8%, 13%, and 1% in groups that had received anthracycline and cyclophosphamide alone, paclitaxel and trastuzumab, and paclitaxel alone, respectively. Grade III or IV New York Heart Association (NYHA) cardiac dysfunction was similarly observed at a much higher frequency in the group that received combined anthracycline and trastuzumab therapy. Increasing age was noted to be a risk factor associated with cardiac dysfunction within this subgroup. Notably, cumulative anthracycline dose did not correlate with cardiac toxicity; however, the vast majority of patients in this treatment arm received the prescribed six doses of anthracycline treatment (4). Results from this trial led to caution in formulating further trials of trastuzumab therapy with concomitant anthracycline.

The optimal schedule for regular cardiac follow-up has yet to determined in the metastatic setting of the treatment of HER2-positive breast cancer. Additional methods of assessing cardiac function both in terms of modality and introduction of newer methods such as biomarkers may play a role in the future of cardiac testing.

Combinations of HER2-Targeting Agents with Endocrine Therapy

Approximately half of HER2-positive MBC is also hormone receptor positive (26). Women with disease co-expressing both HER2 and one or both of the hormone receptors (ER or PR) may have less benefit from antihormonal therapies than with HER2-negative, ER positive disease (27). Preclinical studies suggest that there is cross talk between pathways related to HER2 and ER. Overexpression of HER2 was demonstrated to cause ligand independent down regulation of estrogen receptor and further suppression of ER transcripts (28). Given this association, it was thought plausible that inhibition of HER2 activity may augment endocrine therapy by enhancing ER expression. As validation of this hypothesis, the phase III TAnDEM trial randomized HER2-overexpressing, HR-positive postmenopausal patients to anastrozole alone, or the combination of anastrozole and trastuzumab. At the time of progression, patients were given the option to begin trastuzumab therapy if they were previously randomized to the monotherapy arm. Despite the crossover allowance, a modest (statistically insignificant) trend in OS was noted from combination therapy (28.5 vs. 23.9 months; p = .325) (29). Interestingly, in a *post hoc* exploratory analysis assessing the effects of crossover, median OS was significantly less in the group that received no trastuzumab therapy (i.e., anastrozole alone with no crossover; median OS, 17.2 months) versus survival in groups receiving anastrozole and trastuzumab initially (median OS 28.5 months) or at the time of crossover (median OS 25.1 months).

Direct HER2-tyrosine kinase inhibition with the small molecule HER2 kinase inhibitor lapatinib in combination with endocrine therapy has also been investigated. A phase I trial using the combination of lapatinib and letrozole suggested that the combination was safe and tolerable (30). Subsequently, a phase III trial was undertaken that compared the combination of letrozole plus lapatinib with letrozole plus placebo as first-line treatment of patients with HR-positive MBC, some with HER2-positive disease. Seventeen percent of the total study population (n = 1,286) had centrally confirmed HER2-positive disease with roughly equal distribution in the lapatinib and placebo groups (n = 111 and n = 108, respectively). In a pre-planned analysis of the HER2 positive population, the median PFS increased from 3 months for letrozole-placebo to 8.2 months for letrozole-lapatinib (HR = 0.71; 95% CI, 0.53–0.96; p = .019) (31). Clinical benefit, defined as objective response or stable disease for ≥6 months, was also significantly improved (29% to 48%; OR = 0.4; 95% CI, 0.2–0.8; p = .003) for the combined receptor blockade arm. There was also a (non-significant) trend toward improvement in OS. This regimen won regulatory approval by the U.S. FDA in 2010. In summary, since ER signaling has been suggested as an escape mechanism causing resistance to HER2 targeting agents, it is important to remember that ER+ tumors in the setting of HER2+ disease should also be treated with ER-directed therapies. This paradigm is also suggested by recent results from the TBCRC 006 trial, in which letrozole was used in addition to trastuzumab *and* lapatinib in 64 evaluable patients with HER2+/ER+ stage II/III tumors (32). Overall, in-breast pathologic complete response (pCR; ${}_{yp}T_{0\text{-}is}$) was 27% (ER+, 21%; ER–, 36%). The rate of low-volume residual disease (${}_{yp}T_{1a\text{-}b}$) was 22% (ER+, 33%; ER–, 4%). Thus, in these patients with locally advanced HER2-positive breast cancer, this approach resulted in a high pCR rate even in the absence of chemotherapy. These data support the hypothesis that selected patients with HER2-positive tumors may not need chemotherapy, and more-complete blockade of HER receptors and ER is an effective strategy worthy of further study (32).

Trastuzumab and EGFR Tyrosine Kinase Inhibitors

Whereas trastuzumab binds the extracellular domain of the HER2 moiety (8), a unique class of agents interacts with the intracellular domain of ERBB family proteins. Lapatinib, a dual inhibitor of EGFR and HER2 tyrosine kinase domains, is discussed elsewhere in this chapter (33). Gefitinib and erlotinib, two inhibitors with affinity for the EGFR tyrosine kinase domain, have demonstrable efficacy in non-small cell lung cancer (34,35). Response data for these agents in MBC, however, has been poor. In a pilot study of 22 patients with refractory MBC treated with erlotinib, no clinical responses were observed (36). Limited single agent data exists for gefinitib in the setting of MBC; two trials report activity of the drug in combination with docetaxel, but it is challenging to determine response attributable to the EGFR antagonist (35,37). In the setting of HER2-overexpressing MBC, Eastern Cooperative Oncology Group (ECOG) study 1100 assessed a regimen of daily oral gefinitib combined with weekly trastuzumab, utilizing a phase I/II design. During a planned interim analysis, TTP parameters did not meet pre-specified statistical endpoints for study continuation (38). More encouraging data was yielded from a phase I trial of erlotinib in combination with trastuzumab, spurned by preclinical data suggesting synergy between the agents in breast cancer cell lines (39). Among 14 evaluable patients with heavily pretreated HER2-overexpressing MBC, two partial responses were elicited. There is strong preclinical rationale for combined ERBB receptor blockade to include EGFR-HER2 heterodimeric interactions, HER2-HER2 interactions, as well as HER2-HER3 heterodimeric complexes that can be achieved with various combinations of ERB-targeting reagents, including antibodies and small molecules (40). However, clinical data to interrogate this important hypothesis are currently lacking.

Continuation of Trastuzumab beyond Initial Progression

A majority of the aforementioned trials utilizing trastuzumab-based regimens prescribed the continuation of trastuzumab therapy until the time of disease progression. Beyond the time of progression, the role of further trastuzumab-based regimens was unclear. Before the availability of salvage HER2-targeted therapy with lapatinib (discussed

later), a frequently employed strategy was the continuation of trastuzumab with an alternative chemotherapy beyond the initial time of disease progression. Use of this approach was addressed in an extension of the pivotal phase III trial of trastuzumab in combination with chemotherapy. A total of 247 patients with documented disease progression were enrolled in an extension study. Of these, 154 patients had originally received chemotherapy (group 1) and 93 had received chemotherapy and trastuzumab (group 2). The majority of patients enrolled in the extension trial received a combination of chemotherapy and trastuzumab, with the remainder receiving either trastuzumab alone or a combination of trastuzumab and palliative radiotherapy or hormonal therapy. The most commonly used chemotherapeutic agents used in the extension trial in combination with trastuzumab were paclitaxel, vinorelbine, docetaxel, and fluorouracil, although 8% of patients received concomitant doxorubicin. Although efficacy information from the trial was limited (safety was the primary objective), 14% of patients in group 1 and 11% of patients in group 2 experienced an objective response. These responses were observed both when trastuzumab was combined with chemotherapy and when single agent trastuzumab therapy was employed. The incidence of cardiac toxicity was relatively low, occurring in 9% of patients in group 1 and 2% of patients in group 2 (41). A relatively small retrospective review of the Hellenic Cooperative Oncology Group (HCOG) experience offers a similar suggestion of efficacy for trastuzumab in multiple lines of therapy for advanced disease, demonstrating a significant number of responses with second- and third-line therapy with trastuzumab, associated with improvements in median survival (42).

Despite these encouraging results, a separate retrospective review offers contrasting results. In a series of 184 HER2-overexpressing MBC patients who had received trastuzumab therapy over a 5-year period, relevant clinical endpoints such as time to second progression (TT-SP) and post-progression survival (PPS) were assessed. Among 132 patients who had progressed on trastuzumab-based therapy at the time of analysis, 21 patients experienced rapid progression and did not receive additional therapy, 40 patients received further trastuzumab-based regimens, and 71 patients received further non-trastuzumab-based regimens. In the latter two groups, there did not appear to be significant difference in TT-SP, PPS, RR, or OS (43). Because this data is complicated by issues related to retrospective methodology, further trials were necessary to clarify the role of trastuzumab therapy beyond the time of initial progression.

Further evidence in support of continuation of trastuzumab beyond the time of disease progression comes from a randomized trial conducted in a population of patients with advanced, HER2-overexpressing breast cancer that had progressed on treatment with trastuzumab. Patients (n = 78 in each arm) were then randomized to receive either capecitabine (at 2,500 mg/m^2 on days 1 to 14 every 3 weeks) alone, or in combination with trastuzumab (at 6 mg/kg every 3 weeks). With 15.6 months of follow-up, median times to progression were 5.6 months in the capecitabine group and 8.2 months in the capecitabine-plus-trastuzumab group with an unadjusted hazard ratio of 0.69 (95% CI, 0.48–0.97; two-sided log-rank p = .0338). OS rates were 20.4 months (95% CI, 17.8–24.7) in the capecitabine group and 25.5 months (95% CI, 19.0–30.7) in the capecitabine-plus-trastuzumab group (p = .257). Overall response rates were 27.0% with capecitabine and 48.1% with capecitabine plus trastuzumab (odds ratio, 2.50; p = .0115). Continuation of trastuzumab beyond progression was not associated with increased toxicity (44).

Although some questions and concerns continue regarding the efficacy of trastuzumab beyond progression, in light of the prospective, randomized data in support of treatment in multiple lines, and the potential for synergy by changing the chemotherapy base, continuation of trastuzumab beyond initial progression is widely practiced.

Mechanisms of Trastuzumab Resistance

In the pivotal phase III trial comparing the combination of cytotoxic chemotherapy to trastuzumab alone, an impressive overall response rate of 50% was achieved with combined therapy—substantially improved relative to previous trials of monotherapy with trastuzumab. However, the median duration of response on this therapeutic arm was just 9.1 months (4). In response to the observations that as many as half of chemotherapy + trastuzumab-treated subjects fail to achieve clinical response, and those that do have modest response duration, a significant body of evidence has been generated in the laboratory focused on mechanisms of trastuzumab resistance. Several studies have implicated a role for loss of PTEN in trastuzumab resistance. Reduction of PTEN, a dual phosphatase negatively regulating PI3K and Akt activities, through antisense oligonucleotides led to trastuzumab resistance in *in vitro* and *in vivo* models. Additionally, IHC analyses of clinical specimens demonstrated that PTEN-deficient breast tumors had poorer responses to trastuzumab-based therapy relative to tumors with normal PTEN expression (45). As a potential therapeutic approach in patients with PTEN-loss, it appears that inhibition of the PI3K-Akt pathway (e.g., through use of mTOR inhibitors) may lead to restoration of trastuzumab sensitivity in preclinical assays (46).

Alternatively, aberrant signaling through the insulin-like growth factor-I receptor (IGF-IR) pathway, leading to PI3K-Akt pathway activation, may mediate trastuzumab resistance. An assay of MCF-7 and SKBR-3 breast cancer cell lines revealed that treatment with IGF-I (and subsequent activation of IGF-IR) led to a diminution in trastuzumab-induced cell growth inhibition (47). This is supported a separate preclinical study of IGF-IR inhibition in combination with trastuzumab therapy in MCF-7 cells, showing a synergistic interaction using dual receptor inhibition (48). Similar to IGF-IR overexpression, overexpression of the Met receptor may serve to decrease trastuzumab sensitivity by offering a "bypass mechanism" for cell growth and proliferation. A recently published report suggested that Met knockdown in breast cancer cell lines using RNA interference significantly enhanced trastuzumab sensitivity. Conversely, co-activation of Met and HER2 through use of the ligands hepatocyte-growth factor (HGF) and neuregulin, respectively, led to substantial increases in cell growth (49).

Other purported mechanisms of trastuzumab resistance include limitations in drug distribution secondary to the size of the antibody. Fluorescently tagged trastuzumab injected in mice bearing MDA-MB 435 breast cancer xenografts displayed antibody accumulation in the periphery of tumors. Notably, this was not correlated with increased HER2 expression in peripheral regions. Additionally, vascular distribution of trastuzumab was highly irregular, and distribution of trastuzumab did not correlate with vascular density, as one would expect with unhindered trastuzumab transport (50). Approaches to HER2-overexpressing patients using small molecule inhibitors may help to circumvent such issues with drug delivery. Interestingly, preclinical studies indicate lapatinib has significant activity even in trastuzumab refractory cell lines (51), leading to clinical investigations of lapatinib-based regimens following trastuzumab in subsequent randomized trials (52).

LAPATINIB

Lapatinib Monotherapy

In contrast to trastuzumab, which binds an epitope located in the extracellular domain of the HER2 moiety (8), the orally active dual tyrosine kinase inhibitor lapatinib binds reversibly to the intracellular kinase domain of both HER2 and EGFR (53). Growth inhibition was observed with lapatinib therapy in HER2-overexpressing BT-474 breast cancer cell lines. Xenografts derived from BT-474 cell lines were similarly inhibited by lapatinib treatment (54). A separate analysis of HER2-overexpressing cell lines suggested marked reductions in tyrosine phosphorylation of EGFR and HER2 following exposure to lapatinib. Additionally, lapatinib led to inhibition of Erk1/2 and AKT, downstream effectors of cell proliferation and survival, respectively (55). In a phase I study, 67 patients with EGFR- or HER2-overexpressing tumors were randomly assigned to one of five dose cohorts of daily lapatinib therapy. A total of 4 PRs occurred among 57 evaluable patients; all were in patients with trastuzumab-refractory MBC. Stable disease occurred in a total of 24 patients, 10 of whom were patients with MBC. The most commonly observed adverse events were diarrhea and cutaneous rash, the former in a dose-dependent fashion (33).

A correlative study accompanying the aforementioned phase I clinical trial of lapatinib monotherapy in solid tumor malignancies focused attention on the four patients attaining PR in the clinical trial. Analysis of serial biopsies performed in each of these patients suggested that each of the four patients had elevated baseline levels of active, phosphorylated HER2 (determined by IHC). With lapatinib therapy, a decrease in the extent of HER2 phosphorylation was observed. In three of the four responders, inhibition of activated phospho-Akt and phosphor-Erk1/2 was noted, concordant with preclinical studies suggesting these moieties were inhibited by lapatinib. In contrast to assessment of phosphorylated HER2, level of EGFR phosphorylation at baseline did not seem to distinguish responders from non-responders. Notably however, decrements in EGFR phosphorylation were seen in responding patients (33).

Encouraging data from this phase I trial within the subset of patients with MBC led to the implementation of a phase II clinical trial including both HER2-overexpressing and non-HER2-overexpressing MBC. In 140 patients with HER2-overexpressing disease, an overall RR of 4.3% was determined by investigator assessment. All responders were noted to have overexpression of HER2 characterized as 3+ by IHC; 5 of 6 responders additionally had FISH amplification. No tumor responses occurred among 89 non-HER2-overexpressing MBC patients. As in the phase I monotherapy study, diarrhea and rash were the most commonly observed toxicities (56).

Lapatinib and Capecitabine

Given the limited data to support the clinical utility of lapatinib monotherapy, further efforts have focused on combinations of lapatinib with standard chemotherapeutics. In a series of preclinical experiments, four cancer cell lines with a range of HER2 and EGFR expression (MCF7/wt, BT-474, SKBR-3, and A-431) were exposed to varying concentrations and combinations of lapatinib, trastuzumab, epirubicin, gemcitabine, and 5-fluorouracil. Independent of HER2 and EGFR expression, lapatinib was noted to have synergy with 5-fluorouracil (57). This observation served as the rationale for a phase I trial of lapatinib and capecitabine in advanced solid tumors. Although only 7 of 45 patients enrolled (16%) carried a diagnosis of MBC, one CR and three confirmed PRs occurred; the CR occurred in a patient with MBC treated with lapatinib at 1,250 mg/d and capecitabine at 2,000 mg/m^2/d, representing the optimally tolerated dose regimen. The most common toxicities incurred with this regimen were diarrhea, rash, nausea, palmar-plantar erythrodysesthesia, mucositis, vomiting, and stomatitis (58).

The observed activity of the combination of lapatinib and capecitabine in MBC led to the initiation of a randomized phase III trial. In this study, HER2-overexpressing patients with MBC who had progressed after regimens including an anthracycline, a taxane, and trastuzumab received either capecitabine alone (2,500 mg/m^2/d on days 1 through 14 of a 21-day cycle) or in combination with lapatinib (with the optimal treatment regimen defined from the previous phase I trial). An interim analysis met pre-specified criteria for early reporting given superiority of the group receiving combination therapy. At the time of this analysis, 49 events had occurred in the combination group as opposed to 72 events in the monotherapy group (HR = 0.49; $p < .001$). Median TTP was prolonged from 4.4 months with monotherapy to 8.4 months with combination therapy. Overall RR was higher with combination therapy (22%) as compared to monotherapy (14%), although this was marginally significant ($p = .09$). In contrast to trastuzumab-containing regimens, no symptomatic cardiac events were observed with lapatinib therapy (52). In a more recent published update of the trial, including attempts at correlating response with various biomarkers, lapatinib response failed to correlate with baseline levels of HER2 ECD or EGFR expression (59). In 2007, the U. S. FDA granted approval to lapatinib ditosylate tablets for use in combination with capecitabine for the treatment of patients with advanced or metastatic breast cancer whose tumors overexpress HER2 and who have received prior therapy including an anthracycline, a taxane, and trastuzumab.

Lapatinib and Taxanes

Lapatinib exhibits a chemosensitizing effect when used in combination with paclitaxel in a model of resistant EGFR-overexpressing ovarian cancer cell lines (60). Similar preclinical observations led to the initiation of multiple clinical trials investigating the combination of lapatinib and taxanes. In 192 patients receiving either docetaxel or paclitaxel in combination with lapatinib, the rates of neutropenia and rash were similar to each agent alone, although the frequency of diarrhea was more pronounced. Although the analysis was centered on safety, a preliminary report from one trial assessed suggested a response rate of greater than 70% with the combination of lapatinib and paclitaxel (61).

Data from placebo-controlled randomized trials combining lapatinib and paclitaxel have been reported. Interestingly, one trial evaluated a population of patients with stage IIIb/IIIc/IV at first diagnosis or relapse with either negative HER2 testing (0/1+ by IHC analysis, or no FISH amplification) or no prior testing. Central analysis of HER2 expression was performed in all available cases (representing 78% of test population). A total of 579 patients were randomized 1:1 to receive either lapatinib at a dose of 1500 mg daily with paclitaxel at 175 mg/m^2 every 3 weeks, or placebo and paclitaxel on the same schedule. From the study population, HER2-overexpression was elicited in 15% of patients enrolled in the study. Within this small subset of patients, treatment with paclitaxel-lapatinib resulted in statistically significant improvements in TTP, EFS, ORR, and CBR compared with paclitaxel-placebo. As anticipated, no such difference was observed in the larger subset of patients with normal HER2 expression (62). Although only a relatively small cohort of patients with HER2-overexpression was considered, these data informed the implementation of a prospective clinical

trial in a pre-selected HER-positive population. This phase III, randomized, double-blind study assessed the efficacy and safety of lapatinib plus paclitaxel compared with placebo plus paclitaxel in patients with newly diagnosed HER2-positive MBC. The primary end point was OS. Secondary end points included PFS, ORR, clinical benefit rate, and safety. The addition of lapatinib to paclitaxel significantly improved OS versus paclitaxel (treatment hazard ratio [HR] = 0.74; 95% CI, 0.58–0.94; $p = .0124$); median OS was 27.8 versus 20.5 months, respectively. Median PFS was prolonged by 3.2 months, from 6.5 months with placebo plus paclitaxel to 9.7 months with lapatinib plus paclitaxel (HR, 0.52; 95% CI, 0.42–0.64; stratified log-rank $p < .001$). ORR was significantly higher with lapatinib plus paclitaxel compared with placebo plus paclitaxel (69% vs. 50%, respectively; $p < .001$). The incidence of grades 3 and 4 diarrhea and neutropenia was higher in the lapatinib plus paclitaxel arm; however, just 4% of patients in this group reported febrile neutropenia. Cardiac events were low grade, asymptomatic, and mostly reversible. The incidence of hepatic adverse events was similar in both arms, and there were no fatal adverse events in the lapatinib plus paclitaxel arm (63).

Dual Targeting of the HER2 Receptor: Lapatinib and Trastuzumab

The rationale for dual inhibition of the HER2 receptor with monoclonal antibody and tyrosine kinase inhibitor treatment emerges from preclinical experiments assessing this combination in HER2-overexpressing BT-474 breast cancer cell lines. Treatment of BT-474 cell lines with lapatinib led to only a minimal increase in tumor cell apoptosis with an associated minimal decrease in phosphorylated HER2, Akt, Erk1/2, and most notably, survivin (a member of the inhibitor of apoptosis family of proteins). Similarly, treatment with trastuzumab had little effect on apoptosis or survivin concentration. However, the combination of lapatinib and trastuzumab led to markedly enhanced tumor cell apoptosis and downregulation of survivin (64). In a separate series of experiments examining a broad panel of breast cancer cell lines (including cells maintained in trastuzumab-conditioned media), synergy with concomitant trastuzumab and lapatinib treatment was observed in four cell lines (65).

Data from a phase I trial showed promise for dual inhibition. This open label trial used a two-stage design, with the initial stage comprised of lapatinib dose escalation to establish the optimally tolerated dose. The second stage included patients in an expansion cohort in which pharmacokinetic parameters were assessed. A total of 48 patients with HER2-overexpressing MBC were treated; among 27 evaluable patients, one CR and seven PRs were observed—all in trastuzumab-pretreated subjects. A lapatinib dose of 1000 mg daily was identified as the optimally tolerated regimen for further trials in combination with trastuzumab (66). A subsequent report focused on cardiac safety suggested that the combination of trastuzumab and lapatinib results in no symptomatic cardiac events in a total of 238 patients registered in four separate trials (67).

Recently, overall survival benefit with lapatinib in combination with trastuzumab for patients with human epidermal growth factor receptor 2-positive metastatic breast cancer was reported in the final results from the randomized, phase III EGF104900 study (68). In this campaign, patients with HER2-positive MBC whose disease progressed during prior trastuzumab-based therapies were randomly assigned to receive lapatinib monotherapy or lapatinib in combination with trastuzumab. Lapatinib plus trastuzumab showed superiority to lapatinib monotherapy in PFS (HR = 0.74; 95% CI, 0.58–0.94; $p = .011$) and offered significant OS benefit (HR = 0.74; 95% CI, 0.57–0.97; $p = .026$). Multiple clinical factors, including ECOG performance status 0, nonvisceral disease, <3 metastatic sites, and less time from initial diagnosis until randomization, were associated with improved OS. These data support dual HER2 blockade with a non-cytotoxic salvage regimen in patients with heavily pretreated HER2-positive MBC (68).

NEWER AGENTS TARGETING THE HER2 RECEPTOR

Pertuzumab

Pertuzumab is a second-generation humanized, monoclonal antibody employing the same IgG1 backbone as trastuzumab, but with a different target epitope on the HER2 ectodomain. This first-in-class agent targeted therapeutic is termed a HER dimerization inhibitor (HDI) (69). Whereas trastuzumab binds to the extracellular domain IV of HER2, pertuzumab binds to the extracellular domain II of HER2 and has a complementary mechanism of action (Fig. 72-1). It inhibits ligand dependent HER2-HER3 dimerization and reduces signaling via intracellular pathways such as phosphatidylinositol 3 kinase (PI3K/Akt).

Preclinical data focused on the comparisons between trastuzumab and pertuzumab and the synergy between the two agents. Pertuzumab is thought to act mechanistically by disrupting the HER2-HER3 interaction in the presence of heregulin. Heregulin is thought to promote tumorigenesis and cell proliferation. Agus and colleagues showed in cell lines that pertuzumab more readily disrupted this HRG mediated tumorigenesis than did trastuzumab (70).

Scheuer and colleagues showed that as compared to trastuzumab or pertuzumab monotherapy, there was a synergistic effect of the two agents (71). Interestingly, in both KPL-4 xenograft models and in BT474MI models, not only was there the initial tumor response but also the prevention of additional spread to other systemic sites. The same studies have also shown that the combination therapy was effective in KPL-4 and Calu-3 xenografts even after progression on trastuzumab (71).

Several phase I clinical trials testing pertuzumab as monotherapy or in combination with chemotherapy or trastuzumab in patients with metastatic breast cancer were undertaken in patients who were refractory to standard therapies. These phase I trials showed that pertuzumab was well tolerated (72).

Two phase II studies, both single arm studies, were conducted evaluating pertuzumab in combination with trastuzumab without chemotherapy in patients with HER2-positive metastatic disease who had progressed despite prior trastuzumab. The first study was designed with a target recruitment of 37 patients. However, as 54% of the 11 recruited patients developed LVEF decline, the study was stopped early (73). The response rate was 18%. CBR could not be calculated due to small numbers. A second trial conducted by Baselga and colleagues included 66 patients who had prior trastuzumab therapy and had progressed. These patients were then treated with combination of both pertuzumab and trastuzumab with the primary end point of ORR and/or CBR. The ORR was found to be 24.5% on this study with a CBR of 50%. No clinically significant cardiac events were seen in this trial, in contrast to the Portera study, most likely because the eligibility criteria were more stringent with regards to cardiac dysfunction and study entrance (74).

Another important study was an extension of that initial phase II completed by Baselga (74,75). This extension study

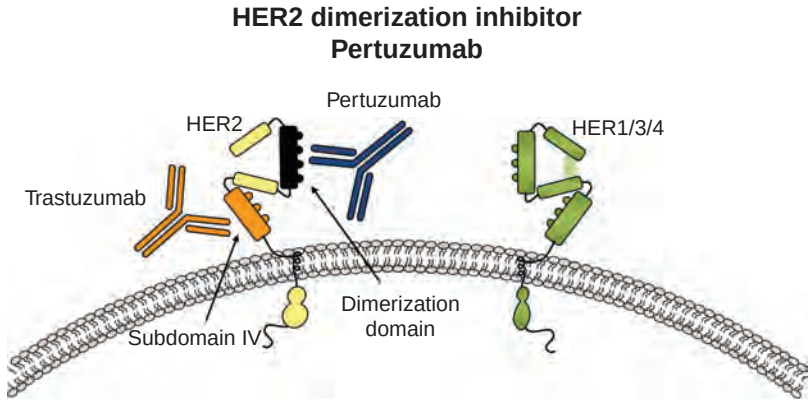

FIGURE 72-1 In contrast to trastuzumab, which binds to a juxtamembrane epitope in subdomain IV of the HER2 extracellular domain (ECD), pertuzumab binds to the dimerization interface contained in subdomain II of the HER2 ECD. Pertuzumab disrupts the ability of HER2 to dimerize with any other HER family member, thus attenuating signaling events triggered by HER family ligands. (Adapted from Cho et al. Structure of the extracellular region of HER2 alone and in complex with the Herceptin Fab. *Nature* 2003(421):756–759; Franklin et al. Insights into ErbB signaling from the structure of the ErbB2-pertuzumab complex. *Cancer Cell* 2004(4):317-328; Baselga J, Swain SM. Novel anticancer targets: revisiting ERBB2 and discovering ERBB3. *Nat Rev Cancer* 2009(9):463–475.)

done by Cortes et al. (75) recruited an additional cohort of patients to assess the efficacy of pertuzumab monotherapy and the reintroduction of trastuzumab in combination with pertuzumab in patients who had already progressed on both drugs. In the pertuzumab monontherapy arm the ORR and CBR were 3.4% and 10.3%. However, in the patients who received dual blockade after progression on pertuzumab, the ORR and CBR were 17.6% and 41.2%. These results are similar to what was seen in the original cohort of patients. Again, there was no additional cardiac toxicity noted (75).

Based on these promising results, the CLEOPATRA (Clinical Evaluation of Pertuzumab and Trastuzumab) trial was undertaken. This was a phase III, double-blind, randomized placebo-controlled trial that evaluated the role of dual anti-HER2 blockade with both pertuzumab and trastuzumab as first-line therapy in metastatic disease. Eight hundred and eight previously untreated metastatic HER2 patients were randomly assigned to receive either docetaxel with trastuzumab either with pertuzumab or placebo. The primary endpoint was independently assessed progression-free survival. The secondary endpoints were overall survival, ORR, and safety. This trial showed that the combination of pertuzumab, trastuzumab, and docetaxel when given in the first line as a treatment for metastatic HER2-overexpressing breast cancer significantly prolonged PFS with an increase of 6.1 months (12.4 months to 18.5 months) (HR 0.62; 95% CI, 0.51–0.75). Recently, a confirmatory OS analysis was performed that demonstrated a significant OS benefit for those subjects randomized to the pertuzumab-containing arm (HR = 0.66; 95% CI, 0.52–0.84, p = .0008) (76). Again, no increase in cardiac side effects was seen (76).

Based on these data, in 2012 the FDA approved the combination of pertuzumab, trastuzumab, and docetaxel as first-line therapy for previously untreated metastatic breast cancer patients.

Other ongoing trials are evaluating this dual blockade with other therapies. The PHEREXA (Pertuzumab Herceptin Evaluation with Xeloda) trial (NCT01026142) is a double-blind phase II trial studying the combination of pertuzumab, trastuzumab, and capecitebine versus trastuzumab and capecitabine in patients who have progressed on prior trastuzumab treatment. The VELVET study is exploring pertuzumab plus trastuzumab combination with vinorelbine. Additionally, MARIANNE (NCT01120184) is a phase III study that is evaluating the combination of pertuzumab with T-DM1. Results from these trials are eagerly awaited.

Antibody-drug Conjugate Ado-trastuzumab Emtansine (T-DM1)

Development of T-DM1

A variation on the antibody targeting model of trastuzumab is to use antibodies to deliver cytotoxic agents directly to the tumors. Trastuzumab-DM1 represents a novel agent in the class of anticancer therapeutics termed antibody-drug conjugates (ADCs). Trastustuzumab-DM1 is comprised of the monoclonal antibody trastuzumab chemically linked to the highly potent antimicrotubule DM1, derived from maytansine (Fig. 72-2) (77). Observations that anti-HER2 ADCs had both *in vitro* and *in vivo* potency and were active in trastuzumab refractory models of HER2-amplified breast cancer led to the testing and development of a trastuzumab-maytansine conjugate with a stable linker. This complex was designed to allow for endosomal reduction and intracellular release of the cytotoxic agent. In this construct, however, maytansine is held to the trastuzumab through a MCC linker that theoretically provides a stable bond between the two moieties, allowing for prolonged exposure and reduced toxicity.

Single Agent T-DM1 for Metastatic Breast Cancer

A phase I study in patients with HER2-overexpressed metastatic disease who had progressed on earlier trastuzumab-based therapy assessed the safety and tolerability of T-DM1 (n = 24) (78). Dose limiting toxicity of grade IV thrombocytopenia was observed, although rapidly reversible, and more importantly, there were no cardiac events requiring

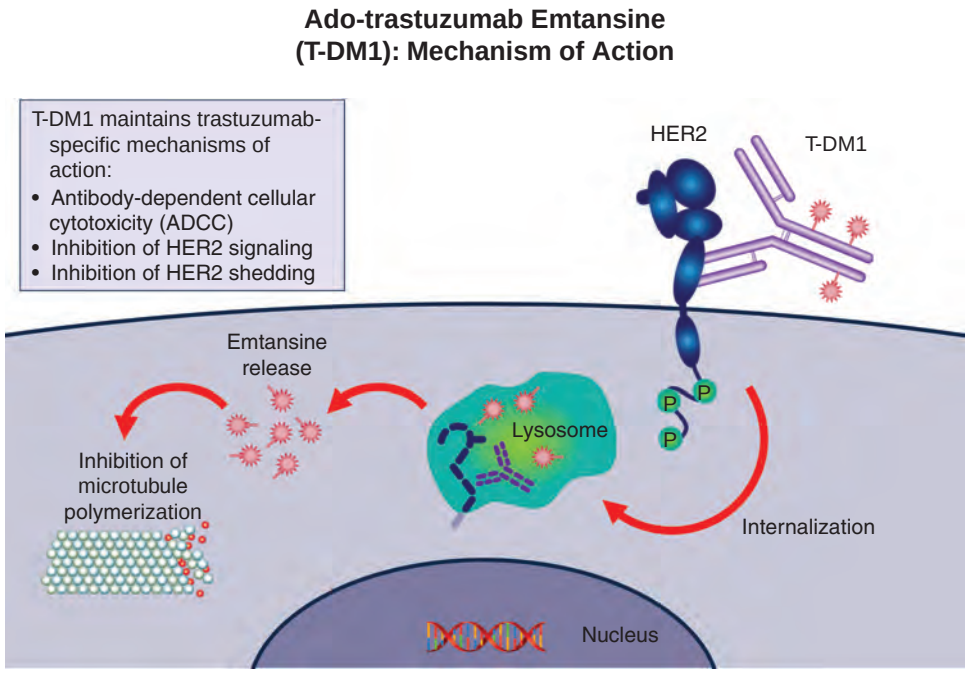

FIGURE 72-2 Following binding of the ADC T-DM1 to the HER2 ECD, the ADC/receptor complex is internalized by receptor-mediated endocytosis. Following endocytosis, the complex enters the lysosomal compartment, whereupon the complex undergoes extensive proteolysis that "frees" the potent emtansine moiety that then targets microtubule assembly, resulting in cytotoxicity. (Adapted from LoRusso PM, et al. Trastuzumab emtansine: A unique antibody-drug conjugate in development for human epidermal growth factor receptor 2-positive cancer. *Clin Cancer Res* 2011;17:6437–6447.)

discontinuation or dose modification. Five of the 24 patients had a confirmed partial response. For the 15 patients treated with MTD of 3.6 mg/kg every 3 weeks, the median progression free survival was 10.4 months.

These promising findings laid the groundwork for two phase II single arm studies of T-DM1 as monotherapy. In a study of 112 patients who had received previous chemotherapy and had progression on trastuzumab, T-DM1 was associated with an objective response rate of 25.9% based on independent review (79). Median duration of response was not reached as a result of insufficient events (lower limit of 95% CI, 6.2 months), and median progression-free survival time was 4.6 months (95% CI, 3.9 to 8.6 months). The response rates were higher among patients with confirmed HER2-positive tumors (immunohistochemistry 3+ or fluorescent in situ hybridization positive) by retrospective central testing (n = 74). T-DM1 was well tolerated with no dose-limiting cardiotoxicity. Most adverse events (AEs) were grade 1 or 2; the most frequent grade ≥ 3 AEs were hypokalemia (8.9%), thrombocytopenia (8.0%), and fatigue (4.5%). In a second study of 110 patients with HER2-positive metastatic breast cancer previously treated with multiple agents, the objective was to treat with T-DM1 as monotherapy to assess both ORR and progression-free survival. In this study, patients had previously been treated with anthracycline, taxane, capecitabine, trastuzumab, and lapatinib. The ORR was 34.5% (95% CI, 26.1%-43.9%) with a clinical benefit rate of 48.2% (95% CI, 38.8%-57.9%). Median PFS was 6.9 months while the median DOR was 7.2 months (95% CI, 4.6 months to not estimatible). By investigator assessment, the ORR was 32.7% (95% CI, 7.1 months to NE) and median PFS was 5.5 months (95% CI, 4.2 to 7.9 months). The most common AEs of any grade were fatigue, nausea, and thrombocytopenia. There was no evidence of LVEF decline to less than 45% and no patient was discontinued due to cardiotoxicity (80).

Pivotal Trial of T-DM1

The phase II studies provided the proof of concept and showed the clinical activity of T-DM1 in heavily pretreated metastatic HER2-positive patients. The phase III EMILIA study sought to assess the safety and efficacy of T-DM1 monotherapy as compared to lapatinib plus capecitabine in patients previously treated with trastuzumab and a taxane (81). A total of 991 patients were enrolled with 496 in the lapatinib plus capecitabine group and 495 in the T-DM1 group. Primary endpoints were progression-free survival and overall survival. Progression free survival in the group treated with T-DM1 was 9.6 versus 6.4 months (95% CI, 0.55–0.77, $p < .001$). Overall survival was also a primary end point and at the second interim analysis, T-DM1 significantly increased median overall survival (30.9 months vs. 25.1 months, 95% CI, 0.55–0.85; $p < .001$). The most commonly reported adverse events were grade 3 or 4 thrombocytopenia (12.9%). Based on this data, in 2013 T-DM1 was approved by the FDA for use in patients with metastatic HER2-positive breast cancer after treatment with trastuzumab and a taxane.

T-DM1 has also been tested in the first-line setting in HER2-positive MBC (82). In a randomized phase II study, patients (n = 137) with HER2-positive MBC or recurrent locally advanced breast cancer were randomly assigned to trastuzumab plus docetaxel (HT; n = 70) or T-DM1 (n = 67) as first-line treatment. ORR was 58.0% (95% CI, 45.5%-69.2%) with HT and 64.2% (95% CI, 51.8%–74.8%) with T-DM1. With a median follow-up duration of 14 months, median PFS was 9.2 months with HT and 14.2 months with T-DM1 (HR = 0.59; 95% CI, 0.36–0.97). T-DM1 had a favorable safety profile versus HT, with fewer grade ≥ 3 adverse events (AEs; 46.4% vs. 90.9%), AEs leading to treatment discontinuations (7.2% vs. 40.9%), and serious AEs (20.3% vs. 25.8%). Remarkably, in this study, first-line treatment with T-DM1 provided a significant improvement in PFS compared to a standard taxane/trastuzumab regimen. Moreover, the safety profile strongly favored T-DM1 over chemotherapy plus trastuzumab.

Future Directions-Combinations of T-DM1 with Other Agents

The MARIANNE trial is a three-arm phase III study that is evaluating combination of T-DM1 and pertuzumab versus T-DM1 and placebo versus trastuzumab plus taxane, all in the first-line setting for advanced breast cancer. This is

the first study to evaluate whether T-DM1 would be effective in earlier settings. Another study, the TH3RESA study is a multicenter phase III randomized trial that is evaluating T-DM1 or chemotherapy of physician's choice in patients with advanced breast cancers who have progressed on both trastuzumab and lapatinib (www.clinicaltrials.gov).

CNS METASTASES: THE ROLE OF HER2 AND TARGETED THERAPY

In data obtained from a large institutional review, it appears that the incidence of central nervous system metastases in breast cancer varies with stage at diagnoses. Only 2.5% of patients with localized disease at initial presentation ultimately developed CNS metastases, in contrast to 13.4% of patients who had metastatic disease at the time of presentation (2). A separate review of autopsy series including 144 patients carrying a diagnosis of breast cancer suggested an incidence of CNS metastases of 26% contrasting with the previous estimate and suggesting a high frequency of clinically occult disease (83). Subsequent to the introduction of trastuzumab therapy, several retrospective reviews of patients receiving trastuzumab suggested an incidence of CNS disease in the range of 25% to 48% substantially higher than the historically reported incidence (84–86). This increase in CNS metastases in the HER2-overexpressing population is supported by preclinical rationale. A subclone of the MDA-MB231 breast cancer cell line, 231 BR was generated with a property of selective metastases to the brain. When this subclone was transfected with varying levels of HER2, correlation was noted with the size and extent of brain metastases after implantation in a mouse model (87).

Risk of CNS metastases in early-stage HER2-positive breast cancer patients was assessed in NSABP B-31, a large randomized trial in which HER2-overexpressing patients received adjuvant chemotherapy alone or chemotherapy followed by 1 year of trastuzumab. In reviewing data among patients with distant recurrence, 28 CNS recurrences occurred in the arm receiving trastuzumab, whereas 35 occurred in the control arm (p = .35) (88). These findings suggest that adjuvant trastuzumab may be associated with a higher risk of CNS metastases as the site of *first* recurrence (since other sites of systemic metastasis are controlled for longer time periods). Thus, while trastuzumab serves to improve the overall clinical outcome in patients, the CNS may serve as a sanctuary site for trastuzumab therapy. Supporting this hypothesis, a study assessed six patients with HER2-overexpressing MBC with CNS metastases who had received WBRT after trastuzumab therapy. The ratio of trastuzumab concentration in serum as compared to CSF was 420:1 prior to WBRT. The ratio declined dramatically after WBRT (76:1) suggesting that disruption of the blood-brain barrier with radiation may serve as a mechanism to more effectively deliver trastuzumab (89).

Newer data come from a recent meta-analysis shows that receipt of adjuvant trastuzumab for 1 year increases the risk of CNS metastases as the *first* site of relapse (90). In this meta-analysis, 9,020 patients from four major trials were included. While the absolute incidence was small (2.6% vs. 1.94% in the control arm), the ratio of CNS events to total number of recurrence events was 16.94% (95% CI, 10.85%-24.07%) and 8.33 for the control arm, suggesting adjuvant trastuzumab is associated with a significant increased risk of CNS metastases as the site of *first* recurrence in HER2-positive breast cancer patients.

Lapatinib has been investigated as a potential treatment approach to the patient with HER2-overexpressing MBC with CNS involvement. In an updated analysis from the randomized phase III trial of capecitabine alone or in combination with lapatinib, it was noted that 13 patients in the monotherapy group had CNS progression, as compared to only 4 patients with combination therapy (p = .045) These data have encouraged further exploration of lapatinib and capecitabine for treatment CNS metastatic disease (52). The National Cancer Institute Cancer Therapy Evaluation Program (NCI/CTEP) 6969 trial included patients with HER2-overexpressing MBC with new or progressive brain metastases and at least one measureable lesion greater than 1.0 cm. Patients received lapatinib at a dose of 750 mg oral twice daily, with tumor measurements by magnetic resonance imaging (MRI) on 8-week intervals (91). Of the 39 patients enrolled, one PR in CNS disease by Response Evaluation Criteria in Solid Tumors (RECIST) criteria was recorded (ORR 2.6%). An additional 30% of patients were noted to have a decrease in the size of their initially noted CNS lesions that did not meet RECIST criteria. A radiographic volumetric analysis of CNS metastases suggested a greater than 30% decrement in tumor volume in three patients, and an additional seven patients had a decrease between 15% and 30%.

Additional data for the use of lapatinib were supported by trial EGF105084 in which eligible patients had HER2-overexpressing MBC, prior treatment with trastuzumab and cranial irradiation, and radiographic evidence of progressive brain metastases with at least one measurable lesion greater than 1.0 cm. Serial imaging was obtained with MRI, and patients were treated with the same dose in NCI/CTEP 6969 (92). Of the 242 patients enrolled, there was a greater than 50% volumetric reduction in CNS tumor load in 15 patients (6%) and a greater than 20% reduction in 41 patients (17%). In the 51 patients in the extension arm, 10 PRs were recorded (20%), and stable disease was observed in 20 patients (39%). These data require more validation. Data from the CEREBRAL trial will be forthcoming and is aimed at answering whether lapatinib or trastuzumab is superior in preventing brain metastases in advanced breast cancer.

With the recent development of T-DM1 and pertuzumab in HER2-positive MBC, newer treatment options may be becoming available for treating metastatic breast cancer with brain metastases. At this point, however, there do not appear to be any clinical trials evaluating use of these newer agents specifically for the treatment of brain metastases. However, other molecules such as Neratinib, which is an irreversible inhibitor of HER1, HER2, and HER4, is being investigated in a phase II trial of patients with metastatic breast cancer with brain metastases (clinicaltrials.gov NCT01494662). Afatinib is also an inhibitor of HER1 and HER2 and is currently being tested for use against brain metastases in the LUX-breast 3 study. Patients with progression after either trastuzumab or lapatinib therapy are randomized to treatment with either afatinib alone, afatinib plus vinorelbine, or investigators' choice of treatments (93).

CONCLUSION

A number of therapeutic advances have been made in the treatment of HER2-overexpressing MBC in recent years. The era of combination therapy with trastuzumab and conventional cytotoxic therapy has been supplanted largely by dual blockade and more targeted therapies aimed at several signaling pathways thought to promote tumorigenesis in HER2-overexpressed breast cancer. The therapy of HER2-overexpressing breast cancer thus represents an exciting frontier in which numerous paradigms for anticancer therapy continue to be established.

MANAGEMENT SUMMARY

- There is level I evidence, based on results of phase III CLEOPATRA trial, that pertuzumab in combination with trastuzumab and a taxane (docetaxel) yields superior progression-free and overall survival in the first-line metastatic setting compared to docetaxel plus trastuzumab. This regimen has secured regulatory approval in the United States and beyond and is a preferred first-line regimen recommended by National Comprehensive Cancer Network (NCCN) guidelines.
- For HER2-positive patients in the first line with ER-positive disease, particularly those with low volume disease burden that is asymptomatic and non-visceral predominant, or for those who are not ideal candidates for chemotherapy-based regimens, combined receptor blockade with an anti-estrogen plus a HER2-targeting agent yields significantly superior progression-free survival compared to anti-estrogen alone, based on data from randomized trials (the TANDEM trial explored anastrozole plus trastuzumab, and the EGF 30008 trial tested the combination of letrozole with lapatinib, the latter garnering regulatory approval by the U.S. FDA).
- For patients with metastatic HER2-positive disease who have progressed following prior treatment with a taxane and trastuzumab, or relapsed within 6 months of completion of an adjuvant trastuzumab regimen, ado-trastuzumab emtansine (T-DM1) has been shown to be significantly superior (both for progression-free and overall survival) to lapatinib plus capecitabine and is arguably better tolerated. Ado-trastuzumab emtansine also has regulatory approval in the United States.
- Upon disease progression following a prior pertuzumab-containing regimen and T-DM1, lapatinib-based regimens (either lapatinib plus capecitabine or lapatinib plus trastuzumab) are a logical next choice. However, neither of these regimens have efficacy datasets yet available in the setting of prior progression after multiple HER2-targeting antibody strategies.
- In later lines of treatment, clinicians regularly default to sequential salvage chemotherapeutics given in combination with trastuzumab in multiple lines, although this practice is not evidence-based.
- It is important to remember that in the era of non-anthracycline-based trastuzumab-containing adjuvant therapy (e.g., TCH), that anthracylines—even as single agents—have activity against HER2-positive disease, particularly in those tumors (~35%) with co-amplification of the topo-isomerase IIα gene (94). Therefore, anthracylines should be given some consideration in the salvage setting in anthracycline-naïve subjects. A wash-out period from prior trastuzumab administration is advised to avoid cardiotoxicity, or anthracyclines could be employed following progression on lapatinib-based regimens or T-DM1, both of which have shorter half lives compared to trastuzumab.
- HER2-overexpressing MBC patients with CNS metastases may benefit uniquely from lapatinib alone or in combination with capecitabine, whereas HER2-antibody-based therapeutics remain to be rigorously tested in the setting of CNS progression.
- For patients being treated with HER2-targeting agents, baseline and then periodic serial assessment of left ventricular ejection fraction (by MUGA or ECHO) remains a recommendation, although not a requirement, since at some point in the natural history of HER2-positive metastatic breast cancer, the risk of further disease progression without HER2-directed treatment may well exceed the risk of congestive heart failure. Therefore, sound clinical judgment is necessary to determine the optimal timing and frequency of LVEF assessment.

CHAPTER 73

Palliative Care in Breast Cancer

M. Jennifer Cheng and Thomas J. Smith

CHAPTER CONTENTS

INTRODUCTION

Breast cancer is still the most common cancer in women and nearly half of those diagnosed will die from it. The American Cancer Society estimates that in 2013 there will be 234,580 new cases of breast cancer and 40,340 deaths in the United States. (1). All oncologists do palliative care, but we can improve the end of life care of our patients by adapting some of the techniques of hospice and palliative medicine (2). In this chapter we will review the following: evolving models of care; predicting end of life; communication issues; incorporation of hospice and advance care planning into standard care; symptom and pain management; managing the time right before death; helping with caregivers; and end with a management summary.

EVOLVING MODELS OF CARE

The models of care for breast cancer patients have changed in the past decades, both during active treatment and near the end of life. The current suggested model of care (3) is shown in Figure 73-1, and illustrates that disease-directed treatment is given concurrently with palliative care along the time course of treatment, with palliative care and hospice care assuming a greater role if the patient is dying.

The American Society of Clinical Oncology (4) and the National Comprehensive Cancer Center Network (NCCN) guidelines (5) now call for concurrent palliative care for all people with serious illness. The recommendations for concurrent care are based on the evidence from multiple randomized clinical trials and show benefits including better quality of life for patients and families; less aggressive end of life care including less death in the hospital; more deaths at the place of one's choice; increased use of hospice; improved communication; improved symptom control; and possibly better survival with no trials showing worse survival.

PREDICTING END OF LIFE: WHY IT IS IMPORTANT, AND HOW TO PREDICT ACCURATELY

Nearly all modern-day breast and other cancer patients want to know their prognosis, treatment options, curability, and estimated length of survival. A consistent theme in a review of 46 studies is that most patients will want this information at the onset, but with some negotiation about the content and extent of the information as the disease progresses (6).

The reason to give people information about their prognosis is to help them with decision making. We have known for decades (7) that people who understood that they had less than 6 months to live, compared to those who do not, lived just as long and are far more likely to die a "good" death. Those who overestimated their survival and wanted life-extending treatments rather than symptom management are 1.6 times more likely to die on a ventilator or with resuscitation, and be readmitted to the hospital. All of these, including chemotherapy in the last weeks of life for breast cancer patients, are considered a sign of poor quality of care (8).

The American Society of Clinical Oncology has made recommendations that oncologists have frank, personalized discussions with patients about prognosis, treatment outcomes, and end of life care transitions, and that such discussions are particularly important near the end of life (9). As stated by ASCO, "Central to all of these goals is the need for realistic conversations about options and alternatives that should occur throughout the course of the patient's illness. Such conversations may currently occur in less than 40% of patients with advanced cancer. *All patients are owed comprehensive information about their prognosis and treatment options, with the amount of detail tailored to the individual patient. All patients must have a regular opportunity to make their preferences about how to live their final weeks and months clear to their oncologist*. Given that the default care plan in

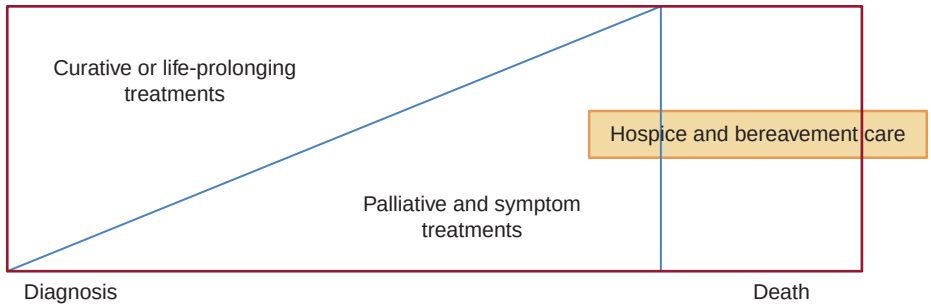

FIGURE 73-1 The changing patterns of care that incorporate palliative and end of life care.

the absence of these conversations is often further systemic therapy, *there is a need to regularly and specifically address the question of whether further anticancer-directed therapy is consistent with the patient's wishes and the current clinical picture*. Only through these discussions do we have the opportunity to match patients' goals with the actual care delivered."

The ability to predict when a person with breast cancer is potentially facing the end of life is straightforward, based on the available evidence. Any person with metastatic breast cancer is facing a terminal illness, and for most patients with HER-2 negative cancer the average survival is still less than 2 years. There is no known harm to addressing end of life issues earlier rather than later, other than the discomfort of raising the issues for patients, families, and healthcare professionals.

Performance status remains one of the best predictors of survival of less than 6 months, regardless of whether Karnofsky (score <60) or ECOG (score >2) is used, and the predictive value has not changed much in the past 30 years. Salpeter and colleagues (10) also note uniform average survival of less than 6 months with any of the following: poor performance status, multiple brain metastases, leptomeningeal disease, spinal cord compression, peritoneal disease and ascites, and progressive disease on chemotherapy, as shown in Table 73-1. All of these are common occurrences in breast cancer and should trigger the recognition that the disease course has changed from stability to predictable end of life.

There are other prognostic aids in common use by palliative care specialists and increasingly by oncologists. The Palliative Performance Scale gives 100 to 0 (PPS, 100 is normal function, 0 is death) scores based on routine clinical observations and is reliable, valid, and accurate. In Ontario, 25% of cancer patients died within 6 months of their first clinical encounter, and the PPS was highly predictive of death (11). For each 10-point decline in the PPS, the hazard of death increased by a factor of 1.7. The PPS is being tested as a referral trigger for palliative care and hospice consultation.

COMMUNICATION ISSUES AND THE SUBSEQUENT PATTERNS OF CARE

Despite our ability to predict with reasonable certainty, and a decades-long emphasis on honest prognostic information, ASCO notes that fewer than 40% of patients receive such information. Only 37% of dying patients remembered a conversation with their oncologist about dying (12). In a more recent study, only 22% of oncologists documented any "end of life" conversations, most such conversations were held by doctors other than the oncologist, and only 33 days before death (13). Half of all oncologists prefer to wait till "no more treatment options are left" before having these conversations (14). Nearly three-quarters of lung and colorectal cancer patients with incurable disease thought a person like themselves could be cured (15). The available data suggests that breast cancer patients have just as many unmet communication needs.

We have listed, in Table 73-2, some of the barriers that oncologists perceive. The skills to conduct these difficult discussions, such as how to be empathic listeners and to break bad news effectively, are readily learnable from programs such as Oncotalk (16). Other options include the free Education in Palliative and End-of-life Care (EPEC®)-Oncology course (http://www.cancer.gov/aboutnci/epeco) available from the National Cancer Institute.

Negotiating the palliative care conversation can be difficult, and introducing hospice services can be particularly stress-producing. We have created a guide for carrying out such discussions as shown in Table 73-3. The discussion goes easier if we have a script, just like with adjuvant treatment or lumpectomy versus mastectomy.

Goals of care and hospice discussions can be challenging for both patients and providers. Here are some tips for enhancing the quality of these conversations: First, *listen for clues*. Knowing they have a serious illness, most patients have thought about death and dying and are looking for permission to openly speak about it. Listen closely to the responses patients give you as their comments about mortality are not always straightforward. When given a vague statement ("I've been thinking about life and what this all means."), rather than overlooking the comment ask, "Tell me more about what you mean." Second, *restate the patient's goals*. Restating, or summarizing, patient's comments minimizes misconceptions, emphasizes the goals as important to the provider, and demonstrates attentive listening. This also provides patients with the opportunity to clarify and elaborate on their goals. Finally, *Ask, Tell, Ask*. (Always ask people how much they want to know, and what they do know. Then tell them, in understandable words. Ask "Now that we have discussed this, what is your understanding of your situation?")

In reality, this is not one talk but a series of discussions at predictable transition points (17). We have outlined these in Figure 73-2.

To date, every study shows that most breast cancer patients want to have all the available information, and will tell us if they do not. Most of us use Adjuvant!, the decision-making tool that has been shown to be useable, well accepted, and lead to better decision making. Most of us print the decision aids to share with the patient. The same types of decision aids have been tested in metastatic breast cancer with good acceptance, no distress, and no harm. They want to know the details, and the survival, so that they can plan just like with adjuvant treatment.

TABLE 73-1

Predicting Survival of Breast Cancer Patients with Metastatic Disease

Setting	*Prediction Models*	*Comment*
HER-2 not amplified		
	1st line modern treatments gave median survival of 19–22 months 2nd line modern chemotherapy gave median survival 16–18 months. (RIBBON-2 Trial) 3rd line chemotherapy with best option eribulin gave median survival of 13 months, versus 10 months with other regimens	Since treatment is not curative, discussing advance directives at the start of metastatic cancer is appropriate. Remember that these figures are from clinical trial patients with ECOG 0-1 and no comorbidities.
Triple negative	11–12 months overall survival in contemporary US patients treated at the best centers	
Specific situations with less than 6 months		
Any metastatic cancer with	KPS <60 ECOG performance status ≥2 Peritoneal or leptomeningeal metastases Hypercalcemia >11.2 mg/dL Spinal cord compression with decreased ability to walk Serum C-reactive protein >10 mg/L and serum albumin <3.5 g/dL	See review by Salpeter et al., 2012 and the supplemental data file available at http://online.liebertpub.com/doi/suppl/10.1089/jpm.2011.0192/suppl_file/Supp_Data.pdf
Any metastatic cancer with brain metastases and 1 or more of the following presentations	KPS <80 (ECOG performance status ≥2) ≥2 brain metastases plus extracranial metastases Triple negative cancer	
Any metastatic breast carcinoma with 3 or more of these presentations	KPS <80 (ECOG performance Status ≥2) Serum lactate dehydrogenase >500 IU/L Any liver metastasis At least 2 sites of metastases Disease-free interval from initial presentation to metastatic disease of <24 months. Recurrent or refractory disease after initial chemotherapy Triple negative cancer

INCORPORATION OF HOSPICE AND ADVANCE CARE PLANNING INTO STANDARD CARE

Best use of hospice requires a basic understanding of the Medicare (and most insurer) hospice benefits. The hospice provider is paid about $150 a day that must include all the services provided. Inpatient hospice is reimbursed at about $500 a day and must cover all the services provided. Currently, inpatient hospice is tightly regulated and patients must have a very high likelihood of dying within 7 to 14 days. There are a few communities with "expanded access hospice" that allow chemotherapy and radiation therapy, but these must still be covered within that $150 per diem, plus charity.

The easiest way to ensure timely hospice referral is to get palliative care involved by consultation. Hospitals with an active palliative care program referred 33% of hospice-appropriate patients to hospice, while hospitals without a program referred only 1%. More use of palliative care would save New York $84 to 234 million dollars (18), allow the end of life care to mirror what people choose—if given the choice, (19) and possibly increase survival (20).

TABLE 73-2

Why We May Not Have Realistic Discussions with People, Why It Matters, and How to Make Discussions a Reality

Barriers	*Reality*	*How to Move to Actuality*
People don't want this information.	People DO want this information. A small percentage will not, but we will not know who they are without asking.	Always "Ask, Tell, Ask" What do you want to know about your situation? What DO you know about your situation? Tell in understandable terms. Ask "Now that we have reviewed this, what is your understanding of your situation?"
It will make people depressed.	It won't make people depressed. Depression is 3-fold more common in those who had no discussion and could not plan.	Ask, Tell, Ask. And screen for depression with "Are you depressed?" or a similar tool.[a]
It will take away hope.	It won't take away their hope.	Ask people "What are you hoping for?"
They will die sooner, or hospice will kill them.	It won't make them die sooner.	Tell patients that the data show hospice and palliative care patients live longer and better.
We cannot really predict.	We CAN give realistic forecasts for survival.	Use a prognostic aid such as the Palliative Prognosis Scale. Remember that the better we know patients the more we overestimate their survival.
It is not culturally appropriate.	It is always culturally appropriate to ask "How much do you want to know about your illness?"	Recognize that cultures will vary within themselves, and change over time, too. "Ask, Tell, Ask."

[a]Skoogh J, Ylitalo N, Larsson Omeróv P, et al. Swedish-Norwegian Testicular Cancer Group. 'A no means no'—measuring depression using a single-item question versus Hospital Anxiety and Depression Scale (HADS-D). *Ann Oncol* 2010;21(9):1905–1909. doi: 10.1093/annonc/mdq058. Epub 2010 Mar 15.

Modified from Mack JW, Smith TJ. Reasons why physicians do not have discussions about poor prognosis, why it matters, and what can be improved. *J Clin Oncol* 2012;30(22):2715–2717. doi: 10.1200/JCO.2012.42.4564. Epub 2012 Jul 2.

The data show we do not use palliative and hospice care early enough, with one third of our patients entering hospice with less than a week to live and the average less than 20 days (21). This influences where people spend their last weeks of life. Over 60% of Medicare cancer patients are hospitalized in their last month of life, 30% die there, 25% are in the Intensive Care Unit, and the average person spends just 8 days in hospice once discharged (22). When one insurer offered concurrent palliative care along with oncology care, which allowed transition to hospice earlier because the patient and family know who would be taking care of them and had been introduced, hospitalizations were reduced nearly 10-fold and costs were 22% less in the last 40 days of life (23).

One large provider is already incorporating "best practices" in their pathways. As soon as incurable disease is identified, someone in the office sets up advance directive and power of medical attorney discussions, and a hospice information visit in the first three visits—not the last three. With this program, hospice use has increased to over 80%, with most patients spending more than a month in hospice care. The survival is as good or better and the cost is one third less (24) so this is being used as one model for national care plans.

There are at least 3 good ways to reliably predict a needed transition to hospice: prior number of regimens, disease status, and performance status. The 2013 NCCN guidelines call for a switch to nonchemotherapy based palliative care with "Failure to achieve a tumor response to 3 sequential chemotherapy regimens or ECOG performance status of 3 or greater." (http://www.nccn.org/professionals/physician_gls/pdf/breast.pdf, page 49) Both ASCO and NCCN endorse that patients with ECOG PS 3 or 4 not routinely be treated with chemotherapy (25). Note ECOG 3 is not "in bed more than 50% of the time" but "*in bed or chair* more than 50% of the time." We use a simple prompt: "Did this patient walk unaided into the clinic?" If not, we do not rule out chemotherapy completely, but ECOG 3 should prompt a discussion about the low chance of response, more toxicity, and a hospice information visit. We do a "hospice information visit" when the person has about 6 months to live. This moves the anxiety about death and hospice further upstream when the patient and family will have more time and perhaps energy to manage it, establishes the care plan, and establishes a link for "who will take care of me when I am not getting chemotherapy?" This has not been formally studied but empirically works well for nearly all patients, except those who do not want to consider hospice ever.

This switch is best accepted if the oncologist has said at the beginning "At some point chemotherapy will not be able to control this cancer, because it will grow resistant, and at some point chemotherapy can do harm with no chance of real benefit." We have found that keeping a list of "Prior treatments and response" makes it easier to summarize the situation for the patient. We also have added "Code status" and Advance Care Planning/Advance Directives to our records. Recent data suggests that less than 15% of cancer patients expected to die within a year, have any Advance Directives in their chart, and that e-mail and other prompts can increase the use of appropriate care planning (Table 73-4) (26).

TABLE 73-3

Useful Language to Negotiate Decisions and Advance Care Planning

Steps	*Useful language and questions*	*Comments*
Establish the setting	"Different people like to receive different amounts of information. How much do you want to know about your current health situation? Are there certain things you would not want to know or talk about?" "Is there anyone else you want to be here?"	Ensure privacy and comfort. Sit down with the patient. While most patients want to know the details of their cancer, some prefer to defer decision making to a family member or friend. If they do, ask why.
Assess patient's understanding of prognosis	"Can you share with me what you think is happening with your cancer/cancer treatment?" "Tell me about your understanding of the most recent tests/studies."	Start with open-ended questions. This allows patients to tell their stories and for you to identify any knowledge gaps.
Assess patient's expectations and goals	"What do you expect in the future?" "What are your hopes for the coming weeks/months?" "What is most important to you right now?" "What are you worried about now? In the future?"	Identify: 1. Patient's expectations and whether there is a disconnect between the patient's expectations and yours. 2. The most important goals for the patient. This will help you formulate the most appropriate plan of care.
Information sharing	"I would like to share with you the test results/your prognosis." "Would it be helpful if I write down the key information on a piece of paper for you to take home?"[a]	Use straightforward language without medical jargon. Deliver information one concept at a time. Pause in between to ask for patient understanding (see *Ask, Tell, Ask*).
Reframe goals	"I wish we had chemotherapy that could cure your breast cancer. But even though there is no cure, I think we can meet some of your other goals such as attending your son's graduation next month."	If patients have unrealistic expectations, gently redirect with "wish" statements and explore "second-best" options.
Identify needs for care	"How are you and your family coping?" "Is there anything you or your family need more help with?" "Are you bothered by pain or other symptoms?"	Most cancer patients have multiple symptoms and supportive care needs—but patients may not volunteer the information.
Hospice information visit referral for patients with 3–6 months prognosis	"Hospice service includes a team of people specialized in taking care of seriously ill patients at home. We routinely set up hospice information sessions for our patients so you will be familiar with what they do, should you need their services in the future."	Standardizing referrals for hospice information visits introduces hospice upstream as part of your clinic's "best practice" and a routine part of care.
Hospice referral	"From our discussion, I hear that it is important to stay at home and have your symptoms controlled. Hospice is one of the best ways to meet these goals. What have you heard about hospice?" "I know there are many misconceptions about hospice. I would like to explain what hospice is and what it can provide."	Emphasize how hospice services can meet patient's needs. Explore patient's understanding and preconceptions of hospice. Most people are not familiar with hospice services.
Summarize and be concrete	Summarize the discussion and strategize next steps. Ask for patient's understanding of key topics, and offer to answer any remaining questions.	Set up follow-up plans.

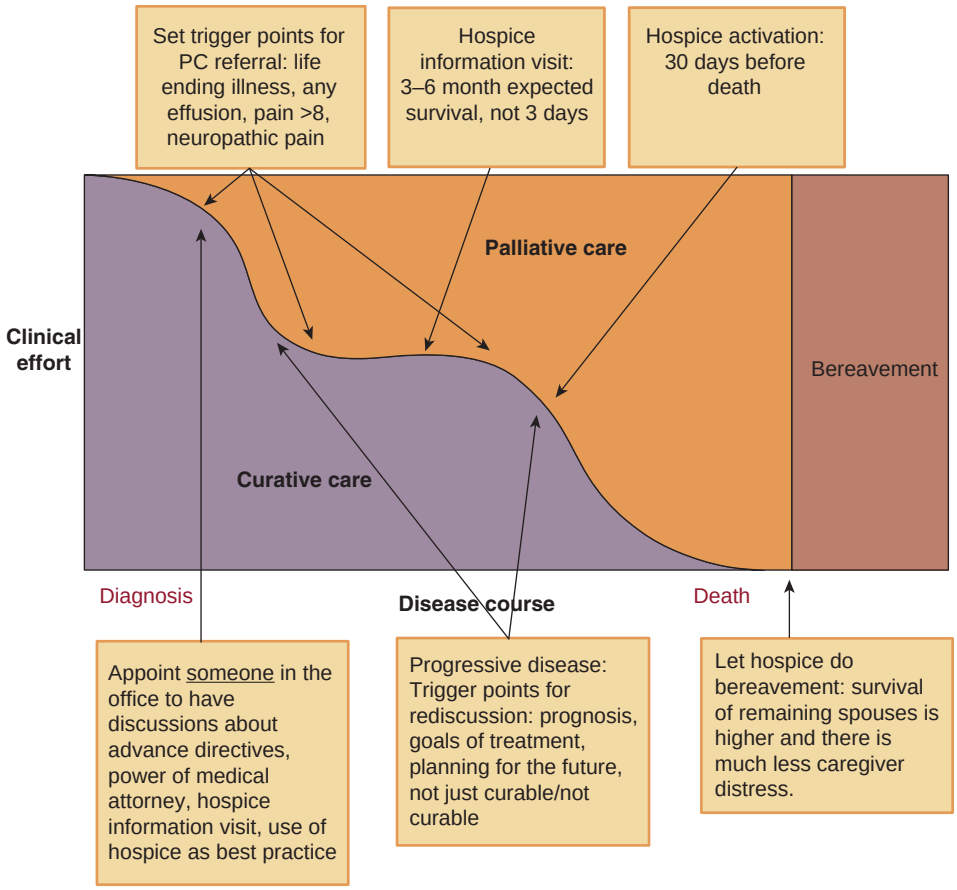

FIGURE 73-2 Triggers to have specific conversations with breast cancer patients.

ASCO is in the process of outlining what every oncologist and oncology office should be able to do as part of "primary palliative care." Most important is "the talk" triggered by progressive disease or a change in performance status. We use the same sort of script we use when talking about adjuvant chemotherapy: "If we are talking about 2nd or 3rd line chemotherapy, there are some other important issues to discuss. Do you have a will? Do you have a Living Will? What does it say about CPR? Who do you want to make medical decisions, if you can't? Have you discussed this with her/him? Are there spiritual issues? Are there family issues? Have you met with hospice yet? (3 to 6 months before death). Have you thought about where you would like to be for your death? Let's start with you doing a life review—what you want people to remember about you. What are you hoping for? What is important to you?" Patients and families almost universally thank us for having such a difficult conversation.

TABLE 73-4

Rearranging the Chart for Transition Prompts

Make headers called:
Prior treatments

1. Doxorubicin and cyclophosphamide, PR for 2 cycles, then PD
2. Cisplatin 75 mg/m^2, PD after 2 cycles
3. Paclitaxel Plus investigational drug, PD after 2 cycles
4. Capecitabine, PD after 2 cycles

Code status: _ _Full _x_DNR __Not discussed yet, discuss

Advance directive: _x_ Present __ Not Done __ Not discussed yet

Power of Medical Attorney: husband, Bill, phone xxx-xxx-xxxx

COMMON SYMPTOMS AT THE END OF LIFE, AND TREATMENTS

Breast cancer patients have multiple symptoms during their troubles with metastatic disease. In Table 73-5 we have tried to list all the common symptoms experienced by dying breast cancer patients, and some of the alternatives.

Pain is still the most common symptom experienced by patients. Most oncologists have become experienced in treating both chronic pain and breakthrough pain with opiates (the preferred term over "narcotics") and ensuring a bowel regimen. Methylnaltrexone subcutaneously has become part of usual care for refractory constipation but due to expense is not often used. For neuropathic pain, gabapentin and morphine work better (27) than either alone. For chemotherapy induced peripheral neuropathy, duloxetine (Cymbalta) is the only drug shown to work better than placebo for treatment, but it only worked for oxaliplatin neuropathy, not taxane neuropathy (28). Intraspinal and epidural treatments relieve pain significantly better than medical therapy, but are underused in practice.

TABLE 73-5

Common Symptoms at the End of Life

Symptom	*Alternatives*
Pain, Somatic	Opioid: Short acting breakthrough + Long acting; + Bowel regimen
Neuropathic pain	Antidepressants (TCA, SNRI) Anticonvulsants (Gabapentin, pregabalin)
Refractory pain	Infusion pumps Percutaneous Kyphoplasty Vertebroplasty/Radiofrequency ablation
Fatigue	Nonpharmacologic: no data. Pharmacologic: American ginseng 2,000 mg/day improved fatigue in a randomized trial compared to placebo; both methylphenidate and modafinil have effect only in those with high levels of fatigue. Dexamethasone 4 mg bid reduced fatigue and improved quality of care late in life.
Depression	Psychosocial interventions and antidepressants work in patients with advanced cancer; methylphenidate (Ritalin) may improve mood in patients with only weeks to live.
Hypercalcemia	Hydration (isotonic saline) + Bisphosphonate (Zoledronic acid superior to Pamidronate). Use a diuretic only if there is fluid overload. For severe symptomatic use Calcitonin to lower the calcium abruptly.
Delirium	Use Assessment Tools such as the CAM (Confusion Assessment Method); MDAS (Memorial Delirium Assessment Scale). Environmental—orientation (place, time, lighting, sounds), family education. Removal/replacement of potentiating medications (psychoactive drugs, corticosteroids; quinolone antibiotics; anticonvulsants; H2 blockers.) Opioid induced neurotoxicity—opioid rotation, dose reduction, hydration. Neuroleptics such as Haloperidol, atypical antipsychotics are the drug of choice.
Nausea/Vomiting	The Cleveland Clinic Protocol for Nausea and Vomiting in Advanced Cancer 1st line: Metoclopramide > Haldol; 2nd line: Olanzapine; 3rd line: Ondansetron Chemotherapy related: 5-HT3 antagonist substance/neurokinin receptor antagonists CNS metastasis related: Dexamethasone Noncomplete Bowel obstruction related: Metoclopramide Cancer related: Scheduled metoclopramide, prochlorperazine
Loss of appetite	Enteral tube feeding/parenteral nutrition do not improve comfort or survival. Megestrol acetate stimulates appetite in about a third of patients.
Bowel obstruction	Antiemetics (Metoclopramide IV > Haldol), Anticholinergics (Glycopyrrolate), Antisecretory (Octreotide), Dexamethasone Pain: Opioid (cautious, can aggravate colic); Opioid-sparing: Ketorolac, Prednisone
Dyspnea	Opioids (strong evidence), nebulized opioids (weak evidence) Benzodiazepine (panic-related) Corticosteroids (carcinomatous lymphangitic spread) Oxygen (mixed evidence: inferior to morphine for subjective dyspnea and hypoxemia; helpful for short term end of life dyspnea)

Fatigue is among the most common symptoms, and is less often noted by physicians. A simple "0–10" scale suffices for diagnosis, and both American ginseng (29) (2,000 mg a day) and dexamethasone (30) 4 mg bid have substantial benefits. The most commonly used drug methylphenidate (31) has little activity compared to placebo except in those with fatigue scores of at least 8/10. Depression is treated just as successfully in advanced cancer patients as the general public; for those with only weeks to live, methylphenidate may give some boost before typical antidepressants can act (32).

Delirium is prevalent at the end of life and often highly upsetting to families and staff. There are simple assessment methods such as the Confusion Assessment Method (CAM) and haloperidol and similar drugs clearly work at low doses (33) and are preferred over benzodiazepines.

Nausea and vomiting at the end of life is usually due to brain or bowel issues, not chemotherapy. The expensive serotonin-inhibitors have less use than simple inexpensive drugs such as metoclopramide, haloperidol, prochlorperazine, and olanzapine (34). Bowel obstruction can be treated with oral atropine but there are few data. Hospice providers have much expertise in this field but nearly all their treatments are empirically derived and not evidence-based.

Dyspnea is reliably assessed with a 0–10 scale just like pain but does not correlate with oxygen levels. Opiates are the mainstay of treatment, started in the same way as pain management with small as-needed doses and assessment one hour after treatment. There is no compelling evidence that any route of administration of opiates—oral, subcutaneous, intravenous, nebulized—is better. Oxygen is the most commonly used remedy but in the largest trial was no more effective than room air, (35) and is only effective if there is hypoxemia. If oxygen is automatically put on in the hospital, we do a twenty minute trial to see if the patient does just as well without it before insisting on a cannula tether and $25 to $150 a day charges at home.

There are other situations near the end of life that will arise in every oncology practice: requests for physician assisted suicide, and the need for palliative sedation. Most oncologists are asked several times a year "Isn't there some way to end this?" yet we get very little training in how to respond to such questions. Experts in the area suggest involvement of colleagues and palliative care specialists to ensure that all the palliative options are available (36). While one in ten US physicians reported "having sedated a dying patient with the specific intention of making the patient unconscious until death," most remain firmly opposed to the concept (37). Palliative sedation is the relief of refractory symptoms with the unintended consequence of sedation to unconsciousness, used only when other methods have failed (38).

CONCLUSIONS

Most breast oncologists provide end of life care but have had little training in the area. The skills of primary palliative care (open communication, symptom management, hospice referral) are readily learnable, with excellent sources available. For secondary and tertiary palliative care we must develop referral patterns to local and regional palliative care specialists just as we do for nephrologists.

The benefits of concurrent palliative care are now well established from multiple randomized trials. Palliative care alongside oncology, with transition to hospice care when appropriate, improves quality of life and symptoms, reduces aggressive and unhelpful end of life care, helps patients understand their illness, reduces caregiver distress, and may allow patients to live longer.

MANAGEMENT SUMMARY

- Nearly all patients want to know all the information about their illness including curability, prognosis, likely outcomes, and advance care planning.
- Concurrent oncology and palliative care for all seriously ill cancer patients is now recommended by ASCO and NCCN.
- Use the natural history of the disease to prompt us to discuss important issues: (i) Discuss curability at onset. (ii) At each recurrence do "Ask, Tell, Ask" about prognosis, advance care planning, and goals of care. At second or third progression ensure a hospice information visit when there are 3 to 6 months left to live.
- For fatigue, American Ginseng 2 g/day or dexamethasone 4 mg bid for 15 days has been proven effective in randomized clinical trials.
- For chemotherapy induced neuropathic pain, duloxetine is the only drug with effectiveness proven in a randomized clinical trial.
- For dyspnea, oxygen is no better than room air in the documented absence of hypoxemia. Opioids are the mainstay of dyspnea treatment, starting at low doses and increasing slowly as with pain management.
- For delirium, low doses of haloperidol or other antipsychotics are more effective than benzodiazepines.

All oncologists do palliative care. We can learn to do this part more effectively by doing assessments of symptoms including depression, spirituality, coping, and goals of care.

CHAPTER 74

Management Summary for the Care of Patients with Metastatic Breast Cancer

Marc E. Lippman

Very unfortunately, metastatic breast cancer remains largely incurable. Therefore, the primary goals of therapy are the alleviation of symptoms, the avoidance of complications of disease progression, and the prolongation of survival so long as a reasonable quality of life can be maintained. Exceptional circumstances may occasionally offer a more optimistic appraisal. Survival curves for metastatic breast cancer are not normally distributed and some patients can survive well over a decade or longer with a proven diagnosis of metastatic disease. These circumstances are most commonly ER-positive patients with remarkable responses to endocrine therapy. Additionally, so-called Stage IV NED patients may have long secondary disease free intervals and recent data reviewed in Chapter 69 suggest that addition of adjuvant systemic chemotherapy in this setting is likely of benefit.

The consequences of a diagnosis of metastatic disease are so life altering for a patient and her family that we believe, under almost all circumstances, that formal histologic confirmation is required. Furthermore, the determination of specific tumor characteristics such as estrogen, progesterone, and HER2 expression (which clearly can change with or without intervening therapy from determinations on primary tumors) provide an additional indication for biopsy. This is likely to become even more important in coming years as the availability of specific targeted therapies become even more widespread. As reviewed in Chapter, these determinations may soon be reliably obtained on circulating tumor cells or even circulating DNA derived from tumor cells.

Local symptoms are often best treated by specific local therapies that are commonly associated with less toxicity than systemic therapy, and, with respect to pain control, generally more effective. Many aspects of localized treatment, including stereotactic body radiation therapy, intracranial stereotactic radiosurgery, and radiofrequency ablation, have greatly improved control of localized sites of metastases particularly in the liver and the CNS. Because at least 90% of all patients with metastatic breast cancer will have bone metastases at some point, lifetime management with bisphosphonates or rank ligand inhibitors is commonly indicated. Whenever possible, multidisciplinary discussion and review with appropriate team members, including surgeons, radiation oncologists, medical oncologists, and experts in palliative care, should be sought. While the data remain controversial, the preponderance of analyses have suggested that mastectomy or other means of definitive local control of breast cancer improves survival for patients presenting at the outset with stage IV disease. If for no other reason than optimal local control, we endorse this for patients felt to have a reasonable survival expectancy (see Chapter 68).

The exact choice of an optimal systemic therapy is almost never limited to a single option or two and the number of active agents has increased in recent years and will almost certainly continue to do so. We strongly urge the participation in clinical trials whenever possible. Choices clearly need to balance patient expectations, urgency of the need for a response, the need for interdigitation of systemic therapy with local treatment, and prior treatments in either the neoadjuvant, adjuvant or advanced disease setting. Unfortunately, costs of therapy may need to be a consideration and the treating physician needs to be aware that often highly marketed (and often exceedingly costly options) are often not proven to offer superiority to generic choices. It is also the case, particularly in the United States, that many patients are treated with anticancer agents beyond the point where reasonable expectations of gain are supportable. It is very important to have frank and honest discussions with patients and their family that fairly assess the likelihood of gain as compared to harms from multiple regimens. We cannot overemphasize the need and value of including palliative care expertise in the equation and appropriately discussing hospice care at the right time. Many oncologists understandably find these discussions difficult and often think it less stressful to initiate multiple lines of therapy even after such treatments hold little hope for serious palliation. Some discussion of hospice care ought, reasonably, to be formally considered after a second line of therapy for metastatic disease for most women. This is particularly true in that adroit management of symptoms with antiemetics, neuroleptics, antidepressants, pain medications, and nutritional support are often either overlooked or incompletely attended to by oncologists. In many cases, patients are not forthcoming about these issues and information about symptomatology needs to be carefully elicited.

SECTION XI

New Breast Cancer Therapeutic Approaches

CHAPTER 75

Newer Targeted Therapy

Ingrid A. Mayer and Carlos L. Arteaga

CHAPTER CONTENTS

Advances in tumor genetics and drug development over the last decade have led to the generation of a wealth of anti-cancer targeted therapies. These drugs aim at targeting a particular vulnerability in the tumor generated in most cases as a result of dependence on an oncogene and/or loss of a tumor suppressor. Several recent examples indicate that these drugs are mainly, if not exclusively, active against tumors of a particular genotype that can be identified by a diagnostic test, usually detecting a somatic alteration in tumor DNA. However, for the majority of targeted therapies in development, there are still no clinical tools to determine which patients are most likely to benefit or, alternatively, be resistant *de novo* to these novel agents or drug combinations. In this chapter, we will review some of the newer (molecule) targeted therapies, the molecular targets and/or pathways they engage, the rationale for their use in breast cancer, pharmacodynamics and predictive biomarkers indicative of drug target modulation and clinical response, respectively, and the latest completed and planned clinical trials with them.

PHOSPHATIDYLINOSITOL-3 KINASE (PI3K)/AKT INHIBITORS

Multiple PI3K families exist in higher eukaryotes. To date only class I_A PI3K has been implicated in cancer. Class I_A PI3Ks are heterodimers consisting of a p85 regulatory subunit and a p110 catalytic subunit. Growth factor receptor tyrosine kinases (RTKs) such as EGFR, HER2, insulin receptor, IGF-IR, MET, etc. also signal via class I_A PI3K (1). These transmembrane receptors do not bind PI3K directly but activate this enzyme by phosphorylating adaptor proteins such as GAB1/2, IRS-1/2, and HER3 (ErbB3), which via YXXM motifs bind the amino terminal domain of p85. This binding relieves the inhibition of p110 by p85 and recruits the p85-p110 heterodimer to its substrate, the lipid phosphatidylinositol-4,5-bisphosphate (PIP2), at the plasma membrane. PI3K (p110) then phosphorylates PIP2 to produce the second messenger phosphatidylinositol-4,5-trisphosphate (PIP3). A Ras-binding domain (RBD) in p110α also mediates activation by Ras. PTEN (phosphatase and tensin homologue) dephosphorylates PIP3, thus, negatively regulating the product of PI3K (2). Several pleckstrin homology (PH) domain-containing proteins, including Akt, SGK, and PDK1, bind to PIP3 at the plasma membrane. The phosphorylation of Akt at Thr^{308} by PDK1 and at Ser^{473} by a complex involving mTOR/Rictor (TORC2) results in full activation of this enzyme. Akt phosphorylates a host of cellular proteins, including GSK3α, GSK3β, FoxO transcription factors, MDM2, BAD, and $p27^{KIP1}$ to facilitate survival and cell cycle entry (3). In addition, Akt phosphorylates and inactivates Tuberin, a GTPase-activating protein (GAP) for the Ras homologue Rheb. Inactivation of Tuberin allows GTP bound-Rheb to accumulate and activate the mTOR/Raptor (TORC1) complex, which ultimately regulates protein synthesis and cell growth and inhibits autophagy (4) (Fig. 75-1).

The PI3K/AKT pathway is the most frequently mutated pathway in breast cancer, with mutation and/or amplification of the genes encoding the PI3K catalytic subunits p110α (*PIK3CA*) and p110β (*PIK3CB*), the PI3K regulatory subunit p85α (*PIK3R1*), receptor tyrosine kinases (RTKs) such as HER2 (*ERBB2*) and FGFR1, the PI3K activator K-Ras, the PI3K effectors AKT1, AKT2, and PDK1, and loss of the lipid phosphatases PTEN and INPP4B (5). The three genes *PIK3CA, PIK3CB*, and *PIK3CD* encode the homologous p110α, p110β, and p110δ isozymes, respectively. Expression of p110δ is largely restricted to immune and hematopoietic cells, whereas p110α and p110β are ubiquitously expressed. The p110α isozyme is essential for signaling and growth of

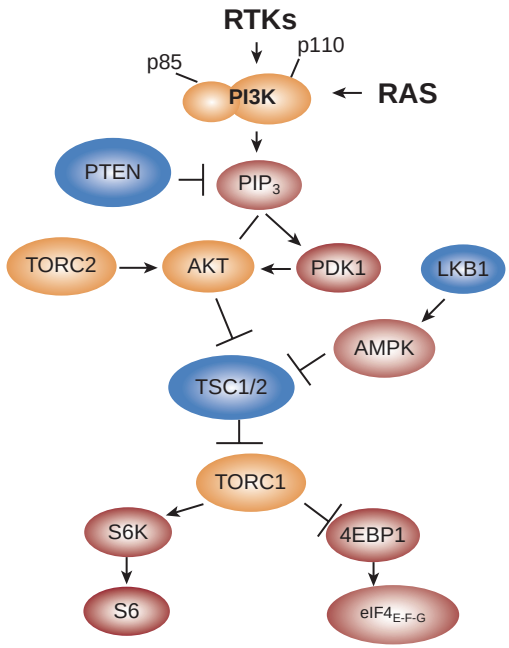

FIGURE 75-1 RTKs activate the p85/p110 PI3K dimer via phosphorylation of adaptor proteins (i.e., GAB1, GAB2, IRS-1, IRS-2, HER3), which have YXXM motifs that engage the N-SH2 domain of p85. This binding relieves the inhibition of p110 by p85 and recruits the p85-p110 heterodimer to its substrate, the lipid phosphatidylinositol-4,5-bisphosphate (PIP2), at the plasma membrane. PI3K phosphorylates PIP2 to produce the second messenger phosphatidylinositol-3,4,5-trisphosphate (PIP3). A Ras-binding domain (RBD) in p110α mediates activation by the small GTPase Ras. PTEN dephosphorylates PIP3, thus negatively regulating the product of PI3K. A subset of pleckstrin homology (PH) domain-containing proteins, including Akt and PDK1, bind to PIP3 and are thereby recruited to the membrane. The phosphorylation of Akt at Thr^{308} by PDK1 and at Ser^{473} by a complex involving mTOR/Rictor (TORC2) results in full activation of this enzyme. Akt phosphorylates a host of cellular proteins, including GSK3α, GSK3β, FoxO transcription factors, MDM2, BAD, and $p27^{KIP1}$ to facilitate survival and cell cycle entry. In addition, Akt phosphorylates and inactivates Tuberin (TSC1/2), a GTPase-activating protein (GAP) for the Ras homologue Rheb. The tumor suppressor LKB1 activates AMPK, which, in turn, can also inactivate Tuberin. Inactivation of Tuberin allows GTP bound-Rheb to accumulate and activate the mTOR/Raptor (TORC1) complex, which ultimately regulates protein synthesis and cell growth. Tumor suppressors are noted in blue and oncogenes in pink.

tumors driven by *PIK3CA* mutations, RTKs, and/or mutant Ras, whereas p110β lies downstream of GPCRs and has been shown to mediate tumorigenesis in PTEN-deficient cells. *PIK3CA* mutations are the most common genetic alterations of this pathway, where ≥80% occur within the helical (E542K and E545K) and kinase (H1047R) domains of p110α. Such mutations confer increased catalytic activity through different mechanisms, but both induce characteristics of cellular transformation including growth factor- and anchorage-independent growth, and resistance to anoikis.

Drug Resistance and Rationale for Combinations

Activation of the PI3K/AKT pathway has been shown to confer resistance to antiestrogen in various experimental models, including PTEN- and INPP4B-deficient cells and in cells overexpressing HER2, IGF-IR, and mutant AKT1 (6). Tumor cells with acquired endocrine resistance have been shown to upregulate IGF-IR, InsR, HER2, and EGFR levels as well as PI3K/AKT/mTOR activity (7). Inhibitors of the PI3K pathway trump this adaptation of ER+ cells to estrogen +deprivation. A recent study showed that in ER+ breast cancer cells treated with the PI3K/TOR inhibitor BEZ235 or with p110 siRNAs, exogenous estradiol prevents BEZ235- and siRNA-induced apoptosis (8). Because most breast cancers that adapt to antiestrogen therapy retain ER, these data imply that unopposed estrogen will protect ER+ tumors from the action of PI3K inhibitors used as single agents.

Clinical evidence suggests that activation of PI3K as a result of overexpression of HER2 or FGFR1 or loss of INPP4B also confer resistance to antiestrogens. Of interest, the activating mutations in PIK3CA correlate with good patient prognosis in some retrospective series. However, PI3K has been shown to interact with ER directly and indirectly, resulting in ER phosphorylation and an increase in estrogen- and tamoxifen-induced as well as ligand-independent ER transcription. In turn, estrogen can rapidly activate PI3K via Ins/IGF-IR, EGFR, and Src. Further supporting cross-talk between these two pathways, Guo et al. reported that a constitutively active mutant of AKT reduces ERα expression, whereas AKT inhibition results in an increase in ERα. Upon inhibition of PI3K/AKT, the transcription factor FoxO3a translocates to the nucleus where it transactivates ERα mRNA; expression of dominant negative FoxO3a reduces ERα levels in MCF-7 cells (9,10). This co-regulation supports the need of combined inhibition of both pathways in ER+ breast cancers with aberrant activation of PI3K/AKT. Indeed, preclinical evidence with ER+/PI3K mutant breast cancer cells suggests that simultaneous inhibition of PI3K and ER is synergistic (8,11), providing a rationale for combinations of antiestrogens with PI3K pathway inhibitors. In breast cancers with *HER2* gene amplification, HER2/HER3 dimers potently activate PI3K which, in turn, is critical for tumor cell progression and survival. Indeed, sustained inhibition of PI3K is required for the antitumor action of the HER2 inhibitors trastuzumab and lapatinib. A significant fraction of HER2+ tumors also harbor somatic alterations in the PI3K pathway that further dysregulate PI3K/AKT signaling and, as a result, confer resistance to HER2 inhibitors (12). In a large-scale siRNA genetic screen, Berns et al. identified PTEN as the only gene whose knockdown conferred trastuzumab resistance (13). Further, induced overexpression "hot spot" *PIK3CA* mutants similarly conferred trastuzumab resistance. Patients with "hot spot" *PIK3CA* mutations and undetectable or low PTEN measured by IHC exhibited a poorer outcome after treatment with chemotherapy and trastuzumab compared to patients without those alterations. An earlier study had also shown that loss of PTEN correlates with a lower response to trastuzumab. More recently, Esteva et al. found that PI3K pathway activation, defined as PTEN loss and/or *PIK3CA* mutations, was associated with a poor response to trastuzumab as well as a poorer overall survival (14). In addition, human breast cancer cell lines containing endogenous mutations in *PIK3CA* are intrinsically resistant to trastuzumab. Human breast cancer cell lines in which *PIK3CA* mutations are ectopically expressed exhibit an attenuated response to lapatinib. On the other hand, loss of PTEN has not been consistently associated with resistance to lapatinib.

A causal role of aberrant activation of the PI3K pathway with *de novo* and acquired drug resistance is further supported by the effects of inhibitors of PI3K/AKT. For example, combinations of trastuzumab with the PI3K inhibitor XL147, or trastuzumab or lapatinib with the dual PI3K-mTOR inhibitor BEZ235, inhibit growth of *PIK3CA* mutant xenografts resistant to anti-HER2 therapies (15). In a model of trastuzumab resistance caused by PTEN loss, targeting mTOR or AKT was able to at least partially overcome resistance. Evidence is also emerging from the clinic that targeting the PI3K axis in addition to HER2 may be a strategy to overcome resistance. For example, in a phase II study, the combination of the TORC1 inhibitor everolimus with trastuzumab and chemotherapy showed a partial response rate of 19% and a clinical benefit rate of 81% in patients with HER2+ metastatic breast cancer that had previously shown progression on trastuzumab plus a taxane (16).

Therapeutic Inhibitors

Several drugs targeting multiple levels of the PI3K network (i.e., PI3K, AKT, mTOR) have been developed (Tables 75-1 and 75-2). A number of ATP-mimetics that bind competitively and reversibly to the ATP-binding pocket of p110 are in early clinical development. These include the pan-PI3K inhibitors BKM120, XL-147, PX-866, PKI-587, and GDC-0941, the p110α-specific inhibitors BYL719, GDC-0032, and INK-1117, the p110δ-specific inhibitor CAL-101, and the dual PI3K/mTOR inhibitors BEZ235, BGT226, PF-4691502, GDC-0980, and XL-765. The pan-PI3K and p110α-specific inhibitors are equally potent against oncogenic p110α mutants. The rationale for the development of isozyme-specific antagonists is to allow higher doses of anti-p110α and anti-p110β drugs to be delivered without incurring side effects caused by pan-PI3K inhibitors. Interim results from a phase I trial with the p110δ-specific inhibitor CAL-101 in patients with hematologic malignancies showed that treatment reduced P-AKT levels >90% in peripheral blood lymphocytes and induced objective clinical responses. Recently completed phase I trials with BKM120, BEZ235, and XL-147 showed that treatment partially inhibited PI3K as measured by levels of P-S6 and P-AKT in patients' skin or tumors, and 2-deoxy-2-[^{18}F]fluoro-D-glucose (FDG) uptake measured by PET. Main toxicities were rash, hyperglycemia, diarrhea, fatigue, and mood alterations (17). Few clinical responses were observed in patients with and without detectable PI3K pathway mutations, although screening for genetic lesions in this pathway was not comprehensive.

Both allosteric and ATP-competitive pan-inhibitors of the three isoforms of AKT are also being developed. AZD5363, GDC-0068, GSK2141795, and GSK690693 are ATP-competitive compounds that have shown antitumor activity

Current Clinical Trials with PI3K Inhibitors

Study Design	*Clinical Trial*	*Type of inhibitor*	*Patient Population*	*Clinicaltrials.gov*
Phase I	Safety and Efficacy of BKM120 and Lapatinib in HER2+/PI3K-activated, Trastuzumab-resistant Advanced Breast Cancer	pan-PI3K	Trastuzumab-resistant HER2+ metastatic breast cancer	NCT01589861
	A Study of PI3-Kinase Inhibitor GDC-0941 in Combination with Paclitaxel, with and without Bevacizumab or Trastuzumab, in Patients with Locally Recurrent or Metastatic Breast Cancer		Trastuzumab-resistant HER2+ metastatic breast cancer; HER2-negative metastatic breast cancer	NCT00960960
	Phase I of BKM120/ Olaparib for Triple Negative Breast Cancer or High Grade Serous Ovarian Cancer	pan-PI3K PARP	Patients with triple negative breast cancer or high grade serous ovarian cancer	NCT01623349
	Phase I Study of PI3 (Phosphoinositol 3)-Kinase Inhibitor BAY80-6946 with Paclitaxel in Patients with Advanced Cancer	PI3Kα and PI3Kβ	HER2-negative metastatic breast cancer	NCT01411410
Phase Ib/II	Phase Ib/II Trial of BEZ235 with Paclitaxel in Patients with HER2 Negative, Locally Advanced or Metastatic Breast Cancer	PI3K/ mTOR	HER2-negative, locally advanced or metastatic breast cancer	NCT01495247
Phase II	A Trial of BKM120 (a PI3K Inhibitor) in Patients with Triple Negative Metastatic Breast Cancer	pan-PI3K	Triple negative metastatic breast cancer	NCT01629615
	BKM120 and Fulvestrant for Treating Postmenopausal Patients with Estrogen Receptor-Positive Stage IV Breast Cancer		Postmenopausal patients with estrogen receptor–positive Stage IV breast cancer	NCT01339442
	FERGI: Study of GDC-0941 or GDC-0980 with Fulvestrant Versus Fulvestrant in Advanced or Metastatic Breast Cancer in Patients Resistant to Aromatase Inhibitor Therapy		Postmenopausal patients with ER+ metastatic breast cancer resistant to aromatase inhibitor therapy	NCT01437566
	Akt Inhibitor MK2206 in Treating Patients with Advanced Breast Cancer	Akt	Metastatic breast cancer	NCT01277757
	MK-2206 and Anastrozole with or without Goserelin Acetate in Treating Patients with Stage II-III Breast Cancer		Patients with Stage II-III ER+ breast cancer	NCT01776008
	MK2206 in Treating Patients with Stage I, Stage II, or Stage III Breast Cancer		Stage I, Stage II, or Stage III breast cancer	NCT01319539
Phase III	BELLE-3: A Phase III Study of BKM120 with Fulvestrant in Patients with HR+,HER2-, AI Treated, Locally Advanced or Metastatic Breast Cancer Who Progressed on or after mTOR inhibitors	pan-PI3K	Postmenopausal patients with HR+,HER2-, AI treated, locally advanced or metastatic breast cancer who progressed on or after mTOR inhibitors	NCT01633060
	BELLE-2: Phase III Study of BKM120/ Placebo with Fulvestrant in Postmenopausal Patients with Hormone Receptor Positive HER2-negative Locally Advanced or Metastatic Breast Cancer Refractory to Aromatase Inhibitor		Postmenopausal patients with hormone receptor–positive HER2-negative locally advanced or metastatic beast cancer refractory to aromatase inhibitor	NCT01610284

in preclinical models and recently entered phase I trials. Allosteric inhibitors such as MK-2206 bind to the AKT PH domain and/or hinge region to promote an inactive conformation of the AKT protein that is unable to bind to the plasma membrane. MK-2206 inhibits AKT signaling *in vivo*, and suppresses growth of breast cancer xenografts harboring *PIK3CA* mutations or *ERBB2* amplification (18). Phase I data showed that treatment with MK-2206 decreases levels of P-AKT, P-PRAS40, and P-GSK3β in tumor cells, peripheral blood mononuclear cells, and hair follicles.

Another approach to block this pathway has been the development of ATP-competitive inhibitors of the mTOR kinase, which block both mTORC1 and mTORC2. Several dual TORC1/2 inhibitors have been identified, including INK128 (Intellikine), CC223 (Celgene), OSI-027 (OSI Pharmaceuticals), AZD8055 (AstraZeneca), AZD2014 (AstraZeneca), and Palomid 529 (Paloma Pharmaceuticals).

Dual PI3K/mTOR inhibitors have also been developed in the hope of overcoming the loss of feedback inhibition or PI3K activation observed with rapalogs. The mTORC1 pathway is one of the prominent negative feedback regulators of the PI3K pathway; inhibition of mTORC1 can release this feedback inhibition and activate the PI3K pathway (19). BEZ235, a dual PI3K/mTOR inhibitor, showed higher antiproliferative activity than rapamycin in a preclinical study trastuzumab-resistant and -sensitive human breast cancer cell lines (15). In breast cancer, dual PI3K/mTOR inhibitors are being combined with everolimus, endocrine therapies (exemestane and letrozole), chemotherapy (paclitaxel), and anti-HER2 therapy (trastuzumab).

Overall, the profile of PI3K inhibitors regarding adverse events has been acceptable, with no unexpected toxic effects. Toxic effects have been primarily mild to moderate and manageable with supportive medication. Dose-limiting toxic effects reported with multiple agents include hyperglycemia, maculopapular rash, gastrointestinal intolerance (anorexia, nausea, vomiting, dyspepsia, diarrhea), and stomatitis. Although some of these toxic effects are "off-target" effects, others may be related to target engagement and directly related to mechanisms of action.

Clinical Trials

Several early-stage clinical trials as both single agents and in combination have already been reported or are underway with AKT inhibitors (allosteric such as MK-2206, and catalytic inhibitors such as GDC-0068 and GSK690693) and all three categories of PI3K inhibitors: (i) pan-PI3K inhibitors that target all p110 isoforms (GDC-0941, XL147, BKM120; the irreversible pan-PI3K inhibitor PX-866) (ii) isoform-specific PI3K inhibitors that target a specific p110 isoform (such as the p110δ-selective inhibitor CAL-101, and the p110α-selective INK1117 and BYL719); and (iii) PI3K/mTOR dual inhibitors that inhibit all p110 isoforms as well as mTOR (SF1126, BEZ235, XL765, and GSK1059615).

PI3K Inhibitors and Endocrine Therapy

A phase Ib trial of letrozole and BKM120 (pan-PI3K inhibitors that target all p110 isoforms) for postmenopausal patients with ER+/HER2– metastatic breast cancer (MBC) evaluated safety and preliminary anti-tumor activity of two different schedules of BKM120 administration in combination with letrozole: continuously or intermittently (5 on/2 off days) (20). Fifty-one patients were accrued in total; 40/51 (78%) had previously progressed on an aromatase inhibitor in the metastatic setting. The dose-limiting toxicity (DLT) in the continuous BKM120 schedule was transaminitis, and in the intermittent BKM120 schedule, mood disorders. Of note, the overall rate of grades 1–3 toxicities was higher in the continuous schedule arm. Six of 20 (30%) patients in the continuous BKM120 schedule arm and 10/31 (32%) of patients in the intermittent BKM120 schedule arm received therapy for >6 months. Interestingly, 45% of evaluable patients with a PI3K mutant cancer maintained stable disease for ≥6 months but duration of therapy. However, this clinical benefit has also been observed in a similar number of patients with PIK3CA wild-type tumors. A large phase II-III neoadjuvant trial with letrozole with or without BKM120 or BYL719 in patients with ER+ operable breast cancer is under way.

PI3K Inhibitors and HER2-targeted Therapy

Early clinical studies have also combined dual PI3K/mTOR inhibitors with trastuzumab. A phase I/Ib dose-escalation study of BEZ235, a dual PI3K/mTOR inhibitor, with trastuzumab aimed to enrich for patients with PI3K pathway alterations by limiting the study to patients with mutations in PIK3CA or PTEN or loss of PTEN by IHC in tumor samples. The maximum tolerated dose (MTD) for BEZ235 is estimated to be 600 mg per day in combination with trastuzumab, and this dose is being carried forward to the dose-expansion cohort. The combination also appears to be clinically active, with a clinical benefit rate (CBR) of 27%. In this study, there does not appear to be an association between PI3K pathway alteration and response (21). Given the short half-life of BEZ235, a twice-daily schedule was investigated in a phase Ib/II study in combination with trastuzumab, but found to be too toxic.

The safety and efficacy of a novel PI3K inhibitor (XL147) administered in combination with trastuzumab or with paclitaxel and trastuzumab are being evaluated in patients with HER2-positive metastatic breast cancer that progressed during previous trastuzumab treatment (NCT01042925).

Combinations of MEK and PI3K pathways inhibitors are being explored in attempts to block escape pathways, which may become prominent when the PI3K pathway is inhibited. Several new generation PI3Kα-selective inhibitors are currently being evaluated in phase I clinical trials, including BYL719 (NCT01219699), INK-1114 (NCT01449370), and GDC-0032 (NCT01296555), as a single agent or in combination with endocrine therapies (letrozole and fulvestrant) or HER2-targeted agents (trastuzumab).

INHIBITORS OF MTOR

mTOR kinase is a serine-threonine kinase and member of the PI3K-AKT pathway that integrates signals from growth factors and nutrients to regulate key metabolic and macromolecular processes, such as mRNA translation, ribosome biogenesis, protein synthesis and cell motility. mTOR nucleates two protein complexes, TORC1 and TORC2, that mediate different functions in part through mRNA translational control (4). TORC1 also contains the regulatory protein Raptor, which recruits substrates to TORC1 for phosphorylation, including the eIF4E binding/inhibiting protein (4E-BP, inhibited by phosphorylation) and ribosomal protein S6 kinases 1,2 (S6K1,2). S6K1,2 phosphorylate S6 and the initiation factor eIF4B, stimulating its RNA binding activity and cap-dependent translation. The second complex, TORC2 contains the rapamycin-insensitive component of mTOR (Rictor). It regulates cytoskeletal organization in response to growth factors and lead to phosphorylation of AKT (in Ser473) and its activation. AKT activates TORC1/Raptor via inactivation of TSC1 (22).

Support for the combination of mTOR inhibitors with either tamoxifen or an aromatase inhibitor (AI) has been demonstrated in preclinical models of antiestrogen-sensitive and -resistant ER+ breast cancer (23). MCF-7 cells expressing constitutively active Akt were able to proliferate under reduced estrogen conditions and were resistant to the growth inhibitory effects of tamoxifen, both *in vitro* and *in vivo* (23). However, co-treatment with temsirolimus inhibited mTOR and restored sensitivity to tamoxifen, primarily through induction of apoptosis, thus suggesting that Akt-induced tamoxifen resistance may in part be mediated by signaling through the mTOR pathway. Further, everolimus has also been shown in *in vitro* (24) and *in vivo* (25) models to restore sensitivity of cancer cells to letrozole.

Rapamycin and its analogs form complexes with FK506-binding protein (FKBP12). This complex then binds to mTOR and inhibits the kinase activity of TORC1 but not TORC2. Formulation problems of rapamycin prompted the development of analogs such as CCI-779 (temsirolimus), RAD001 (everolimus), AP-23573 (deferolimus), and MK-8669 (ridaferolimus). These rapalogs have shown cytostatic activity in preclinical models and clinical trials, particularly in patients with renal cell cancer and in patients with mutations in the TSC complex (upstream of TORC1) who harbor renal angiolipomas. Compounds that target the ATP-binding cleft of mTOR (i.e., OSI-027, AZD8055, INK-128), and are thus active against both TORC1 and TORC2, are also in phase I trials. Of note, treatment with rapalogs results in compensatory stimulation of AKT-TORC1 through activation of TORC2 (19). This has stimulated the interest on development of small molecule catalytic inhibitor of TORC1/2.

CLINICAL TRIALS

mTOR Inhibitors and Endocrine Therapy

Combinations with tamoxifen and aromatase inhibitors have already been evaluated in phase II and III clinical trials (Table 75-3). A phase II, 3-arm study evaluated daily letrozole alone or in combination with daily temsirolimus (10 mg/day or 30 mg/day for 5 days every 2 weeks) in postmenopausal women with locally advanced or MBC; median progression-free survival (PFS) was 11.5 months in the letrozole /temsirolimus 10 mg arm, 13.2 months in the letrozole/temsirolimus 30 mg arm, and 11.6 months in the letrozole alone arm (26). However, the subsequent HORIZON study, a large phase III randomized, double-blind, multicenter trial of temsirolimus plus letrozole versus placebo plus letrozole in postmenopausal women with newly diagnosed locally advanced or MBC, showed that both treatment arms had virtually identical median PFS and ORRs (27). Interestingly, although the combination arm had higher incidence of mTOR inhibitor–related toxicities than the single-agent arm, the occurrence of these toxicities was lower than that seen in several everolimus studies.

In a phase II randomized trial of 270 postmenopausal women (28), those who received 4 months of preoperative therapy with letrozole and everolimus had a clinical response rate of 68% compared with 59% in those receiving letrozole alone, suggesting that both ER blockade and mTOR inhibition augments the efficacy of ER-targeting. Of note, patients in this trial whose tumors had activating mutations in exon 9 of PIK3CA showed strong antiproliferative response (Ki-67) to mTOR/AI combination therapy but poor response to AI alone.

In patients with acquired aromatase inhibitor resistance, the value of blocking ER and the PI3K/AKT/mTOR pathway is shown in several key papers. Results from the phase II TAMRAD study conducted in postmenopausal patients with AI-resistant ER+ MBC found the addition of everolimus to tamoxifen almost doubled time to progression (4.5 months vs. 8.6 months for tamoxifen alone and tamoxifen-everolimus), corresponding to a 46% reduction in risk of progression with combination therapy (29). Interestingly, a subgroup analysis revealed that for the tamoxifen-everolimus arm, this risk reduction was greatest among patients with secondary resistance to endocrine treatment (54%). Higher clinical benefit rates (CBRs; defined as the absence of progression at 6 months) were also observed in patients with secondary hormone resistance who received the combination vs. tamoxifen alone (74% vs. 48%, respectively).

The benefit of everolimus in AI-resistant advanced breast cancer has been further supported by the phase III BOLERO-2 study, which compared the combination of exemestane and everolimus versus exemestane alone in patients with ER-positive MBC (30). Of 724 patients enrolled in this trial, 84% had demonstrated previous sensitivity to endocrine treatment with more than 50% having received ≥3 previous therapies. At interim analysis according to local assessment, the addition of everolimus to exemestane significantly prolonged median PFS by 4.1 months versus exemestane alone (6.9 months vs. 2.8 months, respectively; p <.001); the CBR was 33% among patients receiving the combination compared to 18% for exemestane only (30). These data led to the FDA approval of everolimus for the treatment of postmenopausal women with advanced ER+ breast cancer refractory to prior AIs in July 2012. The safety profile was consistent with AEs previously reported for everolimus. In both studies above, the combined everolimus/endocrine therapy had substantially higher stomatitis (56%), rash (36% to 44%), fatigue (33% to 72%), diarrhea (30% to 39%), and anorexia (29% to 43%) than single-agent endocrine therapy.

In summary, the cumulative clinical experience suggests that targeting mTOR with endocrine therapy should be limited to populations with acquired AI resistance. But considering how heterogeneous ER+ breast cancers are, the difference in patient selection, prior endocrine therapy exposure, and the specific drug combination being tested, potential predictive markers to understand the role of combining mTOR inhibition with antiestrogen therapy are still sorely needed.

mTOR Inhibitors and HER2-targeted Therapy

A phase I-II study of everolimus in combination with paclitaxel and trastuzumab in trastuzumab-refractory HER2-positive metastatic breast cancer (31) demonstrated clinical activity with an ORR of 44% and control of disease for 6 months or more in 74% of the patients. Based on this study, paclitaxel and trastuzumab with either everolimus at a dose of 10 mg/day or placebo is being tested in a phase III randomized study. An additional phase I study combined everolimus with weekly trastuzumab and vinorelbine in pretreated HER2-positive metastatic breast cancer (32). Antitumor activity was noted, with an ORR of 19.1%, disease control rate of 83%, and median PFS of 30.7 weeks. Grade 3 or 4 neutropenia were the dose-limiting toxicities, and everolimus 5 mg/day and 30 mg/week were deemed safe. Since everolimus crosses the blood-brain barrier, the combination of everolimus, vinorelbine, and trastuzumab is now being tested for the treatment of progressive (post-radiation) or new brain metastases (prior to radiation) in patients with HER2+ MBC). Everolimus is also currently in phase III clinical trials in combination with vinorelbine and trastuzumab in locally advanced or metastatic HER2-positive breast cancer

resistant to trastuzumab and previously treated with a taxane (BOLERO-3, NCT01007942).

Novel Strategies/Combinations

Pre-clinical studies indicate that the dual inhibition of IGFR and mTOR may be additive or synergistic and abrogates the feedback activation of AKT due to rapamycin analog mTOR inhibitors. A phase I study of the mTOR inhibitor ridaforolimus and the anti-IGFR antibody dalotuzumab (33) demonstrated that the combination was feasible and well tolerated at doses that were nearly those used for the two single agents and with dose-limiting toxicity of stomatitis, similar to ridaforolimus as monotherapy. A preliminary signal of anti-tumor activity, including partial responses and prolonged progression free survival, was observed in ER+ breast cancer, especially in high-proliferation tumors.

A randomized, phase II study in HER2-positive early-stage breast cancer is assessing whether adding everolimus to trastuzumab for 6 weeks in the neoadjuvant setting improves clinical tumor response rate. Studies with other combinations, including temsirolimus and neratinib (HKI272) (phase I/II) or everolimus and lapatinib (phase II) are also in progress.

CYCLIN DEPENDENT KINASE (CDK) INHIBITORS

A key element in cancer pathogenesis is dysregulation of the G1-to-S cell cycle transition and cell cycle progression (34). During this transition, mitogenic signals converge to activate the expression of D-type cyclins. These cyclins bind CDK4 or CDK6, which, in turn, phosphorylate and inactivate the Rb tumor suppressor and related proteins p107 and p130. The Rb proteins control the activity of the E2F family of transcription factors. Upon phosphorylation, Rb protein uncouple from E2F factors, which, in turn, modulate the expression of genes that coordinate subsequent cell cycle progression (cyclin A and cyclin E), DNA replication (MCM7 and PCNA), and mitosis (cyclin B1 and Cdk1) (35). In breast cancer, several mechanisms contribute to dysregulate CDK function, thus making them a potential target for therapeutic intervention. These include HER2 overexpression, cyclin D1 gene amplification, overexpression of cyclin E, loss of the CDK inhibitors p16 and $p27^{KIP1}$, and functional inactivation or genetic loss of Rb, among others (5,36). Cyclin D_1 is overexpressed in >50% of breast cancers (37).

Published studies support a role for cyclin D1 and activity of a CDK4/6 inhibitor against luminal ER+ breast cancer, its synergism with tamoxifen in antiestrogen-sensitive cell lines, as well as the reversal of acquired endocrine resistance. Cyclin D1 amplification and/or overexpression has been more commonly associated with ER+ tumors (38) and is associated with tamoxifen resistance (39). Further, cyclin D1 can directly activate ER in ligand-independent manner that is also independent of CDK and pRb function (40). Based on the widely accepted paradigm that the entire contribution of cyclin D1 to tumorigenesis is achieved through its activation of Cdk4/6, much effort has been directed toward finding small molecule CDK inhibitors or activators of endogenous Cdk inhibitors (41).

Dinaciclib is a potent, selective inhibitor of CDK1, 2, 5, and 9 with pre-clinical activity in breast cancer cell lines and tumor xenografts. A randomized, multicenter, open-label

TABLE 75-4

Current Clinical Trials with CDK Inhibitors

Study Design	*Clinical Trial*	*Type of inhibitor*	*Patient Population*	*Clinicaltrials.gov*
Phase I	Dinaciclib and Epirubicin Hydrochloride in Treating Patients with Metastatic Triple-Negative Breast Cancer	CDK inhibitor	Metastatic TNBC	NCT01624441
Phase II	PD 0332991 and Anastrozole for Stage 2 or 3 Estrogen Receptor Positive and HER2 Negative Breast Cancer		Stage II or III ER+ BC	NCT01723774
	PD 0332991 and Anastrozole for Stage 2 or 3 Estrogen Receptor Positive and HER2 Negative Breast Cancer		ER+ MBC	NCT01723774

phase II study was conducted to compare the efficacy of dinaciclib and capecitabine in patients with advanced, previously treated breast cancer (42). The study included 19 patients treated with dinaciclib, including 6 patients who crossed over. Partial responses were reported in 2/12 (17%) evaluable patients who received dinaciclib up front (both patients had ER+/HER2-negative cancers) and in 4/15 (27%) evaluable patients who received capecitabine. The median time to progression for dinaciclib (n = 9) and capecitabine-treated (n = 11) patients was 2.8 and 4.2 months, respectively (Table 75-4).

PD0332991 (palbociclib) is an oral, potent, and highly selective inhibitor of CDK4 and 6; at low nM concentrations, it blocks pRb phosphorylation, thus inducing G_1 arrest in sensitive cell lines (43), as well as primary bone marrow cells *ex vivo* (44). A screen for sensitivity using a large panel of human breast cancer cell lines revealed that luminal ER+ lines (including HER2 gene amplified) were most sensitive to growth inhibition by PD0332991, whereas cells with non-luminal and basal-like gene expression were most resistant (45). Analysis of variance identified 450 differentially expressed genes between sensitive and resistant cells. pRb and cyclin D_1 were elevated, and *CDKN2A* (p16) was decreased in the most sensitive lines. PD 0332991 was synergistic with tamoxifen and trastuzumab in ER+ and HER2 gene-amplified cell lines, respectively (45). These data provide a rationale for the clinical development of PD0332991 in ER+ luminal and HER2-overexpressing breast cancer in combination with antiestrogen or anti-HER2 therapy, respectively.

A randomized phase II combining PD0332991 with letrozole (46) enrolled 165 patients with ER+ MBC who had not been previously treated for metastatic disease. The addition of PD 0332991 to letrozole increased median PFS from 7.5 to 26.1 months (HR = 0.37, p <.001). Of note, the majority of patients enrolled had aggressive disease (*de novo* metastatic disease or a short disease-free interval following adjuvant therapy), which may explain the underperformance of the control arm. ORR was 34% in the PD0332991-containing arm and 26% in the letrozole arm. CBR was 70% in patients treated with PD0332991/letrozole versus 44% in the letrozole arm. Grade 3/4 neutropenia increased from 1% to 51% and leukopenia from 0% to 14% in the combination arm, with 71% of patients requiring dose interruptions and 35% requiring dose reductions. Ten percent of patients discontinued PD0332991. Cyclin D1 gene amplification and p16 protein were prospectively evaluated as potential biomarkers, but only ER status was predictive of activity. A phase III trial is expected to initiate accrual in 2013.

INSULIN/IGF-I RECEPTOR INHIBITORS

The insulin/IGF-I receptor network includes the ligand insulin, IGF-I and IGF-II; the insulin and IGF-I transmembrane receptor tyrosine kinases (RTKs); and IGF-binding proteins (IGF-BPs). The IGF-IR is closely related to the InsR, which is activated by both insulin and IGF-II. In normal physiology, ligand-induced activation of the IGF-IR plays a role in fetal growth and linear growth of the skeleton and other organs, whereas insulin-activated InsR regulates glucose homeostasis. A fetal form of the InsR (insulin receptor A), which has been detected in cancer cells, can also bind IGF-II with high affinity. These receptors can assemble and exist as hybrid heterotetramers, where a dimer of α and β chains of the IGF-IR is joined to a dimer of α and β chains of the InsR. The structure of these receptor chains is such that ligand binding to their extracellular domain is required for physical interaction of the tyrosine kinase domains and activation of signaling. Different to other amplified RTKs, constitutive (ligand-independent) activation of these receptors is not seen, even in experimental systems of artificial overexpression (47). There are six high-affinity IGF-BPs that complex with IGFs in extracellular fluids. Most circulating IGF-I is complexed with IGF-BP3; in this complex, IGF-I cannot bind its cognate receptor (48). Of note, most IGF-BPs have higher affinity for the ligands than for the receptors.

Activating mutations of IGF-IR have not been reported in human tumors. However, there are reports of IGF-I and IGF-BP3 gene polymorphisms associated with an increased risk of breast cancer (49). Overexpression of InsR and IGF-IR has been detected in primary breast cancers and overexpression of either receptor has been shown to induce tumors in mice. Phosphorylated InsR/IGF-IR is present in all subtypes of breast cancer, and high levels have been correlated with poor survival. The IGF-IR has been pursued as the main therapeutic target but increasing evidence implicates and InsR and hyperinsulinemic states such as type II diabetes in mammary transformation and breast cancer mitogenesis (50). Higher levels of IGF-IR, IRS-1, and IGF-II have been found in ER+ human breast cancer cells that adapt to estrogen deprivation or that became resistant to tamoxifen (51). Further, induced overexpression of IGF-IR in HER2 gene amplified breast cancer cells confers resistance to trastuzumab (52). Finally, cell lines and primary tumor with acquired resistance to trastuzumab overexpress IGF-IR.

Several therapeutic approaches that inhibit the InsR/IGF-IR axis are in clinical development (Table 75-5) (53).

TABLE 75-5

Current Clinical Trials with IGF-1R Inhibitors

Study Design	*Clinical Trial*	*Type of inhibitor*	*Patient Population*	*Clinicaltrials.gov*
Phase I	MEDI-573 plus standard endocrine therapy for ER+ metastatic breast cancer	IGF-IR I and II	ER+ MBC	NCT01446159
Phase I/II	BYL719 plus AMG479 in patients with solid tumors	IGF-IR	ER+ MBC	NCT01708161
	Cixutumumab and Temsirolimus in Treating Patients with Locally Recurrent or Metastatic Breast Cancer		HER2-neg MBC	NCT00699491
Phase II	Capecitabine and Lapatinib with or without Cixutumumab in Treating Patients with Previously Treated HER2-Positive Stage IIIB, Stage IIIC, or Stage IV Breast Cancer		HER2+ MBC	NCT00684983

Because of the role of the insulin- or IGF-II stimulated InsR, dual targeting of InsR and IGF-IR is increasingly advocated in order to achieve maximal inhibition of this receptor network in cancer cells. These include small molecule ATP mimetics against IGF-IR. Because of the homology of the kinase domains of InsR and IGF-IR, these small molecules (OSI-906 or linsitinib, BMS-754807, XL-228, etc.) inhibit both receptors. Other compounds include neutralizing IGF-IR monoclonal antibodies, recombinant IGF-BPs, soluble receptor fusion proteins, and antibodies against IGF-I and IGF-II (MEDI-573, MedImmune and BI836845, Boehringer). The clinical development of several IGF-IR antibodies has been discontinued recently. At this time, dalotuzumab (MK-0646, Merck) and ganitumumab (AMG-479, Amgen) have been or are being tested as part of novel combinations in patients with breast cancer. Although they have different Fc domains and are either humanized or fully human, they both bind to the ectodomain of the IGF-IR and cause receptor internalization, thus preventing ligand binding and removing the receptor from the cell surface. Interestingly, blockade of IGF-IR with therapeutic antibodies results in compensatory upregulation of circulating IGFs and insulin, which can be manifest clinically as hyperinsulinemia, type II diabetes, or metabolic syndrome. To ameliorate this compensation and potentially enhance their anti-cancer effect, the anti-diabetic drug metformin has been used in combination with IGF-IR antibodies to dampen gluconeogenesis and lower insulin levels.

AMG-479 (ganitumumab) is a fully human monoclonal antibody against IGF-IR. Because of preclinical data suggesting that dual inhibition of ER and IGF-IR results in greater suppression of ER+ breast cancer proliferation, a double-blind, randomized phase II study of AMG-479 added to either exemestane or fulvestrant in postmenopausal patients with ER+ MBC who had progressed on prior endocrine therapy was conducted (54). Patients were randomized to receive AMG-479 with exemestane or fulvestrant versus placebo plus exemestane or fulvestrant. Stratification factors included which hormonal therapy the patient received, as well as the extent of disease. In all, 106 women were included in the AMG 479 group and 50 in the placebo group. Median PFS was 4.8 months among women who received exemestane/AMG479 and 7.3 months for the exemestane/placebo arm (HR, 1.31). Among women who received fulvestrant, it was 3.7 months and 5.4, respectively (HR, 1.11). The objective response rate for patients in the AMG-479 group was 8% versus 13% for those in the control group. CBR was 35% for women on AMG-479 and 31% of women on placebo. Median overall survival at the final analysis was 23·3 months in the ganitumumab group and not reached in the placebo group (HR 1.78, 80% CI, 1.27–2.50; p = .025).

Despite the biological rationale for targeting the Ins/IGF-I receptor pathway, the studies of investigating inhibitors of these receptors in breast cancer have yielded disappointing results. In the absence of a predictive biomarker that can identify tumors that depend on this pathway, it seems unlikely at the time of this chapter that these agents will play a significant role in the treatment of breast cancer.

HISTONE DEACETYLASE (HDAC) INHIBITORS

Epigenetic changes, such as histone hypoacetylation and abnormal methylation of DNA in the promoter region of important genes, contribute to tumorigenesis and drug resistance in several cancers, including breast cancer. Importantly, epigenetic changes may be reversible and thus represent an active and attractive area of basic and clinical investigation (55).

In breast cancer cells, multiple genes are methylated, and thus silenced. Gene methylation is likely related to cancer progression. HDAC inhibitors may also alleviate gene repression that is mediated through promoter hypermethylation. It is presumed that HDAC inhibitors can increase expression of the genes that are not methylated but may not induce the expression of hypermethylated genes. Some of the genes that are often methylated in breast cancer include ERα and the retinoic acid receptor (RAR) β, also critical for cell differentiation. Other hypermethylated genes in breast cancer include cyclin D, Twist, RASSF1A, APC, and HIN-1. Investigators have evaluated hypermethylation of a panel of seven genes in a variety of breast tissues (56). In invasive breast cancers, up to 100% of specimens contained at least one hypermethylated gene, 80% contained two, and 60% contained three or more methylated genes (57). Among 44 DCIS specimens, 95% had

at least one methylated gene. In contrast, the percentage of women with benign breast disease having at least one methylated gene was only 15%. Only one of 8 reduction mammoplasty specimens contained hypermethylated genes.

Suberoylanilide hydroxamic acid (SAHA, Vorinostat) is a small molecule histone deacetylase (HDAC) inhibitor that binds directly at the enzyme's active site in the presence of Zn and is currently in clinical trials in breast cancer (58). Because aberrant HDAC activity has been implicated in a variety of cancers, development of HDAC inhibitors is a rational approach to the design of targeted anti-cancer therapeutics. Several HDAC inhibitors from multiple chemical classes have been developed and are currently in clinical trials (Table 75-6). Of these, vorinostat targets most human class 1

TABLE 75-6

Current Clinical Trials with HDAC Inhibitors

Study Design	*Clinical Trial*	*Type of inhibitor*	*Patient Population*	*Clinicaltrials.gov*
Phase I	Ixabepilone and Vorinostat in Treating Patients with Metastatic Breast Cancer	HDAC Inhibitor,	HER2 negative MBC	NCT01084057
	Study of the Combination of Vorinostat and Radiation Therapy for the Treatment of Patients with Brain Metastases		HER2 negative MBC with brain mets	NCT00838929
Phase I/II	HDAC Inhibitor Vorinostat (SAHA) With Capecitabine (Xeloda) Using a New Weekly Dose Regimen for Advanced Breast Cancer		HER2 negative MBC	NCT00719875
	Trial for Locally Advanced Her2 Positive Breast Cancer Using Paclitaxel, Trastuzumab, Doxorubicin and Cyclophasmide on a Weekly Basis		Stage II/III HER2+ BC	NCT00574587
	Entinostat and Lapatinib Ditosylate in Patients with Locally Recurrent or Distant Relapsed Metastatic Breast Cancer Previously Treated With Trastuzumab		HER2+ MBC	NCT01434303
	Re-expression of ER in Triple Negative Breast Cancers		Metastatic TNBC	NCT01194908
Phase II	Phase II Trial of SAHA & Tamoxifen for Patients with Breast Cancer		ER+ MBC	NCT00365599
	Entinostat and Anastrozole in Treating Postmenopausal Women with Triple-Negative Breast Cancer That Can Be Removed by Surgery		Stage I – III TNBC	NCT01234532
	Azacitidine and Entinostat in Treating Patients with Advanced Breast Cancer		Metastatic TNBC	NCT01349959
	Vorinostat in Treating Patients with Stage IV Breast Cancer Receiving Aromatase Inhibitor Therapy		ER+ MBC	NCT01153672
	Vorinostat and Lapatinib in Advanced Solid Tumors and Advanced Breast Cancer to Evaluate Response and Biomarkers		HER2+ MBC	NCT01118975
	Vorinostat in Treating Women Who Are Undergoing Surgery for Newly Diagnosed Stage I, Stage II, or Stage III Breast Cancer		Stage I - III HER2-negative BC	NCT00262834
	Carboplatin and Paclitaxel Albumin-Stabilized Nanoparticle Formulation with or without Vorinostat in Treating Women with Breast Cancer That Can Be Removed by Surgery		Stage II/ III TNBC	NCT00616967

and class 2 HDACs (59). Among those currently in trials, vorinostat is the most potent HDAC inhibitor that can be administered orally with excellent bioavailability. The most common drug-related adverse with this class of drugs are diarrhea (49%), fatigue (46%), nausea (43%), and anorexia (26%), mostly being <grade 2 (60).

PARP INHIBITORS

Poly-ADP-ribose polymerase (PARP) is an abundant, constitutively expressed nuclear enzyme that catalyzes the transfer of ADP-ribose from NAD+ to target proteins, through which it facilitates DNA repair, cellular proliferation, and signaling to other critical cell cycle proteins and oncogenes (61). At sites of DNA damage, PARP activates intracellular signaling pathways that modulate DNA repair and cell survival through poly (ADP-ribosyl)ation of several nuclear proteins involved in the chromatin architecture and DNA metabolism. Immediate catalytic activation of PARP in response to DNA single- and double-strand breaks has been reported at levels up to 500-fold (62,63).

There are at least three roles of PARP inhibitors in cancer treatment: sensitization to chemotherapy and radiotherapy, synthetic lethality in patients with hereditary mutations in BRCA1/2 genes (inherited defect in homologous recombination), and, finally, leveraging of putative "BRCA-like" defect tumors and defects in DNA repair such as triple negative breast cancer (TNBC).

BRCA1 and *BRCA2* genes encode for proteins critical for DNA integrity and genomic stability (64,65). BRCA1 and BRCA2 are tumor-suppressor proteins essential for cell division, DNA error control, DNA repair and apoptosis. In 2005 Bryant (66) and Farmer (67) showed that BRCA-deficient cells were extremely sensitive to PARP inhibition. Single-agent PARP inhibitors led to impaired SSB repair, causing double strand breaks (DSBs) in replicative cells. In cells with wild-type BRCA, DSBs are repaired via homologous recombination (HR). In BRCA-deficient cells, HR is impaired and alternative pathways lead to complex rearrangements, loss of repair mechanisms, and cell death (so called "synthetic lethality") (68). Significant single-agent activity was recently reported with the PARP inhibitor olaparib in patients with BRCA-deficient MBC. Overall responses ranged from 22% (100 mg bid) to 41% (400 mg bid) with minimal toxicity (69).

There are several molecular and pathologic similarities between TNBC and BRCA-deficient breast cancers, whose homologous recombination-dependent DNA repair is impaired. The association between basal-like breast cancer (BLBC), TNBC, and BRCA pathway dysfunction has therapeutic implications. Although the terms "triple negative" (TN) and "basal-like" are not synonymous, at least 80% of clinical TNBCs (ER/PR/HER2-negative) classify as basal-like (70). In addition, TNBC expresses a high proportion of basal-like cytokeratins (CK) 5, 14, and 17, and overexpress P-cadherin and EGFR (71). Because a clinically applicable test for the basal molecular classification has yet to be developed, the triple-negative phenotype is a reasonable surrogate for the basal-like molecular subtype, a gene expression profile common *BRCA1* mutation carriers (72). Indeed, two-thirds of cancers among 400 patient carriers of a BRCA1 mutation were triple-negative tumors (73). The tight association between *BRCA1* mutations, BLBC, and TNBC has raised the question as to whether *BRCA1* loss of function through other mechanisms participates in the pathogenesis of sporadic basal-like and TNBC—an association that could be exploited therapeutically.

BSI-201/iniparib binds to PARP1 in the NAD binding pocket and inhibits PARP enzyme activity at high μm concentrations. A phase II, open-label, 2-arm randomized, safety and efficacy trial (Study 20070102) investigated BSI-201 (5.6 mg/kg) in combination with gemcitabine/carboplatin in patients with metastatic TNBC (Table 75-7). This is the only randomized study with final safety and efficacy data. The final analysis of 123 randomized patients showed that addition of BSI-201 to gemcitabine/carboplatin improved the clinical benefit rate from 33.9% to 55.7% (p = .015) and ORR from 32.3% to 52.5% (p = .023). Addition of BSI-201 prolonged the median PFS) from 3.6 to 5 9 months (hazard ratio [HR], 0.59; p = .012) and the median OS from 7.7 to 12.3 months (HR, 0.57; p = .014) (74). The incidence of adverse events (AEs) was similar in both groups. The most frequent AEs were fatigue, nausea, neutropenia, anemia, and thrombocytopenia. There was a >5% increase in the incidence of grade 3/4 anemia and thrombocytopenia in patients receiving BSI-201/gemcitabine/carboplatin compared to gemcitabine/carboplatin, but the differences were not statistically significant (74). Following this trial, a phase III study evaluating gemcitabine/carboplatin ± BSI-201 in patients with metastatic TNBC with 0–2 prior treatment regimens in the metastatic setting was completed. The trial did not meet the pre-specified criteria for significance for the co-primary endpoints of OS and PFS. The results of a pre-specified analysis in patients treated in the second- and third-line setting showed an improvement in OS and PFS, consistent with what was seen in the smaller phase II study. Similarly, the addition of BSI-201 did not add to the toxicity profile of gemcitabine and carboplatin (75). It is unclear whether investigation of molecular biomarkers that would identify a responsive group of patients is planned or ongoing. Of note, however, more recent pre-clinical data have shown that BSI-201 does not possess characteristics typical of the PARP inhibitor class. Investigations into potential targets of BSI-201 and its metabolites are ongoing. The following observations regarding the cellular effects of BSI-201 have been made: BSI 201 (i) induces γ -H2AX (a marker of DNA damage) in tumor cell lines (76); (ii) induces cell cycle arrest in the G2/M phase in tumor cell lines (77); and (iii) potentiates the cell cycle effects of DNA damaging modalities in tumor cell lines (78). Additional targets are under investigation.

FIBROBLAST GROWTH FACTOR (FGF) RECEPTOR INHIBITORS

The FGFs and their receptors (FGFRs) play an important role in embryological development such as in brain patterning, morphogenesis, and limb development, as well as physiological functions in the adult such as angiogenesis, wound repair, and endocrine functions. The FGF family consists of 18 ligands that signal through four high-affinity FGFRs (FGFR1-4). FGF ligands bind to receptors in a trimeric complex with heparins, leading to a conformational change in FGFRs, receptor dimerization, kinase activation, and autophosphorylation of intracellular FGFR tyrosines and other transducers such as PLCγ, FRS2 (an adaptor that links to activation of ERK and PI3K), STATs, and Src. Under physiological conditions, this complex FGFR signaling network is tightly regulated. Dysregulation of the FGF signaling pathway results in its aberrant activation, leading to transformation and subsequent enhanced cancer cell proliferation, migration, and survival (79).

Several lines of evidence support a role for FGFRs in breast cancer (80). For example, the mouse mammary tumor virus (MMTV) induces tumors through integration

TABLE 75-7

Current Clinical Trials with PARP Inhibitors

Study Design	*Clinical Trial*	*Type of inhibitor*	*Patient Population*	*Clinicaltrials.gov*
Phase I	Olaparib in Combination with Carboplatin for Refractory or Recurrent Women's Cancers	PARP inhibitor	Women's cancers; males with BRCA mutations	NCT01237067
	AZD2281 Plus Carboplatin to Treat Breast and Ovarian Cancer		Breast and ovarian metastatic cancers	NCT01445418
	Study to Assess the Safety and Tolerability of a PARP Inhibitor in Combination with Carboplatin and/or Paclitaxel		TNBC and ovarian metastatic cancers	NCT00516724
	Phase I of BKM120/Olaparib for Triple Negative Breast Cancer or High Grade Serous Ovarian Cancer		TNBC and ovarian metastatic cancers	NCT01623349
	Veliparib with Radiation Therapy in Patients with Inflammatory or Loco-regionally Recurrent Breast Cancer		Inflammatory or loco-regionally recurrent breast cancer	NCT01477489
Phase I/II	A Study of Oral Rucaparib in Patients with gBRCA Mutation Breast or Ovarian Cancer, or Other Solid Tumor		gBRCA mutation breast or ovarian cancer	NCT01482715
Phase II	A Phase 2 Study of Standard Chemotherapy Plus BSI-201 (a PARP Inhibitor) in the Neoadjuvant Treatment of Triple Negative Breast Cancer		Stage II/III TNBC	NCT00813956
	A Study Evaluating INIPARIB in Combination with Chemotherapy to Treat Triple Negative Breast Cancer Brain Metastasis		TNBC with brain mets	NCT01173497
	Phase II Study of AZD2281 in Patients with Known BRCA Mutation Status or Recurrent High Grade Ovarian Cancer or Patients with Known BRCA Mutation Status/ Triple Neg Breast Cancer		TNBC and ovarian metastatic cancers; BRCA mt cancers	NCT00679783
	PARP Inhibition for Triple Negative Breast Cancer (ER-/PR-/HER2-)with BRCA1/2 Mutations		TNBC metastatic BRCA mt cancers	NCT01074970
	ABT-888 with Cyclophosphamide in Refractory BRCA-Positive Ovarian, Primary Peritoneal or Ovarian High-Grade Serous Carcinoma, Fallopian Tube Cancer, Triple-Negative Breast Cancer, and Low-Grade Non-Hodgkin's Lymphoma		Metastatic TNBC	NCT01306032
	Study of SAR240550 (BSI-201) in Combination with Gemcitabine/ Carboplatin, in Patients with Metastatic Triple Negative Breast Cancer		Metastatic TNBC	NCT01045304
	Two Regimens of SAR240550/Weekly Paclitaxel and Paclitaxel Alone as Neoadjuvant Therapy in Triple Negative Breast Cancer Patients		Stage II/III TNBC	NCT01204125
	ABT-888 and Temozolomide for Metastatic Breast Cancer and BRCA1/2 Breast Cancer		Metastatic breast cancer and BRCA1/2 breast cancer	NCT01009788
	Rucaparib (CO-338; Formally Called AG-014699 or PF-0136738) in Treating Patients with Locally Advanced or Metastatic Breast Cancer or Advanced Ovarian Cancer		Metastatic breast, ovarian, and BRCA mt cancers	NCT00664781

into the genome, thereby transcriptionally activating the expression of nearby genes. *FGF3* and *FGF8*, along with *WNT* genes, are the most common sites of integration of MMTV. Studies in transgenic mice have shown that overexpression of FGF3 and activated FGFR1 in the mouse mammary gland result in invasive mammary carcinomas. A single nucleotide polymorphism (SNP) within the second intron of the *FGFR2* gene has been associated with an increased risk of breast cancer. A SNP in the *FGFR4* gene has been shown to confer a more virulent cancer behavior and poor outcome in multiple tumor types, including breast cancer. *FGFR2* gene amplification occurs in a small cohort of breast cancers that includes all three major clinical subtypes (ER+, HER2+, and triple negative). On the other hand, *FGFR1* is one of the most commonly amplified genes in cancer with approximately 10% of breast cancers, mainly ER+ tumors, exhibiting *FGFR1* amplification. *FGFR1* amplification correlates with the luminal B subtype of ER+ breast cancer and has been shown to confer resistance to tamoxifen (81). FGFRs and FGFR3-activating mutations are found in other tumor types, but evidence of them has not been found in breast cancer. Although FGFRs are constitutively phosphorylated/activated in gene amplified breast cancer cell lines, there is no published evidence of ligand-independent signaling in primary tumors, where the data seem to support enhanced ligand-induced receptor activation.

Expression of the cytoplasmic FGF2 ligand was found to be specific to basal-like breast cancer. This ligand is abundantly expressed in tumor stroma. One study reported elevated levels of FGF2 in nipple aspirates of patients with breast cancer. FGF2 is highly angiogenic, and its overexpression has been associated with resistance to VEGFR inhibitors. Finally, *FGFR*-amplified cell lines exhibit high sensitivity to FGFR inhibitors, suggesting the FGFs and/or FGFRs are a therapeutic target. Based on these data, several pharmaceutical companies have developed drugs targeting FGF ligands and FGFRs, the most common being small molecule TKIs of FGFRs (82). Several of these inhibitors also inhibit receptors in the PDGFR and VEGFR families. More recently, selective FGFR inhibitors have been developed. The kinase domains of FGFR1-3 are highly homologous so more recently developed selective FGFR inhibitors block all three family members. FGFR4 has diverged from FGFR1-3 and consequently these inhibitors are less potent against FGFR4. Other inhibitors include receptor-specific FGFR1-3 neutralizing antibodies and an FGF multi-ligand trap (83).

TKI258 (i.e., dovitinib) is a potent TKI with an IC_{50} of <20 nmol/L for VEGFR1, 2 and 3, PDGFRβ, FGFR1 and 3, FLT-3, KIT, RET, TRKA, and colony-stimulating factor 1 (CSF-1). Dovitinib exerts antitumor activity through inhibition of FGFR and PDGFR and has shown antiangiogenic activity through the inhibition of FGFR, VEGFR, and PDGFR (84). A phase I dose-escalating trial of orally administered dovitinib studied 35 patients with advanced solid tumors. The most frequent drug-related adverse events were gastrointestinal disorders and fatigue. Cardiovascular events were seen in 5 patients (14%). One melanoma patient had a partial response (PR) and 2 patients exhibited stable disease (SD) for >6 months. Five of 14 evaluable patients showed modulation of phosphorylated ERK levels in peripheral blood mononuclear cells (85). A two-step phase II study evaluated dovitinib in patients with previously treated, metastatic, HER2-negative breast cancer. Patients were stratified into four groups according to FGFR1 and hormone receptor (HR) status. Antitumor activity was observed in the FGFR1 amplified/ER+ subset (25% had nonconfirmed PR and/or SD ≥4 weeks). Biomarker analysis suggested that co-amplification of FGFR1 and FGFR3 might identify a subgroup of dovitinib-sensitive tumors (86). These observations were used as the rationale behind the design of an ongoing multicenter, randomized phase II trial of fulvestrant with and without dovitinib for postmenopausal, HER2-negative/ER+ patients with MBC who were on endocrine therapy. Prospective molecular screening is expected to enrich for patients with tumors with FGFR1, FGFR2, or FGFR3 amplification (clinicaltrials.gov; NCT01528345).

AZD4547 is a highly active pan-FGFR small molecule TKI. Its activity against VEGFR2 is approximately 120-fold lower than that against FGFR1. AZD4547 suppresses FGFR signaling and growth in tumor cell lines with dysregulated FGFR expression. In a representative FGFR3-driven human tumor xenograft model, the oral administration of AZD4547 was well tolerated and resulted in potent antitumor activity (87). AZD4547 is currently being evaluated in a phase I clinical trial. A second expansion phase will include patients with FGFR1- and/or FGFR2-amplified cancers (clinicaltrials.gov; NCT00979134). A randomized, double-blind phase IIA study will assess the safety and efficacy of AZD4547 when taken in combination with exemestane versus exemestane alone in patients with ER+ breast cancer with FGFR1 polysomy or amplification (clinicaltrials.gov; NCT01202591).

HEAT SHOCK PROTEIN (HSP) 90 INHIBITORS

Hsp90 is a molecular chaperone that regulates the folding, function, and viability of key proteins within cells (called client proteins) under conditions of environmental stress (88–90). When Hsp90 is inhibited, its client proteins are rendered unstable, ultimately undergoing ubiquitination and proteasomal degradation (89). A number of Hsp90 client proteins, including nuclear steroid receptors, AKT, RAF1, CDK4, HER2, EGFR, BCR-ABL, PDGFRA, and KIT, are important Hsp90 client proteins involved in oncogenesis, cancer cell proliferation, and survival (91,92). Consequently, Hsp90 has become an attractive therapeutic target in cancer.

Several natural products, including geldanamycin, bind selectively to an amino-terminal pocket in HSP90 and inhibit its function (Table 75-8) (93). Geldanamycin is hepatotoxic, but its derivative, tanespimycin (17-AAG, 17-demethoxygeldanamycin; KOS-953) has reduced toxicity (94). HER2 is among the most sensitive client proteins of HSP90, demonstrating degradation within 2 h of inhibition of HSP90 in cultured cells (95). Geldanamycin analogues (17-allylamino-17-demethoxygeldanamycin [17-AAG] and 17-dimethylaminoethylamino-17-demethoxygeldanamycin [17-DMAG]) have demonstrated potent inhibition of HSP90 function and growth of HER2-overexpressing cells *in vitro* and *in vivo* (95,96). In the clinic, initial studies with the tanespimycin (KOS-953) (97) and the second-generation Hsp90 inhibitor, alvespimycin (KOS-1022) (98), have demonstrated safety and antitumor activity and tolerability in combination with trastuzumab in patients with trastuzumab-refractory HER2-overexpressing breast cancer.

As a proof of concept, the phase I of 17-AAG with trastuzumab showed evidence of objective tumor regressions and meaningful clinical benefit for the subset of patients with advanced HER2 positive breast cancer who had progressed on trastuzumab (99). This led to a single-arm phase 2 trial of tanespimycin (17-AAG) plus trastuzumab in patients with

TABLE 75-8

Current Clinical Trials with HSP90 Inhibitors

Study Design	*Clinical Trial*	*Type of inhibitor*	*Patient Population*	*Clinicaltrials.gov*
Phase I/II	Combination of AUY922 with Trastuzumab in HER2+ Advanced Breast Cancer Patients Previously Treated With Trastuzumab	HSP90 inhibitor	HER2+ MBC	NCT01271920
Phase II	Randomized Phase II Study of Fulvestrant with or without Ganetespib in Patients with ER+ MBC		ER+ MBC	NCT01560416
	Open Label Multicenter Phase 2 Window of Opportunity Study Evaluating Ganetespib (STA-9090) Monotherapy in Women with Previously Untreated Metastatic HER2 Positive or TNBC		Metastatic HER2+ or TNBC	NCT01677455

HER2+ metastatic breast cancer after progression on trastuzumab (100). Thirty-one patients were treated with the combination until disease progression. Overall, the combination was well tolerated, with mostly grade 1 diarrhea, nausea, fatigue, and headache as main side effects. The overall response rate was 22%, with a CBR of 59%, a median PFS of 6 months (95% CI, 4–9), and a median OS of 17 months (95% CI, 16–28).

SECTION XII

Site-Specific Therapy of Metastatic Breast Cancer

CHAPTER 76

Brain Metastases

Nancy U. Lin, Brian M. Alexander, and Ian F. Dunn

CHAPTER CONTENTS

The management of patients with brain metastases from breast cancer remains a challenging clinical problem. The goals of treatment are to extend life and improve or stabilize patient symptoms while minimizing treatment-related toxicities. Of note, because of their unique location, even relatively small tumors in the central nervous system (CNS) may result in neurological symptoms that negatively impact quality-of-life (QOL). Intracranial involvement with breast cancer can also occur as leptomeningeal involvement, and this is covered in Chapter 78. Because most systemic therapies do not effectively treat brain metastases, progression in the brain can represent a significant mortality risk. Indeed, for a subset of women with advanced breast cancer, control of CNS disease has become a vital component of overall disease control as well as QOL.

INCIDENCE AND RISK FACTORS

Because of incomplete reporting, the true incidence of brain metastases is difficult to determine with certainty. Registry data from the Netherlands and the United States indicate that among patients with primary lung, breast, melanoma, renal, and colorectal cancers presenting at any stage, the combined incidence of brain metastases is between 8.5% and 9.6% (1,2). Of patients diagnosed with brain metastases, between 13% and 20% will carry a primary diagnosis of breast cancer, making breast cancer the second most common cause of CNS involvement, after lung cancer.

Clinical factors such as disease stage, young age, and African-American ethnicity are associated with an increased risk of developing brain metastases (1). In patients presenting with localized, early-stage breast cancer, overall, less than 5% will ultimately be diagnosed with brain metastases. Among patients with advanced breast cancer not selected by tumor subtype, brain metastases will be diagnosed in approximately 15% (1). These figures likely are an underestimate of the true incidence, given that in autopsy studies from the 1970s and 1980s, up to 30% of patients were found to have CNS involvement at the time of death (3).

Biological risk modifiers include tumor grade, ER status, HER2 status, and *BRCA* mutation status. In studies of early breast cancer patients prior to the widespread introduction of adjuvant trastuzumab, HER2 has been shown to be a risk factor for CNS relapse (4,5). Within the HER2-positive subset, hormone receptor status appears to further influence the risk of CNS relapse, such that patients with ER-negative/HER2-positive tumors experience a higher rate of CNS involvement compared to patients with ER-positive/HER2-positive tumors (6). The risk of CNS as first site of relapse does not appear to be diminished by the use of adjuvant trastuzumab, though the absolute risk is low (<5%) (7). However, in the HERA trial, the overall risk of CNS relapse (first plus subsequent sites) was not increased with the use of adjuvant trastuzumab (8). In the advanced setting, multiple groups have reported a 25% to 55% incidence of CNS relapse among patients with HER2-positive breast cancer, which is significantly higher than historical control data of patients unselected by tumor subtype (9–11). Among deceased patients in the HERA trial, approximately half had developed brain metastases prior to death (8).

There is also increasing evidence that ER-, PR-, and HER2-negative (i.e., triple-negative) tumors are associated with a high risk of CNS relapse. In a database of 1,434 patients with early-stage breast cancer treated with breast conserving therapy, the 5-year cumulative incidence of brain metastases for patients with triple-negative tumors was 7.4%, compared with 0.1% in patients with Luminal A tumors (5). Among over 15,000 women presenting with Stage I–III breast cancer in the National Comprehensive Cancer Network breast cancer

database, triple-negative subtype was strongly associated with CNS relapse, relative to the hormone receptor-positive/HER2-negative subtype (OR 3.5, 95% CI, 2.1–5.85, $p < .001$) (12). The median time to brain metastasis diagnosis is also significantly shorter in triple-negative, compared to ER positive/HER2-negative tumors (5,13). In patients with metastatic triple-negative breast cancer, it has been reported that between 25% and 46% of patients will eventually develop brain metastases (14,15).

Of interest, deleterious *BRCA1* alterations are also associated with a high rate of CNS relapse (16). Whether this is purely attributable to the association between *BRCA1* carrier status and triple-negative breast cancer, or whether there is an additional phenotypic difference conferred by nonfunctional *BRCA1* is not clear at this time. Of note, in at least one study, *BRCA1* mutation carriers were more likely to develop brain metastases, even when compared to noncarriers with triple-negative tumors (17).

METHOD OF SPREAD AND DISTRIBUTION

Parenchymal brain metastases are thought to arise from hematogenous dissemination of tumor cells. Involvement of the cerebrum and cerebellum are common; brainstem involvement remains relatively uncommon. Older studies indicated that approximately half of patients with brain metastases presented with a single lesion. However, with the introduction of magnetic resonance (MR) imaging, a significantly more sensitive technique, current series indicate that only about one-fourth of patients with brain metastases have a confirmed single lesion at initial presentation. The term solitary brain metastasis indicates a single brain lesion in the absence of systemic metastases.

CLINICAL MANIFESTATIONS

Because brain imaging is not generally part of routine clinical care for asymptomatic patients with breast cancer, brain metastases are most commonly diagnosed in the setting of new neurological symptoms. Headaches are present in up to half of patients and are commonly bifrontal. In patients with single metastasis or a dominant lesion, there may be a predominance of the pain on the side of the metastasis. Coexisting nausea or emesis occurs in about half of patients with headaches, and is a predictive factor for the presence of brain metastases. Focal neurologic dysfunction is the presenting symptom in 20% to 40% of patients. Hemiparesis is the most common focal complaint. The distribution of symptoms depends upon the location of the metastases and the presence or absence of surrounding edema. Patients who present with cranial nerve deficits should be thoroughly evaluated for evidence of leptomeningeal or base of skull involvement.

Cognitive dysfunction, including mental status changes, memory problems, or mood or personality changes, is the presenting symptom in one-third of patients. Frequently, neurological examination will elicit additional deficits of which the patient is unaware. However, medications, metabolic abnormalities, and infections are more common causes of encephalopathy in cancer patients than brain metastases, and should be included in the differential diagnosis of altered mental status.

Seizures are the presenting symptom in 10% to 20% of patients with brain metastases, and an additional 10% to 26% will develop seizures at some time during the course of their illness. Supratentorial involvement increases the risk of seizure, whereas seizures are quite uncommon in patients with posterior fossa lesions.

In contrast to melanoma or choriocarcinoma, brain metastases from breast cancer tend not to bleed; therefore, acute cerebral hemorrhage is rarely a presenting symptom.

DIAGNOSTIC EVALUATION

In patients presenting with suspicious neurological signs or symptoms, evaluation with computed tomography (CT) or contrast-enhanced magnetic resonance imaging (MRI) is indicated. Of these approaches, MRI is the more sensitive noninvasive, diagnostic test.

MRI detects more lesions in the posterior fossa, where beam-hardening artifact can make CT difficult to interpret. MRI is also superior in defining the number of CNS lesions, a distinction that may affect clinical recommendations. For example, in a study of 23 patients who underwent both double-dose delayed CT and contrast-enhanced MRI, MRI detected more than 67 definite lesions, compared to only 37 lesions on CT (18).

The differential diagnosis of enhancing mass lesions in a patient with breast cancer includes metastasis, primary brain tumor, abscess, demyelinating disorders, cerebral infarction, hemorrhage, progressive multifocal leukencephalopathy, and posttreatment change (i.e., radiation necrosis, post-surgical change). Radiographic features that may differentiate brain metastases from other CNS lesions include the presence of multiple lesions (which helps to distinguish metastases from primary brain tumors), localization at the junction of the gray and white matter, circumscribed margins, and relatively large amounts of vasogenic edema compared to the size of the lesion. The clinical history can also be helpful in guiding appropriate diagnostic testing. For patients with advanced breast cancer who present with multiple brain lesions, further testing may not be necessary. For patients without evidence of extracranial involvement by breast cancer, consideration should be given to tissue sampling to distinguish between metastatic breast cancer versus metastasis from a non-breast primary, primary brain tumor, or nonmalignant cause. A tissue diagnosis should also be strongly considered for patients presenting with a single brain lesion. In a randomized trial evaluating the role of surgical resection for single brain metastasis, 11% of patients were found to have an alternate diagnosis on pathologic review (19). Finally, the differential diagnosis of dural-based lesions includes meningiomas. Because the incidence of meningioma has been reported to be somewhat higher in breast cancer patients than the general population, and because imaging studies may be inconclusive, tissue diagnosis may be required (20). Thus, in any patient in whom the diagnosis of brain metastases is in doubt based upon the radiographic appearance of the lesion(s), the presence of a single lesion, or the clinical history, obtaining tissue is important to establish the diagnosis conclusively.

Another diagnostic dilemma exists in distinguishing necrosis from tumor progression in patients who have previously received whole-brain radiotherapy (WBRT) or stereotactic radiosurgery (SRS). One approach is to consider supplemental imaging with either positron emission tomography (PET), single photon emission CT (SPECT), functional MRI, or MR spectroscopy (21). With a detection rate of only 61% to 68% compared to contrast-enhanced MRI, ^{18}F-flurorodeoxyglucose (FDG)-PET does not appear sufficiently sensitive for use as a screening tool for brain metastases (22,23). However, ^{18}FDG-PET may be helpful in distinguishing radiation necrosis from tumor progression.

In a study of 32 patients with brain metastases from any solid tumor, ^{18}FDG-PET with MRI co-registration had a sensitivity of 86% and specificity of 80%, though not all groups have been able to replicate these findings (24). Others have found that a dynamic assessment of ^{18}FDG uptake with PET offered higher sensitivity and specificity (25). Another potentially useful tool is Tl-201 SPECT. In one study of 72 patients, the sensitivity was reported at 91% for differentiating between radiation necrosis and tumor progression (26). Finally, a variety of newer techniques are under evaluation, including the use of alternative PET tracers (i.e., ^{18}F-fluorocholine, ^{18}F-flurorothymidine, or L-[methyl-^{11}C] methionine) and quantification of blood vessel tortuosity (21,27). In cases in which the imaging studies remain equivocal, management options include following the patient carefully over time versus proceeding to a biopsy for tissue diagnosis. Symptomatic lesions may require steroids and/or an earlier therapeutic intervention such as surgical resection.

PROGNOSIS

Historically, CNS involvement tended to occur late in the course of metastatic breast cancer, and median survival was poor, on the order of 4 to 6 months. More recently, breast cancer-specific prognostic indices have sought to improve upon the Radiation Therapy Oncology Group (RTOG) Recursive Partitioning Analysis (RPA), a widely used, but older system which was not tumor-type specific and likely underestimated survival in breast cancer patients (28). The Graded Prognostic Assessment (GPA) examined multiple potential risk factors associated with survival in tumor-specific contexts, and found that, for patients with breast cancer, performance status was the only significant prognostic factor (29). Further refinement of the breast GPA included an analysis of the influence of tumor subtype and showed that age and tumor subtype were also prognostic in the final model, which consisted of four groups, with the most favorable group experiencing a median survival in the range of 2 years (Table 76-1) (30). Based on data from retrospective studies, it is likely that improved systemic tumor control is a major contributing factor to this difference between historical and present outcomes, particularly in patients with HER2-positive breast cancer. Although one must interpret retrospective data cautiously because of potential selection bias in terms of prescribed treatment, multiple groups have observed a substantially longer survival in patients with brain metastases who continue to receive anti-HER2 therapy following their CNS diagnosis, compared to those who received either no systemic therapy or chemotherapy without anti-HER2 therapy (31–33). In addition, it appears that death from CNS progression (in the context of controlled extracranial disease) is substantially more common in the setting of HER2-positive disease, compared to triple-negative disease, where systemic therapy is generally less effective (10,15). Together these data suggest that i) improvements in systemic therapy are allowing some patients to live longer than older historical estimates would predict, ii) continuation of systemic therapy is likely beneficial, particularly in patients with HER2-positive disease, and iii) pursuing more aggressive approaches in the CNS among breast cancer patients with well-controlled systemic disease and/or HER2-positive disease may be reasonable.

MANAGEMENT

The management of patients with brain metastases can be divided into symptomatic and definitive therapy. Symptomatic therapy includes the use of corticosteroids for the treatment of peritumoral edema and anticonvulsants for control of seizures, whereas definitive therapy includes treatments such as surgery, radiotherapy, chemotherapy, targeted therapy, and radiosensitizers directed at eradicating the tumor itself.

TABLE 76-1

Prognosis of Breast Cancer Patients with Brain Metastases According to the Diagnosis-Specific Breast GPA (DS-GPA)

	DS-GPA Scoring Criteria					
Prognostic factor	0	0.5	1.0	1.5	2.0	Patient Score
KPS	≤50	60	70–80	90–100	n/a	___
Subtype	Basal	n/a	LumA	HER2	LumB	___
Age, years	≥60	<60	n/a	n/a	n/a	
Sum total						___

GPA, graded prognostic assessment; n/a, not applicable; KPS, Karnofsky performance status; Basal, ER-/PR-/HER2-negative; LumA, ER/PR positive, HER2-negative; HER2, ER/PR negative, HER2 positive; LumB, ER/PR positive, HER2 positive.

DS-GPA Score	*Median Survival Time (Months; 95% CI)*
0–1.0	3.4 (3.1, 3.8)
1.5–2.0	7.7 (5.6, 8.7)
2.5–3.0	15.1 (12.9, 15.9)
3.5–4.0	25.3 (23.1, 26.5)
All	13.8 (11.5, 15.9)

DS-GPA, diagnosis specific grade prognostic assessment.
Modified from Sperduto PW, Kased N, Roberge D, et al. Summary report on the graded prognostic assessment: an accurate and facile diagnosis-specific tool to estimate survival for patients with brain metastases. *J Clin Oncol* 2012;30(4):419–425.

Symptomatic Therapy

Corticosteroids

Corticosteroids are indicated in patients with symptomatic edema, and are thought to exert their effect by reducing capillary permeability, restoring arteriolar tone, and facilitating transport of fluid into the ventricular system. Most patients will improve symptomatically within 24 to 72 hours, although improvement of edema on imaging studies may not be immediately apparent. Patients who present with edema on imaging but who are asymptomatic generally do not require the prophylactic initiation of steroids.

Of the corticosteroids, dexamethasone is the most widely used because of its relatively weak mineralocorticoid activity, which reduces the potential for fluid retention. The usual starting dose is 4 mg every 6 hours, and may be preceded by a 10 mg load, depending on clinical circumstances. Because of potential adverse effects, such as myopathy, hyperglycemia, insomnia, fluid retention, gastritis, and immunosuppression, the dose of corticosteroids should be kept to the minimum effective dose and tapered during or after definitive therapy. Corticosteroid use also increases the risk of *Pneumocystis jiroveci*. In two case series, the median duration of dexamethasone therapy was only 10 weeks before onset of symptoms, and symptoms commonly appeared during tapering of steroid therapy (34,35). Therefore, *P. jiroveci* prophylaxis should be considered for patients for whom the anticipated duration of steroid use exceeds 4 to 5 weeks.

Anticonvulsants

Approximately 10% to 20% of patients with brain metastases present with seizures, and an additional 10% to 26% will develop seizures at some time during the course of their illness. For most patients, confirmation of the diagnosis with electroencephalography is not necessary, and the use of standard anticonvulsants is generally indicated.

To determine whether the routine use of anticonvulsants is indicated in patients without a prior history of seizure, the Quality Standards Subcommittee of the American Academy of Neurology reviewed the results of twelve studies that addressed this question (36). None of the individual studies indicated a significant reduction in seizure incidence between the prophylaxis and nonprophylaxis groups. A meta-analysis of the four randomized trials indicated no difference in seizure incidence (OR 1.09; 95% CI, 0.63–1.89, p = .8), seizure-free survival (OR 1.03; 95% CI, 0.74–1.44, p = .9), or overall survival (0.93; 95% CI, 0.65–1.32, p = .7). Because of the known potential for adverse effects and drug interactions, and the lack of clear benefit, the routine use of anticonvulsants is not recommended in patients without a history of seizures. A possible exception includes patients with lesions in areas of high epileptogenicity (e.g., motor cortex), though a benefit has not been clearly demonstrated in clinical studies.

In the periprocedural setting, a meta-analysis including six controlled trials of patients receiving anticonvulsant drugs in the setting of supratentorial craniotomies has been completed. It showed a non-significant trend (p = .1) for fewer postoperative seizures, though it should be noted that the included trials were generally quite small (37). High-level randomized evidence regarding the use of prophylactic anticonvulsants in the setting of SRS is not available.

Venous Thromboembolic Disease

Venous thromboembolic (VTE) disease occurs in approximately 20% of patients with brain metastases (38). Because of the concern for intracranial hemorrhage (ICH), many clinicians are reluctant to fully anticoagulate patients. However, mechanical approaches, such as the placement of an inferior vena cava (IVC) filter is reported to be associated with complications in two-thirds of patients (39). In addition, VTE recurs in up to 40% of patients with brain metastases treated with an IVC filter alone (40).

Compared to IVC filter placement, anticoagulation is associated with a lower rate of recurrent VTE, and, for most patients with brain metastases, the risk of hemorrhage appears acceptable. In a series of 42 patients treated at Memorial Sloan Kettering Cancer Center in New York who had brain metastases from a variety of solid tumors and who were anticoagulated for VTE, only three patients (7%) experienced ICH, including two patients in the setting of supratherapeutic anticoagulation (40). In a study of 25 patients with either primary or metastatic brain tumors treated with anticoagulation, only one patient experienced an incidentally found, asymptomatic focal intraventricular bleeding event (41). Consequently, the data, though limited, suggests that anticoagulation is preferable to IVC filter placement in most breast cancer patients who develop clinically significant VTE.

DEFINITIVE TREATMENT

The goals of definitive treatment of brain metastases are to relieve and/or stabilize neurological symptoms, to achieve long-term tumor control, and to extend life, while minimizing toxicity. The choice of therapy is influenced by a) the size, number, and location of lesions, b) the presence or absence of neurological symptoms, c) the patient's life expectancy, including the patient's performance status and the status of the patient's extracranial disease, d) prior treatment, e) expected toxicities of treatment, f) availability of systemic treatment options, and g) patient preference. In general, initial management will include some combination of surgical resection, stereotactic radiosurgery (SRS), and/or WBRT. Systemic therapy could be a consideration on a clinical trial, in the context of minimal disease burden in a well-informed patient with close follow-up, or in the context of progressive extracranial disease in which rapid disease control is felt necessary. Given these complex considerations, the optimal care of patients with brain metastases involves close multidisciplinary collaboration in order to avoid overtreatment of patients with a limited life expectancy, as well as potential under-treatment of patients with well-controlled systemic disease and significant CNS-related morbidity.

SURGERY

The role of surgery in patients with brain metastases is to provide relief of symptoms resulting from mass effect of the tumor, to establish a histologic diagnosis, to improve local control, and to provide a potential benefit to survival.

Three prospective, randomized trials have been conducted to evaluate the role of surgery in patients with brain metastases (Table 76-2). The first trial, reported by Patchell and colleagues, randomly assigned 48 patients with a single brain metastasis (6% with a breast primary) to either surgery followed by WBRT versus WBRT alone (19). Patients in the combined-modality arm achieved better local control (20% vs. 52%, p <.02), improved median duration of functional independence (38 weeks vs. 8 weeks; p <.005), and longer overall survival (40 weeks vs. 15 weeks; p <.01), compared to the patients who received WBRT alone. These findings were replicated in a study of 63 patients (19% with

Summary of Selected Prospective Randomized Clinical Trials Evaluating Surgical and/or Radiotherapy-Based Approaches for Management of Brain Metastases

Trial	*Study Design*	*Population*	*N*	*# With Breast Cancer*	*Results*
Trials evaluating whole brain radiotherapy dose-fractionation schedules[a]					
Borgelt et al., 1980 (51)					
First study	30 Gy/10 fractions vs. 30 Gy/15 fractions vs. 40 Gy/15 fractions vs. 40 Gy/20 fractions	Solid tumors	910	166	More rapid symptom improvement with larger fractions (55% of patients achieved improved symptoms at 2 weeks with 30 Gy/10 fractions compared to 43% for other regimens, $p = .06$). No difference in OS among arms.
Second study	20 Gy/5 fractions vs. 30 Gy/10 fractions vs. 40 Gy/15 fractions	Solid tumors	902	146	More rapid symptom improvement with larger fractions (64% of patients achieved improved symptoms at 2 weeks with 20 Gy/5 fractions compared to 54% for the other regimens, $p = .01$). No difference in OS between arms.
Borgelt et al., 1981 (61)					
First study	10 Gy/1 fraction vs. protracted course (20, 30, or 40 Gy/10–20 fractions)	Solid tumors	26[b]	2	No difference in rate of symptom improvement or OS. Shorter duration of improvement (4 weeks vs. 10 weeks, $p = .02$) and TTP (median 8 weeks vs. 11.5 weeks, $p = .07$) with high-dose radiation.
Second study	12 Gy/2 fractions vs. protracted course (20, 30, or 40 Gy/10–20 fractions)	Solid tumors	33[a]	1	No statistically significant difference in rate of symptom improvement, duration of improvement, or OS with high-dose radiation.
Murray et al., 1997 (63)	32 Gy/20 fractions over 10 d followed by boost (24.4 Gy/14 fractions over 7 d) vs. 30 Gy/10 fractions	Solid tumors	429	43	No difference in OS with accelerated hyperfractionation ($p = .52$)
Trials evaluating the role of surgery in addition to WBRT					
Patchell et al., 1990 (19)	Surgery followed by WBRT (36 Gy/12 fractions) vs. WBRT alone	Solid tumors, single brain metastasis	48	3	Improved local control, 80% vs. 48% ($p < .02$), OS (median 40 weeks vs. 15 weeks, $p < .01$), and functionally independent survival (median 38 weeks vs. 8 weeks, $p < .005$).
Noordijk et al., 1994 (42)	Surgery followed by WBRT (40 Gy/20 fractions over 10 d) vs. WBRT alone	Solid tumors, single brain metastasis	63	12	Improved OS (median 10 months vs. 6 months, $p = .04$) and functionally independent survival (7.5 months vs. 3.5 months, $p = .06$).
Mintz et al., 1996 (43)	Surgery followed by WBRT (30 Gy/10 fractions) vs. WBRT alone	Solid tumors, single brain metastasis	84	10	No difference in OS (median 5.6 months vs. 6.3 months, $p = .24$) or proportion of functionally independent days (mean 0.32 for both arms, $p = .98$)

TABLE 76-2 *(Continued)*

Summary of Selected Prospective Randomized Clinical Trials Evaluating Surgical and/or Radiotherapy-Based Approaches for Management of Brain Metastases

Trial	*Study Design*	*Population*	*N*	*# With Breast Cancer*	*Results*
Trials evaluating the role of WBRT in addition to local therapy					
Patchell et al., 1998 (53)	Surgery + WBRT (50.4 Gy/28 fractions) vs. surgery alone	Solid tumors, single brain metastasis status post complete surgical resection	95	9	Improved local control (10% vs. 46%, $p < .001$) and distant control (recurrence in other sites in the brain 14% vs. 37%, $p < .01$). Decreased death due to neurologic causes (14% vs. 44%, $p = .03$). No difference in OS (median 48 weeks vs. 43 weeks, $p = .39$) or functionally independent survival (median 37 weeks vs. 35 weeks, $p = .61$).
Aoyama et al., 2006 (54)	WBRT (30 Gy/10 fractions) + SRS (with 30% dose reduction) vs. SRS alone	Solid tumors, 1–4 lesions, all ≤3 cm	132	9	Improved local control (89% vs. 73%, $p = .002$) at one year. Decreased likelihood of recurrence of tumor anywhere in the brain at 1 y (47% vs. 76%, $p < .001$). No difference in preservation of neurologic function. No difference in primary endpoint of OS (7.5 months vs. 8.0 months, $p = .42$). No difference in death due to neurologic causes (22.8% vs. 19.3%, $p = .64$).
Kocher et al., 2011 (52)	WBRT (30 Gy/10 fractions) vs. observation after either SRS or surgery	Solid tumors, 1–3 lesions, stable systemic disease	359 (199 SRS, 160 surgery)	42	WBRT vs. observation (2 years) Surgery group recurrence Local: 27% vs. 59% DR: 23% vs. 42 % SRS group recurrence Local: 19% vs. 31% Distant: 33% vs. 48% No difference in OS (10.7 months vs. 10.9 months), survival with functional independence 9.5 months vs. 10 months). Patients in observation arm reported better QOL (66).
Chang et al., 2009 (70)	WBRT (30 Gy/12 fractions) + SRS vs. SRS alone	Solid tumors, 1–3 lesions	58	8	Study stopped early due to decrease in HVLT-R total recall at 4 months in WBRT arm (primary endpoint). Local (100% vs. 67%) and distant (73% vs. 45%) control at 1-yr improved with WBRT. WBRT arm had more deaths from systemic causes leading to worse OS (5.7 months vs. 15.2 months).

Trials evaluating dose intensification of radiotherapy					
Kondziolka et al., 1999 (77)	WBRT (30 Gy/12 fractions) + SRS vs. WBRT alone	Solid tumors, 2–4 lesions, all ≤2.5 cm	27	4	Improved local control (local recurrence rate at one year 8% vs. 100%; median time to local recurrence 36 months vs. 6 months, $p = .0005$). Longer time to recurrence of tumor anywhere in the brain (34 months vs. 5 months, $p = .002$). No difference in OS (11 months vs. 7.5 months, $p = .22$).
Andrews et al., 2004 (65)	WBRT (37.5 Gy/15 fractions) + SRS vs. WBRT alone	Solid tumors, 1–3 lesions, all ≤4 cm	333	34	Improved local control at 1 y (82% vs. 71%), $p = .01$). Higher likelihood of stable or improved performance status at 6 months (43% vs. 27%, $p = .03$). No difference in primary end point of OS (6.5 months vs. 5.7 months, $p = .14$). Survival advantage observed in subgroup of patients with a single brain metastasis (median 6.5 months vs. 4.9 months, $p = .04$).
Trials evaluating radiosensitizers					
Mehta et al., 2003 (113)	WBRT (30 Gy/10 fractions) + motexafin gadolinium vs. WBRT alone	Solid tumors	401	75	No difference in OS (median 5.2 months vs. 4.9 months, $p = .48$), time to neurologic progression (median 9.5 months vs. 8.3 months, $p = .95$), or death due to neurologic causes (49% vs. 52%, $p = .60$).
Suh et al., 2006 (114)	WBRT (30 Gy/10 fractions) + efaproxiral vs. WBRT alone	Solid tumors, RPA class I or II	515	107	No difference in OS (median 5.4 months vs. 4.4 months, $p = .16$), time to neurological progression, or death due to neurologic causes. In an exploratory subgroup analysis, improved OS (HR for death 0.51, $p = .003$) and response rate (54% vs. 41%, $p = .01$) in breast cancer patients. A subsequent trial limited to breast cancer patients was negative (116).
Knisely et al., 2008 (118)	WBRT 37.5 Gy/15 fractions) + thalidomide vs. WBRT alone	Solid tumors, multiple (>3), large (>4 cm) or midbrain metastases	175	31	No difference in OS (median 3.9 months for both arms), or in deaths due to neurologic causes.

[a]All fractions given once daily unless otherwise specified.
[b]Represents number of patients assigned to the high-dose arm. These patients were compared to 143 control patients who received a more protracted course of radiation.
OS, overall survival; TTP, time to progression; WBRT, whole-brain radiotherapy; SRS, stereotactic radiosurgery; HR, hazard ratio.

breast primaries) led by Noordijk et al., in which patients treated with surgery and WBRT achieved prolonged survival (median 10 months vs. 6 months; $p = .04$) and functionally independent survival (7.5 months vs. 3.5 months; $p = .06$) compared to patients treated with WBRT alone (42). Of note, only patients with stable or absent extracranial disease appeared to derive a survival benefit from surgery; patients with progressive extracranial disease experienced a median survival of only 5 months irrespective of the allocated treatment. A third study reported no difference in either survival or functionally independent survival with the addition of surgery to WBRT (43). In contrast to the first two trials, nearly half of patients in this study were enrolled with co-existing extracranial metastases, and approximately 40% of patients had a Karnofsky performance status of 70% or less at study entry. In addition, the presence of a single brain lesion was categorized according CT rather than MRI (which could have missed multiple lesions), and 10 of 43 patients randomly assigned to radiotherapy underwent surgical resection at some point in their disease course, which may have further confounded the results.

In patients with multiple brain metastases, the role of surgery to remove all resectable lesions remains controversial, and the data are limited to retrospective series. Wronski et al. reported the largest retrospective series limited to patients with brain metastases from breast cancer (n = 70), and found no statistical difference in survival between patients with single lesions and those with multiple lesions (44). In contrast, Hazuka et al. noted that the median survival of 18 patients undergoing resection of multiple metastases was only 5 months, far shorter than that observed in 28 patients undergoing resection of a single lesion (45). In summary, although some of the retrospective data are encouraging, in the absence of randomized data, it is difficult to distinguish between a true effect from surgery versus selection bias; that is, patients with technically resectable lesions who are candidates for resection may have a better prognosis irrespective of the surgical intervention received.

The potential benefits of surgical resection must be weighed against the risks. Fortunately, advances in surgical techniques, including preoperative functional MRI, intra-operative neuronavigational devices, intra-operative cortical mapping, and intravenous sedation anesthesia have improved the safety of surgical resection of brain metastases, and in some cases, can allow resection of lesions located in eloquent areas (46). In a retrospective cohort study of 13,685 admissions for the resection of metastatic brain tumors from the Nationwide Inpatient Sample, the overall in-hospital mortality rate fell from 4.6% in 1988–1990 to 2.3% in 2000 (47). Consistent with other studies of surgical intervention, mortality and morbidity were also lower in higher-volume centers and with higher-volume surgeons.

Whole-Brain Radiotherapy

For over five decades, WBRT has played a central role in the management of brain metastases and it remains the treatment of choice for the majority of patients who present with multiple (4–5 or more) brain metastases. Early studies supported a survival benefit for brain metastases patients treated with WBRT compared to supportive care or treatment with corticosteroids only (48,49). Breast cancer brain metastases appear to be relatively responsive to WBRT in relation to other histologies such as non-small cell lung and melanoma (50). For patients with brain metastases from breast cancer, estimates of the median expected survival following treatment with WBRT alone improved to 4 to 6.5 months from 1 to 2 months with supportive care only (51). However, in patients with limited brain metastases treated with focal therapies such as surgery and/or SRS, the addition of WBRT did not produce a survival benefit in randomized trials (Table 76-2) (52–55). On the other hand, when considered as adjuvant therapy to SRS or surgery for brain metastases, WBRT has been shown to reduce of risk of elsewhere brain recurrence (52,54,55), preserve neurocognitive function in some patients (56), and prevent neurologic death (52,53). WBRT can also provide effective palliation of neurological symptoms, with durable improvement, or stability of neurological symptoms observed in approximately 70% to 90% of patients (57–59). For patients presenting with cranial nerve deficits, approximately 40% may have an improvement with WBRT (59).

A wide range of WBRT dose-fractionation schedules ranging from 2000 cGy in 5 fractions to 4000 cGy in 20 fractions have been compared for efficacy and toxicity in 2 RTOG randomized trials (Table 76-2) (51,60). While the various schedules showed no significant difference in median survival or duration of symptom palliation, symptomatic relief occurred sooner in patients treated with larger fractions. Even when breast cancer patients were analyzed in a subgroup analysis, time to progression of neurologic function or death did not differ by schedule (60). Further shortened WBRT courses such as 1000 cGy in a single fraction or 1200 cGy in 2 fractions achieve similar survival and palliative benefit as more extended fractionation schemes, but appear to be associated with inferior duration of symptom improvement and time to neurological progression (61). In addition, large fraction size may increase the risk of neurocognitive dysfunction (62). A randomized trial comparing accelerated hyperfractionated WBRT to 3000 cGy in 10 fractions showed no benefit to survival or palliation even among favorable prognostic groups (63). The current standard therapy of 3000 cGy in ten 300 cGy fractions over 2 weeks or 3750 cGy in fifteen 250 cGy fractions provides a balance between prompt palliation and control of the competing risk from brain progression with acceptably low acute side effects (64,65). Many radiation oncologists will use even longer fractionation schedules, such as 4000 cGy in 200 cGy fractions for patients with longer anticipated survival in an attempt to reduce neurocognitive sequelae.

The toxicity of WBRT is generally divided into acute, early-delayed, and late effects. The most debilitating acute and early-delayed effects are fatigue and somnolence, which can be profound. They may arise within the first week of therapy and persist for weeks or months. Other prominent acute and early-delayed effects of WBRT which impact adversely on QOL include alopecia, skin erythema, and loss of taste. For example, the EORTC 22952-26001 study demonstrated overall better health-related QOL scores among patients who did not receive WBRT, with differences most pronounced during early follow-up (e.g., physical functioning at 8 weeks, fatigue at 8 weeks). However, some toxicities were seen later after the course of treatment (e.g., global health status at 9 months, cognitive functioning at 12 months) (66). While the acute and early-delayed effects are generally reversible, the late effects are generally permanent and may be progressive. Of note are the rare, but clinically significant, risks of radiation-related leukoencephalopathy and necrosis which may manifest clinically as significant neurologic or neurocognitive dysfunction.

The potential for neurocognitive function (NCF) changes following WBRT is of substantial concern, particularly for patients who may have long survival. A landmark paper by DeAngelis et al. in 1989 described 12 cases of progressive dementia which developed at a median of 14 months following treatment in a series of 482 patients treated

with WBRT alone or surgery plus WBRT (62). All affected patients displayed cortical atrophy, ventricular dilation, and developed urinary incontinence and ataxia, with some patients showing improvement in clinical symptoms following ventriculoperitoneal shunting. Seven of the patients died of these complications with no evidence of tumor recurrence. Patients had received treatments with relatively large fraction sizes ranging from 300 to 600 cGy and total doses of 2500 to 3900 cGy. With modern radiation doses and fractionation schedules, this risk is somewhat mitigated, with broad measures of NCF often failing to demonstrate a detrimental effect of radiation (56). In terms of longer-term outcomes, a comprehensive neurocognitive assessment of patients treated with WBRT in the phase III trial PCI-P120-9801 revealed that patients with better than median local and distant tumor control displayed significantly improved preservation of executive and fine motor function relative to patients with less than median response to treatment (67). These results support the notion that optimizing local and distant brain tumor control is an important facet of preserving neurocognitive function.

Studies that have utilized in-depth neuropsychometric testing, however, have also demonstrated specific time-dependent changes following treatment, particularly with respect to short-term memory, executive functioning, and attention (55,67,68). Various approaches have been attempted to mitigate these effects. RTOG 0614 was a randomized, double-blind, placebo-controlled trial investigating the potential neuroprotective effects of memantine, a drug used to treat mild to moderate dementia, in 508 evaluable patients receiving WBRT. While not meeting the primary endpoint of improvement in delayed recall (p = .059), potentially due to low statistical power, patients receiving memantine during and after WBRT experienced longer time to cognitive decline and decreased risk of decline in multiple NCF dimensions (69).

Following surgical resection of a solitary brain metastasis, post-operative WBRT has frequently been employed with the goal of decreasing the risk of both local and elsewhere recurrence in the brain. (Local refers to a recurrence at the original site of metastasis and elsewhere to a recurrence elsewhere in the brain.) A randomized trial by Patchell et al. further clarified the effects of post-operative WBRT for patients with a surgical resected solitary brain metastasis (53). In this study, 95 patients were randomized to either WBRT or no further treatment following complete resection of a solitary brain metastasis. The addition of WBRT decreased the risk of local recurrence (10% vs. 46%, p <.01), elsewhere brain recurrence (14% vs. 37%, p <.01), and neurological death (14% vs. 44%, p = .003). No significant difference in overall survival was found, but the higher risk of neurological death observed with surgery alone has been suggested by some as a justification for combined therapy in this group of patients.

Similar results were found in the EORTC 22952-26001 study, which randomized 359 patients with 1 to 3 brain metastases to either observation or WBRT following either surgery (n = 160) or SRS (n = 199) (52). Eligibility criteria included having evidence of controlled extracranial disease or asymptomatic synchronous primary cancer. Overall, patients who received WBRT experienced fewer local (31% vs. 19%) and elsewhere (48% vs. 33%) brain relapses at 2 years, but did not experience any statistically significant gains in either overall survival or preservation of functional independence. The lack of translation of intracranial control to overall survival occurred even though the competing risk of extracranial disease was at least partially mitigated by the eligibility criteria. Among the subset treated with surgery, WBRT reduced the probability of relapse at the initial site of disease from 59% to 27% at 2 years. Of note, only 12% of patients enrolled on the EORTC study carried a primary diagnosis of breast cancer. In a separate, randomized trial evaluating SRS alone versus SRS plus WBRT in patients with 1 to 4 brain metastases reported by Aoyama et al., again, there was no difference in overall survival between the two treatment groups, though it should be noted that breast cancer patients comprised only 7% of the study population (54). There were also no differences observed in neurologic survival or functional preservation between the groups. As expected, the risk of developing a new brain metastasis was higher in the SRS alone arm versus the combined treatment arm (63.7% vs. 41.5%, p = .03). In addition, 12-month local control was greater for combined treatment than SRS alone (88.7% vs. 72.5%, p = .002), and salvage therapy was more frequently required in patients treated with SRS alone. Finally, a study conducted at the M.D. Anderson Cancer Centers and reported by Chang et al. randomized 58 patients with 1 to 3 brain metastases to SRS with or without WBRT was stopped early based on an interim analysis showing worse outcomes of the WBRT arm with respect to the primary endpoint of neurocognitive decline at 4 months based on the Hopkins Verbal Learning Test (70). The study found that the addition of WBRT had similar effects on intracranial control as had the other randomized studies: local control improved from 67% to 100% and elsewhere brain control improved from 45% to 73% at 1 year. Even though improvements in intracranial control were demonstrated, patients in the WBRT arm actually experienced worse overall survival. However, the difference in survival could be explained by excess deaths due to systemic disease progression, rather than intracranial progression or toxicity in the WBRT.

Why improvements in intracranial control do not translate into overall survival benefits is an open question. Potential explanations include the availability of effective salvage at recurrence, a dominant competing mortality risk from extracranial disease, or a combination of both. It should be noted that while patients with progressive extracranial disease at presentation were excluded from the EORTC study, two-thirds of patients developed progressive disease during the course of the study (52). The impact, however, of the elevated risk of local or elsewhere brain recurrence on QOL compared to the toxicity from the addition of WBRT, particularly in patients with long expected survival remains unclear, especially when other low morbidity salvage therapies such as SRS may be effective. In addition, localized boost therapy to the surgical resection cavity using SRS or fractionated stereotactic radiotherapy without WBRT may decrease the risk of local failure to levels comparable or less than that achieved with WBRT (71). Another approach under investigation is the use of hippocampal-sparing techniques, given the very low likelihood of hippocampal involvement in patients with brain metastases, but this hypothesis remains to be confirmed in a prospective, randomized trial (72).

STEREOTACTIC RADIOSURGERY (SRS)

SRS has come to play an increasingly important role in the management of brain metastases, in many cases offering an alternative to surgery, WBRT, or both. SRS involves the delivery of a single large dose of focused radiation to one or more tumor masses with rapid dose fall-off beyond the tumor margin. Tumors are targeted for treatment with the aid of a minimally invasive stereotactic frame, or using x-ray image guidance together with mask immobilization. Non-frame based approaches have also made multiple fraction therapy

using SRS-style set up and localization verification possible. The precise dose localization and shaping afforded by this technique minimize the treatment-related morbidity that may result from normal tissue irradiation. Overall, SRS produces a high rate of local control, which is optimal with doses greater than or equal to 1800 cGy (73). SRS has the potential for noninvasive local tumor control while allowing targeting of multiple lesions and has been evaluated for its potential to supplement, replace, or defer both WBRT and surgery.

Treatment-related morbidity using SRS depends on tumor size and location, radiosurgery dose, and prior treatment. The RTOG performed an SRS dose escalation study to determine the maximum tolerated dose (MTD) in patients previously irradiated for either a primary brain tumor or a solitary metastasis (74). Dose was escalated in 3 Gy increments such that grade 3, 4, and 5 toxicity 3 months following SRS remained less than 20%. For tumors 3 to 4 cm in diameter, the MTD was 15 Gy, for those 2 to 3 cm in diameter the MTD was 18 Gy and for those less than 2 cm the MTD was 24 Gy. On multivariate analysis, increased dose, worsening Karnofsky performance status (KPS), and increasing tumor diameter were associated with higher risk of grade 3 to 5 neurotoxicity. The actuarial incidence of radionecrosis at 12 months post SRS was 8%, and at 24 months, it was 11%. In an analysis summarizing dosimetric factors associated with the development of radiation necrosis in multiple studies using a variety of SRS applications, the volume of brain receiving 12 Gy (V12) was suggested as a potential predictive factor (75).

While surgical resection would be expected to be superior palliation for tumors with symptomatic mass effect, it is unclear if SRS is equivalent to surgery for patients with single small to medium size lesions without symptomatic mass effect. A 2003 retrospective series from the Mayo Clinic evaluated outcomes for patients with solitary brain metastases less than 35 mm treated with either surgery or SRS (76). While patients treated with either modality had similar survival, a significant improvement in local control was observed in the SRS group with no local recurrences (0/26) versus 15% (11/74) in the surgery arm. The overall recurrence rates including elsewhere brain recurrence were not significantly different: 29% in the SRS arm and 30% in the surgery arm; the use of WBRT following surgery or SRS was not significantly different between the groups. While not randomized between the modalities, the 2-year local relapse rates for surgery and SRS alone in the EORTC 22952-26001 study were 59% and 31%, respectively (52). The populations were not balanced, however, with overall larger tumors (albeit more often single rather than multiple) in the surgery cohort.

Patients with multiple brain metastases who were treated with WBRT alone in the past, with SRS reserved for failure, may now be candidates for WBRT and upfront SRS. Early data to support this view came from a single institution randomized trial reported by Kondziolka et al. which evaluated WBRT alone versus. WBRT+SRS for patients with 2 to 4 lesions less than 2.5 cm in size. Study accrual was terminated at 60% (27 patients) following interim evaluation that revealed a significant improvement in local control with combined treatment. Patients receiving both SRS and WBRT had a local recurrence rate at 1 year of only 8% versus 100% for those receiving WBRT alone. The median time to local recurrence was 6 months for WBRT alone, and 36 months following WBRT+SRS (p = .005). Despite the substantial difference in local control, no significant difference in survival between the treatment groups was found in this small study population (77).

To determine if WBRT+SRS could also result in a survival benefit, the RTOG 95-08 trial randomized a total of 333 patients with 1 to 3 brain metastases to WBRT+SRS or WBRT alone with the primary endpoint of overall survival (Table 76-2) (65). The 1-year local control was increased for the combined treatment group (82% vs. 71%, p = .01), a smaller improvement than that observed in the prior study reported by Kondziolka et al. While no significant difference in overall survival or cause of death was observed, several subgroups were identified which showed benefit from combined treatment. Patients with a solitary metastasis derived a survival benefit from the addition of SRS to WBRT, with a median survival of 6.9 versus 4.5 months (p = .04), analogous to the results observed in the first Patchell randomized trial comparing surgery + WBRT with WBRT alone. In addition, patients in RPA Class I (e.g., Karnofsky performance status ≥70, age less than 65, controlled primary cancer, and no extracranial metastases), age less than 50, or those with squamous or non-small cell histology showed significant survival benefit from combined treatment. Patients undergoing combined treatment were more likely to have stable or improved performance status at 3 (50% vs. 33%, p = .02) and 6 months (43% vs. 27%, p = .03). These results suggest that a survival benefit of combining WBRT+SRS may be limited to select patients, while the probability of maintaining a stable or increased performance status may be a more general benefit of combined treatment.

As discussed earlier, the capacity of SRS to achieve local control of multiple intracranial tumors has prompted reevaluation of the role of WBRT in palliative CNS radiotherapy, and has led to increased individualization of treatment recommendations, particularly in patients with 1 to 4 CNS lesions. There is less data to guide decisions regarding WBRT versus SRS in patients with more than 4 lesions. Bhatnagar et al. reported a retrospective review of 205 patients who underwent SRS for treatment of 4 or more metastases in the initial or re-irradiation setting (78). Median overall survival was 8 months. Of note, the total volume of metastases, rather than the total number was predictive for survival. Still, more evidence is needed to examine recurrence patterns, morbidity, and survival in order to help weigh decisions regarding the use of WBRT versus SRS in patients with a large number (>4) CNS lesions, and our general preference remains WBRT in this setting. Should SRS alone be chosen, clinical and radiographic follow-up every 2 to 4 months to detect brain recurrence is warranted.

Another clinical setting well suited for SRS is the treatment of post-WBRT intracranial recurrences. The use of WBRT re-treatment, typically with total doses of 2000 to 2500 cGy in 200 cGy fractions is associated with significant morbidity and a posttreatment median survival of only 3.5 to 5 months (57,79). Re-irradiation of less than 5 brain metastases is best accomplished with SRS, which has far less toxicity than WBRT retreatment (80,81). Kelly et al. reported on a series of 79 patients receiving SRS as salvage therapy for progressive breast cancer brain metastases, 76 of whom had received prior WBRT (82). Most patients had less than 4 lesions treated with SRS, but 23% had 4 or more metastases treated. Median survival in this population was 9.8 months. Favorable prognostic factors in this population included metastases secondary to HER2+ primary tumors and stable systemic disease at the time of SRS.

SYSTEMIC THERAPY

Chemotherapy

The delivery of chemotherapeutic agents through the blood-brain barrier (BBB) is limited by intrinsic drug characteristics, including molecular weight, lipid solubility, and plasma protein binding, as well as host and tumor characteristics, such as active efflux transport and interstitial fluid pressure. In comparison to normal brain, tumor-associated vasculature is frequently disrupted, with disordered, highly tortuous, and more permeable vessels. In preclinical models, it has

been demonstrated that a number of chemotherapeutic and targeted agents can reach brain metastases, albeit to lower levels and with more significant heterogeneity compared to non-CNS metastases (83,84).

To date, no chemotherapeutic agents have gained FDA approval for the treatment of brain metastases from breast cancer. Data are available from case reports, case series, and small prospective trials. Rosner et al. treated 100 consecutive patients with brain metastases from breast cancer with several regimens which included cyclophosphamide, 5-fluorouracil, and prednisone (85). The objective response was 50%, with a median duration of response of 7 months. Compared to the current era, patients were relatively untreated: only 7% of patients had received adjuvant chemotherapy and just under half had received any prior chemotherapy for metastatic disease. Boogerd et al. reported similar results for CMF or CAF regimens in a small case series (n = 22) (86).

The efficacy of temozolomide for brain metastases, including a broad range of solid tumors, has been evaluated in multiple phase II studies. Most of the published studies have indicated only minimal activity in breast cancer patients (Table 76-3) (87,88). In contrast, capecitabine appears to be an active agent in this setting. Rivera and colleagues evaluated capecitabine in combination with temozolomide in a phase I study of patients with brain metastases from breast cancer (89). Of 22 patients evaluable for response, 4 achieved a complete or partial response in the CNS. Given the disappointing results with temozolomide alone, it is likely that most, if not all, of the observed effect is attributable to the capecitabine (90). Platinum agents have also been evaluated, most commonly in combination with other agents, with reported response rates as high as 38% to 40% (91,92). These encouraging findings should be taken into context, however, given that, at least for extracranial disease, the response rates to platinum agents appear to fall off dramatically in later lines of therapy, compared to the first line setting (93,94).

Overall, the paucity of prospective studies evaluating systemic therapy for CNS disease makes any definitive recommendations difficult. Outside of a clinical trial, consideration of off-label use of anthracyclines, capecitabine, and platinum salts seems reasonable in patients whose disease has progressed through more standard (e.g., radiotherapy and/or surgical) approaches, or who have minimal CNS disease burden and agree to close follow-up.

Targeted Therapy

Endocrine therapies have an established role in the treatment of hormone receptor positive breast cancer. Many hormonal agents cross the blood-brain barrier. Although no prospective trials have been conducted in patients with brain metastases from breast cancer, responses in the CNS to tamoxifen and megestrol acetate have been described (95–97). Aromatase inhibitors, which act via inhibition of peripheral conversion of androgens to estrogen, also have reported anecdotal activity in the CNS (98). In animal models, fulvestrant does not appear to cross the blood-brain barrier and no reports of CNS activity have been published to date (99). Unfortunately, by the time most patients with ER-positive disease develop brain metastases, their cancer is typically refractory to further endocrine manipulations. However, endocrine therapy could be considered in patients with minimal prior endocrine therapy exposure and/or those patients who have had a history of prolonged systemic responses to endocrine treatment.

As far as other targeted approaches for brain metastases, anti-HER2 approaches have been most extensively studied (Table 76-4). A CNS objective response rate of 2.6% to 6% was reported in two phase 2 trials of lapatinib monotherapy in a pre-treated population (100,101). When given in combination with capecitabine in a similar patient population, the reported CNS response rate is higher, between 18% and 38% (101–105). Recently, results of the LANDSCAPE trial were published.

TABLE 76-3

Summary of Selected Prospective Clinical Trials Evaluating Chemotherapy for Breast Cancer Brain Metastases

Regimen	*# of Patients (# with Breast Cancer)*	*Patient Population*	*CNS ORR in Breast Cancer Subset*	*TTP/PFS*
Temozolomide (87)	19 (5)	Pre-treated with systemic therapy	0%	<2 mo
Temozolomide (88)	157 (51)	80% prior chemotherapy for MBC; 24% prior WBRT	4%	~2 mo
Capecitabine + temozolomide (89)	24 (24)	33% prior WBRT	18%	3 mo
Cisplatin + temozolomide (92)	32 (15)	~50% prior WBRT	40%	2.9 mo
Cisplatin + etoposide (91)	107 (56)	No prior CNS RT allowed; 36% chemotherapy-naive	38%	4 mo
Patupilone (119)	36 (36)	Progression after CNS RT required	19%	2.8 mo
Vinorelbine + temozolomide (120)	38 (11)	Heavily pre-treated patients	0% (1 minor response observed)	1.9 mo

CNS, central nervous system; ORR, objective response rate; TTP, time to progression; PFS, progression-free survival.

TABLE 76-4

Studies of Lapatinib for HER+ Brain Metastases

Regimen	*Number of Patients*	*Patient Population*	*CNS ORR*	*TTP/PFS*
Lapatinib (100)	39	Heavily pre-treated	2.6%	3.0 mo
Lapatinib (101)	237	Progression after CNS RT	6%	2.4 mo
Lapatinib + capecitabine (101)	50	Progression after CNS RT and through lapatinib monotherapy required	20%	3.6 mo
Lapatinib + capecitabine (103)	138	Heavily pre-treated	18%	NR
Lapatinib + capecitabine (121)	45	No prior CNS radiotherapy allowed	66%	5.5 mo
Lapatinib + temozolomide (122)	17	Heavily pre-treated	0%	2.6 mo

CNS, central nervous system; ORR, objective response rate; TTP, time to progression; PFS, progression-free survival.

In contrast to prior trials, which largely evaluated patients whose CNS disease had progressed through radiotherapy, LANDSCPAE evaluated 45 patients with previously untreated, HER2-positive breast cancer brain metastases. In this study, the CNS objective response rate (defined as at least 50% decrease in sum volume of CNS target lesions by central radiology review) was 65.9% (95% CI, 50.1 –79.5). In a secondary analysis, investigator-assessed CNS response rate by RECIST was reported as 57%. Median TTP was 5.5 months and median time to salvage radiotherapy was 8.3 months. Results of this study have prompted ongoing efforts to design a confirmatory phase 3 trial. In the meantime, the data add to the evidence of CNS activity of this regimen in patients with established metastases. However, it is not clear at this time whether lapatinib plus capecitabine could be used as primary or secondary prevention of brain metastases. Indeed, the CEREBEL trial, which compared lapatinib plus capecitabine versus trastuzumab plus capecitabine and was designed to compare the occurrence of new CNS metastases, did not meet its primary endpoint largely due to an insufficient number of CNS events in both arms (106). One notable result of the study was that patients were required to have CNS screening scans at baseline and 20% of potentially eligible patients were excluded on the basis of the detection of asymptomatic brain metastases, again underscoring the high prevalence of CNS involvement among HER2-positive patients. Notably, a number of other HER2 inhibitors, including neratinib, afatinib, and ARRY-380 are currently being evaluated for the treatment of HER2-positive brain metastases, and results are eagerly awaited.

Angiogenesis inhibitors represent another promising area for investigation. In preclinical models, treatment with anti-angiogenesis inhibitors leads to tumor regressions and improved survival in HER2 positive breast cancer (107). In the past, out of concern for intracranial hemorrhage, patients with brain metastases were excluded from nearly all trials of angiogenesis inhibitors. However, recent data support the general safety of this drug class in patients with brain metastases from solid tumors (108). At least two clinical trials (NCT01004172 and NCT01281696) combining bevacizumab with a platinum salt have been completed, and preliminary evidence of clinical activity has been observed (109).

We sense an increasing willingness to evaluate investigational agents earlier in their development cycle for the treatment of breast cancer brain metastases, and to include patients with active brain metastases in phase I and II clinical trials. Other targeted agents of potential interest in this patient population include PI3K inhibitors, mTOR inhibitors, PARP inhibitors, and cell cycle inhibitors. For example, everolimus, an orally bioavailable rapamycin analog that inhibits mTOR signaling, has clear systemic activity in ER-positive breast cancer and is being evaluated in the phase III setting in HER2-positive breast cancer. Notably, everolimus has demonstrated efficacy against subependymal giant cell astrocytoma, a rare brain tumor, suggesting its potential role in the treatment of CNS disease in breast cancer. A phase II clinical trial evaluating everolimus for breast cancer brain metastases is ongoing (NCT01305941). Anecdotal reports of CNS activity have also been reported in the phase I studies of several PI3K inhibitors, both in triple-negative and HER2-positive breast cancer patients; further exploration of the potential role of this class of agents is, thus, of considerable interest (110,111).

Radiosensitizers

Another approach to maximize the efficacy of radiation is the use of systemic agents as radiosensitizers (Table 76-2). In order to investigate the combination of anti-angiogenic therapies with radiotherapy, the RTOG conducted a phase III study of WBRT with or without thalidomide for patients with brain metastases from solid tumors. The study was closed early after an interim analysis indicated a very low likelihood of demonstrating a survival advantage in the experimental arm (112). Mehta and colleagues randomly assigned 401 patients (75 with breast cancer) to WBRT (3000 cGy) with or without motexafin gadolinium (MGd), a redox active drug that is thought to generate reactive oxygen species via futile redox cycling (113). No difference in overall survival or time to neurologic progression was noted in the overall study population. Finally, Suh and colleagues conducted two phase III trials utilizing efaproxiral (RSR13), an allosteric modifier of hemoglobin (114). Although there was a suggestion of benefit in a subset analysis of breast cancer patients enrolled in the first trial, the subsequent confirmatory trial (ENRICH) was negative.

Other agents under investigation include temozolomide, lapatinib, and the PARP inhibitor ABT-888. In two randomized phase II studies in solid tumor patients, the addition of temozolomide was associated with improvements in PFS but not overall survival (115,116). Studies limited to breast cancer patients have not been reported. A phase I study of WBRT with lapatinib in patients with HER2-positive breast cancer reported that, at the MTD of 1250 mg bid, 20 of 24 patients achieved a CNS objective response by 1 month following completion of WBRT (117). Dose limiting toxicities were found in 5 of 24 patients treated at the MTD, however, exceeding the predefined criteria for declaring feasibility. The regimen is currently being carried forward in a randomized phase II study being jointly conducted between Korean investigators and the RTOG.

In terms of PARP inhibitors, many of the investigational PARP inhibitors appear to cross the blood-brain barrier. Although the precise role of PARP inhibition in breast cancer remains to be fully defined, given the high incidence of brain metastases in patients with triple-negative breast cancer and in *BRCA1* mutation carriers, further exploration of the potential CNS activity of PARP inhibitors is warranted. In order to speed the development of potential radiosensitizers, the RTOG is developing a concept to test multiple potential radiosensitizers based on their preclinical rationale in a randomized phase II design that would involve rotating in and out various experimental arms over time, versus a control arm of WBRT alone.

CONCLUSIONS AND FUTURE DIRECTIONS

Brain metastases may lead to significant morbidity in patients with advanced cancer, and is a particularly feared site of recurrence by patients. HER2-positive and triple-negative tumors appear to be especially likely to spread to the CNS. Advances in surgery and radiotherapy have reduced treatment-related morbidity and allow for treatment of lesions that may not have previously been considered amenable to treatment. However, as patients live longer with metastatic breast cancer, it is likely that an increasing number of patients will develop CNS progression after standard first-line therapies. Thus, the optimal management of patients will increasingly require close, multidisciplinary collaborations. Furthermore, there is a greater need than ever to evaluate novel approaches to CNS metastases in the context of well-designed clinical trials.

MANAGEMENT SUMMARY

- In a breast cancer patient with signs or symptoms of brain metastases, a prompt contrast-enhanced MRI is indicated.
- Twenty percent of patients with brain metastases develop venous thromboembolic (VTE) disease. In patients with clinically significant VTE disease, anticoagulation is indicated.
- Initial treatment of brain metastases is influenced by lesion number, location, and size, and by the status of a patient's systemic disease.
- Supportive therapy includes corticosteroids for patients with symptomatic edema, and anticonvulsants for patients with a history of seizures. In patients without a seizure history, the routine use of prophylactic anticonvulsants is not recommended.
- In patients with single or solitary brain lesions, good performance status, and stable extracranial disease, surgical resection or stereotactic radiosurgery (SRS) is recommended. Surgery is preferred for lesions with symptomatic mass effect, larger lesions, diagnostic purposes, and when the risk of operative morbidity is acceptably low. Whole brain radiotherapy (WBRT) after local therapy reduces the risk of intracranial recurrence but does not appear to affect overall survival.
- For patients with a limited (2–4) number of lesions, good performance status, and favorable extracranial disease status, consideration should be given to aggressive intracranial therapy, with either WBRT followed by SRS, or SRS alone. Initial WBRT reduces the risk of subsequent intracranial recurrence and improves local tumor control in the brain but does not appear to prolong survival. The potential long-term neurotoxicities associated with WBRT must be weighed against the cognitive impairment associated with progressive disease in the CNS. Consideration should also be given to participation in a clinical trial evaluating the use of radiosensitizers or radioprotectants given in conjunction with WBRT.
- For patients with suboptimal control of extracranial disease, poor performance status, and short expected survival, therapy should be directed toward optimal palliation and consideration of hospice referral.
- For patients with recurrent or new CNS lesions after WBRT, the standard-of-care is not well-defined. Because of the complexity of potential options, including SRS, surgical resection, systemic therapy, and/or WBRT retreatment, multidisciplinary management is appropriate, particularly in patients with favorable extracranial disease status. Consideration should also be given to participation in the increasing number of clinical trials targeted to this patient population.

CHAPTER 77

Metastatic Epidural Spinal Cord Compression

Soma Sengupta, Michael W. Groff, Nils D. Arvold, and Patrick Y. Wen

CHAPTER CONTENTS

INTRODUCTION

Epidural spinal cord compression (ESCC), resulting from tumor growth in the spinal epidural space, is an important neurological emergency that can occur in patients with breast cancer. The incidence may be increasing as a result of earlier detection and improved systemic therapy (1). Since the prognosis for good functional outcome is primarily dependent on the degree of impairment at the commencement of treatment, clinicians who care for patients with breast cancer must remain vigilant about the possible presence of ESCC. More than 91% of patients with ESCC have symptoms for longer than 1 week before a diagnosis is made (2), with pain lasting for a mean duration of 6 weeks (3). Compromise of the conus medullaris and cauda equina by epidural metastasis is generally included in a discussion of ESCC because the natural history and management of these problems are similar to those of compression of the spinal cord itself. ESCC is discussed in more detail in several recent reviews (1,4,5)

INCIDENCE

The incidence of ESCC in patients with breast cancer is approximately 4% (2). There are approximately 12,700 cases of ESCC in patients with cancer diagnosed each year in the United States (1,6). The median time from the diagnosis of breast cancer to the onset of ESCC is 42 months, with a range of 0 to 28 years (2). ESCC usually occurs in the setting of widely metastatic disease, although rarely ESCC may be the initial presentation of cancer. In some instances, biopsy of an epidural metastasis is required to establish the diagnosis of cancer.

PATHOLOGY

Epidural metastases most commonly result from hematogenous spread of metastases to the vertebral column (85%). They arise less commonly from metastases to the paravertebral space (5% to 10%) that either secondarily invade bone and then grow into the epidural space or invade the epidural space directly through the intervertebral foramen (Fig. 77-1). In rare instances, direct hematogenous spread to the epidural space or parenchyma of the spinal cord occurs (1,4), but this presentation is more likely with lymphoma than with breast cancer. If ESCC develops as the first manifestation of cancer, the absence of bony or skeletal metastases makes breast cancer an unlikely diagnosis. The vertebral column is the most common site of metastases to bone (7). Vertebral metastases occur in up to 84% in patients with advanced breast cancer (4). This high incidence is related to the fact that cancers of the breast and pelvis are in communication with Batson's vertebral plexus (8,9), a low-pressure valveless venous system that fills when thoracoabdominal pressure is raised (e.g., by maneuvers such as coughing, straining, and lifting). The presence of growth factors in bone marrow may also be a contributing factor (9). Of patients with breast cancer and ESCC, 93%

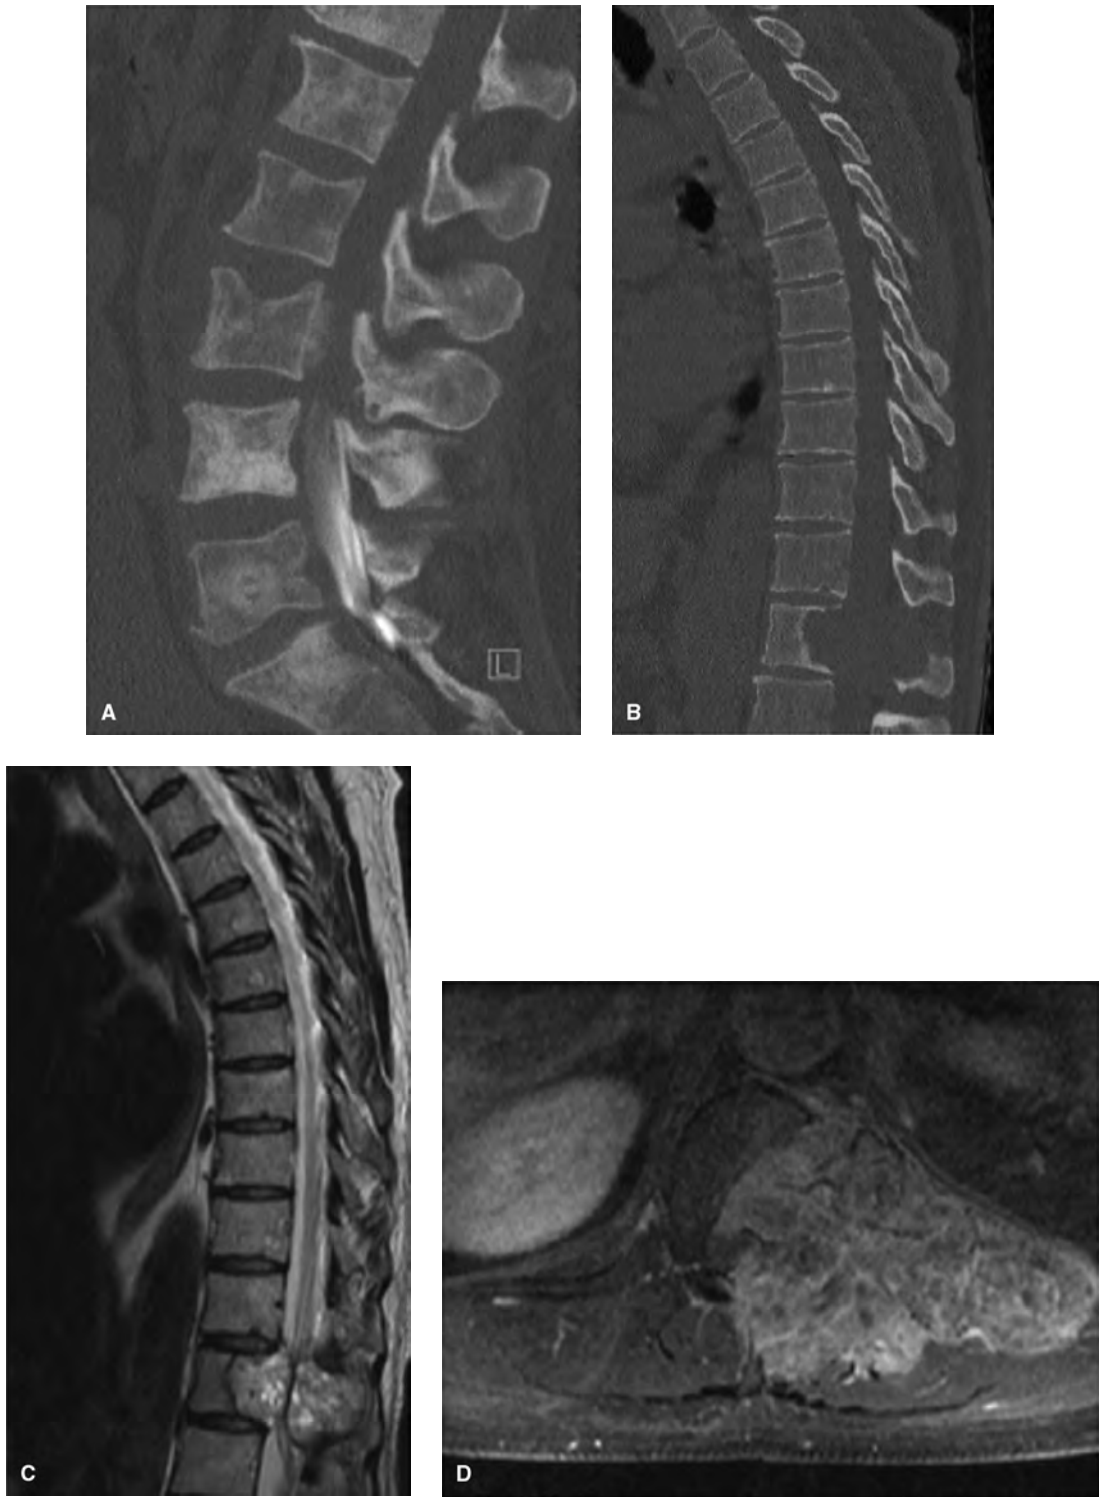

FIGURE 77-1 **(A)** Sagittal postmyelogram CT demonstrating a complete block due to epidural compression from a breast metastasis. The block, located at the L3/4 disc space demonstrates the lower extent of the mass. This was predominantly an epidural mass which occurs in a small minority of cases. **(B)** Sagittal CT scan demonstrating lytic destruction of the T12 vertebral body due to a breast metastasis. Despite the extensive destruction there is no collapse of the vertebral body or kyphosis of the spinal canal. Destruction of the posterior elements is also seen. **(C)** T2-weighted sagittal MRI demonstrating the T12 breast metastasis and the severe spinal cord compression. The spinal fluid appears white on this sequence. The tapering of the spinal fluid on the sagittal image in the region of the mass is characteristic of compression from an extradural mass. **(D)** T2-weighted axial MRI demonstrating the T12 breast metastasis and the severe spinal cord compression. The axial image demonstrates significant paraspinal extension as well.

have known bone metastases at the onset of their neurologic deficit, with a median time from the first bone metastasis to ESCC of 11 months (range, 0 to 7.5 years). Breast cancer is commonly associated with multilevel vertebral metastases, and epidural tumor is multifocal in up to 29% of patients (10). As would be anticipated from their origin in the vertebral bodies, most epidural metastases are situated anterior or anterolateral to the spinal cord (1,5), which has important implications for their surgical management. Sixty or 70 percent of epidural metastases arise in the thoracic spine, 16% to 22% in the lumbosacral spine, and 8% to 15% in the cervical spine (11). These figures are proportional to the volume of bone in each of these spinal regions (12).

Spinal cord damage in ESCC is due primarily to direct compression of the spinal cord by tumor and rarely to compression of radicular arteries that pass through the intervertebral foramen (4). Axonal swelling and white matter edema occur early in animal models of ESCC, whereas gray matter damage occur later (13). Prolonged cord compression results in necrosis of both gray and white matter. Early spinal cord damage is likely caused by venous stasis, whereas arteriolar compression by tumor is probably responsible for the late stage of tissue necrosis (13).

CLINICAL PRESENTATION

ESCC due to breast cancer occurs most commonly in the thoracic spine (9,10,25). The principal symptom of ESCC is pain (14) (Table 77-1). It is the initial symptom in 85% to 96% of patients and precedes other symptoms by a mean of 6 weeks (2,15). Pain is of three types: local, radicular, and referred. Local back pain is usually a constant ache and occurs in almost all patients. Radicular pain is caused by involvement of nerve roots by the tumor mass and is typically described as a shooting pain. It is more common with cervical and lumbosacral lesions than with thoracic lesions (16). With cervical or lumbosacral epidural metastases, radicular pain is typically unilateral. With thoracic disease, however, radicular pain is commonly bilateral, producing a band-like pain or tightness that may be felt more at the lateral or anterior chest wall than in the back itself. Referred pain occurs at a distant site from the lesion and does not radiate. For example, T12-L1 vertebral lesions may be referred to both iliac crests or both sacroiliac joints, whereas C7-T1 lesions may be referred to the interscapular region or to both shoulders (17). The pain of epidural metastasis is often worsened by lying supine, possibly because of filling of vertebral veins in this position. Patients typically report that they are unable to sleep lying down and need to sleep sitting up; this information is often not volunteered by patients but must be sought by direct questioning. The pain tends to be most prominent at night and into the morning, with resolution or improvement over the course of the day (18). The Valsalva maneuver (coughing, sneezing, or straining at stool) exacerbates the pain of epidural metastases, as it fills vertebral veins and raises intracranial pressure, which is then transmitted to the already compromised spinal canal. Pain is also worsened by stretching maneuvers, such as neck flexion in the case of cervical or upper thoracic tumors and straight-leg raising with lumbosacral or thoracic lesions. Escalating back pain in patients with cancer is a particularly ominous indicator of the possibility of ESCC. Tenderness may be present over the vertebral column at the site of the lesion, and there may be referred tenderness at the site of referred or radicular pain. Pain that worsens substantially with movement of the neck or back may be a sign of mechanical instability of the spinal column, which can occur in the setting of vertebral or epidural metastases (18).

The spinal cord usually ends at the level of L1. Therefore, ESCC above L1 will produce a myelopathy, whereas lesions below this level result in a cauda equina syndrome. Myelopathic symptoms include limb weakness in a pyramidal distribution, numbness and paresthesia, and sphincter disturbance (urinary retention, urinary urgency, constipation, or fecal urgency). At the time of diagnosis, 76% of patients complain of weakness, 87% are weak on examination, 57% have autonomic dysfunction, 51% have sensory symptoms, and 78% have sensory deficits on examination (16). In many series, fewer than 50% of patients are ambulatory at diagnosis, and up to 25% are paraplegic (2,3,16); these figures are

TABLE 77-1

Symptoms Associated with Epidural Spinal Cord Compression

Symptom	*Frequency*	*Location*
Back pain	95%	• Localized pain confined to the area with the metastases that progressively increases over time. • Radicular pain due to invasion of the nerve roots, unilateral in the cervical and lumbosacral areas, bilateral in the thoracic region. Pain is worse with Valsalva and at night. • Mechanical back pain due to pathological fractures, pain is exacerbated by any movement.
Weakness	35%–75%	• Upper motor neuron weakness—symmetric. • Lower motor neuron weakness predominantly distal extremities affected and can be unilateral.
Inability to walk	50%–68%	• Tied in with weakness but can also be linked with ataxia due to sensory problems.
Sensory deficits	50%–70%	• Pain, numbness, ataxia.
Autonomic disturbance	50%–60%	• Bowel or bladder disturbance. • High cervical cord metastases can cause respiratory problems.

Adapted from the data reviewed in Cole JS, Patchell RA. Metastatic epidural spinal cord compression. *Lancet Neurol* 2008;7(5):459–466, describing the frequency of symptoms associated with ESCC.

significant because prognosis is related to clinical deficit at presentation. Outcomes might be improved if patients were encouraged to seek treatment earlier.

Signs of a myelopathy include paraparesis or quadriparesis, increased tone, clonus, hyperreflexia, extensor-plantar responses, a distended bladder, or a sensory level. A patch of hyperesthesia may be present at the upper aspect of the sensory level. The sensory, motor, and reflex levels are only an approximate indication of the site of pathology; because sensory fibers retain their somatotopic organization as they ascend in the cord, the actual site of cord compression may be several segments above the apparent sensory level. Furthermore, there may be multiple sites of epidural disease. The entire spinal cord should, therefore, be imaged in all patients with myelopathy.

The myelopathy may be incomplete, and it is a serious error to dismiss the possibility of ESCC on the basis that any particular sign is absent. Neither a sensory level nor an extensor plantar response is necessary to make the clinical diagnosis of ESCC. Dorsal column sensation (vibration and proprioception) and spinothalamic sensation (pain and temperature) must be assessed independently in all patients with cancer and back pain. Because the subjective appreciation of light touch involves both sensory pathways, light-touch sensation may be reasonably well preserved, even in the presence of a clear cut sensory level for pain or vibration sense when these are tested separately. A hemicord or Brown-Séquard's syndrome (characterized by ipsilateral weakness and proprioception loss, and contralateral loss of pain and temperature) may occur, although this is rare in ESCC (10,16). In an oncologic population, Brown-Séquard's syndrome is more typical of intramedullary cord metastasis or radiation myelopathy (19). Involvement of spinocerebellar tracts in the spinal cord can lead to lower extremity ataxia out of proportion to the degree of weakness. Dorsal column involvement can lead to a sensory ataxia with positive rombergism while sparing power and reflexes. Both of these clinical presentations may focus the attention of the unwary examiner on the cerebellum, thereby delaying diagnosis (20). Patients may also present with herpes zoster, presumably as a result of reactivation of latent virus by compression of the dorsal root ganglion by tumor (16).

ESCC at the conus medullaris and cauda equina produces different neurologic symptoms and signs, although pain is still a prominent feature, particularly with cauda equina lesions. Conus lesions typically present with early and marked sphincter disturbance and perineal sensory loss. Anal sphincter tone may be lax, and there may be an absent anal wink. Cauda equina lesions produce patchy lower motor neuron signs related to the lumbar and sacral nerve roots—hyporeflexia or areflexia, myotomal leg weakness, and dermatomal sensory loss; sphincter disturbance tends to occur late and to be less marked than in conus lesions. When the signs include a mixture of upper and lower motor neuron features or dermatomal sensory loss as well as a sensory level, the possibility of coexistent nerve root involvement and cord compression should be considered.

INVESTIGATIONS

Epidural spinal cord compression is a medical emergency requiring expeditious investigation of all patients in whom this diagnosis is suspected. Magnetic resonance imaging (MRI) is the test of choice, although rarely other modalities may be useful.

Plain X-Rays: From 94% to 98% of patients with epidural disease will have visible vertebral metastases on plain spine films (10,21,22,23). However, these are now rarely performed given the widespread availability of MRI.

Radionuclide Bone Scan: Bone scintigraphy is more sensitive than plain radiography in the detection of epidural metastasis (24). Spinal metastases as small as 2 mm can be detected and will pick up bone metastasis 3 to 18 months before x-rays. However, it is poor in delineating the anatomy, and in cancers causing osteolytic lesions, it is less useful (23).

Positron Emission Tomography (PET)/CT: PET/CT is used to stage cancer, and is largely more sensitive and specific in detecting metastases relative to a bone scan (25).

Computed Tomographic (CT) Scanning: CT remains one of the best techniques in assessing the anatomy of the actual vertebral body prior to surgical stabilization (Fig. 77-1A, B). Its sensitivity is limited to about 66% and diagnostic accuracy to approximately 89% in detecting areas of vertebral destruction, assessment of extent of paravertebral soft-tissue extension and impingement of the actual spinal cord (26). If there is a contraindication to use MRI (pacemaker, noncompatible MR implants), CT myelography may still be employed to delineate the level of the block (27) (Fig. 77-1A).

Magnetic Resonance Imaging (MRI): Contrasted MRI is the gold standard investigation in detecting ESCC. MRI has a sensitivity of 98.5% and a specificity 98.9% with an overall accuracy of 98.7% (26) (Fig. 77-1C, D). If ESCC is suspected, the entire spine should be imaged since multifocal disease occurs frequently (28). MRI influences radiotherapy fields and in one study led to simulation alterations in 53% of patients, with 21% being major changes (28).

An unenhanced MRI scan can establish the diagnosis of ESCC. However, a contrast-enhanced scan should also be obtained to look for leptomeningeal metastasis, which may mimic the presentation of ESCC. The entire spine should be imaged, as epidural disease may be present at multiple levels, and the spinal level indicated by clinical examination may be several segments below the level of the lesion (29). It is important to obtain axial scans in addition to sagittal images. A "screening" midline sagittal scan is inadequate; multiple sagittal scans using thin slices should be performed. Coronal images of the spine are not required routinely. Adequate analgesia (including corticosteroids) should be administered before the MRI is performed because the patient must lie motionless for the scan, and lying flat may worsen the back pain. If the patient cannot tolerate the full procedure, or if there is not enough time to perform an MRI of the entire spine, the area of interest should be imaged first, followed at a later time by imaging of the remainder of the spine. When ordering radiologic investigations, a clear distinction should be made between the suspected neurologic level of involvement and the suspected vertebral level; the discrepancy between these is greatest at the inferior end of the spinal cord. Because the spinal cord terminates at the first lumbar vertebra, all of the lumbar segments and some of the sacral segments of the cord are usually situated within the thoracic spine.

EVALUATION OF INDIVIDUAL CONDITIONS

Isolated Back Pain

In patients with breast cancer and isolated back pain without neurologic abnormalities, plain spine radiographs are occasionally the appropriate first line of investigation. Definitive

imaging of the epidural space should be performed if plain films are abnormal. In patients with a clinical picture that is strongly suggestive of epidural metastasis (e.g., back pain that is significantly exacerbated by lying flat and worsened by the Valsalva maneuver), MRI of the spine with contrast should be performed. In patients with local back pain with characteristics that are not strongly suggestive of epidural metastasis, definitive imaging of the epidural space is not indicated if a plain radiograph is normal.

Radiculopathy

Radiculopathy is associated with a high incidence of epidural metastases. In one series of patients with cancer and back pain, 27 of 43 (63%) patients with radiculopathy and without signs of spinal cord involvement were found to have epidural metastases, compared with 27 of 61 (44%) patients with local back pain alone (27). When plain radiographs were abnormal, epidural metastases were found in 20 of 22 (91%) patients with radiculopathy. Similarly, in patients with abnormal findings on plain radiographs, Graus et al. found epidural metastases in 47 of 67 (70%) patients with radiculopathy, compared with 12 of 35 (34%) patients with local back pain alone (30). Importantly, in the series by Graus et al. (30) and Rodichok et al. (27), epidural metastases were found in 9% to 33% of patients with radiculopathy and normal findings on plain radiographs.

Given the high incidence of epidural metastases in breast cancer patients with radiculopathy, it is reasonable to proceed straight to MRI in all patients. It is important to remember that in the thoracic spine, which is the most common site of ESCC in breast cancer, radiculopathy commonly presents as bilateral, band-like dermatomal pain and that, in some situations, lateral or even anterior chest pain may be more prominent than back pain.

Plexopathy

The possibility of epidural metastasis must be considered in patients with breast cancer and a malignant brachial plexopathy because tumor may infiltrate directly along the plexus to the epidural space. Brachial plexus lesions present with pain (usually in the shoulder girdle with radiation to the elbow, medial side of the forearm, and medial two digits) as well as weakness and sensory symptoms in a segmental distribution. Clinical clues to the presence of epidural metastases in the setting of brachial plexopathy include a panplexopathy (as compared to the more usual lower plexopathy with involvement of C7, C8, and T1 nerve roots) and the presence of Horner's syndrome (indicating more proximal involvement). The presence of back pain also suggests that the tumor has grown proximally, but back pain may be absent with epidural extension. Patients with brachial plexopathy require imaging of the brachial plexus with CT or MRI and, if vertebral body collapse or erosion is present, at the C7-T1 levels. If a paraspinal mass is seen definitive imaging of the epidural space should be performed. If MRI is used to image the brachial plexus, the cervical and upper thoracic spine can be imaged at the same time.

Myelopathy, Conus Medullaris, and Cauda Equina Syndromes

Definitive imaging of the epidural space with MRI is required in patients with myelopathy, conus medullaris or cauda equine syndromes. If MRI is not readily available or cannot be performed (e.g., in patients with pacemakers or the occasional patient with severe claustrophobia), CT myelography should be performed.

An unenhanced MRI scan can establish the diagnosis of ESCC. However, a contrast-enhanced scan should also be obtained to look for leptomeningeal metastasis, which may mimic the presentation of ESCC. The entire spine should be imaged, as epidural disease may be present at multiple levels, and the spinal level indicated by clinical examination may be several segments below the level of the lesion. It is important to obtain axial scans in addition to sagittal images. A "screening" midline sagittal scan is inadequate; multiple sagittal scans using thin slices should be performed. Coronal images of the spine are not required routinely. Adequate analgesia (including corticosteroids) should be administered before the MRI is performed because the patient must lie motionless for the scan, and lying flat may worsen the back pain. If the patient cannot tolerate the full procedure, or if there is not enough time to perform an MRI of the entire spine, the area of interest should be imaged first, followed at a later time by imaging of the remainder of the spine. When ordering radiologic investigations, a clear distinction should be made between the suspected neurologic level of involvement and the suspected vertebral level; the discrepancy between these is greatest at the inferior end of the spinal cord. Because the spinal cord terminates at the first lumbar vertebra, all of the lumbar segments and some of the sacral segments of the cord are usually situated within the thoracic spine.

Summary

Isolated Back Pain: Definitive imaging of the epidural space should be performed if plain films are abnormal. If the patients have a clinical picture consistent with ESCC, then an MRI of the spine with contrast should be performed.

Radiculopathy: Given the high incidence of epidural metastases in breast cancer patients with radiculopathy, an MRI spine is recommended.

Plexopathy: Patients with brachial plexopathy require imaging of the brachial plexus with CT or MRI. Note that if MRI is used to image the brachial plexus, the cervical and upper thoracic spine can be imaged at the same time.

Myelopathy: Imaging of the epidural space with MRI is critical if a patient has myelopathy. If an MRI is contraindicated, then a CT myelogram should be performed.

MANAGEMENT

A multidisciplinary approach is needed to manage ESCC. Improvements in systemic therapy, surgery, and radiation have improved survival. Apart from the standard pain scales and performance status assessments, specific scales assessing neurological impairment for spinal cord issues (American Spinal Injury Association and Frankel Score) may be helpful, and these are discussed in more detail in the scoring systems section (15,31).

Pain Control

Nonsteroidal anti-inflammatory agents, narcotic analgesics, and medications for neuropathic pain such as gabapentin are the mainstay of pain control (32).

Corticosteroids

Corticosteroids, usually in the form of dexamethasone, are routinely used in the management of MESCC because they reduce pain and sometimes stabilize or improve neurologic deficits by reducing vasogenic edema (4).

One early study demonstrated that a bolus dose of 100-mg dexamethasone intravenously, followed by a tapering schedule starting with 96 mg a day in four divided doses for 3 days, had a significant and rapid effect on the pain associated with ESCC (33). In a more recent study, no difference in pain, ambulation, or bladder function was seen in 37 patients with ESCC who received either a 10- or a 100-mg bolus of dexamethasone intravenously (34). A randomized controlled trial in 1994, however, showed that in 57 patients with ESCC who proceeded to radiation therapy, high-dose dexamethasone significantly increased the proportion of patients who remained ambulatory after treatment (35).

In general, a bolus dose of 100 mg of dexamethasone is recommended for patients with suspected ESCC who present with significant deficits, followed by a maintenance dose of 24 mg every 6 hours. Steroids may then be tapered over 2 to 3 weeks while the patient receives definitive therapy. The dose may be halved approximately every 3 days if clinically appropriate. In patients who have persistent or worsening pain, steroids may need to be increased or tapered gradually. Patients with minimal deficits can probably be safely treated with a 10-mg bolus of dexamethasone, followed by an initial maintenance dose of 8 to 16 mg daily. The bolus dose of steroids should be given once the clinical diagnosis is made and before an MRI is performed. If MRI demonstrates cord compression (or if myelography shows a block of more than 80%), the high-dose regimen may be used, whereas the low-dose regimen is used for patients with epidural disease without cord compression. Oral and intravenous administration of dexamethasone are equivalent; however, systemic availability is delayed by approximately 30 minutes when given orally. Intravenous dexamethasone is recommended for the initial bolus to provide analgesia quickly, but unless the patient has gastrointestinal dysfunction, oral dexamethasone is generally appropriate. Prolonged use of high-dose dexamethasone is associated with more side effects than low-dose dexamethasone, but for short-term use, the toxicity of the doses is similar. *Pneumocystis jiroveci* prophylaxis is recommended with trimethoprim-sulfamethoxazole, one double-strength tablet once or twice a day, 3 days a week. In addition, H_2 blockers or proton pump inhibitors should be considered to reduce the risk of peptic ulceration during corticosteroid therapy.

Supportive Care

Patients with myelopathy resulting from ESCC require close attention to analgesia, bowel and bladder care, and the prevention of pressure sores. Prophylaxis against venous thromboembolism should always be considered in bedbound patients.

Hormonal Therapy

The incidence of vertebral metastases and ESCC from breast cancer can be reduced by hormonal therapy, but it is not a treatment for ESCC (36). Bisphosphonates such as zoledronate, which induce apoptosis in osteoclasts and inhibit osteoclast-mediated bone resorption (37), and denosumab, a monoclonal antibody targeting the RANK ligand which acts as the primary signal to promote bone removal, can help decrease the incidence of vertebral metastases and ESCC (38).

Scoring Systems

Several systems have been developed to help guide decisions between surgery or radiation therapy (RT) (1). Harrington (39) classified lesions on structural integrity and neurologic dysfunction, and since then there have been many scoring systems described as reviewed in Bhatt et al. (1). Rades et al. (40) described a scoring system for breast cancer involving 510 patients, half assigned to either the test or the validation group, and stratified by eight pretreatment factors (age, performance status, number of involved vertebrae, ambulatory status, other bone metastases, visceral metastases, interval from cancer diagnosis to radiation therapy of ESCC, time of developing motor deficits) plus the radiation regimen were retrospectively investigated. Factors significantly associated with survival in the multivariate analysis were included in the scoring system. This score was found to be reproducible in selecting patients for the radiation therapy group. Bilsky and Smith (18) proposed the NOMS system which considers neurologic factors (N), oncologic factors (O), mechanical instability (M), and systemic disease including comorbidities (S) in guiding treatment decisions regarding surgery versus radiotherapy which many clinicians have adopted, although it remains to be validated prospectively (Table 77-2). The National Comprehensive Cancer Network (NCCN) (41) has proposed guidelines to guide management (see Fig. 77-2). In general, patients with a prognosis of more than 3 to 6 months may benefit from surgery, while patients with a poor prognosis may be better treated with a nonsurgical palliative approach (1).

Surgery

Although the standard management of ESCC is radiation therapy with or without surgery, in reality, less than 10% of patients with ESCC undergo surgery (42). Goals of surgery in ESCC include decompression of neural structures (75% neurologic improvement); pain relief (80% to 95% improvement); debulking or removal of tumor mass; and spinal stabilization to prevent deformity and allow mobilization (reviewed in reference 1) (Fig. 77-3). Indications for surgery include the following (1):

- Progressive neurologic deficit before, during, or after radiation therapy
- Intractable pain unresponsive to conservative treatment
- Need for histologic diagnosis
- Radio-resistant tumor histology (i.e., renal cell carcinoma, melanoma)
- Spinal instability (i.e., vertebral collapse)

Recently the Spinal Instability Neoplastic Score (SINS) has been proposed by the Spine Oncology Study Group (SOSG) to identify the patients who require surgical stabilization. Spine instability is assessed by adding scores related to six factors including location of the tumor within the spine, pain, lesion bone quality, radiographic alignment, vertebral body collapse, and posterolateral involvement of the spinal elements (43,44). SINS scores range from 0 to 18. A score of 0–6 indicates stability, 7–12 indicates indeterminate instability, and 13–18 is indicative of instability. Any patient with a score greater than 7 should have a surgical consultation (43). The SINS has been shown to have a sensitivity of 95.7% and a specificity of 79.5% in identifying potentially unstable or unstable lesions (44). Decompressive laminectomies have been largely superseded by surgical approaches that have access to the anterior column for decompression and stabilization, since the vertebral body is affected in 70% of spine metastases (5). Embolization or vertebral body biopsy procedures are not often utilized in management of patients with breast cancer and rather are reserved for management of vascular lesions and unknown primary metastatic lesions respectively.

TABLE 77-2

Simplified Approach to Treatment of Epidural Spinal Cord Compression

ESCC	*Symptoms*	*Treatment*
Spine unstable or high-grade ESCC	Myelopathy or symptoms from single ESCC site	Surgery → conventional EBRT
Spine stable	Minimal or stable myelopathy	Conventional EBRT alone *or* surgery followed by conventional EBRT if very radioresistant tumor (e.g., melanoma)

This table lays out a simplified approach to NOMS. Several scoring systems have been developed to help guide decisions between surgery or radiation therapy. However, the exception is if surgery is warranted but the patient with metastatic breast cancer cannot tolerate it, then the patient goes on to EBRT directly.

NCCN Guidelines Version 2.2012
Metastatic Spine Tumors

PRESENTATION	TREATMENT	ADJUVANT TREATMENT
No tumor	Evaluate for other causes of pain and/or neurologic symptoms[g]	
Spinal cord compression[d] → Steroids[e]	Surgery[h,i,j] followed by RT (preferred) or Primary RT[k] or In the absence of clinical myelopathy, primary chemotherapy[l] if chemosensitive tumor (eg, lymphoma, germ cell tumor, myeloma)	
No spinal cord compression[d] → Fracture or spinal instability[f]	Surgical stabilization or Vertebral augmentation[m]	Followed by RT[k]
No spinal cord compression[d] → No fracture or spinal instability	RT[k] (preferred) or Chemotherapy[l] (if chemosensitive tumor) or Surgery[j] (selective cases) followed by RT	Consider surgery[j] or stereotactic radiotherapy[k] if: • Deterioration during RT • Intractable pain • Tumor progression

[d]Includes cauda equina syndrome.
[e]The recommended minimum dose of steroids is 4 mg of dexamethasone every 6 hours, although dose of steroids may vary (10-100 mg). A randomized trial supported the use of high-dose steroids (Sorensen PS, et al. Eur J Cancer 1994;30A:22-27).
[f]Spinal instability is grossly defined as the presence of significant kyphosis or subluxation (deformity), or of significantly retropulsed bone fragment.
[g]Consider alternative diagnosis of leptomeningeal disease (See LEPT-1).
[h]Tumor resection with or without spinal stabilization. Surgery should be focused on anatomic pathology.
[i]Regarding surgery, note the following:
- Category 1 evidence supports the role of surgery in patients with epidural spinal cord compression willing to undergo surgery. (Patchell RA, et al. Lancet 2005;366(9486):643-648)
- For surgery, patients with hematologic tumors (lymphoma, myeloma, leukemia) should be excluded, life expectancy should be ≥ 3 mo, and the patient should not be paraplegic for > 24 h.
- Surgery is especially indicated if the patient has any of the following: spinal instability, no history of cancer, rapid neurologic deterioration during RT, previous RT to site, and single site spinal cord compression.

[j]See Principles of Brain Tumor Surgery (BRAIN-B).
[k]See Principles of Brain Tumor Radiation Therapy (BRAIN-C).
[l]See Principles of Brain Tumor Systemic Therapy (BRAIN-D).
[m]Vertebral augmentation: vertebroplasty, kyphoplasty.

Note: All recommendations are category 2A unless otherwise indicated.
Clinical Trials: NCCN believes that the best management of any cancer patient is in a clinical trial. Participation in clinical trials is especially encouraged.

Discussion

FOLLOW-UP	PRESENTATION (Symptom or MRI based)	TREATMENT FOR RECURRENCE OR PROGRESSIVE DISEASE
MRI/CT 1-3 mo after treatment, then every 3-6 mo as clinically indicated →	Progressive disease or Recurrent disease → If previously treated with: RT or Surgery and RT	Consider surgery[j] Consider re-irradiation if recurrent
	Progressive disease or Recurrent disease → If previously treated with: Chemotherapy	Consider RT[k]

[j]See Principles of Brain Tumor Surgery (BRAIN-B).
[k]See Principles of Brain Tumor Radiation Therapy (BRAIN-C).

Note: All recommendations are category 2A unless otherwise indicated.
Clinical Trials: NCCN believes that the best management of any cancer patient is in a clinical trial. Participation in clinical trials is especially encouraged.

SPINE-3

FIGURE 77-2 *(Continued)*

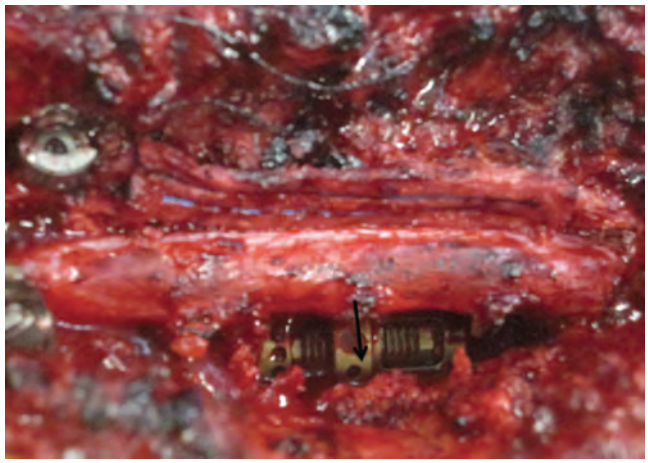

FIGURE 77-3 Intraoperative picture demonstrating exposure obtained with an advanced posterolateral approach, in this case a costotransversectomy. Circumferential decompression has been achieved, the ipsilateral T12 nerve root has been ligated to facilitate exposure of the ventral disease, vertebral body resection and reconstruction with an expandable cage has been performed. Pedicle screws at the left side of the image are part of the posterior instrumented fusion yet to be completed.

In 2005, Patchell et al. reported a phase III prospective, randomized controlled trial that compared surgical decompression followed by radiation therapy to radiation therapy alone in patients with solid tumor ESCC (45). Patients with at least one neurological symptom of ESCC (including pain) and evidence of a solitary epidural metastasis following whole spine MRI were given high-dose steroids and then randomized to receive surgery followed by radiation therapy (n = 50) versus radiation therapy alone (n = 51). Patients with multiple lesions, nerve root compression, radiosensitive tumors (lymphoma, leukemia, multiple myeloma, and germ cell tumors), and paraplegia more than 48 hours prior to entry were excluded. As a result the findings are applicable only to a minority of patients with ESCC.

Most of the previous studies had used a posterior approach, whereas in the Patchell study the approach was chosen by the surgeon based on the location of the tumor (anterior, lateral, or posterior) (45). The study population included 13 breast cancer patients, equally distributed between groups (7 had surgery plus radiation therapy, 6 had radiation therapy alone). The primary end point was the ability to walk immediately following radiation, with duration of ambulation and survival time among the secondary end points. In the group who received surgery, 84% were able to ambulate at the end of radiation therapy, compared to 57% of those who received radiation therapy alone (p = .001). The median duration of ambulation was 122 days with surgery plus radiation therapy, compared to 13 days with RT alone (p = .003). Stability of Frankel Functional Scale and American Spinal Injury Association (ASIA) motor scores, as well as decreased need for opiates and corticosteroids were seen more often in those who underwent surgery. Overall survival was better in the surgery plus radiation therapy group (126 days vs. 100 days with radiation therapy alone; p = .033). Importantly, surgery did not result in prolonged hospitalization; the median hospital stay was 10 days in both the surgery group (interquartile range 2 to 51 days) and the radiation group (0 to 41 days; p = .86). Based on superior posttreatment ambulatory rate in the surgically treated group, the study was stopped at the midpoint analysis and concluded that surgery plus radiation therapy is superior to radiation therapy alone in the treatment of ESCC.

This study suggests that patients with ESCC treated with radical direct decompressive surgery plus postoperative radiation therapy retained the ability to walk longer than patients treated with radiation alone. Surgery permitted most patients to remain ambulatory and continent for the remainder of their lives, whereas patients treated with radiation alone spent approximately two thirds of their remaining time unable to walk and incontinent. In patients with multiple metastases, or in institutions without surgical resources to perform emergency anterior decompression in patients with ESCC routinely, the benefit of surgery is less clear. Also, whether the benefit of surgery applies to radiosensitive tumors such as breast cancer remains to be seen, since breast cancer patients comprised only 13% of the study group. Nonetheless, this is an important study that provides evidence to support surgical decompression in certain patients with ESCC (45).

In contrast to the Patchell study (45), a retrospective study carried out by Rades et al. (46) did not show any benefit from surgery. In this study, 108 patients receiving surgery plus radiation therapy were matched to 216 patients (1:2) receiving radiation therapy alone. Thirteen percent of patients in each group had breast cancer. Groups were matched for 11 potential prognostic factors and compared for posttreatment motor function, ambulatory status, regaining ambulatory status, local control, and survival. Subgroup analyses were performed for patients receiving adequate surgery (direct decompressive surgery plus stabilization of involved vertebrae), patients receiving laminectomy, patients with solid tumors, patients with solid tumors receiving adequate surgery, and patients with solid tumors receiving laminectomy. The outcomes of the end points evaluated after radiation therapy alone appeared similar to those of surgery plus radiation therapy. This study therefore did not confirm the benefit of adding surgery to radiation therapy and suggests that further randomized studies examining the benefit of surgery is needed.

A recent study by Rades et al. (47) suggests that patients older than 65 do not benefit from surgery in addition to radiation therapy as determined by functional outcome, local control of ESCC, or survival. This is in part due to the increased risks of anesthesia or due to the surgery itself (47).

In summary, surgery is recommended for patients whose disease progresses or relapses despite radiation therapy, for spinal instability due to fracture dislocation of the vertebrae, and for patients in whom the spinal cord compression is largely caused by bony fragments in the epidural space rather than tumor. Surgery for patients who are nonambulatory at presentation is probably beneficial, although the data are inconclusive (48). In patients who were treated soon after the onset of paraplegia (less than 48 hours), the Patchell et al. (45) study showed improved outcomes in those who underwent surgery with radiation therapy. Of those who entered the study unable to walk (32 patients), 10 of 16 (32%) regained the ability to walk in the surgery group compared to 3 of 16 (19%) who received radiation therapy alone (p = .012). Additionally, the surgical group maintained ambulation for a median 59 days, compared to 0 days in those receiving only radiation therapy (p = .04). Treatment decisions therefore must be individualized, taking into account the risk of surgery and the patient's overall condition and ability to tolerate therapy.

Radiation therapy is usually administered following surgery to improve local tumor control. Ideally it is performed 2 to 3 weeks after surgery to allow wound healing (49).

Kyphoplasty and Vertebroplasty

Kyphoplasty is a technique that involves percutaneous curettage of the affected vertebral body followed by inflation of a balloon in the body and subsequent injection of cement into the newly formed cavity. In contrast, vertebroplasty involves injection by fluoroscopic guidance of polymethylmethacrylate cement directly into the compromised vertebral body and requires an intact vertebral body. Both techniques help with stabilization and strengthening of compromised vertebrae, and due to stabilization of the anterior column, are thought to relieve pain (50). The SOSG has reviewed the data and literature related to kyphoplasty and vertebroplasty and deemed these procedures as safe in improving pain and functional outcomes in patients with vertebral body metastases, although the outcome is highly operator dependent (50). However, these procedures are relatively contraindicated in patients with ESCC with compression of neurologic structures.

Radiation Therapy

Radiation therapy alone is the most common treatment for ESCC. Although all patients with ESCC should undergo RT, patients with expected survival of less than 3 to 6 months, inability to tolerate an operation, total neurological deficit for more than 24 to 48 hours and multilevel or diffuse disease should probably not undergo surgery and should receive RT alone (1).

In general, patients with breast cancer undergoing focal radiation therapy receive a dose of up to 3,000 cGy (30 Gy) administered over 2 weeks to the metastases plus one or two vertebral bodies above and below. Three- and four-week regimens administering up to 4,000 cGy have also been described, without benefit in motor function, local control of disease, or survival over the standard 2-week regimen (51). Short-course radiation therapy involving two doses of 800 cGy has also been proposed, producing results comparable to those obtained with higher doses in uncontrolled studies (52,53). Single fraction radiation for pain relief has also been proposed for patients with uncomplicated metastases (54). No dose fractionation schedule has proven to be significantly more efficacious than others (1,4,52), but shorter courses may have a higher rate of local recurrence and need for further treatment.

Rades et al. (52) performed a retrospective review of 335 breast cancer patients who received radiation to determine significant prognostic factors. They found that slower development of motor deficit (more than 14 days) and ability to ambulate prior to initiating radiation therapy was associated with a better functional outcome. A short course of radiation (800 cGy in one dose vs. 3,000 to 4,000 cGy over 3 to 4 weeks) did not significantly impact functional status after treatment, but was associated with a higher in-field rate of recurrence (20% at 2 years vs. 10% with standard course RT). Median overall survival was 20 months, but was decreased in patients with visceral metastases, deterioration of motor function after radiation therapy, rapid development of motor deficits (1 to 7 days), and poor performance status. An updated recent analysis from the same group found that an additional favorable prognostic factor on functional outcome was having no visceral metastases, and that additional factors associated with improved survival were having only one or two vertebral metastases, and no other bony metastases (55).

One approach is to recommend the course of radiation based on the patient's expected survival and ability to tolerate treatments. Short-course radiation therapy may be most appropriate for those with an estimated survival of less than 6 months, since the main benefit of long-course RT is reduced local recurrence (52,56).

Radiation therapy should be initiated urgently. It is known that rapid deterioration within 48 hours of the start of RT predicts a poor outcome, and patients who were ambulatory before treatment are likely to remain ambulatory or improve in their performance status overall. In situations in which patients present in the middle of the night, when it is logistically difficult to obtain neuroimaging or commence radiation therapy, the high-dose steroid regimen may be commenced; the radiation oncologists can be notified about the patient, and a spine MRI and radiation planning session performed first thing the following morning.

Reirradiation

The use of radiation therapy for recurrent ESCC, when this involves reirradiating a previously treated segment of spinal cord, poses a potential risk of producing radiation myelopathy (57) and historically has been used sparingly. However, with increasingly effective systemic treatment options, reirradiation of the spine for either recurrent ESCC or recurrent vertebral body metastases is becoming more prevalent, with many reports describing favorable outcomes in selected patients (58,59). Myelopathy is less likely to occur within the limited life expectancy of this population, but since this is a potentially devastating complication of retreatment, particular attention should be paid to cumulative radiation dose to the spinal cord. Nieder et al. (59) examined outcomes of patients who underwent spinal cord reirradiation, recalculating the cumulative doses they received according to the biologically effective dose (BED). With a median follow-up of 17 months, the risk of myelopathy was extremely small if the cumulative BED was not greater than 135.5 Gy in 2-Gy equivalents, the interval between initial radiation and reirradiation was at least 6 months, and the dose for each course of radiation was not greater than 98 Gy in 2-Gy equivalents. Patients who have previously received a maximal dose of radiation therapy to the spine may have an option to undergo decompressive surgery if indicated. Alternatively, in selected cases, reirradiation can be performed using highly conformal techniques, such as stereotactic radiosurgery (SRS), to markedly reduce any further dose to the spinal cord.

Stereotactic Radiosurgery (SRS) and Stereotactic Body Radiotherapy (SBRT)

Recently there has been growing interest in more conformal techniques such as SRS and SBRT, terms that are used interchangeably for treatment of spinal metastases (1,5) and typically refer to treatment courses of between one and five total fractions. SRS/SBRT achieve accurate targeting with multiple highly conformal radiation beams delivering a high dose of radiation to a small target, with rapid dose fall-off to avoid injury to adjacent critical structures (1). SRS/SBRT is typically used for vertebral body metastases at least 3 mm away from the spinal cord and much less commonly for actual ESCC, given that tumor abuts the cord in ESCC and therefore risk of myelopathy may be increased. One clinical trial at Henry Ford Hospital used SRS with a median dose of 1,600 cGy to "decompress" the epidural tumor in patients with ESCC, finding improvement in neurologic function in 81% of patients with a median follow-up of 11.5 months and no cases of SRS-related myelopathy (60). However SRS/SBRT alone for ESCC is considered highly experimental, and if used in the management of ESCC is more often done only after surgical decompression. SRS/SBRT for vertebral body metastases is more technically complex to plan and each treatment takes longer to deliver, but has several potential advantages over conventional radiation: it can avoid irradiating excess marrow; it may interfere less with concurrent chemotherapy; it is accomplished in fewer total

treatments; it can safely deliver a higher dose which may be important for radioresistant tumors; and it may provide a higher degree of pain relief, which is currently being evaluated in the phase II/III clinical trial RTOG 0631, comparing spine SBRT to conventional radiation.

Chemotherapy and Hormonal Therapy

Chemotherapy does not play a significant role in the treatment of ESCC caused by metastatic breast cancer, although Boogerd et al. (61) describe protracted remission of epidural metastases in four patients with breast cancer who received chemotherapy. Chemotherapy may be a more important treatment modality in highly chemosensitive tumors, such as germ cell tumors, lymphoma, and neuroblastoma (12,62,63).

PROGNOSIS

The outcome of ESCC is directly related to the patient's clinical condition at the commencement of treatment. Patients who are ambulant are far more likely to remain ambulant after treatment: 79% to 100% of patients who are ambulant before treatment remain so, whereas only 18% to 69% of nonambulant patients regain the ability to walk (12,16,59,64–66,68). In most series, fewer than 10% of patients who are paraplegic or quadriplegic before treatment regain the ability to walk (12,16,62–65,67), although vertebral body resection has been associated with ambulation rates of 24% to 56% in initially paraplegic patients (45,48).

The prognosis for patients with breast cancer treated with radiation therapy alone has been characterized by Maranzano et al. (66). In this study, the likelihood of responding to radiation therapy was dependent on the pretreatment ambulatory status, whereas duration of response is dependent on the post-treatment ambulatory status. Eighteen of 26 (69%) patients who were nonambulant before treatment became at least partially ambulant with treatment (walking alone or with support). Only 1 ambulant patient of 30 (3%) became nonambulant despite treatment, underscoring the value of early diagnosis.

The median survival of patients with breast cancer in whom ESCC develops is 5 to 14 months (2,64–65). The time from diagnosis of breast cancer to the development of ESCC has been found to be a predictor of survival, with patients who develop ESCC after 3 or more years having a better survival (2). The Patchell study (45) suggests that the addition of surgery to radiation therapy increased absolute survival (126 days vs. 100 days; $p = .033$), as well as the duration of ambulation 122 days vs. 13 days). However, as this study selected radioresistant tumors and only 13% of patients had breast cancer, the role of surgery remains controversial.

Posttreatment ambulatory status is the most important factor influencing survival in patients with breast cancer (2,66). In the study by Maranzano et al. (66), the median survival was 13 months for all patients, 17 months for patients who were ambulant after treatment, and only 2 months for those who were nonambulatory after treatment. The 1-year survival of posttreatment ambulant patients in this study was 66% versus 10% for nonambulant patients. However, local control at the site of spinal metastasis did not appear to be responsible for the improved survival in ambulant patients because most deaths were due to progression of systemic disease rather than relapse in the irradiated spine. In another series reported by Maranzano et al. (65), which included patients with ESCC due to other cancer types, median survival was improved in patients with breast cancer (12 months) than in patients with other tumor types (3 to 7 months). This relatively long survival, in association with the fact that early diagnosis may preserve ambulatory status, underscores the potential value of prompt investigation and treatment of ESCC in patients with breast cancer. Putz et al. (69) examined biological, patient-related, mechanical, and time-dependent aspects influencing functional outcome following treatment of ESCC and found four different prognostic factors with a significantly positive or negative impact on postoperative ambulatory status. The negative factors included vertebral compression fracture, high Tokuhashi score (70) which is based on the Karnofsky Performance Status, number of metastases in the bone, vertebral bodies, internal organs, primary site of cancer, and the presence of neurologic deficits. The positive factors included early decompression (less than 48 hours) and ambulation before treatment. However, given the lack of standardized prognostic tools, prediction of ambulatory outcome after primary surgery in ESCC patients is currently limited. There is an ongoing NIH clinical trial to evaluate whether the Tokuhashi score can be validated. The current NCCN guidelines algorithm can be used to guide in the management of metastatic spinal cord tumors (41) (Fig. 77-2).

MANAGEMENT SUMMARY

- Early diagnosis and treatment of epidural spinal cord compression is very important in preventing serious neurologic disability. Functional outcome is primarily dependent on the degree of neurologic impairment at the commencement of treatment. Optimal outcomes occur when no neurologic findings are present at the time of diagnosis.
- Epidural spinal cord compression should be suspected in any breast cancer patient with back or neck pain, particularly if there is myelopathy or radiculopathy.
- In patients with pain and myelopathy, dexamethasone 100 mg intravenously should be administered immediately, followed by 24 mg orally every 6 hours, with a spine MRI obtained urgently.
- In patients with pain and radiculopathy or with highly suspicious symptoms, dexamethasone 10 mg intravenously should be administered immediately followed by 4 mg orally every 6 hours (or 8 mg orally every 12 hours) and a spine MRI obtained within 24 hours.
- In patients with pain and a low index of suspicion for epidural spinal cord compression, plain spine radiographs or a bone scan should be obtained.
- If epidural spinal cord compression is confirmed on MRI, and any neurologic deficit is mild or stable, treatment is generally radiation therapy to a dose equivalent to 3,000 cGy in 10 treatments.
- Surgical decompression is recommended for patients with a symptomatic single lesion, or an unstable spine, and paraplegia for less than 48 hours.
- Chemotherapy has a limited role in epidural spinal cord compression due to metastatic breast cancer.
- Patients with neurologic compromise should receive adequate analgesia, bowel and bladder care, and prevention of pressure sores. Prophylaxis against venous thromboembolism should be considered in bed-bound patients.

CHAPTER 78

Leptomeningeal Metastasis

Eli L. Diamond and Lisa M. DeAngelis

CHAPTER CONTENTS

Leptomeningeal metastasis (LM) occurs when tumor spreads to the subarachnoid space and cerebrospinal fluid (CSF) that surround the brain and spinal cord. It may be the sole site of central nervous system (CNS) metastasis or may coexist with brain, dural, or parenchymal spinal cord metastases. LM is an increasingly important neurologic complication of solid tumors in addition to its well-recognized association with hematopoietic malignancies. Enhanced clinical detection with improved neuroimaging and prolonged patient survival with better control of systemic cancer contribute to the increased frequency of LM in patients with solid tumors, particularly breast cancer (1).

The frequency of LM in clinical series of patients with breast cancer is estimated at 8%; however, autopsy series of these patients reveal an incidence of 3% to 40% (2). LM usually coexists with disseminated systemic disease, but it can also occur as an isolated site of relapse. The CNS may be a sanctuary site for metastatic disease in patients with breast cancer whose systemic tumor has been controlled with effective systemic therapies (3), particularly HER2-positive breast cancer treated with trastuzumab (4). The repertoire of active agents to treat breast cancer consists mainly of water-soluble drugs that do not penetrate the blood–brain barrier (BBB). There are numerous efflux transporters that comprise the BBB, including P-glycoprotein, other multidrug resistance-associated proteins (MRP), and the breast cancer resistance protein (ABCG2) that extrudes chemotherapeutic agents such as anthracyclines, taxanes, and vinca alkaloids (5). These agents can eradicate disease in systemic sites, but if a microscopic tumor resides in the CNS, they do not cross the intact BBB; thus, these agents allow the CNS tumor to grow, leading to subsequent brain or leptomeningeal metastases. Once a CNS tumor reaches a macroscopic size, the BBB is typically disrupted and, occasionally, systemically administered drugs can be effective against CNS metastases. However, sequestration of a microscopic tumor behind an intact BBB is likely a major explanation for the rising frequency of brain and leptomeningeal metastases in patients with otherwise well-controlled breast cancer.

Determining the diagnosis of LM is often difficult because the presenting neurologic symptoms can be confused with other CNS complications of breast cancer. Neuroimaging and laboratory tests aid in establishing the diagnosis but are limited by a lack of sensitivity, specificity, or both. Optimal therapy has not been defined; difficulties of drug distribution in the CSF, intrinsic drug resistance of the metastases, and neurotoxicity are important factors that limit the success of standard therapies. Nevertheless, in some patients, an aggressive approach is rewarding, and prolonged control of both disease and symptoms is possible. This chapter reviews the clinical presentation of this disorder, the methods of diagnosis, and the recommended therapeutic approaches.

CLINICAL SETTING

CNS metastases in breast cancer have been associated with younger age, premenopausal status, infiltrating ductal histology, estrogen- and progesterone-receptor negativity, aneuploidy, altered p53, and epidermal growth factor receptor (EGFR) overexpression (6). Lobular type breast cancer has a predilection for LM compared to other histologic types of breast cancer, with one autopsy study showing LM to occur in 14% of all cases of lobular carcinoma (2). In a study done by Altundag et al. (7), 3.8% of 420 breast cancer patients with CNS metastases had a tumor of lobular histologic type, but 31.6% of these patients presented with isolated LM, compared to 7% of all patients in the series. Studies have shown an increased incidence of CNS metastases in women with HER2-positive breast cancer as high as 25% to 40% (8). This increase may be multifactorial and includes biologic factors as well as treatment-related factors. The use of trastuzumab, a monoclonal antibody directed against the HER2 receptor, is associated with increased systemic response rates, prolonged disease-free survival, and overall survival for patients with HER2-positive breast cancer. Due to its high molecular weight, it does not cross the BBB, which may explain the emergence of CNS metastases. It has been postulated, however, that trastuzumab does not increase the risk of CNS relapse directly but rather improves systemic control and overall survival, leading to

an unmasking of occult brain metastases that would otherwise remain clinically silent (9). In fact, other studies do not support a direct association between treatment with trastuzumab and increased CNS metastases (10). One study observed a lower rate of LM in patients with brain metastases and HER2-positive disease compared to HER2-negative patients with brain metastases (11).

A wide time interval between the diagnosis of breast cancer and the occurrence of LM has been reported; in large series, it ranges from a few weeks to more than 15 years (2). In rare instances, LM is the initial manifestation of breast cancer. Many patients with a solid tumor have widespread metastatic disease when LM is diagnosed but, in patients with breast cancer, the systemic tumor may be inactive or responding to chemotherapy. Of 48 patients diagnosed with LM reported by de Azevedo et al. (1), 34 (56.7%) had been treated with 3 or more chemotherapy regimens prior to the diagnosis of LM, and 51 (85%) had metastatic disease at the time of diagnosis.

PATHOPHYSIOLOGY

The cerebral and spinal meninges are composed of the dura mater, arachnoid, and pia mater. The leptomeninges include the arachnoid and pia mater. The pia mater is a thin lining, closely adherent to the surface of the brain and spinal cord, separated from the arachnoid by fine trabeculae. It follows the sulci of the cerebral cortex and penetrates the parenchyma of the CNS in association with arterioles. The associated parenchymal perivascular space is termed the Virchow-Robin space (Fig. 78-1). Pathologic evidence suggests several methods by which tumor cells reach the leptomeninges:

1. Hematogenous spread to the vessels of the arachnoid or to the choroid plexus of the ventricles (the latter produces dissemination of malignant cells to the leptomeninges by normal CSF flow);
2. Direct extension from adjacent metastasis in the cerebral parenchyma or dura or the lymphatic paraspinal region;
3. Retrograde access to the subarachnoid space by tumor cells infiltrating the venous system from adjacent calvarial or spinal metastases; or
4. Iatrogenic spread after resection of a brain metastasis.

Tumor dissemination into the CSF after surgical procedures is primarily associated with removal of metastases from the cerebellum, in which the subsequent development of leptomeningeal disease may be as high as 67% (2). The risk of LM after posterior fossa surgery is increased in the setting of piecemeal as opposed to en bloc resection. There does not seem to be a relationship between radiosurgery of a cerebellar metastasis and the development of LM (12).

Autopsy studies demonstrate that leptomeningeal tumor grows in a sheet-like fashion along the surface of the brain, spinal cord, cranial nerves, and nerve roots (2). It usually disseminates widely, but it may be limited to portions of the cerebral or spinal leptomeninges. When tumor cells are closely adherent to one another, multifocal nodules may form, particularly on the cauda equina or ventricular surface of the brain. LM is usually accompanied by a fibroblastic proliferation of the meninges. An inflammatory response may be seen pathologically in the leptomeninges and, occasionally, reactive lymphocytes accompany malignant cells in a CSF specimen. Tumor may ensheathe meningeal arteries and veins within the subarachnoid space and may extend into the Virchow-Robin spaces, with resulting perivascular tumor cuffing and parenchymal invasion; tumor cells may invade into the cranial nerves and spinal roots as well. Invasion may interfere with blood supply to neurons, causing ischemic changes and even frank infarction (2). Neuronal dysfunction may also be caused by local metabolic derangement because of competition between tumor cells and neurons for glucose and other critical nutrients.

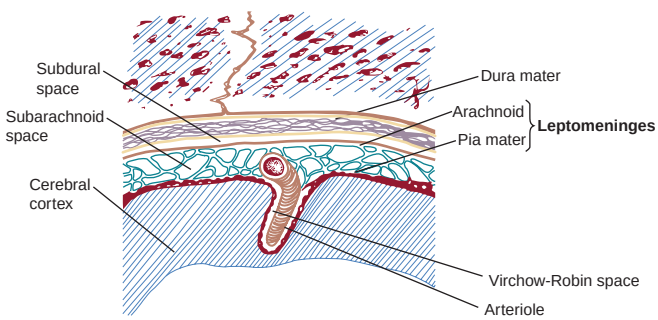

FIGURE 78-1 Relation of the cerebral meninges to the brain.

CLINICAL MANIFESTATIONS

The clinical hallmark of LM is the simultaneous occurrence of multifocal abnormalities at more than one level of the neuraxis (cerebral, cranial nerve, and spinal). A careful neurologic examination often reveals more signs than suggested by the clinical symptoms. Spinal symptoms are the most common presentation of LM (Table 78-1); limb weakness is frequent, usually involving the legs, and may be accompanied by paresthesias and pain in the affected limb. Neurologic examination may reveal asymmetric depression of deep-tendon reflexes, radicular limb weakness, and sensory loss. Signs of meningeal irritation, such as nuchal rigidity, are rare. The most common finding of cerebral dysfunction is a change in mentation. Seizures occur in fewer

than 10% of patients. Cerebral symptoms of LM often result from the obstruction of CSF flow and include headache, changes in mentation (lethargy, confusion, and memory loss), nausea and vomiting, and ataxia. These symptoms often indicate elevated intracranial pressure, which may occur with or without hydrocephalus. The most common cranial nerve symptom is diplopia. Hearing loss, visual loss, and facial numbness also occur. Paresis of the extraocular muscles is the most common cranial nerve abnormality, followed by facial weakness and diminished hearing (2).

METHODS OF DIAGNOSIS

The diagnosis of LM often requires a high index of suspicion. Initial testing may not reveal the diagnosis, and the physician must often resort to a variety of tests combined with clinical findings to establish the diagnosis. Occasionally, a presumptive diagnosis is made and treatment is initiated if the clinical picture is typical, other diagnoses are excluded, and the CSF is abnormal despite a negative CSF cytologic examination (Table 78-2).

Neuroimaging with gadolinium-enhanced MRI should be the first test obtained for a patient with cancer who has new neurologic symptoms. Specific findings on MRI may be sufficient to establish the diagnosis of LM and may eliminate the need for CSF analysis. Neuroimaging is also essential to exclude parenchymal brain (Chapter 76) or spinal epidural lesions (Chapter 77), which may produce a similar clinical picture and may coexist with LM. Gadolinium-enhanced T1-weighted MRI is the best technique for either cranial or spinal imaging. Definitive imaging findings that establish the diagnosis of LM include:

1. Enhancement of the leptomeninges over the convexities or within the cerebral or cerebellar sulci;
2. Tumor nodules or diffuse enhancement of the brainstem, spinal cord, or cauda equina (Figs. 78-2 through 78-4);
3. Enhancement of the cranial nerves; and
4. Enhancement of the basal cisterns or subependymal area.

Despite the sensitivity of MRI, it is negative in 33% of patients with positive CSF cytology, but it is negative in only

FIGURE 78-3 Sagittal gadolinium-enhanced spine magnetic resonance imaging reveals thickening and nodular enhancement of the leptomeninges adjacent to the cervical spinal cord.

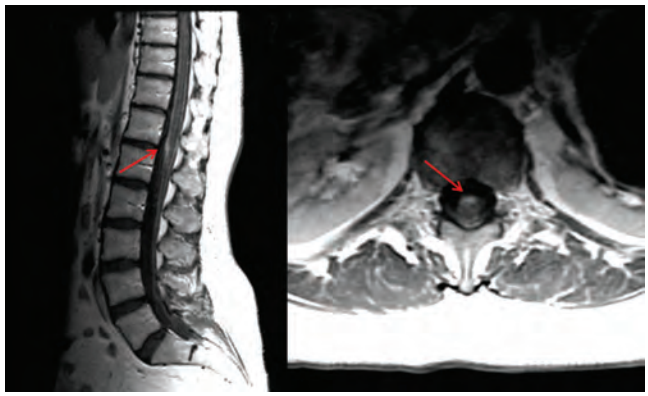

FIGURE 78-4 Sagittal and axial gadolinium-enhanced spine magnetic resonance imaging reveals leptomeningeal enhancement with a nodule (*red arrow*) overlying the upper cauda equina.

10% to 25% of patients with solid tumors compared with 48% to 55% of patients with hematologic malignancies (2,13). The radiologic diagnosis of LM may be missed in a patient receiving bevacizumab because of diminution of post-gadolinium enhancement (14). Rarely, ^{18}F-fluorodeoxyglucose (FDG) positron emission tomography (PET) CT may establish a diagnosis of LM (15).

In the absence of diagnostic radiographic abnormalities, other imaging findings that suggest LM include hydrocephalus or small superficial metastases deep in sulci. Patients clinically suspected of having LM need to undergo CSF analysis to establish the diagnosis when neuroimaging is negative or inconclusive. The presence of "definitive" radiographic findings in patients not known to have cancer cannot be attributed automatically to metastasis because primary leptomeningeal tumors, infection, postoperative conditions, or even changes after lumbar puncture can mimic subarachnoid metastases. These patients require documentation of malignancy to establish the diagnosis.

The established gold standard to diagnose LM is the demonstration of malignant cells in the CSF, typically obtained by lumbar puncture. Malignant cells are not identified in the CSF of patients with parenchymal, dural, or epidural metastasis, and they indicate metastasis to the subarachnoid space (2). The initial lumbar CSF cytologic examination gives positive results in up to 50% of patients with LM, but the yield increases to 90% if three lumbar punctures are performed (2). Nevertheless, 10% of patients with LM will still have a negative CSF cytologic examination after 3 lumbar punctures. The detection of malignant cells can increase when larger volumes (>10 mL) of CSF are available for analysis and occasionally when a CSF sample is taken from an alternate site; examination of cisternal CSF can be more sensitive, particularly in those patients with cerebral or cranial nerve symptoms (2). The failure to detect malignant cells in the CSF may be a sampling error because tumor cells are not equally distributed throughout the CSF due to adherence of the cells to CNS structures, or it may indicate that the tumor is localized. In an autopsy study of 30 patients with LM (2), there was a positive CSF cytologic evaluation in 76% of patients with multifocal or disseminated LM, but in only 58% of those with focal disease (2).

Because of the relatively low sensitivity of CSF cytology, newer technologies have been used to improve detection of malignant cells in the CSF. *In vitro* methods include immunocytochemistry, flow cytometry, fluorescence *in situ* hybridization (FISH) for aneusomy of chromosome 1, and polymerase chain reaction (PCR) (in which genetic alterations of the tumor cells are used for amplification) (16). Furthermore, the CellSearch (Veridex) detection platform has demonstrated potential for identification and enumeration of circulating tumor cells in the CSF of patients with breast cancer (17).

The CSF of most patients with LM has abnormalities in the routine chemistries and white blood cell count. An elevated protein concentration is the most common abnormality but is usually less than 100 mg/dL; there is a normal gradient of protein along the CSF axis, and a normal ventricular CSF protein concentration is less than 20 mg/dL. Up to one-half of patients have pleocytosis, usually mononuclear. About one-third of patients have a low CSF glucose concentration, defined as less than 70% of a simultaneous serum glucose concentration. Measurement of intrathecal tumor markers has also been used to diagnose LM. Carcinoembryonic antigen (CEA) and the breast cancer antigen (CA15-3) are elevated in the CSF of some patients with breast cancer (18), but the CSF levels must be compared with serum concentrations because extremely elevated serum levels can cross the BBB and be detected in the CSF. For CEA and CA15-3, the expected serum:CSF ratio is 100:1, and therefore, concentration in the CSF of these markers greater than 1% of the serum concentration is suggestive of LM (2). Like CSF protein levels, tumor marker values are lower in the ventricular than lumbar CSF, thus making interpretation from this region difficult. Elevation of β-glucuronidase, total lactic acid dehydrogenase (LDH), or the percentage of the LDH-5 isoenzyme are established tumor markers and can be indirect indicators of LM. However, these biomarkers are nonspecific and may be elevated in infections and other disorders of the CNS (2).

Proteins associated with angiogenesis have been studied as potential CSF biomarkers of LM. Increased concentration of vascular endothelial growth factor (VEGF) in the CSF is reported to be sensitive and specific for the diagnosis of LM from breast cancer (19), as well as decreased concentration of tissue plasminogen activator (tPA); combining these two markers predicted LM with 100% sensitivity in one study, although with a false-positive rate of up to 27% (20). CSF protein profiles of soluble adhesion molecules, cytokines, and chemokines have been used to discriminate between LM and other processes (21). Mass spectrometry–based methods have investigated protein expression patterns in CSF from breast cancer patients with and without LM and have found reproducible peptide profiles that might assist in diagnosing LM (22).

CSF is usually sampled in patients suspected of LM to establish the diagnosis with the demonstration of malignant cells. However, lumbar puncture may be necessary to measure the intracranial pressure (ICP). Headache, nausea, vomiting, and lethargy may be clinical indicators of increased ICP in patients with LM. Plateau waves, which are marked increases in ICP often triggered by a change in body position, may be manifest as transient decreased consciousness, visual disturbances, or gait difficulties; they are often confused with seizures because of their brief duration. Elevated ICP may be a consequence of hydrocephalus resulting from impairment of CSF flow. Hydrocephalus is almost always communicating in this situation and is easily diagnosed on cranial imaging. However, marked elevation of ICP can occur in patients with LM in the *absence* of hydrocephalus. These patients may have normal or small-appearing ventricles on MRI or CT scans. In these patients, lumbar puncture is needed to detect the elevated ICP. Increased ICP requires specific therapeutic intervention and is an absolute contraindication to intrathecal

chemotherapy until the condition is corrected (discussed below). Failure to diagnose increased ICP is a common mistake in the management of patients with LM and can be the cause of persistent neurologic symptoms, failure to respond to treatment, and treatment-related neurotoxicity.

TREATMENT

There is no standard treatment that has been demonstrated to prolong overall survival in LM, and numerous controversies remain regarding the role and timing of different treatment modalities. Sustained remissions are rare, and patients usually succumb to their neurologic disease. However, vigorous treatment of LM can, in some patients, palliate symptoms, achieve disease control, and prevent further neurological deterioration for a meaningful period of time. Supportive care involves anticonvulsant medications, treatment of painful radiculopathy, and the use of corticosteroids to ameliorate symptoms of elevated ICP. Corticosteroids are usually ineffective in reversing neurologic deficits from LM because there is little edema in the underlying CNS parenchyma. The following are general principles regarding the implementation of radiotherapy (RT), intrathecal chemotherapy, and systemic chemotherapy in the treatment of LM.

All patients with LM should undergo enhanced MRI of the entire neuraxis to search for bulky disease. Radiation should be administered to symptomatic areas (i.e., cranial irradiation for cranial neuropathies), whether or not structural disease is identified on imaging, and possibly to bulky disease because RT is usually the most effective modality for treating focal LM nodules. It is also the most reliable modality for the relief of symptoms such as cauda equina syndrome and pain.

Complete neuraxis RT is discouraged even for diffuse bulky tumor because it does not control the disease and is associated with acute morbidities such as esophagitis and severe myelosuppression, particularly in patients who are heavily pretreated or who are receiving systemic chemotherapy. Whole brain RT can enhance the neurotoxicity of chemotherapy administered into the CSF and should be reserved for patients with symptoms from the brain or cranial nerves. Bulky tumor deposits seen on MRI impair CSF flow and cause an accumulation of drugs proximal to the flow obstruction; focal RT can occasionally restore normal CSF dynamics if it also shrinks the tumor nodules (2). Intrathecal chemotherapy should not be administered concurrently with whole brain RT to reduce the risk of neurotoxicity. Radiotherapy is effective at palliating a region of LM, but the process involves the entire subarachnoid space and, therefore, treatment must encompass that whole compartment. Chemotherapy is often used to accomplish this.

Bulky leptomeningeal tumor develops its own vascular supply, which has a disrupted BBB. Therefore, intravenous chemotherapy may reach an enhancing subarachnoid nodule, but most systemic drugs do not achieve sufficiently high levels in the CSF and cannot eradicate tumor cells floating in the CSF or clusters less than 1 mm thick that do not generate their own blood vessels. For this reason, chemotherapy has been administered directly into the CSF. Direct CSF instillation achieves a higher concentration of drug in the subarachnoid space because the initial volume of distribution is smaller than the vascular compartment and the clearance half-life is longer in the spinal fluid for some agents. In addition, intra-CSF instillation often reduces or spares systemic toxicity, although the CSF can act as a reservoir for some drugs, such as methotrexate, that can slowly leak into the peripheral circulation and cause mucositis and myelosuppression. A disadvantage of chemotherapy administration into the CSF is the frequent occurrence of CSF flow abnormalities, which may result in nonuniform distribution of the drug throughout the CSF pathways, thereby reducing efficacy and increasing local toxicity; flow obstruction can cause a drug instilled in the ventricle to penetrate slowly into the periventricular tissue and cause leukoencephalopathy (2). Moreover, intra-CSF chemotherapy does not penetrate into bulky tumor deposits or infiltrated roots or cranial nerves and therefore cannot treat nodular disease effectively.

Despite these limitations, there is still a role for intrathecal chemotherapy, particularly in patients with minimal bulky disease. However, there must be normal CSF flow before the drug is instilled. CSF flow abnormalities usually correlate with bulky disease identified by neuroimaging, and flow disruption should be presumed in these patients. However, impaired CSF flow can be present despite normal neuroimaging. Radionuclide CSF flow studies using indium may be performed prior to intrathecal chemotherapy administration because they often demonstrate abnormalities of CSF dynamics that result in compartmentalization of CSF pathways. Involved-field RT to a site of bulky tumor may restore normal CSF flow and thus permit normal distribution of intra-CSF chemotherapy throughout the subarachnoid space.

Intra-CSF chemotherapy can be instilled directly into the lumbar subarachnoid space or the ventricular system through an Ommaya reservoir. Intraventricular administration is recommended because this approach ensures delivery of a drug into the CSF and allows for simple repetitive administration. Lumbar punctures result in inadvertent epidural or subdural injection in 10% of procedures. Most important, delivery of a drug into the ventricular system ensures more reliable and uniform drug distribution. Three agents are routinely instilled into the CSF: methotrexate, thiotepa, and cytarabine (including liposomal cytarabine or DepoCyt). Only methotrexate and thiotepa have intrinsic activity against breast cancer. Intra-CSF administration of methotrexate usually is performed twice a week initially, and the frequency is gradually tapered. The dose is fixed at 12–15 mg because the volume of CSF is identical for all patients regardless of size. Intra-CSF thiotepa has been studied in patients with LM from solid tumors, including breast carcinoma. The dosage is usually 10 mg and is administered twice weekly initially. The frequency is decreased over 1 to 3 months. In a comparative randomized study of intraventricular methotrexate versus thiotepa in 52 patients with solid tumors, 25 of whom had breast carcinoma, there was a slight survival advantage with methotrexate (23). Thiotepa has a rapid half-life in the CSF that may limit its effectiveness. No evidence shows that combination intra-CSF chemotherapy is better than single-agent therapy, and toxicity is additive (24).

Liposomal cytarabine (DepoCyt) is a sustained-release form of cytarabine that maintains cytotoxic levels in the CSF for 10 days or more. The dose is 50 mg twice monthly, and then it is decreased to monthly treatments. Adverse side effects include arachnoiditis and headaches which can be severe. All patients must be treated with dexamethasone 4 mg twice a day beginning 2 days prior and continuing at least 2 days following each dose of DepoCyt. In an open label trial of DepoCyt, 110 patients, 34% of whom had breast cancer, had a response rate comparable to twice weekly methotrexate. An increased time to neurological progression was seen, favoring DepoCyt; this may be due to prolonged tumor exposure to cytotoxic concentrations of drug (25).

A new area of investigation is intrathecal trastuzumab for LM from HER2-positive breast cancer. There have been reports of clinical and radiographic response to both

monotherapy with intrathecal trastuzumab (26,27) and combination intrathecal treatment (28), and this is currently being explored. Another therapeutic approach in development is tumor selective radioimmunotherapy, including intrathecal iodine-labeled monoclonal antibodies; these targeted therapies may inhibit leptomeningeal tumor growth, but none have been developed specifically for breast cancer (29).

An increasingly important approach to the treatment of LM is the use of systemic chemotherapy, which is either lipophilic and can penetrate into the subarachnoid space or is administered in high doses to reach the leptomeninges (30,31). This approach has the benefits of reaching the entire CSF, regardless of CSF flow dynamics, and treating both bulky and microscopic disease. However, it can subject patients to the systemic toxicities of chemotherapy, and many patients have been extensively pretreated by the time LM emerges. Lassman et al. (32) studied high-dose methotrexate at 3.5 g/m^2 in 32 patients with or without radiotherapy and intrathecal chemotherapy, 29 of whom had breast cancer. Patients had recurrent parenchymal or leptomeningeal metastases. An objective response or stable disease was seen in 9 patients (28%), and median overall survival was 19.9 weeks with 1 patient alive more than 135 weeks; most of these patients had breast cancer and LM with or without brain metastases and had stable or improved disease with reasonable toxicity. Treatment with higher doses of methotrexate (8 g/m^2) has been associated with 84% cytologic clearing of CSF and survival of 23.7 weeks (33).

Capecitabine, an oral analog of 5-flurorouracil (5-FU), has been effective despite limited penetration of 5-FU into the CNS. In one study, patients with parenchymal or LM from breast cancer received 1,000 mg/m^2 capecitabine twice daily for 14 days in a 21-day treatment cycle; 43% of patients had a complete response, and 43% had stable disease. Treatment was well tolerated, with no observed neurological toxicity. Median overall survival was 13 months, and the median progression-free survival was 8 months (34). Successful treatment of LM with a combination of capecitabine and trastuzumab has also been described (35). Wilson et al. (36) reported resolution of extensive LM with weekly docetaxel therapy.

There may be a role for newer targeted therapies in the treatment of LM, but this has yet to be studied. Lapatinib, a dual tyrosine kinase inhibitor targeting EGFR and HER2, is thought to penetrate the BBB and has been shown to have activity against cerebral metastases of HER2-positive breast cancer in combination with capecitabine (37), but this has yet to be reported in the treatment of LM. Other targeted treatments that demonstrate potential to cross the BBB are under investigation, including poly (adenosine diphosphate ribose) polymerase (PARP) inhibitors, histone deacetylase (HDAC) inhibitors, polo-like kinase 1 (Plk1) inhibitors, and the microtubule-stabilizing agent sagopilone (38). Novel second-generation analogs of eribulin are being studied for their potential to enter the CNS as well (39).

Elevated ICP can rarely be corrected with whole brain RT, but usually antitumor treatment cannot restore adequate CSF dynamics to normalize ICP. Many of these patients must be treated with a ventriculoperitoneal (VP) shunt to correct the elevated pressure. Omuro et al. (40) examined 640 patients with LM, and 6% had VP shunt placement; 62% of these patients had breast cancer. After VP shunt placement, 77% had symptomatic improvement with decreased headache, decreased nausea and vomiting, and improved level of alertness. Three patients had shunt malfunction, and one developed a subdural hematoma. No deaths were attributed to complications of the procedure.

Placement of a VP shunt can be lifesaving; however, it can complicate subsequent treatment for LM, particularly involving the administration of intrathecal chemotherapy. A subcutaneous reservoir with an on-off device may be placed in series with the shunt valve, but these devices often function poorly. The newer programmable shunts can be opened and closed easily, but they are programmed with an external magnet, and each time the patient has an MRI scan, the shunt must be reprogrammed to ensure flow through the shunt. More important, when a VP shunt is turned off, CSF flow dynamics remain impaired and unable to distribute intrathecal chemotherapy adequately. Therefore, once a shunt is placed, intrathecal chemotherapy should never be administered into the ventricular compartment again. It may be administered by lumbar puncture, but it will not reach the entire CSF compartment, and this is likely useful only for those with predominately spinal disease. In patients with a shunt, systemic chemotherapy or RT are better options because they do not require normal CSF flow to distribute the agent throughout the subarachnoid space.

PROGNOSIS

Response criteria in LM are not standardized. Most reported studies define response to treatment as the normalization of CSF and improvement of clinical symptoms, and there is some evidence that cytologic response is associated with clinical improvement (41). The concentration of tumor markers in the CSF may also be associated with response to treatment, and their rise may herald disease progression even in the setting of normalization of the CSF cytology (41).

The median survival in patients with untreated LM is 1.5 to 2 months (2). Early diagnosis and treatment may improve clinical outcome although there are conflicting data regarding the efficacy of intrathecal or systemic chemotherapy or RT in the treatment of LM. Of solid tumors, breast cancer responds best to treatment with a median survival of 6 months, and 15% of patients survive more than 1 year. Many reports suggest that a patient's clinical condition at diagnosis is a key determinant of outcome. A study of 85 patients with LM from solid tumors (42) suggests that radiographically apparent LM may portend a worse prognosis; another study (11) suggests that LM of triple-negative breast cancer may be associated with shorter survival and greater likelihood of CNS death. There is currently no evidence that elevated ICP is of prognostic significance, but this has not been studied.

Systemic and intrathecal chemotherapy are the only treatment modalities shown to improve survival in LM when compared to spinal and whole brain RT (31); however, RT relieves symptoms more effectively. Intrathecal methotrexate seems to provide improved survival compared with no therapy in most studies, with a median survival of 3–6 months in general and a median survival of 15 months in those who respond (2). Boogerd et al. (43) randomized 35 patients to receive appropriate systemic therapy and RT to clinically relevant sites, with or without intrathecal methotrexate. Patients who received intrathecal chemotherapy did not have additional survival benefit or improved neurological response but did have an increased risk of neurotoxicity.

TOXICITY

Toxicity from treatment of LM is primarily neurologic, and systemic toxicities (typically myelosuppression) arise primarily from systemic chemotherapy. Systemic complications of intrathecal methotrexate include stomatitis and myelosuppression. Low-dose oral leucovorin protects

against these toxicities in patients receiving intrathecal methotrexate, and the authors typically administer 10 mg of leucovorin twice daily for eight doses to all patients receiving intrathecal methotrexate. Intra-CSF thiotepa can cause myelosuppression, particularly when concurrent systemic chemotherapy is administered.

Spinal RT can contribute to depressed bone marrow function, particularly if the patient is heavily pretreated or receiving concurrent systemic therapy. Mucositis can also occur with radiotherapy to the cervical or upper thoracic region. Fatigue is almost universal and can be exacerbated by any of the treatment modalities used against LM.

Neurotoxicity after irradiation of the nervous system or after intra-CSF or systemic chemotherapy is a significant obstacle to treating patients with LM aggressively. The most common neurologic complication of intra-CSF chemotherapy is transient aseptic meningitis, which develops within hours of injection and produces headache, fever, stiff neck, and confusion. It does not necessarily recur on subsequent injections, and corticosteroids can prevent or ameliorate the reaction (2). While any drug delivered into the CSF can cause aseptic meningitis, it is most severe with liposomal cytarabine. Intra-CSF methotrexate causes leukoencephalopathy, but so can any drug instilled into the subarachnoid space. The risk of leukoencephalopathy rises with increasing total methotrexate dose, prolonged CSF methotrexate levels, and concurrent cranial RT (2). Leukoencephalopathy can often be identified first on cranial MRI in which increased signal, predominantly in the periventricular white matter, can be seen on T2-weighted or fluid-attenuated inversion recovery (FLAIR) images (Fig. 78-5). Patients develop apathy, memory loss, gait disturbance and, later, urinary incontinence. Clinical abnormalities correlate loosely with the severity of changes seen radiographically. Focal leukoencephalopathy can result from high local cerebral concentrations of methotrexate around an Ommaya reservoir catheter, particularly if inadvertent separation of the catheter occurs or if intraventricular pressure is elevated (2). Clinically significant complications related to the Ommaya reservoir are uncommon but include infection of the reservoir, bacterial meningitis, and intracerebral hemorrhage. Any drug can also cause myelopathy after lumbar injection.

If neurologic decline occurs, treatment-related toxicity must be distinguished from progressive leptomeningeal tumor. If the latter occurs, the chemotherapy agent should be changed, RT administered to bulky areas, or both. Patients must also be monitored for progression of their systemic disease although most patients with breast cancer die of progressive LM.

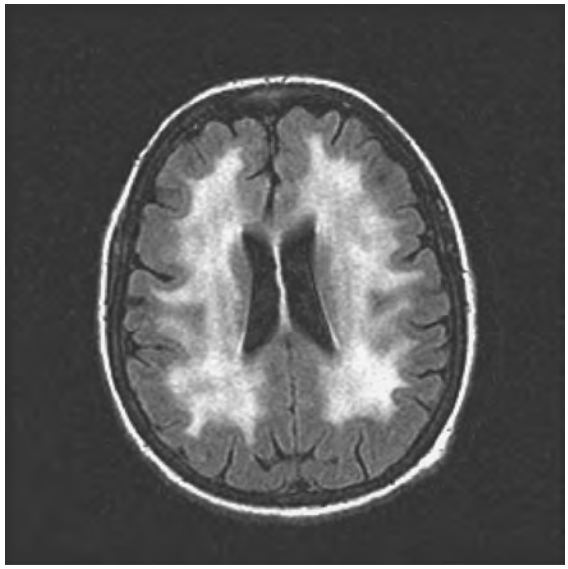

FIGURE 78-5 Leukoencephalopathy. Fluid-attenuated inversion recovery (FLAIR) magnetic resonance image of a patient with breast cancer treated with intrathecal methotrexate only for leptomeningeal metastasis. There is extensive white matter hyperintensity that is bilateral and symmetric. She had no cognitive impairment.

MANAGEMENT SUMMARY

- Leptomeningeal metastasis is an increasingly common complication of breast cancer.
- Early diagnosis is important before the patient develops severe neurologic deficits that cannot be reversed with treatment, and good performance status is associated with a better response to therapy.
- Diagnosis can be established by the demonstration of tumor nodules or enhancing disease in the subarachnoid space on MRI or the finding of tumor cells in the CSF. Serial CSF cytology and measurement of tumor markers may aid with diagnosis and monitoring responses to treatment.
- Treatment usually requires focal RT to symptomatic sites or areas with bulky disease followed by chemotherapy.
- The optimal choice of chemotherapy depends on a thorough assessment of the neurologic and systemic extent of disease. Patients with multiple nodules may be treated best with systemic chemotherapy, whereas those with positive CSF cytology but negative imaging can be treated with intra-CSF chemotherapy alone and thus spared the toxicity of systemic drug administration. Intrathecal methotrexate, thiotepa, and cytarabine have all been reported to have some efficacy.
- For patients with advanced disease and poor performance status, it is often appropriate to pursue management of symptoms with supportive medications and potentially palliative focal RT but not to proceed with chemotherapy.
- Despite treatment, most patients do poorly, and the median survival is about 4–6 months although some survive for years with vigorous treatment.

CHAPTER 79

Brachial Plexopathy in Patients with Breast Cancer

Nathan I. Cherny and Pauline T. Truong

CHAPTER CONTENTS

The brachial plexus is a somatic nerve plexus formed by intercommunications among the ventral rami of the lower four cervical nerves (C5–C8) and the first thoracic nerve (T1). The brachial plexus, which provides motor and sensory innervation of the upper extremity, is subdivided into roots, trunks, divisions, cords, and branches. Nerve roots exit through the vertebral interspaces joining to form the superior (C5–6), middle (C7), and inferior (C8–T1) trunk. The plexus trunks are located between the anterior and middle scalene muscles, bifurcating into anterior and posterior divisions within the supraclavicular fossa. These merge to form cords which pass over the first rib, coursing under the clavicle into the axilla. The terminal branches, located at the lateral border of the pectoralis minor muscle, include the axillary, musculocutaneous, radial, median, and ulnar nerves.

In patients with cancer, symptoms and signs of brachial plexus injury may be attributable to acute brachial neuritis, trauma to the plexus during surgery or anesthesia, metastatic spread of tumor, transient or permanent radiation injury, or radiation-induced tumors. In patients with breast cancer, metastatic spread of tumor, iatrogenic injury from radiation therapy and surgery, and second primary cancers are the most common causes of such signs. Careful evaluation of the clinical history, symptoms and signs, as well as electrodiagnostic and imaging studies are helpful in diagnosing the cause of a brachial plexopathy.

TUMOR INFILTRATION OF THE BRACHIAL PLEXUS (METASTATIC BRACHIAL PLEXOPATHY)

Despite the proximity to the draining axillary lymph nodes, tumor infiltration of the plexus is relatively uncommon. Even among specialist consultation services in a major cancer center, this diagnosis represented only 5% of the neurologic consultations evaluated by the neurology consultation service (1) and only 4% of patients referred to a cancer pain service (2). Early and accurate diagnosis is critical to prevent

irreversible nerve damage and chronic neuropathic pain and to determine the prognosis and treatment of the tumor.

Clinical Symptoms and Signs

Pain

Eighty-five percent of patients with tumor infiltration present with pain that is moderate to severe, often preceding neurologic signs or symptoms for up to 9 months (3,4). The pain distribution depends on the site of plexus involvement. Typically, the pain radiates in the sensory distribution of the lower plexus, usually involving the shoulder girdle and radiating to the elbow, medial side to the forearm, and the fourth and fifth fingers (consistent with involvement of the lower plexus C7, C8, T1) (3,4).

Other, less common clinical presentations are occasionally observed, including pain localized to the posterior aspect of the arm or to the elbow, a burning or freezing sensation and hypersensitivity of the skin along the ulnar aspect of the arm, or pain referred to either the shoulder girdle or the tip of either the index finger or thumb (consistent with infiltration of the upper plexus C5–6 by tumor rising in the supraclavicular nodes).

By the time of diagnosis of a brachial plexus lesion, 98% of patients have pain that is most often reported as severe. In Kori's series (3), 2 of 78 patients with malignant brachial plexopathy had pain as the only symptom or sign of tumor recurrence and required exploration and biopsy of the plexus to establish the diagnosis.

Paresthesias

Paresthesias occur as a presenting symptom in 15% of patients with tumor, in an ulnar distribution from infiltration of the lower plexus, or with a median nerve distribution in lesions of the upper plexus.

Lymphedema

Lymphedema is rarely a presenting symptom of tumor infiltration of the brachial plexus (3,4), but it does occur in about 10% of patients, most often in patients who received previous radiation therapy to the plexus and who subsequently develop recurrent tumor.

Weakness

Focal weakness, atrophy, and sensory changes in the distribution of the C7, C8, and T1 roots occur in more than 75% of patients. In one series of patients with brachial plexopathy arising from any tumor type, 25% of patients presented with whole-plexus motor weakness (panplexopathy) (3).

Horner's Syndrome

Patients with a panplexopathy or a Horner's syndrome have a higher likelihood of epidural extension and should undergo imaging of the epidural space as part of their evaluation.

Palpable Masses

Careful physical examination commonly reveals palpable supraclavicular or axillary lymphadenopathy. Occasionally, tumor infiltration in the distal plexus is associated with a palpable mass or fullness in the clavipectoral triangle. In all cases, these areas need careful evaluation.

Relationship to Natural History

In 12 of 78 patients with tumor infiltration of the brachial plexus included in the Kori series, the plexus lesion was the only evidence of tumor, and other metastases appeared only after several months (3). In two patients, the plexus lesion was the only sign of recurrence for 4 years. In one patient, surgical exploration after 2 years of plexopathy signs proved to be normal, but because of progressive worsening of neurologic signs, a second exploration was carried out, confirming tumor recurrence.

RADIATION INJURY TO THE BRACHIAL PLEXUS

Regional Nodal Radiation Therapy

Radiation therapy (RT) plays an important role in the curative treatment of women with early stage breast cancer. Randomized trials and meta-analyses have demonstrated that, in patients with node-positive disease, the addition of adjuvant radiation therapy to the regional lymph nodes improves locoregional control and survival compared to radiation to the breast or chest wall alone. Regional nodal radiation therapy generally includes the axillary and supraclavicular lymph nodes in patients with high risk disease. Late adverse effects from breast/chest wall RT, generally appearing months to years after treatment, may include skin and soft-tissue fibrosis, cardiac and lung injury, rib fracture, and secondary malignancies. Although very little of the plexus is usually exposed in radiation treatment of the breast or chest wall, the addition of radiation to the regional nodes can expose substantial portions of the plexus to the potential for radiation damage (5).

Pathophysiology of Radiation Injury

Factors that can contribute to radiation injury of the brachial plexus include age, total radiation dose, dose per fraction, radiation treatment volume, length and volume of the plexus receiving radiation, and combined chemotherapy (6,7).

There are three possible types of peripheral nerve damage after radiation therapy:

1. A very high dose of radiation may cause severe vascular damage to the blood vessels supplying a segment of a nerve. This type of peripheral nerve damage occurs within months to years after irradiation.
2. Extensive fibrosis of the adjacent and overlying connective tissues may damage a peripheral nerve trunk situated within intact tissue. This tends to be a very late phenomenon, occurring many years after radiation.
3. Extensive fibrosis of the adjacent and overlying connective tissues may damage a peripheral nerve trunk situated within tissues previously subjected to surgical dissection. The microvascular disruption caused by the previous dissection makes these tissues more vulnerable, and, consequently, fibrosis may develop more rapidly, after a few months to years.

Fibrosis and decreased vascularity may destroy peripheral nerves and prevent the regeneration of their proximal normal portions. The degree of connective tissue injury at the time of or preceding radiation therapy may be important in influencing the subsequent development of connective tissue fibrosis.

Clinical Syndromes of Radiation-Induced Brachial Plexopathy

Three distinct clinical syndromes of brachial plexopathy related to radiation therapy have been reported in patients with breast cancer: (i) reversible or transient radiation injury, (ii) ischemic brachial plexopathy, and (iii) radiation fibrosis of the brachial plexus. All three are uncommon

clinical entities, each with a characteristic clinical presentation and course.

Transient Radiation Injury

Transient brachial plexopathy has been described in breast cancer patients immediately following radiotherapy to the chest wall and adjacent nodal areas. In retrospective studies, the incidence of this phenomenon has been variably estimated as 1% to 20% (8–10).

In a retrospective study of 63 patients, Fulton et al. reported radiation-induced plexopathy in 19 cases, including 14 with transient and 5 with permanent injury (8). Transient plexopathy did not appear to predispose patients to the development of permanent plexopathy. In a review of 565 patients treated with adjuvant radiation doses of 50 Gy in 5 weeks using megavoltage radiation therapy, Salner et al. identified 8 (1.4%) cases of transient brachial plexopathy (9), with the onset of symptoms occurring 3 to 14 months (median 4.5 months) following irradiation. Seven of 8 patients received adjuvant chemotherapy; in 6 patients, symptoms began following drug treatment. There was a temporal clustering of these cases, suggesting a possible neurotropic viral component. The symptoms and signs of paresthesia and weakness did not conform to any anatomical pattern, but most commonly affected the distribution of the lower plexus. Weakness occurred in 5 of 8 patients, and was profound in two cases. All patients regained full strength. In 3 patients, residual paresthesias persisted.

In contrast to older series, clinical experience in the modern era suggests that lower estimates are more accurate. In a long-term follow-up study of 1,624 patients, Pierce et al. found that radiation-induced plexopathy was transient in 16 cases. Mild symptoms, with minimal pain and weakness, were predictive of resolution (11). Similarly, in a series of 419 patients who received radiation to the axillary nodal region, Galper et al. reported that 5 (1.2%) developed a transient brachial plexopathy (10).

Radiation-Induced Ischemic Brachial Plexopathy

Case reports during the era of extensive nodal surgery and outdated radiation techniques have described radiation-induced ischemic brachial plexopathy arising decades after treatment. Gerard et al. reported a case of subclavian artery occlusion occurring 19 years after radiation to the breast and axillary nodes following radical mastectomy (12). The patient's symptoms occurred acutely after carrying a heavy object and holding her left arm outstretched above the shoulder. The syndrome was acute in onset, nonprogressive, and painless, in contrast to the typical progressive nature of radiation fibrosis. Rubin et al. described one case of radiation-induced arteritis of large vessels and brachial plexopathy occurring 21 years after local radiation for breast cancer. Arteriography revealed arteritis, with ulcerated plaque formation at the subclavian-axillary artery junction, consistent with radiation-induced disease, and diffuse irregularity of the axillary artery. The risk of this uncommon entity in contemporary practice is unclear but is likely rare with the use of less extensive nodal surgery and modern techniques in radiation therapy planning, which optimize dose homogeneity and limit normal tissue exposure.

Radiation Fibrosis

Radiation fibrosis of the brachial plexus is a well-described clinical entity characterized by progressive and irreversible neurologic dysfunction of the brachial plexus. The risk of developing chronic brachial plexopathy has been estimated as 0.6% to 14%, varying with study era, radiation therapy prescription and techniques, and other treatment factors, including extent of nodal surgery and the use of chemotherapy (3,13–15).

Symptoms and Signs: Symptoms of radiation fibrosis, including weakness, paresthesia, and pain, typically develop months to years after radiotherapy (13,16,17) though in many cases no latency is apparent (18). The natural history of brachial plexus fibrosis is variable. Motor dysfunction may be incomplete or may progress to a severe paresis (18). Even with advanced radiation fibrosis, severe pain is relatively uncommon at presentation and its presence should prompt evaluation for recurrent tumor (3).

Weakness Arm weakness is the dominant symptom of radiation fibrosis. Motor weakness typically involves the muscles innervated by the upper plexus alone or both the upper and lower plexus (3,4,16,18). Weakness in a distribution of the lower plexus alone is uncommon (18).

Pain Although pain is a presenting symptom in less than 20% of patients with radiation injury to the brachial plexus, its prevalence increases with time (3,18,19). The pain is commonly described as mild discomfort associated with aching pain in the shoulder or hand. At the time of diagnosis, 65% of patients will report discomfort or pain in the arm; in 35%, it is severe (3).

Parasthesias In over 50% of affected patients, paresthesias are a prominent symptom (3). They are commonly reported to occur in the thumb and forefinger but often involve the entire hand. These symptoms are often confused with carpal tunnel syndrome but may be differentiated clinically and by electrodiagnostic studies.

Lymphedema Lymphedema of the ipsilateral arm was observed in 16 of 22 patients with radiation fibrosis in Kori's series (3) and in a substantial proportion of those reported by others (4). Olsen et al. found that lymphedema is a common late consequence of radiation therapy that occurs in approximately 25% of patients, and that it was not predictive of brachial plexus fibrosis (20).

Radiation Skin Changes Radiation skin changes were noted in approximately one-third of the patients with radiation injury, but these changes were not predictive of an underlying plexopathy (3).

Uncommon Osteoradionecrosis of the ribs and, rarely, of the humeral head can be noted on plain radiographs (21). Horner's syndrome is occasionally present (4,18).

Radiobiology and Dose Fractionation Considerations

Tumors and normal tissues differ in their sensitivities to radiation therapy. The therapeutic ratio of radiation therapy, which represents the balance between maximizing tumor control versus minimizing normal tissue complication, is affected not only by the total radiation dose, but also by the fraction size or dose per fraction, overall treatment time, and volume of normal tissue exposure. Radiobiological models based on cell culture experiments and clinical studies have been developed to describe the sensitivities of tumor and normal tissues to different fractionation schedules (22). The most widely used model is the

linear-quadratic equation, in which the Biological Effective Dose (BED) = Total Dose (TD) × (1 + Dose per Fraction/α/β ratio). This model, which assumes dual mechanisms for cell kill resulting in nonrepairable (α) and repairable (β) damage, predicts that the biological effect of radiation will be directly proportional to the total dose and dose per fraction (22,23). In the evaluation of different dose fractionation regimens, this equation can be used to calculate the biological effective dose and determine the isoeffective dose in tumors and normal tissues with similar kinetics.

Much of the data reporting high rates of radiation-induced brachial plexopathy in patients with breast cancer were from older eras that used techniques that result in field overlap, equipment such as orthovoltage and Cobalt units, and dosing schedules that would be considered suboptimal by modern standards.

The most commonly used fractionation schedules in North America for adjuvant radiation therapy for breast cancer deliver 1.8 to 2 Gy per fraction, 5 days a week to total dose of 45 to 50 Gy over 5 weeks. The risk of brachial plexopathy associated with conventional fractionation nodal irradiation using 2 Gy per fraction delivering a biological effective dose of 50 Gy or less to the plexus is approximately 1% (11,24). In a series of 1,624 patients treated with breast conserving surgery and adjuvant radiation therapy with a median follow-up time of 79 months, Pierce et al. reported that nodal radiation therapy, chemotherapy use, and total radiation dose to the axilla were factors significantly associated with the development of brachial plexopathy. Among patients treated with nodal irradiation, the incidence of brachial plexopathy was 1.3% with total doses of 50 Gy or less to the axilla, compared to 5.6% with total doses greater than 50 Gy (11). In a study with 449 patients treated with postoperative radiation therapy to the breast and lymph nodes who were followed for 3 to 5.5 years, Powell et al. reported that the incidence of brachial plexopathy was 5.6% in 338 patients who received 45 Gy in 15 fractions (dose per fraction 3 Gy, BED 56 Gy in 2 Gy fractions) and 1% in 111 patients who received 54 Gy in 27 to 30 fractions (dose per fraction 1.8 Gy, BED 51 Gy in 2 Gy fractions) (24). Although the difference was not statistically significant (p = .09), the observation of a higher risk of brachial plexopathy in association with the use of both a higher dose per fraction and a higher biological effective dose is in keeping with radiobiological principles described by the linear-quadratic model.

The last decade has witnessed renewed interest and debates regarding the safety and efficacy of altered fractionation regimens, in particular hypofractionation or the delivery of a higher dose per fraction and smaller number of total fractions. Radiobiological modeling suggests that if the α/β ratio of a tumor is similar or less than that of the critical normal tissue, then hypofractionation with a concomitant reduction in total dose may confer similar tumor control and normal tissue effects compared to conventional fractionation (25). Hypofractionation is supported by data from randomized controlled trials compared to conventional fractionation radiation therapy in women with early breast cancer (26–29). In the Standardization of Breast Radiotherapy (START) B trial from the United Kingdom, 2,215 women with early-stage breast cancer were randomized between 1999 and 2001 after primary surgery to radiation therapy 50 Gy in 25 fractions with 2 Gy per fraction over 5 weeks versus 40 Gy in 15 fractions using 2.67 Gy per fraction over 3 weeks. Regional nodal radiation was delivered in 7% of enrolled subjects (29). Brachial plexopathy was prospectively evaluated and was reported if damage to the brachial plexus was suspected and the patient had symptoms of pain, paresthesia, numbness, or other sensory symptoms graded on a 4-point scale. Suspected cases of brachial plexopathy were subject to confirmation by neurophysiological assessment and MRI. At a median follow-up of 6 years, locoregional control was equivalent, and there were no cases of brachial plexopathy in 82 women who received 40 Gy in 15 fractions or in 79 women who received conventional fractionation 50 Gy in 25 fractions to the regional nodes (29).

Older studies using a large dose per fraction (greater than 3 Gy) without adequate reductions in the total dose have resulted in high rates of brachial plexopathy (5%–70%). In a review of the literature evaluating brachial plexus injury with different hypofractionated radiation schedules, Galecki et al. reported that the risk of brachial plexopathy was less than 1% with regimens using dose per fraction between 2.2 and 2.5 Gy with reductions in total dose to 34 to 40 Gy to ensure that the biological effective dose to the brachial plexus is less than 50 Gy in 2 Gy fractions. In contrast, even when the dose per fraction was lower (between 2 and 2.17 Gy), but the total dose was not reduced, yielding biological effective doses greater than 55 Gy, the risk of brachial plexopathy increased steeply from 2% to 15% (7). These findings suggest that the hypofractionated nodal radiation regimen used in this trial is associated with low risks of brachial plexopathy; however, larger patient samples receiving regional nodal irradiation and using longer follow-up times are essential to fully assess this risk.

Advances in Radiation Therapy Planning and Delivery

In contemporary practice, the goal of safe and effective implementation of nodal irradiation in women with high risk breast cancer has been advanced by technological innovations in radiation therapy planning and delivery. Overlaps between breast or chest wall fields with the supraclavicular and/or axillary fields can be readily avoided with isocentric techniques. Optimizing dose homogeneity and reducing hot spots and brachial plexus exposure can be achieved with tools including image-based 3D-conformal radiation therapy planning, multileaf collimation, mixed megavoltage beam energies, intensity-modulated radiation therapy, and rigorous adherence to normal tissue dose-volume constraints. Standardized methods to delineate the brachial plexus in image-based radiation therapy planning have been developed and validated (30). Computer-assisted image segmentation methods to allow rapid and accurate identification of the brachial plexus are now available (31). Guidelines in data collection and reporting on radiation dose-volume parameters and clinical outcomes have also been formulated (32). These resources will be useful in the design of future prospective trials examining the risk of radiation-induced brachial plexopathy in women with breast cancer.

POSTAXILLARY DISSECTION NEUROPATHIC PAIN (POSTMASTECTOMY SYNDROME)

Prevalence

Chronic neuropathic pain of variable severity is a common sequela of surgery for breast cancer. Although chronic pain has been reported to occur after almost any surgical procedure on the breast from lumpectomy to radical mastectomy, it is most common after procedures involving axillary dissection, occurring in 25% to 70% of patients (33–35,36).

The risk for, and severity of, pain is correlated positively with the number of lymph nodes removed (36) and the presence of tumor in the upper outer quadrant of the breast (35) and is inversely correlated with age (36). There is conflicting data as to whether preservation of the intercostobrachial nerve during axillary lymph node dissection can reduce the incidence of this phenomenon (37).

The incidence is reduced, but not avoided, when axillary dissection is avoided either by sentinel node excision without full dissection (36) or when nodes are irradiated without dissection (38).

Clinical Features

The pain is usually characterized as a constricting and burning discomfort localized to the medial arm, axilla, and anterior chest wall. Pain may begin immediately or as late as many months following surgery. The natural history of this condition appears to be variable, and both subacute and chronic courses are possible (39). The onset of pain later than 18 months following surgery is unusual, warranting careful evaluation to exclude recurrent disease. On examination, there is often an area of numbness within the region of the pain. Chronicity of pain is related to the intensity of the immediate postoperative pain (40), postoperative complications, and subsequent treatment with chemotherapy and radiotherapy (41).

Etiology

It is most commonly associated with neuropraxia of the intercostobrachial nerve during the process of axillary lymph node dissection (42,43). There is marked anatomic variation in the size and distribution of the intercostobrachial nerve, and this may account for some of the variability in the distribution of pain observed in patients with this condition (44).

Differential Diagnosis

This syndrome must be differentiated from postmastectomy phantom breast pain (45), neuroma pain (46), postmastectomy frozen shoulder (47), axillary web syndrome (48), and breast cellulitis (49). In some cases of pain after breast surgery, a trigger point can be palpated in the axilla or chest wall.

OTHER CAUSES OF BRACHIAL PLEXOPATHY AND NEUROPATHIC ARM PAIN

Second Malignant Primaries

Uncommonly, a malignant peripheral nerve tumor or a second primary tumor in a previously irradiated site can account for pain recurring late in the patient's course (50). Primary tumors of the brachial plexus are uncommon (51), and nerve sheath tumors that occur years after radiation therapy are generally thought to be a late effect of radiation therapy (52). This condition must be differentiated from recurrence of breast cancer, which may also occur in a plexus previously damaged by radiation fibrosis (53).

Carpal Tunnel Syndrome

Among patients with a past medical history of breast cancer who were referred for evaluation of arm pain, 4 of 30 were found to have carpal tunnel syndrome (4). Although electrophysiological abnormalities that are consistent with carpal tunnel syndrome occur twice as frequently ipsilateral to the resection among women who have undergone mastectomy (54), it is an infrequent cause of arm pain in this population, and the diagnosis requires demonstration of a prolonged sensory latency that is greater than that recorded for the radial and ulnar nerves (55,56).

Lymphedematous Brachial Plexus Compression

Some authors have suggested that lymphedema alone can produce a compression injury of the brachial plexus (4,54). Ganel et al. performed a series of electromyographic studies on women who had undergone mastectomies with or without subsequent radiation therapy. On the basis of an increased prevalence of "F" wave latency abnormalities ipsilateral to previous mastectomy in women with lymphedema, lymphedema was suggested to be the cause of an entrapment brachial plexopathy (54). Vecht inferred this diagnosis in one of 28 patients evaluated for arm pain on the basis of negative imaging studies and a nonprogressive neurological deficit in a patient with lymphedema (4). In the absence of demonstrable reversibility of the neurologic deficit with effective management of the lymphedema or surgical evaluation of the plexus to exclude recurrent tumor or radiation fibrosis, this diagnosis should be approached with clinical skepticism.

Pathologic Fracture of the Humerus

Pathological fractures or fracture dislocations of the humerus may traumatize adjacent nerves of the infraclavicular plexus (57). Fractures or dislocations of the neck of the humerus may cause axillary nerve compression, whereas midshaft fractures, which are less common, may damage the radial or ulnar terminal nerves.

DIAGNOSTIC INVESTIGATIONS

There are many potential causes of plexopathy in cancer patients, the most common of which are tumor infiltration and radiation fibrosis. In patients with symptoms suggestive of plexopathy with a history of previous radiotherapy, it is critical to distinguish between tumor infiltration and radiation-induced fibrosis. When radiological findings are nondiagnostic, electrophysiological studies may assist in making the distinction.

Cross-sectional imaging is essential in all patients with symptoms or signs compatible with plexopathy. Both MRI and CT scanning are commonly used in these settings.

Magnetic Resonance Imaging (MRI)

Although there are few comparative data on the sensitivity and specificity of MRI to CT in evaluating lesions of the brachial plexus, MRI is widely thought to be the best choice for evaluating the anatomy and pathology of the brachial plexus (58). MRI is a noninvasive procedure that can assess the integrity of the vertebral bodies and may differentiate tumor from radiation fibrosis as well as fully visualize the adjacent epidural space. Additional advantages include its superior soft-tissue resolution and the ability to readily reconstruct images in multiple planes.

As illustrated in Figure 79-1A and B, T1-weighted images best define the relationship of tumor to the surrounding structures. Both tumor and radiation fibrosis generate intense images. The most common findings observed with radiation fibrosis are thickening and diffuse enhancement of the brachial plexus without a focal mass and/or soft-tissue changes with low signal intensity on both T1- and T2-weighted images, with or without enhancement of

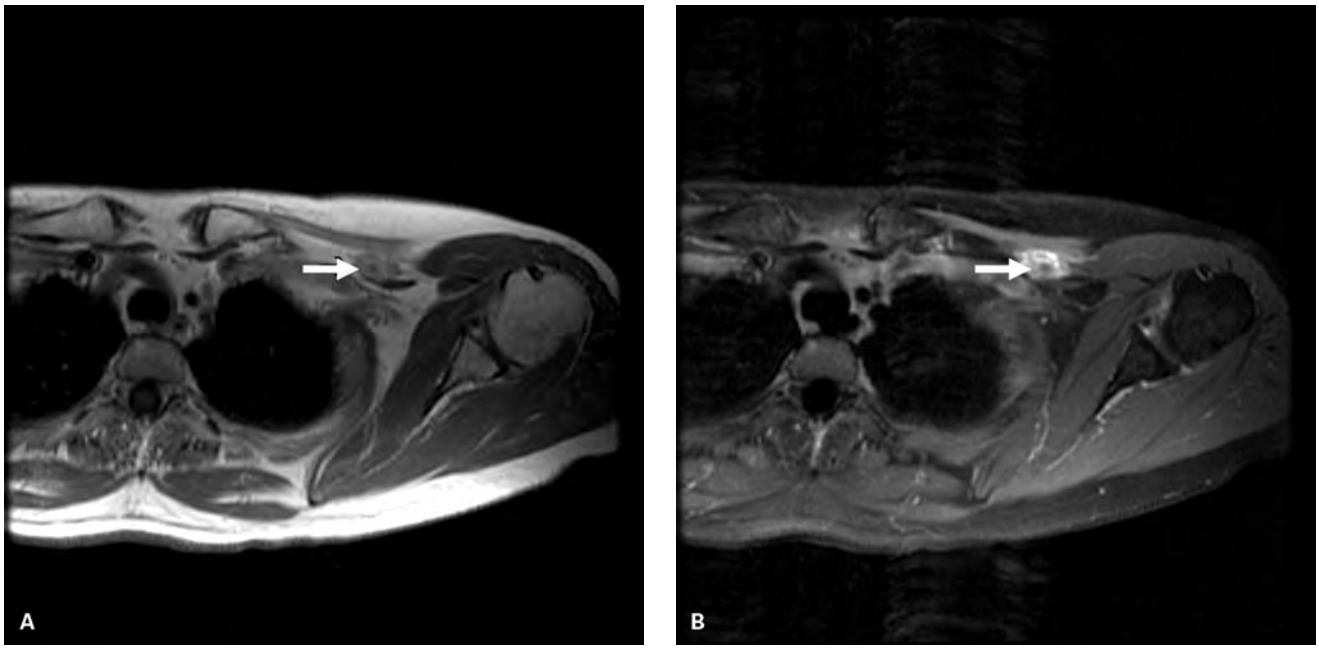

FIGURE 79-1 **(A)** Pre-contrast T1 MRI image of a brachial plexus tumor (*arrow*). **(B)** Post-gadolinium contrast T1 MRI image of a brachial plexus tumor (*arrow*).

multiple plexus elements (58). A prospective study using MRI for detection of malignant brachial plexopathy yielded a sensitivity of 96%, specificity of 95%, positive predictive value of 96%, and negative predictive value of 95% (59).

Because patients with brachial plexus lesions are at high risk for developing epidural cord compression from direct tumor infiltration along the plexus into the epidural space or from hematogenous spread of tumor to the vertebral body (3), imaging should include the adjacent epidural space. Imaging of the epidural space is essential if spinal cord compression is suspected and in the evaluation of patients who have any of the clinical findings that are commonly associated with this complication, including panplexopathy, Horner's syndrome, vertebral body erosion or collapse at the C7-T1 levels, or a paraspinal mass detected on CT scanning. Accurate imaging with MRI determines the extent of epidural encroachment (which influences prognosis and may alter the therapeutic approach) and defines the appropriate radiation target volumes.

Computed Tomography (CT) Scan

Recent years have witnessed tremendous improvements in the techniques of CT imaging, which have enhanced the value of this modality in imaging of the brachial plexus. Modern spiral CT enables simultaneous x-ray source rotation and patient table translation as well as retrospective multiplanar and three-dimensional reconstruction. In many cases, these approaches are very helpful, particularly in the identification of mass lesions in the plexus and adjacent infiltration of the neural foramina. Modern CT imaging is often a very useful initial modality, particularly in situations when MRI is not readily available.

CT scanning techniques to image the brachial plexus should include both bone and soft-tissue windows and should be contrast enhanced to give clear definition of vascular structures. Adequate imaging requires scanning from C4 to T6 vertebral bodies using a large gantry aperture to include both axillary fossae so that the symptomatic plexus may be compared with the normal contralateral side. Vascular enhancement allows for identification of vascular structures that relate to the plexus. Because a high concentration of contrast can produce a streaking artifact, some experts recommend that intravenous contrast should be administered contralateral to the suspected lesion. The elements of the brachial plexus are depicted as nodular or linear areas of soft-tissue density that can be difficult to identify.

The typical appearance of radiation fibrosis of the plexus on CT studies is a diffuse infiltration and loss of tissue planes without a mass lesion. There is often associated arm lymphedema, evident on CT, and, occasionally, radiation necrosis of the clavicle, rib, or humeral head may be identified at the adjacent level (21). Tumor infiltration of the plexus cannot be differentiated from radiation fibrosis by CT studies when diffuse infiltration is noted. In such cases MRI, PET/CT, or image-guided biopsy of the brachial plexus mass should be considered.

Positron Emission Tomography (PET) Scanning

Compared to conventional imaging techniques, PET and PET/CT scanning have both greater sensitivity and specificity in detecting metastases from breast cancer (60). As illustrated in Figure 79-2, the fused ^{18}F-fluorodeoxyglucose (FDG)-PET and CT images give two pieces of critical information within a single study: the extent of viable tumor and its exact location. Because it provides biological and functional information, FDG-PET often is complementary to CT or MR. This is particularly true when trying to differentiate between radiation fibrosis and recurrent tumor.

Despite these generalizations, published information specific to the detection of brachial plexopathy is remarkably limited (61–63). In a study of 19 patients with symptoms suggestive of brachial plexopathy, 14 had abnormal uptake of ^{18}FDG in the region of the symptomatic plexus. Of those with abnormal findings in the plexus, only 33% had a lesion identifiable on CT imaging (63).

Electrophysiologic Studies

Electrophysiologic studies may be useful in distinguishing tumor infiltration from radiation fibrosis (64). Electrodiagnostic studies in patients with radiation fibrosis typically include widespread infraclavicular demyelinating conduction blocks on motor nerve conduction studies and myokymic discharges and fasciculation potentials on needle electrode examination. Widespread myokymia is strongly suggestive of radiation-induced plexopathy.

In malignant plexopathy, electromyography (EMG) typically reveals fibrillation potentials and positive waves characteristic of denervation in the distribution of the brachial plexus that is consistent with plexus signs and symptoms. A normal EMG in the cervical paraspinal muscles is usually adequate to exclude the presence of root disease. In the rare instances that myokymia is observed in patients with tumor infiltration of the brachial plexus, it is localized and may be isolated to one muscle group alone (65); this contrasts with the widespread myokymic discharges seen in radiation-induced plexopathy.

Surgical Exploration

The differential diagnosis of tumor infiltration from radiation injury to the plexus may be made in the majority of cases using the clinical criteria, imaging, and electrophysiologic studies. However, if these diagnostic approaches fail to define the nature of the neurologic disorder, exploration of the plexus may occasionally be diagnostic (66). In additional to traditional open exploration, minimally invasive laparoscopic methods have been developed and described (67). Such exploration should be undertaken only under the following circumstances:

1. The CT, MRI, and PET scans are normal or show no evidence of change from before the onset of symptoms.
2. A work-up, including tumor markers establishing the full extent of disease, has been completed and shows no evidence of diffuse metastatic disease.
3. The site of neurologic involvement is certain (for example, a lesion that can be localized to either the upper or lower plexus). This factor is important in determining the appropriate surgical approach. Upper plexus dysfunction may best be assessed through a supraclavicular approach, whereas involvement of the lower plexus is best assessed through a posterior scapular approach or a high posterior thoracotomy, commonly used to explore apical tumors of the lung (68).

TREATMENT OF BRACHIAL PLEXOPATHY IN BREAST CANCER

The care of patients with brachial plexopathy requires an integrated approach involving primary therapy appropriate to the specific cancer diagnosis along with symptomatic pain management.

Primary Therapies

Treatment of Radiation Fibrosis

The management of patients with radiation fibrosis begins with the establishment of an accurate diagnosis to rule out metastatic disease. There are no proven methods to reverse neurologic damage. Splinting the arm at the chest wall, preventing subluxation of the shoulder joint, and using intensive physical therapy to manage lymphedema are common approaches to managing the musculoskeletal pain syndromes associated with this disorder.

Evidence-based treatments other than symptomatic care are lacking. There is some data that antioxidant therapy with a combination of pentoxifylline and vitamin E may partially reverse radiation fibrosis, particularly when treatment is started soon after the initial radiation insult (69). No specific experience has been reported using this approach in radiation-induced plexopathy. Hyperbaric oxygen therapy has been suggested to reduce radiation damage. However, a double-blinded randomized trial of hyperbaric oxygen therapy did not yield substantial relief in patients with radiation-induced brachial plexopathy (70). Finally, some authors have suggested the use of neurolysis with pedicle omentoplasty to treat radiation fibrosis (71). Anecdotal data suggests that this procedure frequently results in reduced pain and that progression of neurologic deficit can be arrested in some cases (71). In the largest series, Le-Quang reported on 60 patients followed from 2 to 9 years and advocated early surgery as soon as possible after the onset of paresthesias (71). Surgical exploration of the brachial plexus is difficult and may risk iatrogenic injury to the nerve, leading to worsening pain syndrome.

Treatment of Tumor Infiltration

The treatment of tumor infiltration of the brachial plexus depends on the status of the patient's disease, the extent of neurologic involvement, and any prior history of radiation therapy to the brachial plexus. There is compelling clinical evidence to suggest that steroids provide pain relief in patients with tumor infiltration of the brachial plexus, and they are often used to provide analgesia during therapy (72).

Antitumor therapy with either systemic therapy (chemotherapy or hormonal therapy) or radiation therapy may provide tumor shrinkage with symptomatic improvement (73). Radiation therapy is the treatment of choice for patients with rapidly progressive neurologic signs, patients unresponse to systemic treatment, or patients with epidural spinal cord compression. High-quality CT and MRI should be used to define the target volume in these cases. The dose of radiation therapy employed varies. In the reported series, a dose of 30 Gy delivered over a 3-week period or 50 Gy delivered over a period of 5 weeks represents the most commonly used dose ranges (3,9,74,75).

There is conflicting data about the likelihood of benefit from palliative radiotherapy for malignant brachial plexopathy in breast cancer. In a review of the published experience and his own experience, Ampil reported that the total delivered dose, rather than the width of the therapy port, was the most important factor in achieving optimal symptomatic palliation (75). In his series of 23 patients, significant pain relief was achieved in 77.2% of patients for a median of 3 months; the observed objective response rate was 46%. In another series, Nisce and Chu reported that 12 of 47 patients (25.5%) with metastatic brachial plexopathy and breast cancer had complete pain relief for a mean duration of 15 months, and 23 (49%) had partial pain relief for a mean duration of 6 months (76). These researchers suggested that higher radiation doses (50 Gy) were more effective than lower doses. In Kori's retrospective review, radiation doses of 20 to 50 Gy delivered to the plexus relieved pain in 46% of cases (3). Neurologic improvement was minimal, and persistent, chronic pain was the most significant problem. In Fulton's experience with 44 breast cancer patients with definite (n = 31) or probable (n = 13) brachial plexopathy, 9 of the 17 patients treated with radiation therapy improved (8).

In patients with tumor infiltration of the brachial plexus with evidence of metastatic disease in other sites, systemic chemotherapy is a reasonable approach. In patients who have received previous radiation therapy to the region, systemic therapies with either cytotoxic or hormonal agents may offer the only reasonable antitumor treatment. Chemotherapy or hormonal therapy may provide sustained relief from malignant brachial plexopathy in responding patients (73). Since most responses are partial and subsequently followed by relapse, pain often returns when disease recurs. Indeed, worsening pain is often the earliest indicator of recurrence or progression.

THE MANAGEMENT OF PAIN ASSOCIATED WITH BRACHIAL PLEXOPATHY

Analgesic Pharmacotherapy

Primary antitumor therapies should be considered for patients with tumor invasion of the brachial plexus. All patients with pain should initially be treated with analgesic pharmacotherapy in accordance with the World Health Organization (WHO) three-step analgesic ladder (77).

Opioids in the Management of Brachial Plexus Pain

A trial of opioid therapy should be administered to all patients with pain of moderate or greater severity, irrespective of the pathophysiological mechanism underlying the pain. Patients who present with severe pain are usually treated with a pure agonist opioid. Until recently, patients with moderate pain have been conventionally treated with a combination product containing acetaminophen or aspirin plus codeine, dihydrocodeine, hydrocodone, oxycodone, and propoxyphene. Recent years have witnessed the proliferation of new opioid formulations that may improve the convenience of drug administration for patients with moderate pain. These include controlled-release formulations of codeine, dihydrocodeine, oxycodone, morphine, and tramadol in dosages appropriate for moderate pain. Opioid analgesics should be used in accordance with usual standards of practice (78). The persistence of inadequate pain relief should be addressed through a stepwise escalation of the opioid dose until adequate analgesia is reported or unmanageable side effects supervene. The severity of the pain should determine the rate of dose titration. An understanding of the strategies used to prevent or manage common opioid toxicities is needed to optimize the balance between analgesia and side effects.

Adjuvant Analgesics

Even with optimal management of adverse effects, some patients do not attain an acceptable balance between pain relief and side effects. Several types of noninvasive interventions including adjuvant analgesics, a switch to another opioid, and the use of psychological, physiatric, or noninvasive neurostimulatory techniques should be considered for their potential to improve this balance by reducing the opioid requirement. Adjuvant analgesics are drugs that have a primary indication other than pain but have analgesic effects in some painful conditions. The use of adjuvant analgesics can contribute substantially to the successful management of pain caused by brachial plexopathy.

Corticosteroids

Corticosteroids are frequently used in the management of neuropathic pain due to infiltration or compression of neural structures by tumor. Patients with advanced cancer who experience pain and other symptoms that may respond to steroids are usually given relatively small doses (e.g., dexamethasone 1–2 mg twice daily). A very short course of relatively high doses (e.g., dexamethasone 100 mg I.V. followed initially by 96 mg per day in divided doses) can be used to manage a severe exacerbation of pain associated with malignant brachial plexopathy (72). The dose should be gradually lowered following pain reduction to the minimum needed to sustain relief.

Centrally Acting Adjuvant Analgesics Used for Neuropathic Pain

Neuropathic pain is generally less responsive to opioid therapy than nociceptive pain, and, in many cases, the outcome of pharmacotherapy may be improved by the addition of a centrally acting adjuvant analgesic. This subject has been recently reviewed by the neuropathic pain working group of the International Association for the Study of Pain (79). Several antidepressants and calcium channel $\alpha 2\text{-}\delta$ ligands are included in their list of first-line medications.

Antidepressant drugs are commonly used to manage neuropathic pain, and the evidence for analgesic efficacy is greatest for the tertiary amine tricyclic drugs such as amitriptyline, doxepin, and imipramine. The secondary amine tricyclic antidepressants (such as desipramine, clomipramine, and nortriptyline) have fewer side effects and are preferred when concern about sedation, anticholinergic effects, or cardiovascular toxicity is high. Duloxetine, a selective serotonin and norepinephrine reuptake inhibitor (SSNRI), has demonstrated potential efficacy in neuropathic pain. It is generally well tolerated, and dosing is simple, starting at 30 mg/day

and titrated after 1 week to 60 mg/day. The potential efficacy of venlafaxine, another SSNRI, has also been demonstrated at dosages of 150 to 225 mg/day.

Gabapentin and pregabalin both bind to the α2-δ subunit of voltage-gated calcium channels, decreasing the release of glutamate, norepinephrine, and substance P. Gabapentin is generally well tolerated, and the main adverse effects are somnolence and dizziness. Several weeks can be required to reach an effective dosage, which is usually between 1,800 and 3,600 mg/day (administered in three divided doses). When it is effective, pain relief may be seen as early as the second week of therapy, but peak effect usually occurs approximately 2 weeks after a therapeutic dosage is achieved. Pregabalin produces dose-dependent side effects similar to those of gabapentin. Treatment can be initiated at 75 mg twice daily and can be titrated up to 300 mg twice daily. The onset of pain relief with pregabalin can be more rapid than with gabapentin.

The so-called second-line adjuvant analgesics all have less evidence of potential efficacy. Second-line anticonvulsants include carbamazepine, lamotrigine, oxcarbazepine, topiramate, and valproic acid. Second-line antidepressant medications include bupropion, citalopram, and paroxetine. Other agents that may be considered in this setting include mexiletine and baclofen.

Anesthetic and Neurosurgical Techniques

Invasive anesthetic and neurosurgical techniques should only be considered for patients who are unable to achieve a satisfactory balance between analgesia and side effects from systemic analgesic therapies. Techniques such as intraspinal opioid and local anesthetic administration (80), locoregional infusion of local anesthetic (81), intrapleural local anesthetic (82), or intraventricular opioid administration (83) can potentially achieve this end without compromising neurological integrity. The use of neurodestructive procedures such as brachial plexus neurolysis (84); chemical, surgical, or radiofrequency rhizotomy (85); or dorsal root entry zone (DREZ) lesioning (86) should be based on an evaluation of the likelihood and duration of analgesic benefit, the immediate and long-term risks, the likely duration of survival, and the anticipated length of hospitalization.

Rarely, patients have been treated with a forequarter amputation of the limb for relief of the discomfort of a lymphedematous, functionless arm. This extreme approach is often not successful in providing significant pain relief but does improve patient complaints of a heavy lymphedematous useless extremity.

MANAGEMENT SUMMARY

- Early diagnosis of tumor infiltration of the brachial plexus is important to institute prompt cancer therapy and prevent the development of chronic neuropathic pain and neurological dysfunction.
- Evaluation consists of a careful history, a detailed neurological examination, and MRI or CT imaging. Electrodiagnostic studies should be performed if the radiographic studies are negative for both soft-tissue and bony disease. An evaluation to assess for evidence of metastatic disease should follow, and, if negative, surgical exploration should be considered to allow for biopsy of adjacent lymph nodes and soft tissue.
- In patients presenting with brachial plexopathy after previous radiation therapy, the history and physical findings and follow-up on CT and MRI may be helpful to distinguish tumor recurrence from radiation fibrosis but none of these may be definitive. When uncertainty remains, biopsy should be considered to provide tissue confirmation to guide the treatment decision (e.g., in a patient with progressive symptoms of brachial plexopathy but without other evidence of distant metastases in whom documentation of recurrent disease will result in a decision to initiate anticancer treatment).
- Radiobiological modeling and clinical data suggest that the risk of brachial plexopathy may be kept acceptably low (<1%) by not exceeding a biologically effective dose (BED) of 50 Gy in 2 Gy fractions. Hypofractionation regimens using a modestly increased dose per fraction with concomitant reductions also have low likelihood of brachial plexopathy. Hypofractionation using a high dose per fraction (greater than 3 Gy) without appropriate reductions in total dose should be avoided.
- Prospective studies are needed to establish the risk of brachial plexopathy in women with breast cancer treated in the contemporary era of sentinel node staging, adjuvant chemotherapy, image-based radiation treatment planning, and altered fractionation schedules.

CHAPTER 80

Ophthalmic Metastases

Christopher A. Barker, Beryl McCormick, and David H. Abramson

CHAPTER CONTENTS

Ophthalmic metastases refer to secondary malignant neoplasms occurring in or around the eye. The uvea is the highly vascular middle layer of the eye and the most frequent site of metastasis. The choroid comprises the majority of the uvea and is the predominant location for uveal metastasis. Less frequently, metastases can arise in other parts of the uvea (ciliary body and iris), as well as extraocular structures (bones and soft tissues of the orbit, eyelids, extraocular muscles, and optic nerve). Importantly, metastases in any of these locations can dramatically affect vision. The contribution of vision to quality of life is significant; therefore, ophthalmic metastases can be a disabling sequela of breast cancer. This chapter presents concepts related to the epidemiology, biology, diagnosis, management, and outcome of ophthalmic metastases in patients with breast cancer.

EPIDEMIOLOGY

The true prevalence of ophthalmic metastases from breast cancer has been difficult to precisely determine, but necropsy and clinical series have provided estimates. Studies performed in the 1970s suggested that 10% to 37% of patients dying with, or of, metastatic breast cancer harbored orbital and/or ocular metastases on post mortem histologic examination (1,2). However, a similarly designed study from a more recent era suggest 0% to 8% of patients harbor ocular metastases (3). Many have suggested that improvements in systemic therapy have led to a decreased prevalence of ophthalmic metastasis. These studies have clearly demonstrated that breast cancer metastasizes to the eye more frequently than other carcinomas.

Because of the prevalence of ophthalmic metastases noted in necropsy studies, several prospective screening studies have been carried out in visually asymptomatic patients with contemporary ophthalmic assessment methods (visual acuity assessment, slit-lamp examination, indirect ophthalmoscopy, with or without ultrasonography, see Table 80-1). Two of the studies were unable to identify any patients with ocular metastases, and concluded that screening was not worthwhile (4,5). Another study found choroid metastases in 5% of screened patients (6). Of note, the latter study involved a younger group of patients with greater burden of disease and took place in an earlier time period than the former studies. The prevalence of ophthalmic metastases among patients with vision problems is likely higher than asymptomatic patients. One study reported that of 152 metastatic breast cancer patients with ophthalmic symptoms or signs, 58 (38%) were found to harbor choroid metastasis (7).

Risk factors for the development of ophthalmic metastases are ill-defined. Some studies suggest that early age at initial diagnosis of breast cancer may be associated with higher risk (8). Others have noted a higher risk of ophthalmic metastasis in patients with greater disease burden (having metastasis in more than one organ, or the presence of brain or lung metastasis, but not liver or bone metastasis), but not initial tumor stage or presence of estrogen receptor on the primary tumor (6). Gender does not appear protective as men with breast cancer have been reported to develop ophthalmic metastasis.

BIOLOGY

The reason that breast carcinoma has a predilection to metastasize to the eye is unknown. Researchers investigated a small group of patients with ocular metastases from breast cancer, and found no clear aggregation of breast cancer in the family of affected patients, or any associations with common *BRCA1* or *BRCA2* gene mutations. However, the investigators noted that most women with ocular metastases were younger than 51 years at the time of initial diagnosis, suggesting an as of yet unidentified genetic relationship (8). The association of specific genetic aberrations and organ metastases from breast cancer has been described previously, and may explain the predilection (9).

Using animal models, investigators have reported that more than 50% of mice receiving an intracardiac injection of the r3T breast cancer cell line develop choroidal metastases. Pigmented abnormalities in the brain of mice with choroid metastases were frequently noted, suggesting a common mechanism in the development of brain and choroid

metastases. Moreover, in mice with choroid metastases, metastasis in the bone and lung metastases were observed in 71% and 92% of the animals. However, only 29% of the mice with choroid metastasis harbored liver metastasis. Animals with bone metastasis were not significantly more likely to harbor choroid metastasis. It was hypothesized that CXCR4 expression on r3T cells might explain the predilection for choroidal metastases, but this was not supported by experimental data (10).

DIAGNOSIS

Most patients diagnosed with ophthalmic metastases present with symptoms and signs listed in Table 80-2. In a study of 264 patients evaluated at a single ophthalmic oncology center for uveal metastases from breast cancer, the most frequently noted symptoms were blurred vision (88%), floaters (5%), and photopsia (5%) (11). These or other unexplained problems listed in Table 80-2 should prompt referral to an ophthalmologist for further evaluation.

Ophthalmic evaluation should include indirect ophthalmoscopy with photography (Fig. 80-1). Common features of choroid metastasis from breast cancer include: yellow color (99%), plateau configuration (77%), lack of retinal exudate (97%) or hemorrhage (98%), and presence of subretinal fluid (64%). Uveal metastasis is bilateral in 38% of patients, unilateral in 62%, and multifocal in 48% (11). Pain is a feature of metastasis, which is rare in primary eye tumors. Ophthalmic ultrasonography may be a helpful diagnostic adjunct to detect the metastatic tumor if secondary exudative retinal detachment is present. Uveal metastases typically demonstrate thickened, dome-shaped choroid lesions with moderately high internal acoustic reflectivity. Fluorescein angiography may be a useful diagnostic adjunct and typically demonstrates early hypofluorescence and diffuse late staining in uveal metastases. Biopsy by fine needle aspiration is rarely required by experienced clinicians because of the characteristic appearance, and can be complicated by hemorrhage, tumor seeding, and vision loss.

Extraocular metastases in the orbit may lead to ptosis, proptosis, enophthalmos, heterotropia, or diplopia (Fig. 80-2). Palpation of the orbit may reveal a mass or indurated periorbital skin and orbital firmness with resistance to retropulsion of globe. For suspected orbital metastases in the bones, computed tomography of the orbits is recommended. Contrast-enhanced magnetic resonance imaging is superior for the evaluation of soft tissue abnormalities.

Most uveal metastases can be identified with ophthalmic assessments without sophisticated imaging. However, a prospective study of patients with choroidal metastases revealed that 26% of patients harbored asymptomatic brain metastases on contrast enhanced CT of the brain (12). MRI of the brain is the most sensitive diagnostic test for brain

TABLE 80.2

Symptoms and Signs of Ophthalmic Metastases

Site	*Symptoms*	*Signs*
Iris	Asymptomatic	Iris mass (usually superior)
	Blurred vision	Uveitis
		Glaucoma
		Pseudo-hypopyon
Ciliary body	Asymptomatic	Dome-shaped or sessile mass (usually inferior)
	Blurred vision	Uveitis
	Pain	Glaucoma
		Sectorial cataract
		Lens subluxation
		Shallow anterior chamber
Vitreous	Floaters	Vitretis
	Blurred vision	
Choroid	Asymptomatic	Yellow placoid lesions (usually superior and temporal)
	Blurred vision	Serous retinal detachment
	Metamorphopsia	Alteration of retinal pigment epithelium
	Pain	Choroidal detachment
	Diplopia (rare)	Glaucoma
Retinal	Blurred vision	Vitretis
	Floaters	Black infiltrative retinal mass with retinitis-like appearance
Optic disc	Asymptomatic	Diffuse or localized disc swelling
	Blurred vision	Disc hemorrhage
		Disc edema
Extraocular	Diplopia	Proptosis
		Enophthalmos
		Heterotropia
Cerebral	Field defects	Strabismus
	Hemineglect	Field loss
	Abnormal color vision	
	Blurred vision	
	Diplopia	

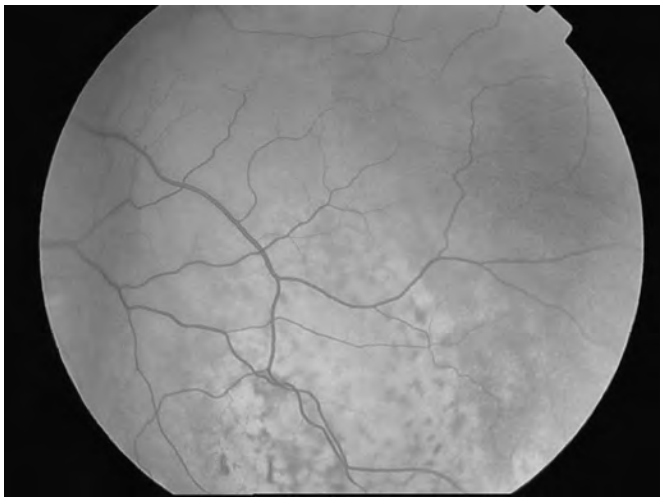

FIGURE 80-1 Ophthalmoscopic photograph of diffuse intraocular breast cancer metastases causing blurred vision.

metastasis and should be undertaken in any patient with newly diagnosed uveal metastasis because of the high likelihood of brain metastasis and implications for treatment planning. Systemic imaging should be considered for the patient with previously unrecognized metastases to characterize the extent of disease.

MANAGEMENT AND OUTCOME

The goal in managing ophthalmic metastasis is palliation. For patients that present without symptoms, careful observation can be considered. Otherwise, therapy to reduce vision impairment and alleviate pain should be undertaken. Therapy can be systemic and non-specific or local and targeted. The extent of disease and necessity for extra-ophthalmic treatment frequently guides the modality employed. Most data comes from retrospective clinical studies, with the notable exception of two prospective studies.

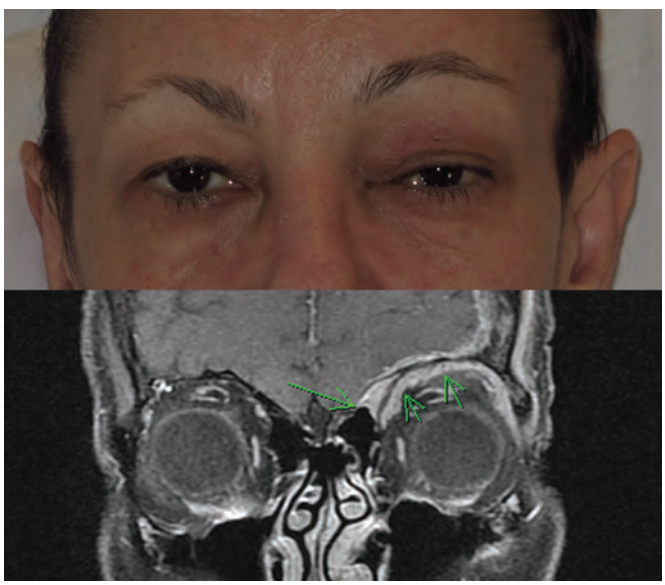

FIGURE 80-2 Clinical photograph and T1 contrast enhanced fat saturated magnetic resonance image of the orbits in the coronal plane demonstrating left superior orbital metastasis causing proptosis and diplopia.

Observation

In the largest series of patients with uveal metastases from breast cancer published, observation was employed in 18% of patients with choroid metastasis and 9% of patients with iris metastasis. Remarkably, regression during observation was noted in 50% of choroid metastases, but none of the iris metastases. Recurrence was noted in 9% of choroid metastases, and 50% of iris metastases (11). Appropriate selection of patients for this management strategy is challenging.

Systemic Therapy

Systemic therapy is often employed in the presence of extra-ophthalmic disease that is progressive or symptomatic. Hormonal therapy, cytotoxic chemotherapy, and biologic therapy have all been reported in small studies. In the largest series of patients with uveal metastases from breast cancer reported, 9% and 29% or 5% and 27% of patients with choroid or iris metastasis received hormone therapy or chemotherapy, respectively. Metastasis regression and stability was noted in 65% and 16% of patients with choroid metastasis and in 50% and 33% of patients with iris metastasis treated with hormone therapy or chemotherapy, respectively. Recurrence of the metastasis was noted in 11% and 17% of patients with choroid and iris metastasis treated with hormone therapy or chemotherapy, respectively (11).

Little data exists on the relative efficacy of different systemic therapeutics for ophthalmic metastases. Although it is likely that ophthalmic metastasis will respond to agents that specifically target the primary tumor phenotype, this has not been well documented. Hormone therapy generally has a slower time to response than chemotherapy, and, therefore, may not be a good initial therapy for patients with rapidly progressing symptoms. HESA-A is a novel compound that was reported to yield a 100% rate of vision improvement in a prospective double-blind placebo-controlled study of patients with choroid metastasis from breast cancer, the reported details of which are limited (13).

Radiation Therapy

Radiation therapy for ophthalmic metastasis is most commonly used with high-energy photon teletherapy (external beam), but proton teletherapy and brachytherapy are other effective treatment modalities. In the largest series of patients with uveal metastases from breast cancer reported, external beam radiation therapy was the most commonly used management strategy and given to 59% and 64% of patients with choroid and iris metastasis (11).

A single center prospective study (95-08) carried out by the Arbeitsgemeinschaft Radiologische Onkologie (ARO) of the German Cancer Society provides the best evidence regarding the safety and efficacy of external beam radiation therapy for choroid metastasis (14). In this study, 50 patients underwent treatment of 65 eyes with choroid metastasis between 1994 and 1998; the majority of the patients (n = 31, 62%) had metastatic breast cancer. All patients received 40 Gy in 20 fractions of 2 Gy with 6 MV photons using a lens-sparing beam arrangement; a single lateral field was used for unilateral metastasis, while parallel opposed lateral fields were used for bilateral metastases. Median survival after treatment was 10 months in patients with breast cancer. Acute side effects were mild: 50% of patients experienced grade 1 dermatitis or conjunctivitis. Late side effects were noted in 2 patients: one patient experienced optic

neuropathy 2 years after radiation therapy and the other patient developed retinopathy concurrent with tumor recurrence. One patient underwent enucleation for painful glaucoma caused by tumor recurrence. Of the 50 symptomatic eyes, visual acuity increased in 36%, stabilized in 50%, and decreased in 14%. Of 15 asymptomatic eyes, visual acuity improved in 20% and stabilized in 80%. By ultrasonography, 38% of metastases completely regressed, while 44% partially regressed, and 17% remained unchanged. Complete regression was significantly more common among breast cancer patients. Regression rates were higher in patients that underwent chemotherapy after radiation therapy. Recurrence was noted in 13% of breast cancer patients 5 to 16 months after radiation therapy. Of note, no patient receiving unilateral irradiation experienced recurrence in the fellow eye, suggesting that bilateral irradiation is unnecessary for patients with unilateral involvement. Some have hypothesized that exit dose to the fellow eye from unilateral irradiation may be sufficient to control subclinical disease (15).

Radiotherapeutic alternatives to conventional photon teletherapy have been reported. Proton therapy is typically delivered in fewer fractions than photon therapy. In one study of patients with choroid metastasis from various primary cancers (the majority being breast cancer), 2 fractions of 14 Gy yielded a tumor regression rate of 84%, with 47% of eyes demonstrating stable or improved visual acuity (16). Brachytherapy involves placement of a radiation emitting source near the metastasis. This typically entails a procedure under anesthesia, but may be completed within a few days. Moreover, reirradiation of the ocular metastases may be facilitated using the precise doses delivered with brachytherapy. In a series of 13 patients treated with plaque brachytherapy for uveal metastases from breast cancer (31% of whom had received prior ocular teletherapy), 93% of patients demonstrated tumor regression (17).

Other Local Therapies

Other local therapies have been reported in small series of patients with choroid metastases from breast cancer. Transpupillary thermotherapy (TTT) may be useful for small tumors with minimal subretinal fluid, and was reported to be successful in a patient with breast cancer (18). Likewise, photodynamic therapy (PDT) has been reported to have a successful outcome in a patient with choroid metastasis from breast cancer (19). Laser therapy was reported to induce regression with associated improved visual acuity in a series of 7 patients with choroid metastasis from breast cancer (20).

MANAGEMENT SUMMARY

- Ophthalmic metastases have been reported in 0% to 37% of patients dying with, or of, breast cancer, in 0% to 5% of visually asymptomatic patients with metastatic breast cancer, and in 38% of breast cancer patients with vision problems.
- Most patients presenting with ocular metastases report blurred vision, photopsia, and floaters.
- Clinical evaluation by an experienced ophthalmologist is necessary to establish the diagnosis. Upon detection of uveal metastasis, brain imaging should be performed given the high frequency of concurrent brain metastasis and implications for therapy.
- Management of ophthalmic metastasis can consist of systemic therapy, radiation therapy, or other local therapy, and is commonly dictated by severity and progression of symptoms and presence and burden of extra-ophthalmic disease.
- Conventional photon external beam radiation therapy is the most frequently used local therapy and has proven to be safe and effective when given to 40 Gy in 2 Gy fractions.
- Ipsilateral eye irradiation provides good tumor control and may spare ophthalmic morbidity in patients without evidence of bilateral metastases.

CHAPTER 81

Management of Isolated Liver Metastases

Rebecca Miksad, Douglas W. Hanto,
Robert D. Timmerman, and Steven Come

CHAPTER CONTENTS

INTRODUCTION

About half of patients with metastatic breast cancer develop liver metastases, a finding that generally portends a poor prognosis (1): median overall survival (OS) of 4 to 22 months (1,2). Since liver metastases commonly occur in the setting of concurrent extrahepatic metastases, liver involvement is generally considered to be a manifestation of disseminated disease, and patients are usually treated with systemic therapy (2) (see Chapters 33 and 34). However, in modern studies a minority of patients manifests metastatic breast cancer limited to the liver (1,2). Localized, liver-directed treatments have achieved some success in other cancers, especially when disease is limited to the liver, and these approaches have been applied to breast cancer patients. Published studies have evaluated the safety and benefit of a range of liver-directed treatments: hepatic resection (Table 81-1), radiofrequency ablation (RFA), transarterial chemoembolization (TACE) with and without drug-eluting beads, radioembolization, intraarterial chemotherapy, stereotactic body radiation therapy (SBRT), brachytherapy, and interstitial laser therapy (ILT) (Table 81-2). However, the comparative efficacies of these approaches remain unknown because there are limited prospective studies and no randomized controlled trials (Table 81-3). Furthermore, identifying appropriate patients remains a challenge, and the carefully selected patients in published series may represent good prognosis subgroups independent of the therapeutic approach.

Nevertheless, studies suggest that treatment of metastatic breast cancer limited to the liver may benefit some patients. In addition, as improvements in systemic therapies offer better control of metastatic disease and longer survival, more patients may need localized management of liver metastases. This chapter reviews localized, liver-directed treatment of hepatic metastases in breast cancer, details specific clinical considerations for each treatment option, and describes the available data for common and emerging approaches.

GENERAL SELECTION CRITERIA FOR LIVER-DIRECTED TREATMENT OF METASTATIC BREAST CANCER IN THE LIVER

Careful patient selection is essential to optimize the risk-benefit ratio of liver-directed approaches for all cancers with liver involvement (Table 81-4). The patients most likely to benefit from liver-directed approaches have a good overall prognosis (see Chapters 30 and 31) such that progression of other disease sites and/or comorbidities do not negate any disease control achieved in the liver. General criteria are controlled primary disease, limited metastatic disease in the liver (both number and size of lesions), longer disease-free intervals, a younger age, and a higher performance status (1–3). On the basis of the more extensive experience of liver metastases in colorectal cancer, the presence of extrahepatic metastatic or residual primary breast cancer is commonly (4), although not always (5,6), considered a contraindication to liver-directed therapy.

Evaluation before proceeding with liver-directed therapy for metastases from breast cancer should define the extent of disease as well as the potential responsiveness to systemic therapy. These factors may aid risk assessment and decision making regarding the role of liver-directed and/or systemic therapy. Commonly used imaging studies are (i) computed tomography (CT) of the chest to rule out pulmonary and mediastinal disease; (ii) triphasic CT scan of the abdomen and pelvis to evaluate the number and location of liver metastases in order to facilitate procedure planning and to rule out other intraabdominal disease; and (iii) a bone scan to rule out bone metastases. A PET scan may be useful to identify extrahepatic disease (see Chapters 33 and 34), and magnetic resonance imaging (MRI) may provide more detailed evaluation of the liver.

The need for thorough staging was highlighted in a series of 90 breast cancer patients evaluated for resection of liver metastases: 60% were deemed ineligible preoperatively because of extrahepatic metastases, 22% had unresectable extrahepatic disease at exploratory laparotomy, and only 10% ultimately underwent resection (7).

Palliative liver-directed treatment may also be beneficial if liver metastases impair quality of life. However, recent improvements in outcomes for endocrine-responsive, *HER2/neu*-amplified cancers and palliative single-agent chemotherapy have improved the effectiveness and tolerability of systemic therapy (8). Therefore, the risks and benefits of liver-directed therapies should be evaluated in context of potential systemic treatment options (2) (see Chapters 72–79).

SURGICAL APPROACH

Hepatic Resection

Hepatic resection (metastectomy) is the most commonly available liver-directed option for breast cancer patients. The morbidity and mortality of hepatic resection has declined significantly over the past two decades because of improvements in (i) understanding of intrahepatic segmental anatomy; (ii) imaging techniques (three-dimensional CT and intraoperative ultrasound) to characterize the tumor; (iii) anesthetic management; (iv) surgical techniques (preoperative portal vein embolization, segmental and anatomic resections, vascular inflow occlusion, maintenance of low central venous pressure, devices for safer division of the liver parenchyma and for maintenance of hemostasis); (v) laparoscopic hepatic resection approaches; (vi) understanding of negative risk factors (steatosis, remnant liver volume, and preoperative chemotherapy); and (vii) postoperative care. As a result, surgical resection is a technically safe option for most patients with metastatic breast cancer limited to the liver.

Patients deemed to be surgical candidates after preoperative screening undergo additional evaluation in the operating room. Prior to hepatic resection, patients are often explored to rule out extrahepatic, intraabdominal disease. Intraoperative ultrasound may identify additional liver lesions not imaged preoperatively, characterize the exact location of the lesion(s), and define the proximity of lesions to venous structures. The value of this additional exploration was demonstrated by a series of 108 breast cancer patients considered for hepatic resection after extensive preoperative evaluation with imaging (6). Over a 20-year period, 23% were found to have unresectable extrahepatic or hepatic disease during abdominal exploration, and an additional 13% had unexpected, but resectable, intraabdominal disease (6). Of the 85 patients who ultimately underwent hepatic resection, an R0 (microscopically negative margin) resection was attained in only 65%, while an R1 microscopically positive margin) resection was achieved in 18%, and an R2 resection (macroscopically positive margin) was carried out in 17% (6).

Selection Criteria for Hepatic Resection

In addition to the general selection criteria outlined above, hepatic resection candidates must have lesions that can be completely resected while leaving an adequately sized liver remnant along with its hilum (i.e., vascular and ductal continuity to the body). Because the function and architecture of the liver are integrated, adequate liver function can be maintained if there is a critical volume of intact liver and a contiguous bile duct system (20% of a normal liver, 40% of the liver if steatosis is present). If a small liver remnant is anticipated, a patient may benefit from preoperative portal vein embolization (right or left) of the lobe to be resected. This causes hypertrophy of the opposite lobe (the lobe that will become the liver remnant), thereby decreasing the risk of postoperative hepatic insufficiency.

Although there are limited data, the combination of hepatic resection and RFA has been explored for metastatic disease in both lobes or when one or more lesions are technically unresectable (4). In addition, while patients with extrahepatic metastases are traditionally excluded from resection, some series include patients with controlled extrahepatic disease (6).

TABLE 81-3

Liver-Directed Therapy for Metastatic Breast Cancer: Summary of the Evidence

Liver-Directed Therapy		
Surgical resection	Pro	• Data available from a large number of case series over 20+ years • Compared to other liver-directed treatment options, more extensive data suggesting a 5-year survival benefit in appropriately selected patients • Relatively available
	Con	• Invasive procedure requiring hospitalization • Risk of postoperative complications and decreased liver function • Many patients not eligible because of comorbidities and extent of liver disease • Best results obtained for patients with small and/or few lesions
Nonsurgical liver-directed therapies	Pro	• Less invasive than surgical resection • More patients may be eligible • Compared to surgical resection, decreased risk of postprocedure complications and decreased liver function • Procedure may be accomplished in outpatient setting or with short hospital stay • Efficacy may be improved by combining modalities • Approaches supported by data for colorectal and hepatocellular cancer
	Con	• Data in breast cancer limited to relatively few, heterogeneous case series • Data for survival and tumor control are mixed • Treatment modalities and operator expertise may not be readily available • Despite generally good safety results, serious complications have been reported

Outcome of Hepatic Resection for Metastatic Breast Cancer

Most published series of outcomes after hepatic resection for metastatic breast cancer involve small, nonuniform patient populations. The survival data reflect this heterogeneity: median overall survival in 26 published series (more than 600 patients) ranges from 15 to 63 months, and the 5-year survival rate ranges from 18% to 61%, with more modern series reporting rates from 30 to 40% (3,4,6,9). Postoperative mortality is commonly zero (3,4,6), although rates up to 6% (n = 17) (10) in small series have been reported. Significant or severe morbidity rates range from 0% (11) to 44% (12).

Despite the limits of case series data, several favorable prognostic factors have emerged for hepatic resection of metastatic breast cancer. Consistent with the colorectal and primary liver tumor literature, a better prognosis for resection is observed when patients have a smaller tumor burden in the liver (12). In addition, a longer length of time between

TABLE 81-4

Summary of Patient Selection Guidelines for Liver-Directed Therapies

General Selection Guidelines Associated with Best Outcomes	• Good overall prognosis • Good performance status and few comorbidities • Documented response to preprocedure systemic therapy • Smaller lesions and fewer number of lesions in the liver • Metastatic disease isolated to the liver only • Longer disease-free interval between treatment of primary cancer and development of hepatic metastasis • Liver lesions that can be completely eradicated by the procedure
Procedure-Specific Guidelines	
Resection	• Adequate anticipated liver remnant (may be able to enhance with preoperative embolization) • Good operative risk
RFA	• Lesion size less than 3 to 5 cm in diameter • Limited number of lesions (usually 3 or fewer)
TACE	• Adequate liver function • No portal vein thrombosis or other contraindication
SBRT	• Well-demarcated lesion • Adequate anticipated liver remnant

initial diagnosis and the development of liver metastases (7,13,14) is associated with improved survival in some series (13,14), but not all (4,6,12,15,16). The type of resection attained may also be important: An R0 resection (22%–61% 5-year survival) is associated with improved survival compared to an R2 resection (0%–16% 5-year survival) (6,17,18). However, an earlier series of 54 patients did not demonstrate the same benefit: median survival was 40 months for R0 resections, and 31 months for R1 and R2 resections (p = .56) (9). In this series, the only significant prognostic predictor of median survival was hormone receptor status: 44 months if positive and 19 months if negative (9). This result was substantiated for 5-year and median survival in a subsequent study (6): 3.52 years for estrogen-receptor- (ER-) positive primary tumors compared to 1.5 years for ER negative (p < .02). A similar result was found for the ER status of the metastatic tumor in a series that also reported improved survival for *HER2/neu*-positive metastases (p = .02) (19).

A large (n = 85) contemporary series of liver resection for metastatic breast cancer demonstrated a median survival of 32 months and a 5-year survival of 37% (6). Multivariate analysis identified three factors correlated with poor outcome: (i) the absence of response to pre-resection chemotherapy (p = .008); (ii) an R2 resection (p = .0001); and (iii) a lack of repeat resection for recurrent liver disease (p = .01). The most important predictor of survival in this series was the completeness of the resection, with only 10% of R2 resection patients surviving 5 years, compared with 42% of R1 and 43% of R0 patients. Patients who developed recurrent liver metastases and then underwent re-resection had a 5-year survival of 81%, while those who did not had a 5-year survival of 29%. Although the presence of extrahepatic disease did not affect prognosis in this multivariate analysis, the subset of patients with extrahepatic disease at the time of hepatectomy had a lower 5-year survival (16%) compared to patients with resected or controlled extrahepatic disease (25%) and those without extrahepatic disease (43%).

A more recent, similarly sized (n = 86) hepatic resection series produced a higher median survival (57 months) and a slightly higher 5-year survival (44%) (13). Similar to prior series, multivariate analysis demonstrated that estrogen-receptor-negative primary breast disease (p = .009) and preoperative progressive disease (p = .003) were associated with decreased overall survival. These two large surgical case series span several decades during which time there were significant advances in systemic and hormonal therapy. Therefore, in addition to standard limitations of retrospective analysis, interpretation of the surgical literature in this disease is limited by potential confounders from treatment pattern changes over time.

In summary, although the data are limited to case series, hepatic resection for metastatic breast cancer can be performed safely and may result in favorable median and 5-year survival rates for appropriately selected patients. However, hepatic resection has not been compared in a randomized trial with systemic chemotherapy alone or in combination with nonsurgical, liver-directed options.

NONSURGICAL, LIVER-DIRECTED, LOCALIZED TREATMENT OPTIONS

The data for nonsurgical, liver-directed, localized therapy are most thoroughly developed for primary hepatocellular cancer (HCC) and for metastatic colon cancer. However, there are emerging data for metastatic breast cancer. The lack of randomized, controlled clinical trials limits interpretation of survival benefit and comparative efficacy. In general, nonsurgical, liver-directed therapies can be done percutaneously, allowing for a shorter recovery time and facilitating the administration of systemic treatment.

Transarterial Chemoembolization and Intraarterial Chemotherapy

Tumors in the liver are often primarily supplied by the hepatic artery, in contrast to the nontumor liver parenchyma which receives blood supply from portal vein. Transarterial chemoembolization (TACE) takes advantage of this blood supply pattern by instilling cytotoxic agents mixed with iodized oil into the hepatic artery feeding the tumor and then embolizing this vessel (often with gelatin sponge particles) to cut off the tumor blood supply. Because of the differential blood supply, the nontumor liver parenchyma suffers relatively less harm. Attempts to further minimize hepatic damage and subsequent side effects, have led to development of related techniques: delivery of chemotherapy through the use drug-eluting beads, radioembolization in which radioactive particles are instilled instead of chemotherapy (intraarterial brachytherapy or selective internal radiation therapy [SIRT]) and "bland embolization," in which the only treatment is embolization (no chemotherapy or radiation).

Hepatic arterial infusion of chemotherapy (HAI) follows the same principles as TACE, but embolization is not performed. Chemotherapy may be distilled once during a single procedure, or a pump may be placed for longer-term, continuous infusion.

The technical success of TACE is demonstrated by the presence of hyperattenuating iodized oil within the tumor on unenhanced CT (20). Because the size of the liver tumor may not change after liver-directed therapy, the extent of necrosis (or lack of enhancement) observed on imaging may more accurately reflect treatment efficacy (21,22). A surrogate endpoint for response is the apparent diffusion coefficient (ADC), which measures the mobility of water in tissues: viable tumor cells restrict the mobility of water while necrotic tumor cells allow increased diffusion (20). In one study of TACE for patients with metastatic breast cancer (n = 14, prospective chart review), no tumors met the Response Evaluation Criteria in Solid Tumors (RECIST) criteria for complete response, but the ADC increased by a mean of 27% after treatment (20).

Overall treatment efficacy may be improved by combining TACE with other localized treatments such as radiofrequency ablation (23) and SBRT. However, the best sequencing of and the optimal interval between each therapy is unknown.

Selection Criteria for TACE

Although TACE and intraarterial chemotherapy techniques were developed to spare the nontumor liver, complications commonly stem from liver damage, especially if there is inadequate functional reserve or poor blood flow to the liver. Therefore, TACE selection criteria have a special focus on hepatic reserve. Commonly accepted contraindications to TACE for metastatic breast cancer are derived from the literature for other malignancies: (i) absence of hepatopetal blood flow (portal vein thrombosis), (ii) encephalopathy, and (iii) biliary obstruction (21). Relative contraindications are (i) serum bilirubin over 2 mg/dL, (ii) lactate dehydrogenase over 425 U/L, (iii) aspartate aminotransferase over 100 U/L, (iv) tumor burden involving more than 50 percent of the liver or both lobes of the liver, (v) cardiac or renal insufficiency, (vi) ascites, (vii) recent variceal bleed, and (viii) significant thrombocytopenia. Although there are limited prognostic data for metastatic breast cancer treated

with TACE, these contraindications are primarily related to technical issues and the patient's ability to tolerate tumor necrosis and injury to the nontumor liver.

Despite these selection criteria, "postchemoembolization syndrome" (fever, pain, nausea, and elevated liver function tests) is commonly seen after TACE in 60% to 80% of patients (21). These symptoms tend to be worst the first several days after the procedure and may persist for several weeks. For hepatocellular cancer, the disease in which TACE is most studied, a meta-analysis of 37 trials including about 3,000 patients demonstrated a 2.4% (range 0%–9.5%) 30-day mortality rate, primarily due to liver failure (21). This meta-analysis identified serious complications ranging from acute liver failure (7.5%), acute renal failure (1.8%), upper gastrointestinal bleeding (3%), to hepatic or splenic abscess (1.3%) (21). Other reported potentially serious complications from TACE are tumor rupture, encephalopathy, acute cholecystitis, acute pancreatitis, and arterial damage. Because of these side effects and complications, patients are commonly observed in the hospital postprocedure (21).

Outcome of TACE for Metastatic Breast Cancer

The largest study of TACE for metastatic breast cancer is a case series of 208 patients (24) for whom three TACE sessions were planned at least four weeks apart from November 1998 to February 2006. The majority of patients had liver only disease (n = 159), and chemoembolization was pursued in place of systemic therapy (24). In this series, patients who were adequately "downsized" by chemoembolization proceeded to laser-induced thermotherapy (LITT), a subgroup included in a subsequent report (24). With a maximal RECIST response 12 weeks after the first TACE session, post-TACE MRI imaging documented stable disease in 50%, progressive disease in 36.5%, and partial response in only 13% of patients. Most patients tolerated the procedure well, and the 3-year survival was 33% from the time of the first TACE procedure (24).

The same author also reported the results for 161 patients (out of 314 patients treated with TACE from November 2001 to November 2006) (25) who were subsequently treated with LITT (the extent of overlap between the patient groups in the two reports is not clear). For the selected group of patients downsized sufficiently for LITT, TACE produced a 27% reduction in tumor size. After combination therapy (TACE + LITT), 38.5% had a complete response, 5% had a partial response, and 12.4% had stable disease. However, 44% of the group had disease progression after initial stabilization that required additional TACE. Overall, the 3-year survival was similar to prior report that focused on TACE alone: 36.6% at 3 years and 13.7% at 5 years (25).

The most recent retrospective chart review reports the results of 44 patients who underwent TACE and systemic chemotherapy (SC) compared to 43 patients who underwent SC therapy alone (26). The criteria for treatment choice were not described, and patients received various chemotherapy regimens. Response rates (59.1% vs. 34.9%) and 3-year survival (47.6% vs. 7.4%) were higher for patients who received TACE compared to those who did not. Multivariate analysis results were similar to those seen in the surgical literature: estrogen receptor negative status of the primary tumor and short disease-free interval (less than 24 months) were associated with poor prognosis (26).

A prior retrospective chart review evaluated 48 metastatic breast cancer patients treated with TACE (n = 28) or systemic chemotherapy (n = 20) (again, criteria for treatment choice not described) (27). With no grade III or IV adverse events, TACE had a 35.7% response rate (30% 2-year survival), while systemic chemotherapy had a 7.1% response rate (11% 2-year survival). Recently, a study of 14 patients with 27 lesions evaluated with magnetic resonance (MR) imaging showed a median survival of 25 months and a 35% OS at 3 years (20). Finally, a 40-patient case series explored the safety of drug-eluting beads loaded with doxorubicin for patients with metastatic breast cancer to the liver (22). The median survival was 47 months, with a mild side effect profile, and response as per modified RECIST was 50% at 12 months (22).

Hepatic Artery Infusion

Although not widely employed, HAI is utilized in some centers for colorectal cancer liver metastases, and there are limited data in breast cancer (28,29). In the most recent HAI study for breast cancer metastatic to the liver (n = 10), 40% progressed during HAI therapy (29).

In summary, it is difficult to establish a survival benefit for TACE for breast cancer metastatic to the liver in the absence of randomized, controlled trials.

Radiofrequency Ablation

Radiofrequency ablation (RFA) is a minimally invasive technique that uses extreme heat to destroy cancer cells. An electrode is inserted into the tumor and high frequency alternating current is transmitted from the tip of the probe into the surrounding tissue. As the tissue molecules become excited, heat (over 60°C) is generated, and coagulative necrosis occurs (30). The amount of tissue destroyed is related to the impedance properties of the tissue and the distance of the tissue from the electrode (30). Tissue destruction may be modulated by the cooling effect of a heat sink such as blood vessels located adjacent to the tumor: heat is carried away, and the necessary temperature for coagulative necrosis may not be reached (30).

Sites treated with RFA frequently cavitate after the procedure, forming a distinctive scar band. The risk of complications increases with proximity to the porta hepatis. Rarely, hepatitis, infection, and injury to larger bile ducts and nearby bowels may occur. Patients with preexisting liver damage such as cirrhosis and those with larger tumors are more likely to experience complications. Although not typical, needle track seeding has been reported. Given the generally limited risks, RFA can be done as an outpatient procedure.

Selection Criteria for RFA

In addition to the general selection criteria for localized treatment of liver metastases, tumor size and the number of liver metastases are important selection criteria for other tumor types treated with RFA, both for achieving local control and for predicting a survival benefit. However, there are few prognostic data for metastatic breast cancer. In colorectal cancer, fewer lesions and smaller tumors are associated with improved survival. Similar size limitations are observed for hepatocellular cancer (HCC): RFA induced a complete response in 80% of HCC tumors 3 cm or less but was substantially less effective in HCC tumors larger than 3 cm (50% response) (31). Although it is unclear if these size limitations can be extrapolated to the metastatic breast cancer setting, it seems likely given physical limitations of RFA.

Outcome of RFA for Metastatic Breast Cancer

While RFA has been extensively studied for colorectal liver metastases (32), there is growing case series evidence for metastatic breast cancer. In the largest case series to date

(n = 52), follow-up imaging demonstrated complete necrosis in 97% of tumors that had a mean diameter of 2.5 cm (33). Consistent with the concept that metastatic breast cancer is a systemic disease, 53% of patients in this series developed new intrahepatic metastases, and the 5-year survival was 27% (33).

Similar recurrence results were seen in a case series of 24 breast cancer patients with 64 liver metastases treated with RFA and followed for a median of 19 months: 58% developed new metastases, the majority of which occurred in the liver (71%) (34). However, most patients with disease limited to the liver were disease-free at last follow-up. In contrast, a separate series demonstrated good survival for both those with and without extrahepatic metastases at the time of RFA: Six of 11 patients with extrahepatic disease were disease free after a median follow-up of 15 months (35). Several small series also report post-RFA survival: with a median follow-up of 16 months, one study reported 64% of patients were alive in a group of 14 patients with 16 tumors treated with RFA (36), while a second study of 12 patients reported a 30% 5-year survival (5).

In the largest series to date, the primary negative prognostic factor for survival was larger liver metastases (larger than 2.5 cm) (33). A separate series (n = 40) that evaluated hormone receptor status and *HER2* overexpression found only the presence of extrahepatic disease to be associated with poor survival after RFA (37).

In most reported cases for metastatic breast cancer, RFA was used in combination with systemic chemotherapy, and very few side effects (mild right upper quadrant discomfort and asymptomatic pleural effusion) were noted, but none required specific treatment (5,33,36–38). RFA has also been combined with surgical resection (4). Based on these data and the experience in other malignancies, RFA for metastatic breast cancer limited to the liver may be beneficial for select patients. The data for patients with concurrent extrahepatic disease are mixed.

Stereotactic Body Radiation Therapy

Stereotactic body radiation therapy (SBRT) approaches evolved from intracranial stereotactic radiosurgery (SRS) and stereotactic radiotherapy (SRT) to treat tumors outside the cranium and are therefore subject to physiologic movement. The term *stereotactic* describes the correlation of the tumor target position to fiducials with a reliable and readily known position (39). Unlike conventionally fractionated radiotherapy (CFRT), stereotactic radiation is completed with a limited number of high-dose fractions called oligofractionation (40).

While a large safety margin can be added to CFRT to compensate for tumor motion, the potent radiation dose in each fraction (10–20 gray [Gy]) of SBRT means that the tumor must be tracked to accommodate its motion without damaging normal tissue (39). Fiducials, often gold seeds, are placed such that they maintain the same relationship to the tumor despite physiologic movement and can be used to define the tumor target accurately. Fiducials define a coordinate system used in SBRT treatment and planning to achieve a conformal and compact dose distribution that treats effectively, controls for motion (4-D therapy), and minimizes normal tissue damage (41).

Patient Selection for SBRT

The most important feature for patient selection for SBRT is the predicted volume of viable liver left to function after therapy (rather than the number and size of tumors to be treated). As with surgical resection, it is essential that an adequate parenchymal remnant be preserved after SBRT along with its connecting hilar structures (i.e., vessels and ducts) so as not to isolate the remnant. With surgical resection performed according to the liver vascular anatomy, it is unlikely that a preserved remnant would be isolated. However, with SBRT's characteristic heterogeneous dosimetry, islands of liver tissue may be spared the threshold toxic dose. Nonetheless, such islands isolated from an intact vascular pedicle or unable to drain bile will eventually involute over weeks and months post treatment.

Based on the surgical literature, the critical liver volume (minimal liver remnant) is considered to be about 20% to 30% of the liver (around 500 to 700 ml) (42). Damaging more than this amount may lead to hepatic insufficiency or failure. The threshold dose beyond which the liver parenchyma no longer functions is fractionation dependent and not fully characterized. Several groups use 17 Gy for three fractions and 21 Gy for five fractions as the threshold dose (43). The dose damaging the vascular pedicle and bile ducts in a serial fashion is likely higher, in the range of 36 to 41 Gy. In some circumstances, a preplan is required to assess the critical volume and finally determine appropriateness of SBRT for liver-directed therapy.

For optimal SBRT treatment, tumors should be well demarcated on planning imaging. Tumors close to the central biliary structures are more prone to complication, but this is not an absolute contraindication. Patients with cirrhosis with hepatic insufficiency require a larger critical volume to be spared. Patients in frank liver failure, however, should not be treated with SBRT as even a mild radiation hepatitis could lead to death (44).

Outcome of SBRT for Metastatic Breast Cancer

As with all liver-directed therapies for breast cancer, there are no high level population cohort or randomized trials describing outcomes after SBRT for liver metastases. Furthermore, the majority of reports, even prospective trials, pool outcomes from a variety of primary sites, with breast cancer primaries typically constituting a minority. Despite these obvious shortcomings, the prospective trials and some retrospective reports demonstrate consistent treatment techniques and outcomes that may provide insight. Furthermore, while metastases from colon cancer have been shown to be more radioresistant, there is no such concern for breast cancer. While the impact on overall survival cannot be demonstrated from published reports, several series show that liver SBRT for breast cancer can durably control tumors and is tolerable in most patients.

Early retrospective reports of multiple tumor types in multiple areas of the body showed promise for SBRT and helped define selection criteria (44). Subsequently, four phase I dose escalation studies to find the ideal treatment dose were performed. Using a single fraction with dose escalated from 14 to 25 Gy, Herfarth et al. treated 37 patients with 60 lesions (4 primary liver tumors and 56 metastatic tumors, 14 of which were breast cancer) (46). No major complications were reported and the actuarial freedom from local failure rate at 18 months was 67% (46). However, an updated report with long-term follow-up showed higher rates of recurrence even at the highest dose level (47). A consortium of centers lead by the University of Colorado escalated a three-fraction regimen from 36 to 60 Gy attaining very high tumor control rates at the highest levels. The dose was escalated so long as the critical volume of 700 cc of normal liver could be spared the threshold dose of 15 Gy or less (40). The group from Princess Margaret Hospital escalated dose among 68 patients (12 with breast cancer)

to predefined limits to avoid radiation-induced liver disease (none observed at the highest dose levels within a bin, up to 60 Gy in six fractions). The median dose was lower than other reports (41.8 Gy in six fractions) as was the tumor control (71% at one year) (48). Finally, a study from the University of Texas Southwestern escalated a five-fraction regimen to a dose of 60 Gy. This study demonstrated a dose response relationship for local control with increasing dose potency (49).

Institutional retrospective and phase II prospective reports have confirmed the phase I findings. Rusthoven and coworkers built on the Colorado consortium phase I study with a multicenter phase II trial using the 60 Gy in three-fraction dose. This experience of 47 patients (63 lesions) included around 10% breast cancer patients. With median follow-up of 16 months, only three treated tumors progressed, producing a 2-year local control of 92% and median survival of 20.5 months (50) (all tumor types).

SBRT reports specific to breast cancer are also emerging. Thirty-nine patients with metastatic breast cancer (13 with liver metastases) were treated with SBRT for limited oligometastatic disease, resulting in a 6-year overall survival of 47% for the breast cancer cohort overall (51). Factors associated with a better outcome on univariate analysis for the overall breast cohort in an earlier report of the same patients population were: smaller tumor volume, bone-only disease, one metastatic lesions, stable/regressing lesions before SBRT (51).

Toxicity after SBRT

The most commonly discussed complication of liver radiotherapy is radiation-induced liver disease (RILD), which is a clinical syndrome of anicteric hepatomegaly, ascites, and elevated liver enzymes (particularly serum alkaline phosphatase) occurring 2 weeks to 4 months after completion of hepatic irradiation. RILD has most commonly been described in the context of large-volume liver irradiation to doses at or beyond the threshold. Clinically apparent RILD has rarely been described after SBRT, likely owing to the efforts to reduce the amount of nontumor tissue exposed to high and intermediate doses.

Early CT follow-up to assess response after SBRT can be hindered by a zone of *hypo*density seen on imaging that corresponds to normal tissue volume that received approximately 30 Gy (42,45). This phenomenon is of uncertain etiology, and there is no known clinical consequence (45). After a few months, the adjacent normal tissue may appear to have increasing *hyper*density (45).

Acute toxicity after SBRT includes fatigue and nausea consistent with acute radiation hepatitis. Depending on the position of the treated tumor, other potential SBRT complications include damage to the extrahepatic bile ducts, stomach, small bowel, kidney, large bowel, or lung (rare). Cytoprotectants (e.g., sucralfate) and acid blockers may help prevent and/or treat gastric or duodenal erosion (mucositis). Late toxicity such as bowel obstruction, gastric perforation, biliary sclerosis, and lung fibrosis have been occasionally observed.

Interstitial Laser Therapy

Localized tumor destruction can also be achieved through hyperthermic coagulative necrosis caused by laser light delivered through quartz diffusing laser fibers placed directly in the tumor (55). ILT has been used to treat tumors up to 5 cm and can be performed through a variety of modalities: percutaneously with local anesthesia in the outpatient setting, laparoscopically, or intraoperatively (55). The reported ILT serious complication rate (1.5%) is low, with four symptomatic pleural effusions, two liver abscesses, one bile duct injury, and no deaths occurring in a series of 452 patients (55). However, there were 41 (9%) asymptomatic pleural effusions and 20 (4%) asymptomatic subcapsular hematomas incidentally detected on imaging (55).

Accurate positioning of the laser can be ensured using real-time imaging; MR is preferred over CT and ultrasonography because of the heat sensitivity of the MR sequence and its ability to demonstrate the degree of necrosis by rapidly depicting temperature changes. Monitoring with MR imaging also minimizes destruction of healthy tissues and increases safety (55).

Patient Selection for ILT

Patient selection for ILT follows general guidelines for liver-directed therapy, and some suggest fewer than 5 lesions, with none measuring more than 40 mm in diameter (56).

Results of ILT for Metastatic Breast Cancer

The largest published experience with ILT for metastatic breast cancer included 232 patients with 578 liver metastases treated with ILT and systemic chemotherapy (1993 to 2002). Although 31% of patients had concurrent bone metastases, all patients had five or fewer hepatic metastases with no lesion larger than 5 cm in diameter (55). The rate of local liver recurrence 6 months after ILT was less than 5%, the median survival was 4.3 years, and the 5-year survival rate was 41% (calculated from the date of diagnosis of the target liver metastasis rather than the date of ILT treatment) (55). While ILT may be promising, data are limited for metastatic breast cancer to the liver.

OTHER LIVER-DIRECTED THERAPIES

Two radiation-based liver-directed therapies, brachytherapy (57,58), and radioembolization (59), are currently being developed for other cancers and the first reports in breast cancer are emerging.

MANAGEMENT SUMMARY

- Breast cancer patients with metastatic disease limited to the liver is uncommon and firm evidence regarding their management is scarce.
- For patients with liver metastases as the first site of metastases, thorough staging is indicated.
- In addition to surgical resection, there are a variety of nonsurgical liver-directed therapies that may offer local control with fewer side effects.
- The data for all liver-directed therapies in metastatic breast cancer is limited and there are no comparative randomized, controlled clinical trials.
- Case series evidence suggests that a variety of liver-directed therapies can be used successfully in carefully selected patients, with low morbidity and encouraging survival rates. Selected articles are listed in Table 81-1 for surgical approaches and Table 81-2 for nonsurgical approaches. A summary of the evidence is provided in Table 81-3.

- Careful selection is required to identify candidates for liver-directed therapy and, in many situations, systemic treatment is preferred (i.e., substantial extrahepatic metastases). A proposed algorithm for the management of a patient with metastases to the liver is given in Figure 81-1.
- Guidelines for patient selection are largely extrapolated from experience with liver-directed therapies for hepatocellular cancer and for colorectal cancer metastatic to the liver. Considerations for the selection of liver-directed therapy are given in Table 81-4.
- We advocate development of and enrollment in prospective clinical trials to address the unanswered question of comparative efficacy among liver-directed and systemic treatment options.

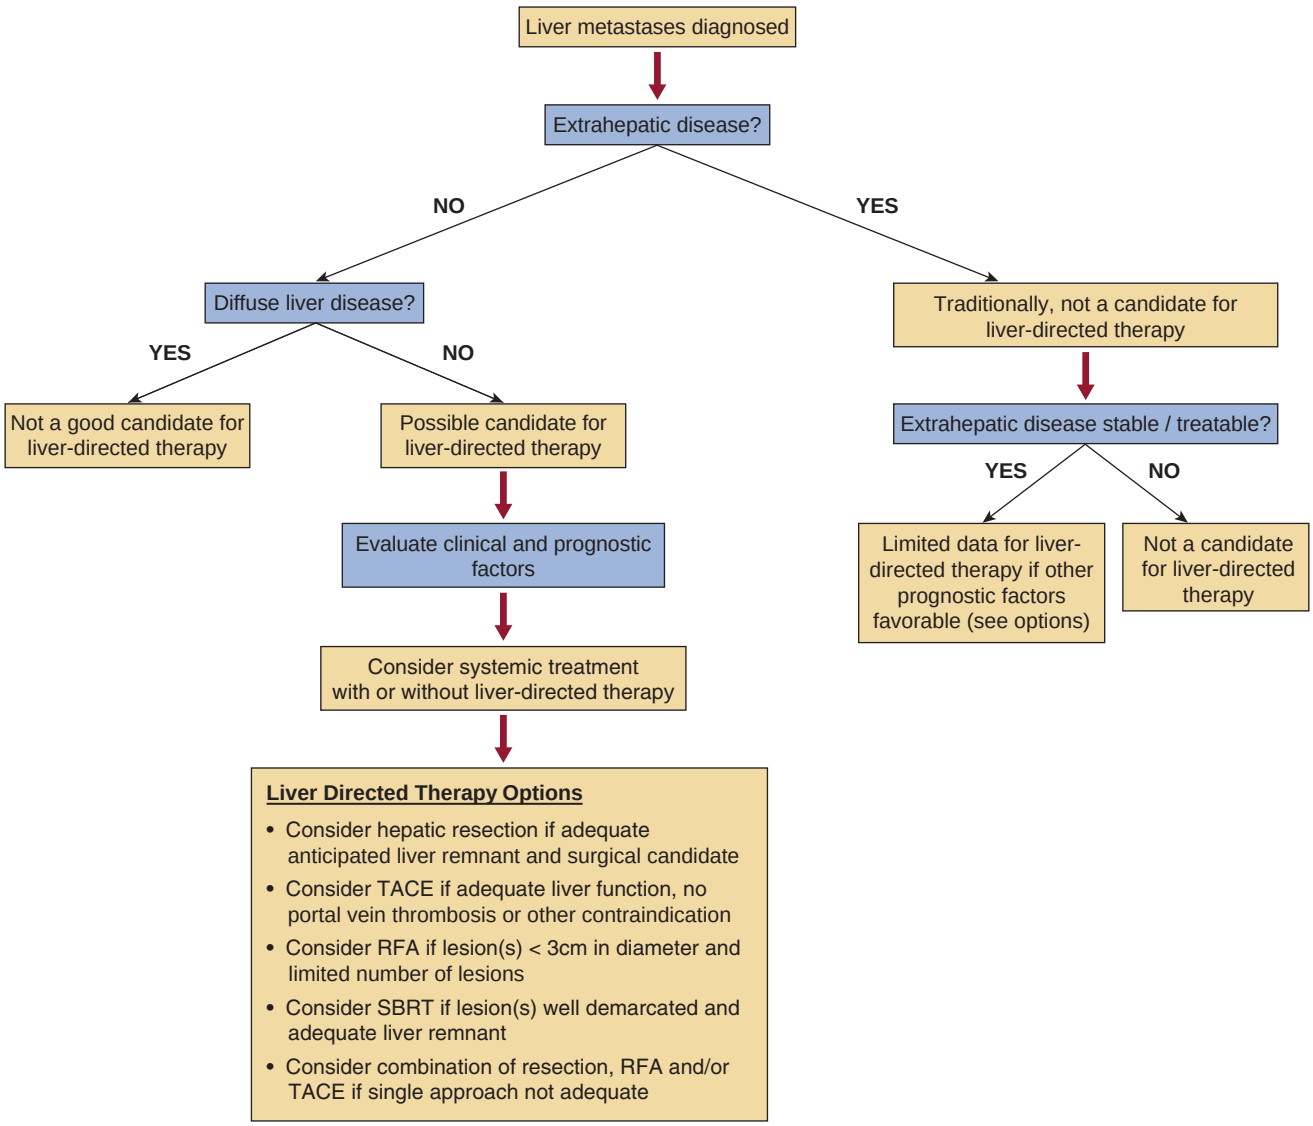

FIGURE 81-1 **Liver-directed treatment options for breast cancer metastatic to the liver.** The decision to proceed with a liver-directed approach for the treatment of breast cancer metastatic to the liver must be made after carefully balancing the risks and benefits of all options. Given the biology of the disease and the paucity of clinical trial data about liver-directed options, the authors believe that a bias toward systemic therapy is an appropriate starting point. In addition, the proposed algorithm should be individualized for each patient and modified as needed to take advantage of local expertise in specific treatment modalities. RFA, radiofrequency ablation; SBRT, stereotactic body radiotherapy; TACE, transarterial chemoembolization.

CHAPTER 82

Medical Treatment for Bone Metastases

Stephen V. Liu and Christy A. Russell

CHAPTER CONTENTS

MEDICAL TREATMENT FOR BONE METASTASES

Skeletal metastases are a common event in breast cancer, responsible for profound patient morbidity and representing a significant public health burden. While the precise epidemiology of bone metastases in breast cancer is elusive, they affect over 7% of all women diagnosed with breast cancer in the United States (1). Bone is the *initial* site of metastasis for 47% of women with relapsed breast cancer (2) and the *only* site for 20% of women with metastases (3). The incidence may vary by subtype: among patients whose initial metastasis is to the bone, 82% will express either estrogen receptor (ER) or progesterone receptor (PR). Nonetheless, these events are common in all subtypes, noted in 69% of women who die from breast cancer (2). Importantly, the development of bone metastases is not a fatal event. Patients with skeletal metastases can have a prolonged survival, particularly when compared to patients with visceral involvement. One study reported a median survival of 24 months for patients with only skeletal metastases compared to 3 months for patients with liver metastases. As our treatment for advanced breast cancer evolves, we are likely to see further improvements in survival, increasing the chances for patients to develop bone metastases during their lifetimes. Because of the high incidence of bone metastases and the potential for extended survival, the cumulative morbidity of skeletal involvement in breast cancer is high and the potential for impaired mobility and loss of independence highlights their clinical relevance.

The morbidity from bone metastases has been difficult to objectively quantify. While helpful, the use of pain scores and analgesic logs is subject to various potential biases. As a result, the impact of bone metastases is often quantified by the incidence of skeletal-related events (SRE). SRE definitions vary by study but operationally represent a composite of pathologic fractures, spinal cord compression with vertebral compression fracture, hypercalcemia of malignancy, requirement for radiation to bone, and necessity for surgical intervention for pathologic fractures or cord compression (4). Unfortunately, SRE are common in breast cancer. In the absence of bone-targeted therapy, the rate of pathologic fracture for patients with bone metastases from breast cancer is 35% (5) and up to 70% of patients with bone metastases will have at least one SRE by 2 years (6). SRE are associated with decreased survival in breast cancer. Patients with a pathologic fracture have a 32% increased risk of death compared to those without a fracture (7). The clinical significance of SRE, however, extends far beyond survival. SRE have been associated with significant declines in physical and functional well-being as well as overall quality of life (8). The resulting economic impact of bone metastases in breast cancer is staggering, with an estimated national cost burden of nearly $4.5 billion annually (1).

Insight into the pathophysiology of bone metastasis has facilitated recent therapeutic advances. The tropism of breast cancer cells to bone has yet to be fully explained. Transcriptome analyses of breast cancer cells predisposed to metastasize to the bone have revealed a gene expression profile that mimics osteoblasts in a process called *osteomimetism*. These changes may facilitate survival of these cells in the bone microenvironment (9). Under normal physiologic conditions, osteoclast differentiation is directed by osteoblasts via signaling in the receptor activator of NF-κB (RANK) ligand pathway (10). The interactions between these molecules results in normal bone remodeling: a balance between bone formation and resorption. In the setting of bone metastases, normal homeostasis is disrupted. Osteoclast activation is felt to be an early event in the development of bone metastases in breast cancer, often associated with lytic bone lesions. Dysfunction of osteoblasts has been implicated in blastic bone metastases and is relevant in breast cancer, where mixed lesions are frequently encountered.

This dysfunction may be mediated by the RANK ligand pathway, an emerging target in the treatment of bone metastases. An increase in bone resorption can compromise the integrity of the affected bone, leaving it vulnerable to the development of SRE. This process can be mediated by several factors. One contributing factor is an increase in osteoclast precursors in the presence of tumor cells, a shift potentially mediated by tumor necrosis factor α (11). Another mechanism is activation of osteoclasts by breast cancer cells, which can upregulate RANK ligand and inhibit osteoprotegerin, which normally inhibits excessive osteoclast activation. Once activated, bone resorption can elicit a chemotactic response from tumor cells, cyclically propagating the process (12). Agents targeting this pathway, however, have provided inroads in stopping this cycle and preventing some of the morbidity associated with skeletal metastases.

Bisphosphonates are a class of medications commonly used in patients with bone metastases from breast cancer. Early-generation bisphosphonates such as clodronate do not contain nitrogen. These agents are metabolized to adenosine triphosphate (ATP) analogues that cannot be hydrolyzed, interrupting multiple cellular processes including bone remodeling (13). Nitrogen-containing bisphosphonates, including pamidronate, ibandronate, and zoledronic acid, accumulate in the bone microenvironment and are released during bone resorption. They are then internalized by osteoclasts where they affect their activity and survival. One target for nitrogen-containing bisphosphonates is farnesylpyrophosphate synthase (FPPS), an enzyme in the mevalonate pathway that is responsible for the prenylation of small guanosine triphosphatases (GTPases), which are critical for osteoclast survival (14). This indirect effect of nitrogen-containing bisphosphonates is augmented by a direct effect related to production of triphosphoricacid 1-adenosin-50-yl ester 3-(3-methylbut-3-enyl) ester (ApppI), an ATP analogue that induces osteoclast apoptosis (15). The effect of bisphosphonates may extend beyond the osteoclast. Preclinical studies have shown that zoledronic acid inhibits angiogenesis in several *in vitro* and *in vivo* models (16). In patients receiving zoledronic acid, there is an early and sustained reduction in circulating levels of vascular endothelial growth factor (VEGF), a cytokine involved in angiogenesis (17). Zoledronic acid also modulates migration and adhesion of endothelial cells by targeting integrins and sensitizing cells to tumor necrosis factor (TNF)–induced programmed cell death (18). In addition, nitrogen-containing bisphosphonates prevent adhesion of cancer cells to bone, which may interfere with tumor seeding and invasion (13). Nitrogen-containing bisphosphonates may also induce cell death by activating cytotoxic T-cells in the host, though the clinical role of this effect awaits further clarification (19).

Agents targeting the RANK ligand pathway have also demonstrated activity, primarily through inhibition of osteoclast function to suppress bone resorption (20). Denosumab is a humanized monoclonal antibody targeting RANK ligand that has recently garnered FDA approval in this setting (21). Similar to zoledronic acid, the activity of denosumab is mediated by several mechanisms, including a potentially similar antiangiogenic effect (22). Multiple randomized studies have shown a decrease in SRE with the use of bisphosphonates and denosumab, which are outlined next.

First-Generation Bisphosphonates

The initial use of bisphosphonates to alter bone metabolism extends back to the 1970s when etidronate, a first-generation bisphosphonate, was used in the treatment of Paget's disease of the bone (23). Subsequently, reports were published showing the benefit of etidronate in the treatment of both osteoporosis and hypercalcemia of malignancy (HCM). Another first-generation bisphosphonate, clodronate, was evaluated in small phase II studies followed by a randomized, double-blind, placebo-controlled trial comparing daily oral clodronate 1600 mg/day to placebo in patients with metastatic breast cancer with bone involvement (24). This study demonstrated a significant reduction in the development of HCM and vertebral fractures in patients receiving clodronate as well as a 33% reduction in all skeletal events. As a result of these trials, clodronate is approved outside of the United States for women with metastatic breast cancer and bone involvement. Despite this approval, the first-generation bisphosphonates are not optimal for long-term use. Etidronate adequately inhibits bone resorption, but also inhibits bone mineralization. Clodronate is poorly absorbed in the gastrointestinal tract and can cause local irritant toxicity, reducing the likelihood of long-term adherence.

Second-Generation Bisphosphonates

Further drug development led to the design of aminobisphosphonates, which are potent inhibitors of osteoclastic activity that do not alter bone mineralization. Examples of drugs in this class are pamidronate and alendronate. In light of the initial encouraging results of clodronate, multiple clinical trials were initiated with pamidronate for women with breast cancer metastatic to bone. Initial small studies sought to optimize the dose and schedule of intravenous pamidronate and had various endpoints including amelioration of bone pain and sclerosing of lytic bone metastases. Subsequently, two large placebo-controlled, randomized clinical trials (Aredia Protocols 18 and 19) were initiated in the early 1990s (25). Both of the trials' eligibility criteria included metastatic breast cancer and at least one predominantly lytic bone metastasis measuring ≥ 1 cm in its greatest dimension. Women enrolled in Protocol 18 received a stable endocrine regimen for their metastatic cancer, and those on Protocol 19 received cytotoxic chemotherapy. Patients were randomly assigned to receive either pamidronate 90 mg intravenously over 2 hours or an intravenous placebo, given every 3 to 4 weeks for 24 cycles. Patients were serially evaluated for any evidence of an SRE, defined here as pathologic fracture, spinal cord compression, or hypercalcemia. The primary efficacy endpoint was the skeletal morbidity rate, expressed as the number of events per year. Although the two trials were independently performed, their common time frame and eligibility criteria allowed the investigators to combine their efficacy data.

In this trial, 367 women were randomized to pamidronate and 384 women were assigned to placebo. The addition of pamidronate to systemic therapy for advanced breast cancer resulted in a significant improvement in multiple parameters. The skeletal morbidity rate was 2.4 events per year in the pamidronate group versus 3.7 in the placebo group ($p < .001$). Overall, skeletal events were seen in 51% and 64% of these same groups, respectively ($p < .001$). The median time to first skeletal event was 12.7 months with pamidronate and 7 months with placebo ($p < .001$), and the time to first fracture was 25.2 months and 12.8 months for these groups, respectively ($p < .003$). Although this was designed as a 24-month trial, only 31.3% of the pamidronate patients and 25.8% of the placebo patients completed 24 months of treatment. Despite the compelling skeletal benefits seen with pamidronate, there was no survival difference between the two arms. As a result of these and the previous smaller trials, the FDA-approved pamidronate for the treatment of women with bone metastases in July 1996.

Third-Generation Bisphosphonates

Following the development of pamidronate, more potent third-generation bisphosphonates entered testing. The potential benefits of increasing potency are to shorten the intravenous infusion times and allow for oral formulations with greater efficacy. Three of these potent heterocyclic, nitrogen-containing bisphosphonates began to enter clinical study: risedronate, ibandronate, and zoledronic acid (or zoledronate). Zoledronate is reported to be the most potent of these third-generation bisphosphonates with respect to bone resorption without affecting bone mineralization.

Ibandronate, in both the intravenous and oral form, has been compared to placebo in the setting of bone metastases. Ibandronate 50 mg orally when compared to placebo (26) significantly reduced the risk of an SRE in 564 randomized patients ($p < .001$). In a second trial of similar patients, ibandronate either 2 or 6 mg intravenously was compared to placebo (27). The 2-mg dose was ineffective, but the 6 mg dose significantly reduced the skeletal morbidity rate ($p < .03$). However, ibandronate is not currently approved in the United States for the ancillary treatment of skeletal metastases.

A large international, multicenter, randomized, double-blind clinical trial was performed comparing pamidronate with zoledronate in patients with bone metastases from not only breast cancer but also multiple myeloma (4). Patients participated as one of three strata: patients with multiple myeloma; patients with breast cancer receiving chemotherapy; and patients with breast cancer receiving hormonal therapy. Patients were randomized to receive pamidronate 90 mg over 2 hours in 250 mL of 0.9% sodium chloride or zoledronic acid either 4 mg or 8 mg administered in 50 mL of hydration over 5 minutes. Because of the observation of creatinine elevation in the zoledronic acid arms, two protocol adjustments were made during the conduct of the trial: the infusion duration was increased from 5 to 15 minutes with the volume of hydration increased to 100 mL; and the 8 mg zoledronic acid dose was reduced to 4 mg. Although the original trial was designed as a 13-month efficacy and safety trial, a 25-month extension phase was subsequently performed and reported. The primary efficacy endpoint of the trial was the percentage of patients in each treatment group who experienced at least one SRE during the 25-month study period. For this study, SRE were defined as pathologic fracture, spinal cord compression, radiation therapy to the bone, or surgery to the bone. Other endpoints included time to first SRE, skeletal morbidity rate, multiple event analysis, and overall survival.

This landmark trial included 1,130 women with metastatic breast cancer and 412 of these women entered the extension study. The proportion of patients who experienced at least 1 SRE in the 4 mg zoledronate and the pamidronate groups were similar (46% vs. 49%, respectively). The skeletal morbidity rate was reduced a nonsignificant 40% from 0.9 to 1.49 events per year, respectively, for the same two groups ($p = .125$). A multiple event analysis which measured the first and all subsequent SRE was found to be statistically superior for those receiving 4 mg of zoledronate versus pamidronate with a risk ratio = 0.799 ($p = .025$). Adverse events that were reported as drug-related were infections, arthralgias and myalgias, cytopenias, fever, eye disorders, electrolyte abnormalities, and injection site reactions and were similar among the initial three groups. With regard to renal toxicity, clear differences among the groups were seen prior to protocol amendments that increased the zoledronate infusion time from 5 to 15 minutes and increased the infusion volume. After this change, the reported increase in serum creatinine rate was seen in 10.7% of the 4 mg zoledronate patients and 9.3% of the pamidronate group. Based on the efficacy and safety results from both this trial and other trials comparing zoledronate to placebo, in February 2002 the FDA approved the use of zoledronic acid for patients with bone metastases not only from breast cancer but also from a wide variety of solid tumors. As a result of this approval, patients with breast cancer and bone metastases were routinely placed on either pamidronate or zoledronate delivered every 3 or 4 weeks for a minimum of 1 year accompanied by systemic therapy for the cancer.

Despite the emergence of intravenous bisphosphonates as a standard of care for the reduction of SRE, the dilemma continued as to whether the potency of oral ibandronate was adequate to match the efficacy of zoledronate. Barrett-Lee et al. recently presented preliminary data from a large phase III randomized trial comparing oral ibandronate to intravenous (IV) zoledronate in the treatment of breast cancer patients with bone metastases (28). Between 2006 and 2010, 1,405 newly diagnosed metastatic breast cancer patients with bone metastases were randomized to IV zoledronate (4 mg every 3 to 4 weeks) or oral ibandronate (50 mg/day) for up to 96 weeks. The primary statistical endpoint was noninferiority of oral ibandronate compared to zoledronic acid for the endpoint of the SRE rate (number of SRE/year). Secondary endpoints included time to first SRE, proportion of patients with SRE, pain scores, side-effect profiles, and survival. With a median follow-up of 18.4 months, ibandronate failed to meet the criteria for noninferiority to zoledronate for the primary statistical endpoint of SRE rate, but was similar in time to first SRE and survival. Renal adverse events were stated to be more frequent in the zoledronic acid group, although the specific incidence and severity were not presented. ONJ rate was low in both arms with no statistical difference. Although ibandronate is not approved in the United States for treatment of bone metastases, it is widely used in the United Kingdom and Europe for this indication. This is the first randomized trial comparing oral ibandronate with any other bisphosphonate therapy and will serve to educate both physicians and their patients regarding the optimal option for systemic therapy for bone metastases from breast cancer.

RANK-Ligand Inhibitors

Despite the significant reduction in SRE with intravenous bisphosphonates, not all bone morbidity is prevented. In addition, intravenous bisphosphonates carry the risk of inducing renal insufficiency as well as acute toxicities such as bone pain and fever. With the recognition that RANK-ligand is a mediator of osteoclast differentiation and survival, RANK-ligand inhibitors were thought to have potential in the treatment of bone metastases. Denosumab is a fully humanized monoclonal antibody that binds to and neutralizes RANK-ligand, thereby inhibiting osteoclast maturation and function.

Initially, Lipton et al. reported on a phase II randomized trial assessing the efficacy and safety of five different dose regimens of denosumab in 255 women with breast cancer and bone metastases that had not been previously treated with an IV bisphosphonate, and compared the efficacy to those treated with a bisphosphonate (29). The primary endpoint of the trial was the median percentage change in urinary N-telopeptide/creatinine ratio (uNTX/Cr) from baseline to week 13. It has been shown that the bone turnover marker uNTX/Cr is elevated in women with bone metastases from breast cancer. Elevated levels of uNTX/Cr are associated with an increased risk of skeletal complications. Presumably, a drug that more efficiently reduces these levels will be more effective in preventing skeletal-related

events. Patients were randomly assigned to receive denosumab subcutaneously every 4 weeks at a dose of 30, 120, or 180 mg; or denosumab every 12 weeks at a dose of 60 or 180 mg; or an open-label intravenous bisphosphonate every 4 weeks. Patients received 24 weeks of treatment and had a subsequent 32 weeks of follow-up. The study showed that the suppression of uNTX/Cr was greater with denosumab than intravenous bisphosphonates, though the degree of suppression was similar between all of the tested doses of denosumab. Based on data from this trial and pharmacokinetic and pharmacodynamic modeling, denosumab at a dose of 120 mg every 4 weeks was felt to be optimal.

Subsequently, a large phase III randomized, double-blind, double-dummy clinical trial was performed comparing denosumab 120 mg subcutaneously to zoledronic acid 4 mg intravenously every 4 weeks (21). Throughout the study, the dose of zoledronate was modified based on the creatinine. The primary statistical endpoint was the time to the first on-study SRE (noninferiority endpoint). Secondary endpoints included the time to the first on-study SRE (superiority endpoint), and the time to the first and subsequent on-study SRE (multiple event analysis).

Between April 2006 and December 2007, 2,049 patients with metastatic breast cancer and bone metastases were randomized. The trial revealed that denosumab significantly delayed the time to first on-study SRE by 18% when compared to zoledronic acid ($p < .001$ noninferiority; $p = .01$ superiority). The median time to the first SRE was 26.4 months for the zoledronic acid group, and had not been reached in the denosumab group. Denosumab also reduced the risk of developing multiple SRE by 23% and was associated with a lower mean skeletal morbidity rate of 0.45 events per patient per year versus 0.58 events with zoledronic acid. There were differences between the two groups in various adverse events. Acute-phase reactions and renal toxicity were more common in the zoledronic acid group and hypocalcemia was more common in the denosumab group. Although osteonecrosis of the jaw (ONJ) was numerically more common in the denosumab versus zoledronate group (2.0% vs. 1.4%), this was not statistically significant. As a result of these efficacy and safety data, in November 2010 the FDA gave approval to denosumab with the indication of treating bone metastases in patients with solid tumors, including breast cancer.

A tabulation of the larger phase III clinical trials as discussed above is summarized in Table 82-1. Although the trials had similar endpoints, no comparison should be made between the trials because of differing entry criteria and clinical factors for the women participating in the trial.

ASCO GUIDELINES

In 2011, the American Society of Clinical Oncology (ASCO) published a clinical practice guideline update on the role of bone-modifying agents (BMA) in metastatic breast cancer (30). The guidelines were based on a literature search using MEDLINE and the Cochrane Collaboration Library and evaluating studies published between 2003 and 2010. The primary outcomes evaluated were SRE and time to SRE. Secondary outcomes were adverse events and pain. The guideline group addressed seven specific clinical questions as follows:

1. Indications and timing for using BMA to reduce the risk of SRE
2. The role of BMA as treatment for extraskeletal metastases
3. The renal and ONJ safety concerns of BMA
4. The optimal duration of therapy
5. The best intervals between dosing
6. The role of BMA in controlling pain from bone metastases
7. The role of biochemical markers of bone turnover

The following are the guideline recommendations based on these questions:

1. BMA are recommended for patients with metastatic breast cancer with evidence of bone destruction. Choices for therapy are as follows: subcutaneous denosumab 120 mg every 4 weeks; IV pamidronate 90 mg over no less than 2 hours every 3 to 4 weeks; or IV zoledronic acid 4 mg over no less than 15 minutes every 3 to 4 weeks.
2. One BMA is not recommended over another.
3. If using a bisphosphonate, recommendations were made regarding dose adjustments for renal function and monitoring of the creatinine.
4. If using denosumab, no adjustments are needed for renal function, but for patients with poor renal function, close monitoring for hypocalcemia is recommended.
5. Patients should have a dental examination and routine preventative dentistry before initiating a BMA.
6. Biochemical markers to monitor BMA use are not recommended for routine care.

TABLE 82-1

Summary of Highlighted Phase III Randomized Trials

Phase III Trial	*Treatment*	*Patients*	*% with SRE*	*Skeletal Morbidity Rate (SRE/year)*	*Time to SRE (months)*	*Multiple Events Analysis (time to first and subsequent SRE)*
Lipton et al. (32)	Placebo	384	64%	3.7	7.0	NR
	Pamidronate	367	51%	2.4	12.7	
Rosen et al. (35)	Pamidronate	555	49%	1.49	NR	RR 0.799 ($p = .025$)
	Zoledronate	561	46%	0.9	NR	
Barrett-Lee et al. (36)	Ibandronate	699	67%	0.543	HR 0.11	NR
	Zoledronate	705	56%	0.444		
Stopeck et al. (38)	Zoledronate	1020	NR	0.58	26.4	RR 0.77 ($p = –.01$)
	Denosumab	1026	NR	0.45	Not reached	

NR, not reported.

SPECIAL CONSIDERATIONS

Duration of BMA Therapy

Women with metastatic breast cancer continue to see extension of their survival as a result of improvements in available systemic and supportive therapies. The majority of clinical trials evaluating the efficacy of BMA have durations of therapy ranging from 1 to 2 years. However, with improved survival of women with metastatic disease, especially those with only skeletal metastases, the optimal duration and schedule of the BMA has become a clinical challenge. Amodori et al. have presented the initial results of phase III prospective, randomized, open-label study (ZOOM) to assess the safety and efficacy of zoledronic acid given quarterly (4 mg every 12 weeks) versus monthly (4 mg every 4 weeks) in women who had received approximately 1 year of prior zoledronic acid for bone metastases (31). Between 2006 and 2010, 425 women were randomly assigned to one of these arms. The primary statistical endpoint for this noninferiority study was skeletal morbidity rate (SMR; skeletal events/year). Secondary endpoints included time to first SRE, bone pain, and bone marker (NTX) levels. The mean SMR was 0.26 in the quarterly arm and 0.22 in the monthly arm, indicating the efficacy of the quarterly arm was not inferior to the monthly arm. Adverse events were similar between the two arms with both renal insufficiency and ONJ infrequently reported. The authors pointed out study design limitations, such as an open-label design and different clinic visit frequencies between the arms, among others. Reference was made to an ongoing study (OPTIMIZE-2), which has a similar design and may be able to verify the results of the ZOOM trial. OPTIMIZE-2 is a phase III randomized, double-blind multicenter trial that has completed accrual comparing monthly versus every three monthly zoledronic acid for patients with metastatic breast cancer that were treated with between 9 and 12 doses of zoledronic acid over the prior year (Trial Identifier NCT00320710). No data have been reported from this trial.

Regardless of the schedule used after the first year, there are even less data studying duration of therapy. In this setting of inadequate data, several international breast cancer guideline groups have commented upon the use of BMA therapy beyond 2 years. The NCCN (32) has stated the following: "Current clinical trial results support the use of bisphosphonates for up to 2 years. Longer durations of bisphosphonate therapy may provide additional benefit, but this has not yet been tested in clinical trials. The optimal duration of treatment with denosumab is not known." The 2011 ASCO Clinical Practice Guidelines (30) suggest that with regard to duration of BMA use, the guidelines panel suggests that "once initiated, bone-modifying agents be continued until evidence of substantial decline in a patient's general performance status. The Panel stresses that clinical judgment must guide what constitutes a substantial decline." Although clinicians may decide to continue BMA beyond 2 years, it should be done while recognizing the lack of long-term adverse event data with respect to the risk of ONJ, the newly emerging atypical femur fractures, or chronic renal dysfunction.

Osteonecrosis of the Jaw (ONJ)

With the approval of pamidronate in 1996 and zoledronic acid in 2002, thousands of patients with either multiple myeloma or metastatic breast cancer were exposed to prolonged infusions of these agents. In 2003, a letter to the *Journal of Oral and Maxillofacial Surgery* was published describing what is now known as ONJ in 36 patients receiving either pamidronate or zoledronic acid (33). The majority of these cases were associated with tooth extraction, but some were spontaneous. This led to multiple case studies of ONJ in the literature. Clinical descriptions of ONJ were proposed and published by multiple societies including the American Academy of Oral and Maxillofacial Surgeons (AAOMS), the American Dental Association, and many others (34). The AAOMS has defined BMA-related ONJ as an area of exposed bone in the jaw persisting for over 8 weeks in patients without prior craniofacial radiation to the jaw. The pathogenesis of ONJ continues to be inadequately defined, and although the use of osteoclast inhibitors appear to increase the risk, the contributions of other factors such as the histology and location of the bone metastases, the use of concurrent chemotherapy and/or steroids, and underlying dental pathology are inadequately defined. Dental risk factors of ONJ have been described to include surgical procedures involving the jaw, ill-fitting dentures, periodontal disease, and dental abscesses. Preventative recommendations that have been published include a thorough dental examination and completion of dental procedures including extractions prior to the initiation of intravenous bisphosphonates or denosumab. Patients on BMA should be encouraged to maintain excellent oral hygiene and to continue regular dental visits as well. There are multiple specialty society recommendations regarding the treatment of documented ONJ, but most recommend consultation with an oral maxillofacial surgeon or dental oncologist with experience in managing patients with ONJ.

To better define the incidence, risk factors, and outcomes of ONJ, Saad et al. evaluated these endpoints in a combined analysis of three phase III trials in patients with metastatic cancer to the bone receiving either denosumab 120 mg subcutaneously or zoledronic acid 4 mg every 4 weeks (35). These three trials required on-study oral examinations at entry on the trial and every 6 months thereafter. An independent blinded committee of dental experts adjudicated all suspected episodes of ONJ. Of the 5,723 patients studied in the three trials, 276 were thought to potentially have ONJ, and 89 (1.6%) of the patients were subsequently adjudicated. Notably, 5447 patients had no reported oral events. The incidence rate of ONJ for the patients receiving zoledronic acid was 1.3% and for denosumab was 1.8% ($p = .13$). The median time from BMA initiation to ONJ was 14 months (range 4 to 30 months) with no differences between the two groups. Reported associated oral events included jaw pain in 80%, an associated tooth extraction in 61%, and a local infection in 48% of patients. The location of ONJ was limited to the mandible in 73%, maxilla in 22%, and both in 4% of patients. The authors conclude that with the current use of BMA, ONJ is an infrequent event and will not differ significantly between zoledronate and denosumab. Because investigators were actively surveilling patients for any dental events and educating their patients on appropriate preventative dentistry, a low incidence of ONJ may be anticipated for patients with bone metastases when following these simple standards.

Hypocalcemia

Although both pamidronate and zoledronate are approved for the treatment of hypercalcemia of malignancy, their use in patients who are normocalcemic may carry the potential risk of inducing hypocalcemia. In light of this risk, pamidronate and zoledronate therapeutic clinical trials required that patients be given both oral calcium and vitamin D supplements. Although it is likely that adherence to these supplements was not optimal, the incidence of hypocalcemia was infrequently reported. As more potent suppressors of

osteoclastic activity become available, the risk for clinically relevant hypocalcemia can increase. In the phase III trial comparing zoledronic acid with denosumab, oral calcium and vitamin D supplementation were required. Despite this, 3.4% of the patients receiving zoledronic acid and 5.5% of those on denosumab experienced hypocalcemia. Body et al. have recently summarized the incidence of hypocalcemia in the three pivotal phase III trials comparing denosumab with zoledronic acid in patients with bone metastases from multiple primary malignancies, including breast cancer (36). Of the 2836 patients who received zoledronic acid, 5.0% experienced hypocalcemia compared to 9.6% of the 2,841 patients who received denosumab. Grade 3 and 4 hypocalcemia were seen in 1.4% and 3.1% of patients, respectively, and 1.7% and 3.7% of patients required intravenous calcium. The incidence of hypocalcemia was twice as common in patients who reported taking no supplements. For those receiving denosumab, the risk of hypocalcemia was most common in the first 6 months, with the median time to hypocalcemia reported as 2.8 months. This comprehensive evaluation of hypocalcemia in a large number of patients confirms that hypocalcemia can be an expected adverse event of BMA. Calcium and vitamin D levels should be corrected prior to initiation of these therapies and the risks are highest in patients receiving denosumab.

FUTURE DIRECTIONS

Given the clinical relevance and ongoing morbidity of bone metastases in breast cancer, the optimal treatment strategy continues to evolve. The optimal agent and duration of therapy remains unclear, as discussed previously. The frequency of administration is also being debated. One study compared the standard treatment schedule of zoledronic acid to a marker-directed schedule based on uNTX levels, though the study was underpowered due to slow recruitment (37). Several novel classes of BMA are being developed that exploit distinct targets of bone metabolism. One molecule recently implicated in osteoclast function is Src. In preclinical models, an orally bioavailable Src-inhibitor, saracatinib, prevents bone resorption and migration of human osteoclast precursors (38). In early clinical studies, saracatinib significantly decreases uNTX/Cr levels, prompting ongoing studies examining its role in the adjunctive treatment of bone metastases from breast cancer (39). Dasatinib is a small molecule that inhibits several tyrosine kinases, including Src. This has led to a trial of dasatinib with zoledronic acid in patients with breast cancer metastatic to bone (Trial Identifier NCT00566618). Inhibition of mTOR (mammalian target of rapamycin) can also decrease osteoclast activity (40). This serves as the rationale for a phase II study (Trial Identifier NCT00466102) of the mTOR inhibitor everolimus in women with breast cancer and skeletal-only metastases. In addition, some investigators are exploring strategies to prevent bone metastases in women with breast cancer. As the mevalonic acid pathway is strongly implicated in bone metabolism, inhibitors of this pathway, such as statins, may alter the bone microenvironment in a way that prevents bone metastases. A retrospective study of 841 patients showed that statin use in women with breast cancer was associated with decreased rates of metastases specifically to bone but not to other distant sites, though prospective data are lacking (41).

Recently, there have been many powerful advances in the management of bone metastases in breast cancer. The unmet need for new treatment strategies has long been recognized given the clinical complications associated with skeletal metastases. A greater understanding of the physiology of bone metabolism has led to exciting discoveries. In the past decade alone, two agents, zoledronic acid and denosumab, have been approved in the United States for the adjunctive treatment of skeletal metastases in breast cancer patients and many other agents are undergoing preclinical and clinical evaluation. Much remains unclear but as we gain greater insight into the complex interactions between breast cancer and the bone microenvironment, our efforts to prevent the morbidity of bone metastases will be met with greater success.

MANAGEMENT SUMMARY

- Patients with bone metastases from breast cancer should be offered therapy with a bone-modifying agent in the absence of contraindications.
- BMA should be used as an adjunct to systemic therapy for the underlying malignancy.
- Appropriate bone-modifying agents include subcutaneous denosumab, IV pamidronate, and IV zoledronic acid.
- For patients receiving a bisphosphonate, creatinine clearance must be monitored and dose adjustments should be made as necessary.
- The use of calcium and vitamin D supplements should be explored in patients receiving bone-modifying agents, particularly with denosumab use.
- Routine dental care should be performed prior to initiation of a bone-modifying agent.
- Continuation of the bone-modifying agent for up to 2 years is certainly acceptable, although the optimal duration of therapy remains unclear.

CHAPTER 83

Local Management of Bone Metastases

J. Sybil Biermann, Albert J. Aboulafia, and James A. Hayman

CHAPTER CONTENTS

Historically, published information and clinical trials relating to the skeletal complications of malignancy combined data that included a variety of different primary sites. Many of the diagnostic and treatment strategies that were recommended for patients with metastatic bone disease as a whole are not applicable today for the unique group of patients with metastases secondary to breast cancer. It is only recently, and not widely, appreciated that skeletal metastases that result from breast primary differ dramatically from the other primary sites with respect to clinical presentation, prognosis, and treatment. Additionally, the introduction of bisphosphonates and more recently denosumab has dramatically changed the treatment strategy for patients with metastatic breast cancer to the skeleton, rendering much of the prior literature less useful. Only a few have published articles relating to the treatment of skeletal metastases focused on the cohort of patients with primary breast cancer rather than combining data with patients with skeletal metastases from any primary site. Table 83-1 presents web site resources for patients.

Although there has been an increasing appreciation for the differences in treatment among patients with metastatic bone disease from breast and other primary sites, the goals of treatment remain the same. They include relief of pain, restoration or maintenance of function, and avoiding hypercalcemia, metabolic derangements, bone marrow invasion, spinal cord compression, and pathological fracture.

More widespread use of sensitive imaging techniques such as magnetic resonance imaging (MRI) and positron emission tomography (PET) has created the ability to detect bone metastases at an earlier stage, often identifying asymptomatic disease. Although in general the number of patients coming to surgery for skeletal stabilization has decreased, carefully selected patients will reap major benefits from surgical intervention in terms of pain control and function.

INCIDENCE

It is estimated that there were 1.66 million new cases of cancer diagnosed in the United States in 2013. Half of those cancers will include breast, kidney, lung, thyroid, and prostate, which have a proclivity for skeletal metastases. This number far exceeds the estimated number of primary sarcomas of bone (3,010 per year), with many occurring in patients under the age of 40 years. Breast cancer is the most common cancer and the second leading cause of cancer-related morbidity among women in North America and Western Europe. In those patients who develop metastases, the skeleton is the most frequently involved site. Radiographic studies have demonstrated skeletal metastases in 70% to 80%, and autopsy studies as high as 85%, of patients who die of their disease. The most common sites of skeletal involvement include the spine and long bones (i.e., femur and humerus) (1). In part, due to the long survival of patients with breast cancer, bone metastases are common, and their potential impact on quality of life, morbidity, and mortality is significant. Certainly not all skeletal metastases will require treatment. Although the spine is the most common site of metastases from breast to bone, it is estimated that only one-third of spinal metastases will become symptomatic during the course of the patients' life. The treatment of a given skeletal lesion depends on a variety of factors including the clinical presentation. In a group of 115 cases of orthopaedic surgical management of breast cancer to bone, patients with solitary bone metastasis had a median 65-month survival, while those with visceral disease also had a median survival of 13 months (2).

CLINICAL PRESENTATION

The clinical presentation of a patient with skeletal metastases will depend on a variety of factors. For the majority of patients with metastatic breast cancer, the primary is known before skeletal metastases become symptomatic. The clinical presentation of a patient with skeletal metastases from breast cancer may be initiated due to the onset of a symptomatic bone lesion (i.e., pain, radiculopathy, or pathological fracture) or the result of an imaging study that was performed as part of a staging evaluation (at the time of initial diagnosis or routine follow-up), or less commonly for unrelated reasons. The diagnostic workup and treatment for these conditions will depend greatly on whether the scenario takes place in the setting of a known history of breast cancer or not and whether the bone lesion is solitary or not. It is fundamentally important that in evaluating a patient with a destructive lesion of bone, a logical, thorough, and meticulous algorithm be followed in order to avoid major errors in diagnosis and treatment and minimize potential complications (3).

The majority of patients presenting with bone metastases report pain as an initial symptom, although there may be asymptomatic identification if the patient has a subsequent bone scan. In evaluating the treatment choices for patients with long bone (humerus, femur, tibia) metastasis it is particularly important to identify whether the pain is associated with weight bearing and relieved by rest, as this is one prognostic indicator of the likelihood of pathologic fracture (4). Careful assessment of the patient's analgesic use relative to pain reporting is important, as large doses of narcotics may obfuscate the severity of the symptoms and lead to undertreatment locally.

The various clinical presentations that a patient with suspected metastatic breast cancer to bone may present include the following:

1. New onset of skeletal pain *with* a known history of breast cancer (symptomatic)
2. New onset of skeletal pain *without* a known history of breast cancer (symptomatic)
3. Discovery of an asymptomatic lesion in a patient *with* a known history of breast cancer (as part of routine staging or follow-up or less likely an incidental finding)
4. Discovery of an asymptomatic lesion in a patient *without* a known history of breast (cancer as part of routine staging or follow-up or less likely an incidental finding)

DIAGNOSIS AND IMAGING OF BONE METASTASIS

Diagnostic Evaluation

Although it is true that for any patient over age 40 with a destructive bone lesion the most likely diagnosis is metastatic tumor or myeloma, the presumptive diagnosis of metastatic disease is strengthened if the patient has a history of breast cancer. However, all too often the assumption is made that a bone lesion is metastatic in a patient with a history of breast cancer and the assumption proves to be wrong. Conversely, a patient with a very remote history of breast cancer (20 years or more) and bone pain is not suspected of having potential metastases due to the lack of appreciation of the potential delayed presentation of skeletal metastases in breast cancer. As with any patient with a potentially malignant bone lesion, the patient with breast cancer requires a logical and systematic approach to evaluation in order to optimize outcomes, avoid unnecessary procedures and expenses, and expedite medical and emotional support.

The first step in evaluating a patient with a skeletal lesion requires a careful history and physical examination. The history should include the presence or absence of prior cancer diagnosis, the stage of disease, the histology, and accounting of any prior imaging studies and treatment to date. Although generally nonspecific, the presence or absence of pain, the character of pain, the onset, severity, duration, aggravating, and alleviating factors, and response to analgesics should be noted. These aspects of pain can be quantified using such tools as a 0 to 10 pain scale or the Brief Pain Index (5) pain related to skeletal metastases is usually described as a dull, aching pain that may be exacerbated with activity or weight-bearing when the lower extremities are involved. Night pain is more common in metastatic disease than in conditions such as arthritis, mechanical low back pain, or tendonitis.

A general history regarding risk factors for other cancers should also be elicited such as smoking, alcohol abuse, sun or toxin exposure, obesity, and family history.

Plain Radiographs

Plain films are the initial study to be obtained in the patient with suspected bone metastasis. Bone metastases from breast cancer may be lytic, blastic, or mixed. Use of bisphosphonates may result in a shift of the spectrum to a higher incidence of sclerotic metastases (6).

Typically lesions are poorly marginated, originate within the medullary space but cause some adjacent cortical destruction, with a characteristic "moth-eaten" appearance. Especially in the setting of pathologic fracture or insufficiency of bone, there may be adjacent periosteal reaction. Soft-tissue masses extending outside the bone may be present, particularly in deposits of long-standing.

Approximately 30% to 50% of the bone must be destroyed prior to the lesion being evident on the plain film. Generally surgical intervention is not considered in cases with less bone destruction. Although plain films are arguably the best modality for determining necessity of surgical intervention, they are not as sensitive as other modalities, particularly MRI, for determining the presence or absence of metastases.

Bone Scan

Bone scans remain relatively nonspecific as indicators of metastatic disease, with positive findings present on bone scans with unrelated causation, including arthritis, occult insufficiency fractures, and prior bone trauma. Additionally, bone scan, being a test of metabolic function, does not indicate the degree of structural damage, information important in determining which treatment modality might be most appropriate. Most skeletal metastases from breast cancer show increase radiotracer uptake at the site of involvement. Exceptions to this generalization include extremely aggressive lytic metastases (that would like be apparent on plain radiographs) and some estrogen-receptor-negative metastases, particularly those involving the cervical spine (7).

Computed Tomography Scanning

In patients with known metastatic breast cancer being followed with chest, abdomen, and pelvis computed tomography (CT) scanning, CT detected metastatic bone lesions in 43 of 44 (98%) patients with bone metastases. The remaining patient had a solitary, asymptomatic bony metastasis in shaft of femur. Bone scan was positive in all patients with bone metastases. There were 11 cases of false-positive findings on bone scan. These findings suggest that in patients with known metastases, CT scanning alone is likely sufficient to evaluate bone metastases and, in fact, bone scanning is more likely to lead to findings of false positivity (8).

Magnetic Resonance Imaging

MRI is the single best imaging modality to assess bone marrow. However, changes within the bone marrow due to skeletal metastases may be difficult to distinguish from marrow changes from nonneoplastic conditions. Benign conditions that may alter the appearance of the bone marrow on MRI include trauma, infection, radiation, the administration of growth factors (i.e., pegfilgrastim [Neulasta], filgrastim [Neupogen], granulocyte colony-stimulating factor), and osteoporosis.

With regard to decision making for intervention for symptomatic metastases, however, MRI is less useful. MRI signals are determined by paramagnetic qualities and on vascularity, depending on the sequences used, rather than structural factors. Cortical bone is relatively poorly imaged by MRI. In fact, MRI may artifactually indicate or overstate cortical erosions or bone destruction. Although MRI plays an important role in the assessment of etiology of local bone pain, it is of minimal utility in determining which patients may benefit from surgery.

Positron Emission Tomography, with or without Computed Tomography

PET scan and PET–CT are indicated for evaluating the response to treatment for patients with metastatic breast cancer. As a result, PET scans and PET–CT scans that have been performed for patients being followed with visceral metastases are discovering asymptomatic skeletal lesions. Both the PET scan and the CT scan portion of the PET are capable of discovering bone metastases prior to their becoming symptomatic. The sensitivity of PET and PET–CT compared with other imaging modalities such as the bone scan have not been well studied. Siggelkow et al. (9) in a study involving 57 patients with breast cancer found that PET scan had a relatively low positive predictive value of 74.5% and a relatively high predictive value of 98.3%. It is likely that the combination of the PET and CT will prove to be sensitive and specific when read by an experienced clinician.

EXTERNAL BEAM RADIATION THERAPY

Because bone metastases are so prevalent among women with metastatic breast cancer, treatment with external beam radiation in such patients is not uncommon. Although a number of systemic options are now available for treating diffuse bony metastatic disease, such as bisphosphonates and radionuclides, external beam radiation remains the least invasive and most effective established local therapy for the treatment of localized bony metastases. The most common reason for its use in this setting is pain control, but it can also be used to prevent progression of lesions that if left untreated could lead to fracture or spinal cord or cauda equina compression. Accordingly, the primary objective of such treatment should be to improve or maintain patients' quality of life and physical function for the duration of their lives with the least toxicity and inconvenience.

There are a surprising number of issues to consider when assessing whether such treatment has been successful. Not only is there the degree of pain relief but also the rapidity of its onset as well as its durability. One must also take into account potential acute (e.g., nausea and vomiting) and late toxicities (e.g., fracture or spinal cord damage), the possible need for retreatment, the potential to reduce dependence on narcotics thereby reducing any associated side effects, how well such treatment results in the ability of patients to maintain or improve their physical function, and the convenience of treatment. When surveyed, patients with bone metastases ranked from most to least important the duration of pain relief, likelihood of complications, degree of pain relief, mobility, dependence on narcotics, and last, the length of treatment (10).

When making decisions about whom to treat and how best to treat them, there are a number of issues to consider. One important factor is the natural history of the patient's disease. In the case of metastatic breast cancer, survival is typically longer than for the average patient with bone metastases, with median survival on the order of 2 to 3 years. Although physicians are not very good at estimating patients' life expectancies (11), it still needs to

be taken into account when deciding how best to manage these patients. The number of bony lesions and the presence of visceral metastases are also relevant, as are the extent of bone destruction and the presence of an associated soft-tissue mass. The site of the lesion can also influence the likelihood of toxicity (e.g., spine vs. extremity). Other issues to consider include the patients' performance status, any comorbidities, prior treatment with adjuvant or palliative radiation, and their ability and willingness to come for daily treatment. At the societal level, there are also the direct medical costs of treatment, the burden on family and friends, and the ability to access a nearby treatment facility in a timely fashion to consider.

When making decisions about where to treat, it is necessary to pay particular attention to patients' symptoms and any recent imaging studies, including plain x-ray images, CT scans, MRI scans, bone scans, or fluorodeoxyglucose (FDG)-PET scans. CT and MRI are especially helpful in defining the extent of any associated soft-tissue mass. Typically, the field arrangements used to treat patients with bone metastases are relatively straightforward and often consist of two opposed treatment fields or sometimes even a single rectangular field.

Conventional External Beam Radiation

Although there is general consensus regarding its efficacy, there is controversy about how best to deliver external beam radiation for the treatment of painful bone metastases. Numerous studies have reported overall response rates in the range of 60% to 70%, with complete response rates between 20% to 30% (12). The onset of pain relief usually occurs within 3 weeks of the completion of treatment, and the duration of pain relief is typically on the order of 3 to 5 months (13). The likelihood and severity of acute toxicity depends on the site and size of the field being treated, but is generally tolerable. The likelihood of patients developing significant late complications is also very low, with pathologic fracture and spinal cord compression rates in the range of only 2% to 3%.

When it comes to treatment with radiation, higher doses typically result in improved outcomes. However, this does not necessarily appear to be the case for palliative radiation for bony metastases. In a study completed over 20 years ago, the Radiation Therapy Oncology Group (RTOG) randomized 266 patients with solitary bone metastases to 40.5 Gy in 15 fractions or 20 Gy in 5 fractions and 750 patients with multiple bone metastases to 30 Gy in 10 fractions, 15 Gy in 5 fractions, 20 Gy in 5 fractions, or 25 Gy in 5 fractions and initially reported no differences in outcomes (14). Of note, in this trial pain was assessed by the treating physician, not the patient. Interestingly, these results did not lead to the use of short-course radiation. Instead, practice patterns in the United States over the past several decades have been heavily influenced by an unplanned reanalysis of these data in which patients with both solitary and multiple bone metastases were combined into a single group and the primary end point was redefined; it reported longer-course radiation (e.g., 30 Gy in 10 fractions) to be more effective (15).

Over the past decade, evidence has been mounting in patients with uncomplicated bony metastases, typically defined as lesions that have not been previously irradiated and have or will not soon result in fracture or spinal cord compression or require surgical intervention, that single-dose radiation treatment is just as effective as fractionated radiation therapy. In the Bone Pain Working Group trial 765 patients with painful bone metastases, 36% of whom had breast cancer, were randomized to 8 Gy in 1 fraction or either 20 Gy in 5 or 30 Gy in 10 fractions (16). They found no differences in terms of patient-reported time to improvement in pain, maximal pain relief, time to progression of pain, analgesics used, acute toxicity, pathologic fracture, or spinal cord compression. Patients treated with single fractions were retreated at a rate of 23% versus 10% for those receiving multiple fractions, although it was unclear whether this represented lower efficacy of single fractions or just a lower threshold to retreat patients after a single fraction.

The Dutch Bone Metastasis Study randomized 1,171 patients, 39% of whom had breast cancer, to either a single 8 Gy fraction or 24 Gy in 6 fractions and reported nearly identical results (17). Again, differences in patient-reported response rates, duration of response, use of pain medication, side effects, and quality of life were nonexistent between the two arms, while the retreatment rate was higher in the single-fraction group (25% vs. 7%). One difference in this study was that the rate of pathologic fractures was twice as high as in the single-fraction group; however, the absolute rates were still extremely low (4% vs. 2%). In a follow-up study, these investigators found that single-fraction patients who did not respond or who had progressive pain were much more likely to be retreated than multiple-fraction patients (35% vs. 8% and 22% vs. 10%, respectively), supporting the assertion that physicians are more willing to retreat patients with single fractions (18). They also reported that retreatment with radiation is highly effective in both patients without either an initial response (66% response rate after single fractions and 33% after multiple fractions) or progressive pain after an initial response (70% for single fractions and 57% after multiple fractions). Another issue especially relevant to patients with breast cancer, who, as noted above, often have prolonged survival, is whether single fractions provide pain relief that is as durable as fractionated radiation. To address this issue, the Dutch investigators looked specifically at 320 patients enrolled in their study who survived for greater than 52 weeks, 63% of whom had breast cancer (19). The mean duration of response and progression rates in this subgroup were similar between single- and multiple-fraction patients, 29 versus 30 weeks and 55% and 53%, respectively, again with high response rates following retreatment. Therefore, while the rates of progression among patients with prolonged survival are relatively high, these data suggest that it may be preferable to retreat those patients who progress rather than initially treating all patients with longer treatment courses. These investigators also examined cost and quality-of-life issues associated with single- versus multiple-fraction radiation using data from their trial and concluded that single fractions are less costly, associated with comparable quality-adjusted survival, and therefore are more cost-effective (20).

More recently the RTOG conducted another bone metastases trial limited to patients with either breast (50%) or prostate cancer and randomized 898 such patients to either a single 8 Gy fraction or 30 Gy in 10 fractions (21). Again the response rates were similar, while the retreatment rate was higher in the patients treated with single fractions (18% vs. 9%). Interestingly, the rate of acute toxicity was greater in the multiple-fraction arm than in the single-fraction arm (17% vs. 10%). Data from a Canadian trial confirmed this result and also found that the prophylactic use of antiemetics reduced the likelihood of nausea and vomiting when treating the lumbar or pelvic region (22).

In addition to the studies mentioned above, at least 12 other randomized trials have been performed examining this issue. The results of these trials have been summarized in several systematic reviews (12,23), and meta-analyses

(13,24), all of which fail to demonstrate a difference between single and multiple fractions. These data led Cancer Care Ontario to develop evidence-based guidelines on fractionation for palliation of bone metastases that recommended the use of single fractions for symptomatic uncomplicated bone metastases (25). More recently, the American Society for Radiation Oncology (ASTRO) developed a guideline that came to a similar conclusion (26). It is therefore interesting to note that when radiation oncologists are surveyed regarding the use of single fractions in this setting many are reluctant to use them (27,28) and these results have been confirmed by several studies of actual treatment records (29–32). When patients are surveyed, some have expressed a preference for single fractions, while others favor multiple fractions (27).

To date, treatment of so-called complicated bone metastases has been less well studied. As noted above, significant experience now exists regarding the efficacy of retreating bone metastases with radiation. However, the optimal retreatment regimen has not yet been identified but is currently the subject of a large international randomized trial comparing retreatment with single versus multiple fractions (33). As discussed elsewhere in this chapter, patients with bone metastases that have or are about to cause a pathologic fracture often undergo surgical stabilization. Although the data supporting its use in this setting are limited, multiple-fraction radiation is typically employed postoperatively (34).

Another related issue that is also not well studied concerns bone remineralization. In the only randomized study to investigate remineralization, Koswig and Budach (35) reported significantly more remineralization 6 months following 30 Gy in 10 fractions than 8 Gy in a single fraction (173% vs. 120% mean increase in bone density, respectively) and suggested that multiple fractions be considered when this is felt to be an important issue. Radiotherapy is also frequently used to treat bone metastases that are causing actual or impending spinal cord or cauda equina compression. In all these settings, it is still generally accepted that patients be treated with conventional fractionated radiation (e.g., 30 Gy in 10 fractions).

Stereotactic Body Radiation Therapy

Advances in the delivery of external beam radiation have recently led to interest in treating spine metastases more aggressively with radiation using an approach known as stereotactic body radiation therapy. Based on the same principles as stereotactic radiosurgery, stereotactic body radiation therapy generally refers to the use of very precise, highly conformal radiation therapy delivered to an extracranial site in one to five treatments. To achieve these goals patients typically need to be reproducibly immobilized, imaged at least immediately prior to, and sometimes during, treatment to confirm proper patient positioning, and treated with multiple, often noncoplanar and unopposed, static beams or dynamic arcs to achieve highly conformal treatment plans that spare adjacent critical normal tissues. Although initially developed for treating lung lesions, this approach is also starting to be used to treat spine metastases in patients who have previously received dose-limiting treatment to the spinal cord or in those who are felt to have such a good prognosis that more aggressive treatment may be considered.

Preliminary results from several centers in breast cancer patients have been encouraging with response rates upward of 90%, response duration of 13 months, little to no long-term toxicity, and retreatment rates between 0% to 15% (36,37). Investigators from MD Anderson recently reported results from their phase I and II prospective single arm study with comparable results (38). In addition, the RTOG is conducting a phase II and III trial comparing a single 16 Gy treatment delivered with SBRT to a single 8 Gy fraction delivered with conventional treatment techniques for treatment of painful spine metastases. The study is ongoing but has reported preliminary data from the phase II component that such treatment is feasible and tolerable in a multi-institutional setting (39).

Hemibody Radiation Therapy

At the other end of the spectrum, hemibody irradiation has been used in the past to treat diffuse bony disease and is effective in that setting with response rates of 70% to 90% (40,41). However, because of newer systemic options (e.g., bisphosphonates and radionuclides, see Chapter 82) as well as concerns regarding acute toxicity, mostly gastrointestinal, and the ability to deliver subsequent myelosuppressive chemotherapy, its use has generally declined.

SURGICAL MANAGEMENT

A large proportion of patients with metastatic breast cancer will require some type of intervention for symptomatic disease to bone. Wedin et al. (42) looked at a population of patients in Sweden with metastatic breast cancer to bone, and of 641 patients with breast carcinoma presenting with symptomatic skeletal metastasis during 1989 to 1994, 107 (17%) subsequently underwent surgery. Metastases were located in long bones (77 patients), spine (14 patients), and pelvis (6 patients). The median survival postoperatively was 6 months. It is likely that the rate of operation in this population is diminishing. In another study of patients presenting with bone metastases, Cazzaniga et al. (43) reported on a series of 459 patients presenting with metastatic breast cancer, and in their 28-month follow-up, new skeletal-related events were observed in 122 patients (26.6%).

Patients can be expected to have a relatively lengthy survival on average after surgical intervention, and surgical efforts should be directed at reasonably durable reconstructions. Durr et al. (44), looking at a group of patients undergoing orthopaedic surgery for fractures or impending fractures secondary to metastatic breast cancer, noted survival rates of 59% after 1 year, 36% after 2 years, 13% after 5 years, and 7% after 10 years.

The evaluation of the outcomes of surgical intervention in patients with bone metastases has been markedly hampered by the variability in presentation of patients with regard to site and disease status and the variability in treatment approaches. No prospective randomized data are available to compare outcomes of surgical interventions with different techniques, or even comparing surgical intervention to nonsurgical care. The participation of a multidisciplinary team can help address issues of integration of imaging findings, prognosis, coordination with other forms of care, and examination of potential surgical benefit versus morbidity (45).

The health care costs of skeletal-related events in the metastatic breast cancer population are significant. Delea et al. (46) evaluated a group of 617 patients with breast cancer and metastatic disease to bone, about half of whom had had one or more skeletal-related events. After matching cases based on propensity scores, there were 201 patients each in the skeletal-related events and no skeletal-related events groups, with mean follow-up of 13.8 and 11.0 months, respectively. In the skeletal-related events group, costs of

treatment of skeletal-related events were $13,940 (95% confidence interval [CI], $11,240–$16,856) per patient. Total medical care costs were $48,173 (95% CI, $19,068–$77,684) greater in skeletal-related events versus no skeletal-related events patients (p = .001). Along the same lines, Zhou et al. (47) evaluated a group of women with breast cancer who presented with fractures, and for older women with early-stage breast carcinoma, the direct costs for bone fracture were estimated at $45,579, and 57% of those costs came from treating the bone fracture (32% came from inpatient hospital costs, and 25% came from noninpatient hospital costs), 25% came from other excess treatment costs, and 18% came from excess long-term care costs.

There are special considerations in the management of pathologic fractures secondary to malignancy compared to conventional fracture management in normal, traumatized bone. Typically fixation is more difficult in the involved bone, not only at the site of the metastatic deposit but also in adjacent bone, which is often osteoporotic in the metastatic breast cancer population. In contrast to traumatic fractures, fracture healing in the metastatic setting is relatively poor due to multiple factors, including local tumor regrowth, effects of chemotherapy and radiation therapy, and overall catabolic state of the patient. Additionally, the prolonged time for immobilization and protected limb function is unacceptable in the palliative setting of a patient with limited lifespan in whom prompt restoration of function is paramount. Because of this, excision of bone and prosthetic reconstruction is more frequently utilized, as well as load-sharing intramedullary devices (rather than load-bearing plate and screw constructs, which also require screw fixation in bone). Prosthetic replacement may be preferable in some situations where long bones are fractured adjacent to a joint in such a way that fixation in the small, periarticular segment cannot be achieved. Definitive fixation with prosthetic implants allows for immediate weightbearing and may be associated with a lower reoperation rate than with use of intramedullary fixation (48). In general, functional outcomes are better in the lower extremities than in the humerus with this approach (49).

Preoperative Assessment and Counseling

In considering patients for possible surgical intervention, multiple levels of assessment must take place in order to ensure an intervention that provides effective palliation, has an acceptable complication risk, and is consonant with the patient's wishes.

It is difficult to document when or if surgical intervention for bone metastasis may be associated with prolonged survival. For the most part, goals of surgical intervention in long bones is with the goal of providing pain relief and improving function. However, this is not always apparent to the patient and family, and in order to ensure that expectations of all parties are aligned, detailed preoperative counseling regarding the palliative nature of the intervention is necessary. In most cases of intervention, a nonsurgical alternative can be provided for consideration, which typically includes altered or protected weightbearing (sometimes wheelchair status) and an increase in narcotic use.

The identification of the bone metastasis and its contribution to the pain and disability the patient is experiencing is critical and typically can be achieved only by a careful history and musculoskeletal examination. It is important not to assume that the metastasis is *de facto* the source the pain, but rather to exclude other potential causes of pain including arthrosis of adjacent joints, tendinopathies, bursitis, and other bone, joint, and soft-tissue maladies.

The risks of surgery should be carefully itemized, including the possibility of life-threatening complications or a possible clinical deterioration, leading to failure to leave the hospital, as high as 10% in some series. Infection, particularly in arthroplasty, can be catastrophic, requiring long-term suppressive antibiotics at best, and necessitating multiple reoperations and even amputation, at worst.

Anticipated prognosis must be carefully weighed against surgical recovery and surgical risks. Typically, patients should have a minimum expected 6-week longevity in order to benefit from long bone stabilization with intramedullary devices, and about 3 months in order to benefit from arthroplasty.

The patient must be sufficiently robust to withstand surgery. If a patient is nonambulatory, the reasons for this and the duration should be carefully assessed preoperatively before considering surgery to restore lower limb long bone function. If general fatigue and disability are limiting factors rather than the skeletal issues, or if the patient has been nonambulatory for a considerable period of time, the prognosis for restoration of ambulation may be quite poor.

Chemotherapy effects must be considered. Platelets normally should be above 50,000 in order to withstand surgical blood loss and may need to be higher (100 K) for pelvic or open spine cases. Neutrophils must be over 1 K in order to adequately guard against infection. If the patient is on myelosuppressive therapy, this should be discontinued in such a time frame that a nadir below this level will not be anticipated.

Site-Specific Surgical Considerations

Pelvis

Reconstruction of the fractured or severely involved pelvis secondary to bone metastases remains one of the more challenging aspects of orthopaedic oncology. Successful surgical restoration involves effective transfer of loads normally three times body weight from the femur to the sacrum, bypassing or reconstructing damaged or missing bone.

A number of reconstructive options have been described, including the use of Steinmann pins threaded through remaining intact pelvis combined with cement and protrusion rings to create sufficient integrity for hip replacement (50,51). Another option is to excise the affected area of the pelvis entirely and replace it with a saddle prosthesis that spans the gap between femoral shaft and upper ileum. A minimum of 2.5 cm of intact ileum is necessary to stabilize the pelvis, and complications of this procedure include dislocation of the saddle element off the pelvis. All reconstructions for the pelvis entail relatively lengthy operative times and the potential for significant blood loss. In selected highly symptomatic patients with limited ambulatory goals, girdlestone resection can be contemplated for palliation and improved sitting.

In selected patients with lytic lesions of the acetabulum refractory to radiation who may be poor surgical candidates, percutaneous cementoplasty can be considered. In this procedure, liquid polymethylmethacrylate (PMMA) is injected percutaneously into the lytic defect with the intent of providing some structural support without an extensive surgical procedure to completely reconstruct the acetabulum. This can provide pain relief and immediate improvement in structural support (52,53). This technique is primarily suited to periacetabular lesions.

Radiofrequency ablation has been reported in combination with cementoplasty in a small series of bone metastatic patients with 100% initial pain relief (54), but more research is needed to evaluate this combined modality approach (55).

Femur

Proximal Femur (Neck and Peritrochanteric): In contrast to pathologic fractures arising from osteoporosis of the femoral neck in elderly patients, pathologic fractures of the femoral neck, even nondisplaced fractures, should be considered for hemiarthroplasty. Fixation with screws along the femoral neck, while effective in nondisplaced osteoporotic fractures, is fraught with the complications of persistent pain, nonhealing, and need for additional surgery. In contrast, replacement of the proximal femur (femoral neck) with hemiarthroplasty results in predictable pain relief and early functional recovery (Figs. 83-1 and 83-2) (56). Use of a long-stemmed prosthesis can guard against subsequent fractures distal to the implant. Resurfacing of the acetabulum is usually unnecessary unless there is coexistent, symptomatic arthritis. In proximal femur fractures, arthroplasty may yield more durable results than intramedullary nailing (57,58).

With regard to femoral shaft fractures, or impending shaft fractures, treatment has been described with a number of intramedullary implants (59). Although in past decades surgical treatment algorithms for long bone metastases focused on open procedures and cement augmentation, newer fixation options allow for excellent fixation proximally and distally, with implants inserted proximally or distally to the fracture site with smaller incisions and less necessity for augmentation locally with bone cement. With the opportunity to bypass the fractured site there is in general a lower blood loss and speedier recovery. In a series of 182 surgical interventions for metastatic disease of the femur, treatment of 97 impending pathologic fractures yielded better results than treatment of 85 completed pathologic fractures with less average blood loss (438 ml vs. 636 ml), shorter hospital stay (7 vs. 11 days), greater likelihood of discharge to home as opposed to an extended care facility (79% vs. 56%), and greater likelihood of resuming support-free ambulation (35% vs. 12%). Prophylactic intramedullary nailing of the femur, rather than intramedullary nailing of completed fractures, results in shorter hospital stays, lower perioperative complication rates, and better functional outcomes (60).

Femoral nailing of pathologic fractures or impending fractures can be associated with hypoxia and pulmonary complications thought to be related to tumor and fat embolism. Acute oxygen desaturation and hypotension occurred in 11 of 45 patients in a small series of patients in whom this was rigorously studied (61). In prophylactic intramedullary nailing of the femur, venting (creation of small distal "vent" in the bone) may decrease intramedullary pressures and the risk of fat and tumor embolization (62).

Lesions of the distal femur, including the condyles and of the proximal, periarticular tibia, are relatively less common. Lesions refractory to external beam therapy or those that have fractured can be treated with segmental replacement or resurfacing arthroplasty. Due to the high rate of wound healing complications following radiation and the disastrous results of infection, liberal use of soft-tissue flaps, generally the gastrocnemius, should be considered for reconstructions

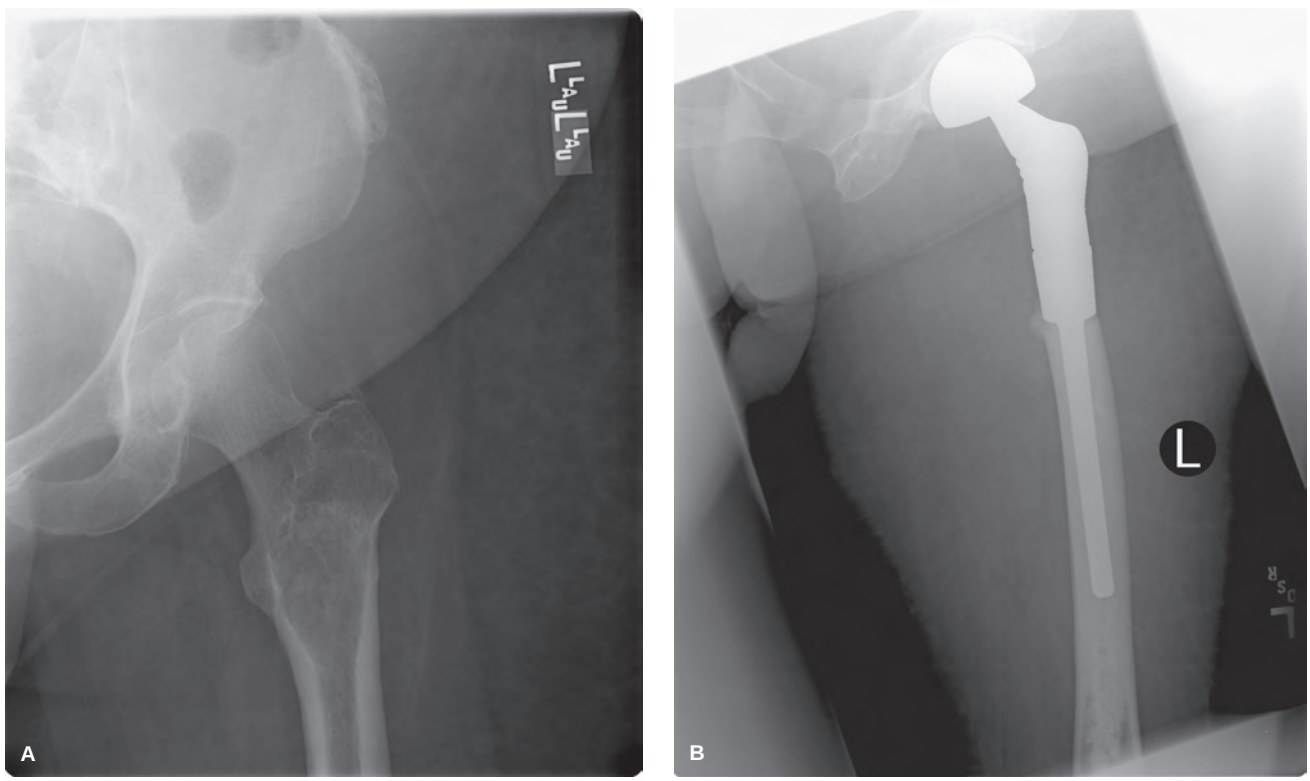

FIGURE 83-1 **(A)** Anteroposterior proximal femur in 60-year-old woman with metastatic breast caner. Plain film shows disease in proximal femur extending into femoral neck and head. Patient had prior external beam therapy and presentation with 3-week history of debilitating groin pain and inability to walk. **(B)** Postoperative plain film shows long-stemmed hemiarthroplasty. Patient was able to return to ambulatory status prior to succumbing to disease 1 year later.

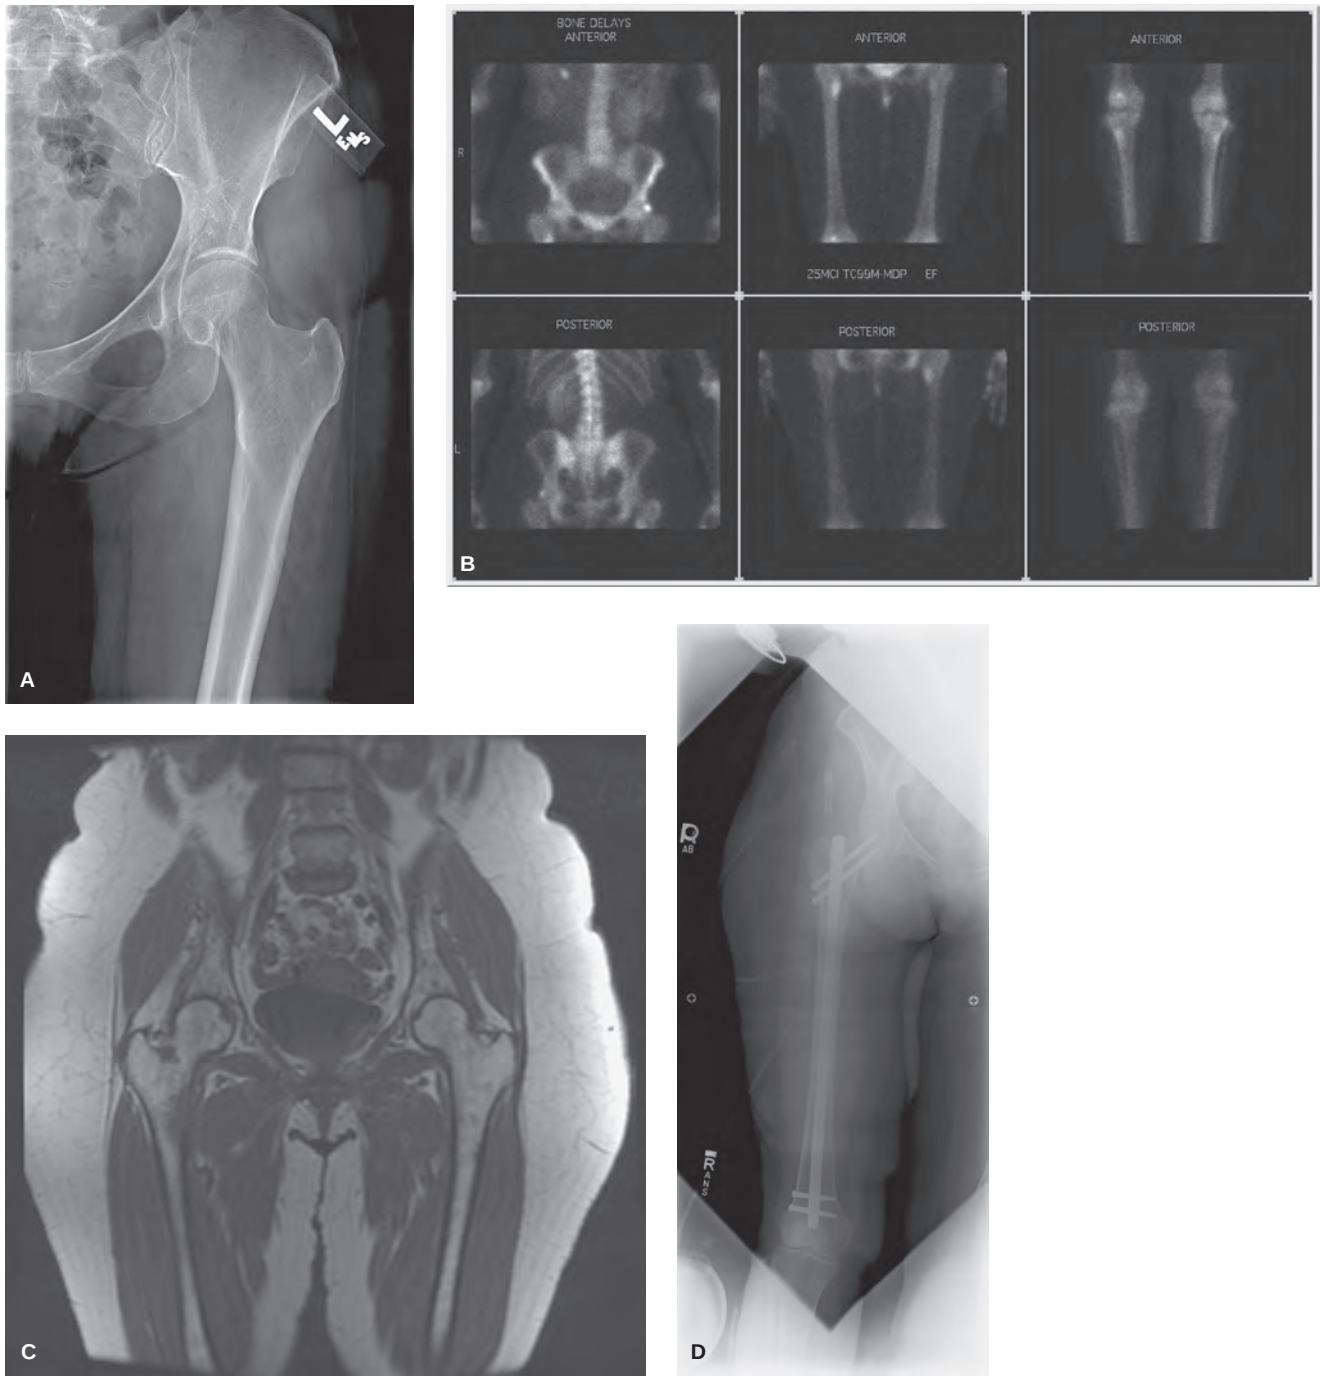

FIGURE 83-2 **(A)** Anteroposterior proximal femur in 56-year-old woman with 2-month history of increasing weightbearing pain in the femur and a history of breast cancer treated 1 year previously. Lytic destructive disease present extending from trochanter to proximal shaft. **(B)** Tc-94m methylene-diphosphonate (MDP) scan shows uptake in proximal right femur subtrochanteric region. **(C)** Coronal T1-weighted magnetic resonance image shows marrow replacement of proximal shaft of femur as well as other lesions in ilium. **(D)** Anteroposterior femur plain radiograph following intermedullary nailing of the femur. Percutaneous biopsy prior to nail placement confirmed metastatic breast cancer. Patient resumed ambulation without pain.

in this location. Patients with symptomatic metastatic disease to the femur who can undergo palliative intervention should be treated. Survival rate is higher for patients with metastatic breast cancer to femur than for other tissue types with a relatively low complication rate (63).

Humerus

The humerus is more typically involved later in the disease process in bone metastasis. Considerations include the potential for considerable disability, particularly if the dominant extremity is involved, in activities of daily living, and the potential to lose the ability to live independently.

Disease in the proximal humerus typically is extensive and requires excision of the involved bone rather than stabilization (64). Involvement of the attachments of the rotator cuff to the humerus leads to difficulty in reconstructing this defect with a conventional shoulder replacement, and segmental replacing systems should be considered. Regaining of full functional range of motion of the shoulder is rarely a possibility due to muscle insertion loss; however, regaining a stable, painless shoulder will allow the patient to use the elbow, wrist, and hand more successfully and free the opposite limb from a "tending" function.

From the proximal one-sixth of the humerus to the distal fourth of the humerus, stabilization of destructive lesions can be carried out using an intramedullary nail. These devices are inserted through small incisions in the shoulder area typically with relatively short operative times and minimal blood loss (65). The limb can be used for light activities within days.

In the distal fourth of the humerus, due to the unique anatomical considerations compounded with the adjacent elbow joint, interlocked nails are not an option. Approaches to the distal humerus include open curettage and plating and segmental replacement of the distal humerus with elbow joint replacement. Although generally done under tourniquet to reduce blood loss, these interventions have longer operative times and higher complication rates than locked nailing.

Spine

The vertebral column is the most common of all sites of bone metastases to the spine, with the spine metastases present in the majority of patient succumbing to metastatic disease from breast cancer. Manifestations of spinal involvement include pain, vertebral collapse, and neurological compromise from either tumor or extruded fracture fragments.

Pain is the most common presenting symptom from spinal metastases. While bony involvement may be treated with radiation therapy, the symptoms arising from vertebral collapse are likely to be refractory to radiation treatment and more responsive to measures to reintroduce more normal height to the vertebrae. Often patients are able to localize the offending levels, which is very helpful in targeting treatment in the patient with diffuse spine involvement. Vertebral compressions fractures can cause pain, spinal deformity (kyphosis, due to forward collapse, or scoliosis due to rotatory or sagittal plane bending), loss of height, or pulmonary or visceral compromise due to volume restrictions. Nerves exiting the spinal column may experience compression due to loss of height. Spinal cord compression can occur from either direct epidural extension of tumor, from collapsed fracture fragments forced into the spinal canal, or from tenting of the spinal cord due to deformity, most commonly kyphosis. Careful examination of the patient to ascertain the cause of pain and presence or absence of myelopathy is essential in the initial evaluation and management of the patient with spinal metastasis.

Surgical intervention potential for spinal metastatic disease has changed greatly in the past decade. Newer surgical approaches allow for improved access to all spinal levels. Improved instrumentation systems that allow for better fixation in compromised bone and more intraoperative flexibility are now available. Vertebral body replacing systems have allowed for greater opportunity to remove diseased segments with safe, structural supports (66).

Surgical intervention can be considered even in patients with multiple levels of disease or with relatively advance stage cancers. Sciubba et al. (67) reported on a series of 87 patients undergoing 125 spinal surgeries to evaluate prognostic variables. Presence of visceral metastases, multiplicity of bony lesions, presence of estrogen receptors (ER), and segment of spine (cervical, thoracic, lumbar, sacral) in which metastases arose were compared with patient survival. Those with ER positivity had a longer median survival after surgery compared to those with ER negativity. Patients with cervical location of metastasis had a shorter median survival compared with those having metastases in other areas of the spine. The presence of visceral metastases or a multiplicity of bony lesions did not have prognostic value.

Preoperative functional status likely has an impact on the effectiveness of spinal decompression procedures, and early surgical intervention should be considered in patients with spinal metastases and neurological findings. North et al. (68) evaluated results in 61 open spinal procedures for spine metastases. Preoperatively, 53 of 61 (87%) patients in the study population suffered neurological symptoms (e.g., weakness) and 52 (85%) were ambulatory. Postoperatively, 59 (97%) were ambulatory. Most patients who survived 6 months (81%) remained ambulatory, as did 66% of those alive at 1.6 years. The median postoperative survival was 10 months. The risk factors for loss of ambulation were preoperative loss of ambulatory ability, recurrent or persistent disease after primary radiotherapy of the operative site, a procedure other than corpectomy, and tumor type other than breast cancer. Prognostic factors for reduced survival were surgical intervention extending over two or more spinal segments, recurrent or persistent disease after primary radiotherapy involving the operative site, diagnosis other than breast cancer, and a cervical spinal procedure.

Percutaneous structural options for the symptomatic treatment of painful collapse of spinal vertebrae without neurological abnormalities include vertebroplasty and kyphoplasty. Percutaneous vertebroplasty is a radiographically image-guided procedure in which the surgeon or radiologist injects liquid PMMA into the collapsed vertebrae under image intensification with the intention of improving pain by increasing the structural integrity of the affected bone. Vertebroplasty was initially used for benign vascular tumors, but its use has spread to osteoporotic fractures as well as vertebral collapse secondary to metastatic or myelomatous bone tumors. Complications from vertebroplasty largely result from inadvertent extrusion of the PMMA into undesirable and unplanned areas outside the vertebral body, inducing posterior leakage with the potential disastrous consequence of cord trauma.

Kyphoplasty was introduced to essentially perform vertebroplasty in a more controlled fashion. In kyphoplasty, a small balloon or "bone tamp" is introduced under fluoroscopic guidance into the vertebral body through a percutaneous transpedicular approach and then inflated to create a

"space" into which the PMMA can then be injected. It offers the advantage of significantly greater height restoration (69) and a lower rate of cement extrusion and leakage outside the vertebral body (70). The inflatable tamp compresses adjacent compromised bone and potentially occludes alternative pathways for the cement to extrude while creating a space for the cement to occupy. Due to the increased procedural time and instrumentation, kyphoplasty is associated with higher expense and increased exposure to radiographic contrast agents. Randomized trials comparing vertebroplasty and kyphoplasty, or, indeed, either of these procedures compared to nonoperative management, have yet to be performed. However, reports of kyphoplasty have indicated that it is associated with safe, reliable pain relief, restoration of vertebral height, and even when cement is extruded it is generally without neurologic complication (71–73). Combinations of radiofrequency ablation with percutaneous bone stabilization may prove helpful in the spine and elsewhere (74).

MANAGEMENT SUMMARY

- Asymptomatic breast cancer metastases may occur, particularly in the setting of widespread metastases to bone, and can be managed medically.
- Pain that is controlled by analgesics and not weight-bearing in nature or associated with spinal compression may be improved with the initiation of bisphosphonates or the beginning of new systemic therapy; bone metastases in these situations may be observed and followed radiographically to assess whether systemic treatment may be sufficient. Progression in pain or radiographic findings would indicate the potential indication for radiation or surgery or both.
- External beam radiotherapy usually improves pain due to bone metastases.
- Patients with uncomplicated painful bone metastases should ideally be treated with a single 8 Gy fraction.
- Multiple-fraction radiation should still be used for patients at significant risk for pathologic fracture, following surgical stabilization and for patients with spinal cord or cauda equina compression.
- Prophylactic surgery for stabilization should be considered in medically appropriate candidates with weight-bearing pain in the long bones, particularly the femur.
- Spinal decompression surgery should be strongly considered for patients with spinal involvement and neurologic compromise.
- Patients with frank long bone or pelvic fractures should be considered for stabilization of fractures or joint-replacing surgery.
- Percutaneous kyphoplasty can be considered for patients with symptomatic vertebral collapse secondary to bone metastatic involvement without neurologic involvement.
- Radiofrequency ablation is a relatively new technique available at selected centers and may be considered in selected patients with failed radiation therapy who do not have lesions requiring surgical stabilization.

SECTION XIII

Breast Cancer in Special Populations

CHAPTER 84

Breast Cancer in Older Women

Gretchen Kimmick, Kevin S. Hughes, and
Hyman B. Muss

CHAPTER CONTENTS

BACKGROUND: EPIDEMIOLOGY AND BIOLOGY

Disparities in breast cancer outcome in older women, where older is typically defined as age over 65 years, has drawn attention to the disease in this group which comprises almost one-half of all new cases. High incidence is due to the fact that age is a major risk factor for breast cancer; U.S. cancer statistics from 2004 to 2008 show that breast cancer occurred in 1 of 15 women aged 70 years and older and 1 of 28 women aged 60 to 69 years, compared to 1 of 27 women aged 40 to 49, and 1 of 203 women younger than 39 years (1). We also know that although breast-cancer-specific survival has improved over recent decades, improvements have occurred preferentially in women diagnosed at ages younger than 70 years (2). If the U.S. Census Bureau predictions hold true, by 2060 the number of older women age 65 to 84 years will nearly double and those 85 and older will nearly quadruple (Fig. 84-1A), resulting in a substantial increase in the number of breast cancer diagnoses in older women. Research thus far has only begun to determine how much of the disparity in age-related breast cancer mortality can be reduced. Epidemiologic studies have compared survival rates of older women with breast cancer to age-matched older women without breast cancer and to younger women with breast cancer. Compared to controls without breast cancer, matched for age, comorbidity, prior mammography use, and sociodemographic factors in a linked Surveillance, Epidemiology and End Results (SEER)-Medicare dataset, women with early-stage breast cancer (stage 0-I) who received standard treatment had similar mortality, while women diagnosed with stage II or greater disease had significantly greater mortality (adjusted hazard ratio for death, 1.5, 95% CI, 1.5–1.6) (3). Compared to younger women with breast cancer, survival disparities also appear to be most pronounced with higher stage, higher risk disease. In the Finnish Cancer Registry, survival rates were similar in older and younger women with node-negative disease, whereas with node-positive disease the 10-year relative survival was best for women 41 to 45 years (49%) and poorest in women over 75 years (35%) (4). Mortality trends seen between 1990 and 2003 in the Surveillance, Epidemiology, and End Results (SEER) program show that there was a decrease in mortality in younger and older women with estrogen receptor-positive disease, but, in estrogen receptor-negative disease, mortality decreased in women younger than 70 years and stayed stable in women age 70 and older (2). The detection of early-stage disease in older women, therefore, is important. For women with higher stage, higher risk tumors, the causes of differential outcomes by age is a topic of active research.

Studies of patterns of care in older breast cancer patients show that they are at risk for "less than standard" management, even after controlling for factors such as comorbidity, cognitive status, social support, and functional status. In addition, lack of receipt of standard, guideline concordant care increases the risk of poor outcomes. In a study using a SEER-Medicare linked dataset from 1992 to 2003, older women with early stage cancer who received standard treatment were significantly less likely to die within 5 years than were

FIGURE 84-1 Population projections for women in the United States (in thousands). (From U.S. Census Bureau, Population Projections, Last Revised: 2012-12-14T16:41:27.218-05:00.)

women who did not receive standard therapy (16% vs. 39% for stage I disease, respectively, and 33% vs. 64% for stage II disease, respectively) (3). This is true even for women over age 80 years, where 5-year breast cancer survival is 90% for standard breast conserving surgery with systemic therapy, compared to 46% with no treatment, 51% with tamoxifen alone, and 82% with mastectomy alone (5). The rate of guideline concordant care and associated lower survival reported in population studies is confounded by patient, tumor, physician, and other factors. Admittedly, delivery of standard care depends on the risk-benefit ratio, which is sometimes difficult to assess in older, possibly frail, women. The use of potentially toxic adjuvant therapies in older women is not well supported by the literature because they have traditionally been excluded from randomized clinical trials. Furthermore, as a group, older women are perceived as having more indolent breast cancers that require less aggressive therapy.

In older women, the rate of local recurrence of ductal carcinoma in situ (DCIS) is lower than in younger women. Pathologic features of DCIS, however, do not appear more indolent in older women (6). Some authors attributed the lower local recurrence rate to immunohistochemical and genetic differences; HER-2/neu is less often overexpressed in DCIS in older patients, whereas ER, PR, bcl-2, cyclin D1, Ki-67, and p53 expression is similar (7).

With invasive breast cancers, the incidence of biologically aggressive phenotypes is less common in older women. Infiltrating ductal cancer is the most common histologic type. The more indolent histologic types, although still rare, are seen more commonly in older than in younger women. Mucinous carcinomas represent only 1% of breast cancers in premenopausal women, but 4% to 5 % in women aged 75 to 85 years and approximately 6% in women more than 85 years old (8). Papillary cancers are very rare in all age groups: 0.3% of cancers in premenopausal women and less than 1% in older women. The vast majority of breast cancers in older women are hormone receptor-positive, HER2-negative, so-called luminal A and B tumors. Markers of lower cell proliferation are common, including lower thymidine-3H labeling index, diploidy, lower histologic grade, normal p53 expression, and less overamplification of epidermal growth factor receptor (EGF-1) and c-erb-b2 (HER-2/neu) (8). Despite the apparent less aggressive phenotype, a large report, spanning 60 years and including 2,136 elderly women treated with surgery and without adjuvant systemic therapy, showed no difference in the rate of distant metastases between women over age 70 years compared to women age 40 to 70 years (9). Some attribute this to the fact that very low estrogen levels in older women affect the expression of progesterone receptors, which are less frequently positive, and androgen receptors, increasing the metastatic potential of the cancer. More aggressive tumors, such as ER/PR negative and HER2 positive cancers, however, do occur in even the oldest old patients and pose a higher recurrence and mortality risk regardless of age. In women age 70 and older with stage I–II breast cancer, for instance, tumors expressing HER2 carried 10 times the risk of recurrence at 5 years (30 vs. 3%) and lower cancer-specific survival rates (86% vs. 98%) compared to HER2 negative tumors (10).

LIFE EXPECTANCY—THE COMPLICATED INTERDEPENDENCE OF AGE, COMORBIDITY, AND FUNCTIONAL STATUS

As age increases, life expectancy decreases (Table 84-1), but even at age 80, the average woman's life expectancy is 9.6 years. Most patients and clinicians realize that the range of expected life expectancy varies more as we get older due

TABLE 84-1

Average Remaining Lifetime Expectancy for Women at Various Ages

Age (y)	*Life Expectancy, Women (y)*
60	25.3
65	20.9
70	16.7
75	12.9
80	9.6
85	6.8
90	4.7
95	3.2
100	2.3

Table shows average number of years of life remaining life at the given age. Calculated using the longevity calculator of the official Web Site of the U.S. Social Security Administration (http://www.ssa.gov/cgi-bin/longevity.cgi).

to other existing illnesses (comorbidities), the presence of frailty and disability, and other factors. Geriatricians use the Comprehensive Geriatric Assessment (CGA) to assess domains of functional status, comorbidity, medication use, cognition, social support, and nutritional status. The CGA can detect treatable geriatric syndromes in cancer patients, but it is time-consuming and rarely used in medical oncology practice. Instead, its components, screening tools, and abbreviated versions are in development. There are also tools to estimate survival, using information available clinically or excerpted from a geriatric assessment, that may assist in complicated treatment decisions in older patients. Some of these tools are available online, at ePrognosis (http://www.eprognosis.org). Several groups of experts, including the International Society of Geriatric Oncology (SIOG) and the National Comprehensive Cancer Network, recommend some form of comprehensive geriatric assessment be performed in older patients with cancer (11,12).

Functional status is a strong and significant indicator of mortality risk. In oncology, the Eastern Cooperative Oncology Group (ECOG) and Karnofsky (KPS) Performance Status are typically used to measure functional status. These measures correlate well with cancer-related mortality, but they do not correlate as well with functional status assessed in the CGA, and may underestimate the degree of functional impairment in older patients (13). In a CGA, functional status refers to one's ability to perform daily tasks, which allow one to care for oneself—activities of daily living (ADL)—and other tasks that allow one to live independently—instrumental activities of daily living (IADL). ADL and IADL are also strong predictors of survival. In addition, self-rated health is an independent risk factor for cancer-related and overall mortality (14). Compared to those rating themselves as "healthy," the relative risk of cancer-related mortality for patients rating themselves as "moderately healthy" or "not healthy" was 4.2 (95% confidence interval [CI], 1.9–9.4), and the relative risk of mortality from other causes was 3.0 (95% CI, 1.2–7.8)—even after adjusting for the presence of major chronic diseases, age, medication use, smoking, alcohol consumption, physical activity, body mass index, systolic blood pressure, serum cholesterol concentration, education, marital status, and a family history of chronic diseases. Dementia, an important geriatric syndrome, and progressive functional decline are determinants of life expectancy as well (15). Related issues of poor social support and limited access to transportation may lead to delays in diagnosis with resulting increase in the likelihood of inadequate treatment of cancer in patients aged 65 and older.

The presence of comorbidity increases with increasing age and complicates management of breast cancer because as comorbidity increases, both overall mortality (16,17) and breast-cancer-specific mortality increase. Comorbid conditions that impose functional limitations and that are expected to progress, such as diabetes with end-organ damage, steroid- or oxygen dependent chronic obstructive pulmonary disease, or a known terminal illness, definitely limit survival (18). With aging, heart and cerebrovascular diseases become increasingly more important as causes of death (Fig. 84-2). In addition, there is an interaction between comorbidity and stage of disease, such that the effect of comorbidity on survival varies by breast cancer stage (18); among patients with three or more comorbid conditions, prognosis is poor regardless of stage.

In conclusion, not only age but also geriatric indices, including functional status and comorbidity, are important in predicting overall survival, breast-cancer-related survival, and treatment tolerance. Consideration of these and other factors will ultimately help us optimize treatment strategies for older women with breast cancer.

PREVENTION

Like younger women, older women should be encouraged to maintain a healthy life style that includes exercise and weight control. Overall, available data suggest that few older women are likely to be good candidates for pharmacologic strategies of breast cancer prevention; the risk/benefit ratio is rarely favorable. (See Chapter 21 for a detailed review of breast cancer prevention strategies.)

SCREENING

Breast cancer screening, also discussed in Chapter 11, involves serial mammography, clinical breast examination, breast self-examination, and in some high-risk situations, although not typically in older patients, breast MRI. For older postmenopausal women, the higher probability of developing breast cancer as compared to younger women translates to a greater likelihood that a newly detected breast mass or mammographic abnormality is likely to be a breast cancer. In one study comparing mammographic results of women aged 50 to 64 years (n = 21,226) to women aged of 65 years and older (n = 10,914), Faulk and colleagues found that mammography had a higher positive predictive value, a higher yield of positive biopsies, and a greater cancer detection rate per 1,000 studies in older women (19). Finding an early cancer in an older woman, however, may not lengthen or improve her life and raises concern of overdiagnosis. The current questions about screening older women are, therefore: (i) Do older women who are screened live longer than those who are not screened (due to finding cancers at a more curable stage)? (ii) Do older women who are screened have a higher quality of life than women who are not screened (due to finding cancers earlier when they require less aggressive treatment)? (iii) Do older women require screening less frequently than yearly (due to slower-growing cancers)? (iv) Is there an age at which screening mammography should cease?

The answers to the first of these two questions are not directly available. Large randomized trials show that routine annual or biannual mammography in women aged 50

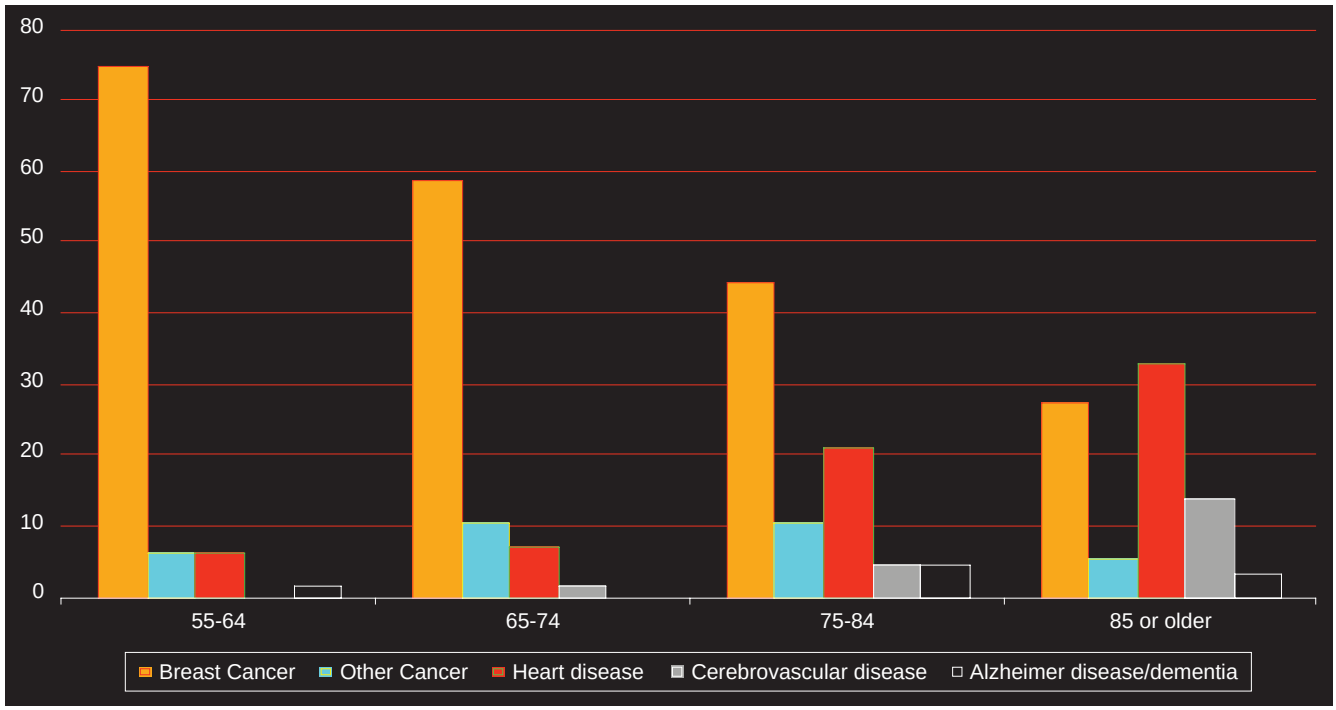

FIGURE 84-2 Cause of death within age-groups (percent). (Data from Yancik R, Wesley MN, Ries LAG, et al. Effect of age and comorbidity in postmenopausal breast cancer patients aged 55 years and older. *Jama* 2001;285:885–892, with permission.)

to 75 years is associated with a reduction in breast cancer–related mortality of 25% to 30% within 5 to 6 years of initiation (20). As only two of these trials included women older than 75 years, the optimal upper age limit for mammographic screening is still a matter of debate (21). The U.S. Preventive Services Task Force recommends biennial screening mammography be performed in women between the age of 50 and 74 years, but concludes that the evidence is insufficient to assess the additional benefits and harms of screening mammography in women age 75 and older (22). Population-based studies suggest that cancers detected by screening mammogram in older women may result in lower stage cancer at diagnosis, but there is no demonstrable survival benefit. The frequency of screening mammography in women older than age 75 is an area of debate. The fact that breast cancers in older women tend to have features suggesting slower growth suggests that less than annual screening is reasonable. Prospective data to support screening mammography in older women do not exist.

An upper age limit for screening mammography does not exist. Most experts deem that screening is justifiable as long as the benefits outweigh the risks. One study claimed that, since high bone mineral density (BMD) was associated with increased risk of breast cancer, that women should first be screened with BMD and, if high, should have screening mammogram (23). After age 80, when life expectancy is most likely less than 10 years, screening mammogram can probably be discontinued. In fact, the risks of screening women over age 80 may outweigh the benefits. In a cohort study of 2011 women age 80 and older, for instance, there was no difference in breast cancer rates, stage, or death between screened and unscreened women, but among the 1,034 women screened, 11% had false-positive mammograms that led to 19 benign breast biopsies (24). The use of a framework or decision aid for guiding decision-making about screening that is based on life expectancy, risk of dying of cancer, and procedure-related complications has also been suggested (25,26).

In 1991, Medicare made screening mammography every 2 years a covered benefit and, in 1999, annual screening was made a covered benefit. During the first years of Medicare coverage, most older women were unaware that screening was a Medicare benefit, which led the Health Care Financing Administration to publicize mammography coverage. Self-reported 2-year mammography screening rates for women more than 65 years old increased from 43% in 1990 to 64% in 1998. Even with screening mammography as a covered benefit and after several national informational campaigns, 60% of a sample of 1,000 older female Medicare beneficiaries in Michigan between 1993 and 1997 either had not undergone a mammogram or had undergone only one (27). Attention to factors associated with lower mammography use improves screening rates. The physician's recommendation is probably the most important stimulus for obtaining screening mammography in older women. On-site mobile mammography, personalized mailings, and emphasis on the reassurance that mammography brings recipients are also helpful in improving screening rates.

The American Geriatrics Society Clinical Practice Committee published guidelines for breast cancer screening in older women (see Table 84-2) (28). The committee recommended annual or biennial mammography until age 75 years and then biennially or every 3 years thereafter in women with a life expectancy of 4 or more years. Overall, while it is less clear that mammography saves lives in women over age 75, it definitely finds cancers at an earlier stage, thus allowing less aggressive treatment and perhaps a better quality of life and survival. Longer intervals between mammograms are likely adequate and careful clinician breast exam may be beneficial. Mammography for women with a life-expectancy

TABLE 84-2

Breast Cancer Screening Recommendations for Older Women

Technique	*Recommendation*
Mammography	Annual or biennial mammography until age 75 and biennial or every 3 y thereafter, with no upper age limit for women with an estimated life expectancy of 4 or more years.
Clinical breast examination	Annual
Breast self-examination	Monthly

of at least 5 years and intact mental function and mobility makes good medical sense.

TREATMENT OF THE PRIMARY LESION IN THE OLDER PATIENT

After the publication of the NSABP Protocol B-06 in 1985, it became accepted that women with invasive breast cancer should be offered the choice between modified radical mastectomy and breast conservation (lumpectomy, axillary dissection, and breast irradiation). Since that time, breast conservation has become the more common surgical approach, and axillary dissection has been replaced by sentinel node biopsy, with the addition of axillary dissection reserved for the highest risk cases (see Chapters 41 and 42).

Older women should be offered the option of breast preservation, because body image and the loss of a breast are important issues regardless of age. In addition, breast preservation is a much less morbid procedure, mostly done as an outpatient procedure, and is thus preferable to mastectomy in the older individual with comorbidities. There should be a low threshold for the use of preoperative endocrine therapy to increase the rate of lumpectomy or decrease the extent of surgery as discussed elsewhere in this chapter (adjuvant therapy). In fact, women aged 70 and older are more likely to prefer breast conservation than mastectomy. Individualization of treatment is appropriate, and decisions should be made based on patient preference, overall health, tumor stage, and biology.

Today, most older patients can receive effective surgical treatment with minimal mortality risk and morbidity. Operative mortality rates for breast surgery are very low, at 1% to 2%. The main factor influencing surgical morbidity is not age but the presence of comorbidity and frailty. There may be at least a short-term decrease in cognitive function after general anesthesia in elderly patients, and even a slight decrease in cognition in an older frail patient may mean the difference between independence and consignment to assisted or total care. Attention should be paid to functional status and comorbid illnesses in making decisions about surgical management.

MANAGEMENT OF THE AXILLA IN OLDER PATIENTS

In the management of invasive breast cancer, sentinel node biopsy is preferred in the patient with clinically node-negative disease. Axillary dissection may also be omitted in women who have breast conserving surgery and pathologically involved nodes, as long as surgical margins are negative, the tumor is less than 5 cm, there are fewer than three involved nodes and the nodes are not matted, there is no extranodal extension of tumor, and in the absence of neoadjuvant endocrine or chemotherapy; these recommendations are based on the eligibility criteria for the Z11 trial (see Chapters 37 and 38). In the elderly woman with clinically benign preoperative nodal exam, however, axillary evaluation may not always be necessary.

Axillary lymph node dissection may lead to arm morbidity and other complications, especially in the elderly. In a longitudinal cohort study of 571 patients with stage I and II breast carcinoma who were 67 years of age and older, the risk of arm dysfunction during the 2 years after initial treatment was more than four times higher for women who underwent axillary dissection compared with women without axillary dissection (83% vs. 17%; $p = .0001$) (29). In a study that randomized women age 60 and older to axillary clearance or not, however, after the first postoperative visit (at which point the physician and patient assessment of quality of life related to arm symptoms was worse for women who had the axillary dissection), disruptions in quality of life disappeared within 6 to 12 months and there was no long-term difference in arm movement or pain (30). Thus, despite the potential morbidity, for elderly women with clinically positive axillary lymph nodes who can tolerate surgery and do not meet the Z11 criteria noted above, axillary dissection represents the best treatment. Alternative treatments, such as irradiation and tamoxifen (if the tumor is ER- or PR-positive) may play a role in controlling disease for a short time in patients too ill to have surgical treatment.

For older women with clinically negative nodes and a hormone receptor-positive tumor, in whom chemotherapy is unlikely to be used, axillary evaluation by sentinel node biopsy may be superfluous and add morbidity without benefit. A retrospective study of patients treated with lumpectomy plus tamoxifen, but without irradiation or axillary dissection, for instance, found low rates of recurrence in the ipsilateral axilla at 5 and 10 years; axillary relapse rates were 4.3% and 5.9%, respectively (31). Axillary recurrence was also low among older women who did not have axillary surgery in the Cancer and Leukemia Group B (CALGB 9343) trial (32). This trial, done in conjunction with RTOG and ECOG, included women age 70 and older with small (≤2 cm), clinically or pathologically node-negative, ER-positive or PR-positive primary breast cancers treated by lumpectomy plus tamoxifen who were then randomized to receive breast irradiation or not. Axillary surgery was not a requirement for study entry. In the radiation arm none of the 200 women who did not undergo axillary dissection had an axillary recurrence, whereas 2.9% (6 of 204) who did not undergo axillary clearance or have breast radiation had axillary recurrence. Finally, the International Breast Cancer Study Group (IBCSG) trial 10-93 randomized women age 60 and older with clinically node-negative, operable breast cancer, in whom adjuvant tamoxifen was indicated, to axillary clearance or not (30). Of participants in this trial, 80% had hormone receptor-positive breast cancer. At a median follow-up of 6.6 years, axillary recurrence (~2% overall), disease-free survival (67% vs. 66%. HR 1.06; $p = .69$), and overall survival

(75% vs. 73%, HR 1.05; $p = .77$) were not significantly affected by axillary surgery. Even in the absence of axillary evaluation or treatment, therefore, axillary recurrence is rare in older women with small, ER-positive tumors treated with tamoxifen, radiation, or both.

In summary, for older women with ER-positive or PR-positive cancers that are 2 cm or less who undergo breast conservation therapy, for whom chemotherapy is unlikely to be beneficial regardless of node status, axillary evaluation, even with sentinel node biopsy, has little utility. For tumors greater than 2 cm, or ER-negative and PR-negative tumors, sentinel node biopsy has utility for determining who might best benefit from adjuvant chemotherapy or axillary treatment. For the node-positive patient who does not meet the Z11 criteria, axillary dissection remains the standard for those who can tolerate the procedure.

BREAST RADIATION AFTER LUMPECTOMY

Older women tolerate breast irradiation as well as younger women, but consigning an older person to 4 to 6 weeks of radiation therapy may be exhausting and be detrimental to her quality of life. Thus, the schedule and duration of adjuvant breast radiation may be obstacles for older patients. One approach to this problem has been the development of radiation therapy schedules that are more tolerable for older patients. Two retrospective analyses examined the use of once-weekly radiation schedules. Rostom et al. reported the use of once-weekly irradiation for 84 older patients with breast cancer (stages I to IV) (33). Treatment was well tolerated. Reactive fibrosis, skin thickening, or both occurred in 25 patients; symptomatic pneumonitis was reported in 4 patients; and brachial plexopathy occurred in 1 patient. Among patients with stage I and II tumors, local tumor control and cosmetic results were encouraging. Maher et al. (34) evaluated a regimen that included once-weekly radiation therapy for a total of seven fractions and concurrent tamoxifen in a group of older women with a mean age of 81 years (range, 64 to 91 years). At a median follow-up of 36 months, the overall survival rate was 87%, the disease-specific survival rate was 88%, and the local recurrence rate was 14%. With the high dose per fraction, 39% of patients experienced moderate fibrosis at the primary site. No rib fractures, radiation pneumonitis, or brachial plexopathy were seen.

Another approach to decreasing the inconvenience of radiation therapy is accelerated partial breast irradiation (APBI) using external beam radiation or intracavitary balloon brachytherapy, and which treats only the affected area of the breast and requires about 1 week for completion (35). This usually requires two treatments per day, obviating some of the convenience gain hoped for in the elderly. APBI is discussed in great detail elsewhere in this text (see Chapter 35), but there are some data specific to the elderly. Smith et al. (36), using the National Medicare Data set for women age 67 or older, identified that brachytherapy produced significantly greater morbidity than whole breast radiation (WBRT) at 5 years (fat necrosis 8.26% vs. 4.05% and breast pain 14.55% vs. 11.92%). They also found a significant difference in ultimate mastectomy rates in favor of WBRT (3.95% APBI vs. 2.53% WBRT), although we would be hard pressed to call this difference clinically relevant. However, another report by Khan et al. found no difference in local recurrence, cosmesis or toxicity when comparing women over 70 versus women 70 or younger treated with brachytherapy (37). Finally, targeted intraoperative radiotherapy (IORT) offers the option of radiation given as a single dose intraoperatively, markedly decreasing inconvenience for the patient. Initial reports suggest a low rate of in breast recurrence (38).

While shorter courses of radiation seem feasible and likely effective in older women, the question remains whether older women need radiation after breast preservation at all. Standard local treatment for breast cancer has similar disease-free and overall survival benefits in older and younger women, but older women have more deaths from illnesses other than breast cancer (11% vs. 2%; $p = .0006$) (39,40). In CALGB 9343, only 3% of all study patients died of breast cancer while 47% died of other causes and survival was the same with or without radiation (32).

Of note is the lower risk of ipsilateral breast tumor recurrence (IBTR) in older women, with or without radiation. A regimen of breast-conserving surgery and breast irradiation was found to yield a 10-year rate of local treatment failure of 4% in older women compared with 13% in women younger than 65 years (39). Similar findings were seen in the Milan trial 3 without breast irradiation, where women treated with quadrantectomy younger than 45 years had an IBTR rate of 17.5% versus 3.8% for women older than 55 years (41).

An alternative approach has been to use tamoxifen alone after lumpectomy as a means of obviating the need for radiation therapy in women with hormone receptor-positive tumors. A retrospective study of patients treated with lumpectomy plus tamoxifen, but without radiation, demonstrated ipsilateral breast cancer recurrence rates of 5.4% and 8.7%, and incidences of distant metastases of 6.2% and 13.4%, 5 and 10 years after initial surgery, respectively (31). In a controlled clinical trial comparing quadrantectomy versus quadrantectomy plus radiotherapy in postmenopausal women older than 55 years with breast cancers smaller than 2.5 cm, a low local relapse rate (3.8%) was found for patients who had quadrantectomy alone at a median follow-up of 39 months (41). Two other small studies addressing the same issue, however, showed higher locoregional recurrence rates (about 10%) in women older than 70 years who were treated with local excision and tamoxifen alone, without adjuvant radiation (42,43).

This question has been more completely studied in CALGB 9343 (32), which randomly assigned 636 women 70 years of age or older with clinical stage I (T1N0M0), ER-positive breast carcinoma treated by lumpectomy plus tamoxifen and radiation (317 women) or tamoxifen alone (319 women). The only significant difference in outcome between the two groups was in the incidence of locoregional recurrence. Freedom from in breast recurrence at 10 years was 98% in the group randomized to tamoxifen plus radiation and 91% in the group randomized to tamoxifen alone. The difference in freedom from ultimate mastectomy at 10 years (98% with irradiation and 96% without) did not reach statistical significance. No significant differences were seen between the two groups with regard to distant metastases, all-cause mortality, or breast cancer-specific mortality. Decreasing IBTR by 7% at 10 years did not have an impact on ultimate breast conservation, distant metastases, or death from other causes. It should be noted that this trial accepted minimal margins (no ink on tumor) and that with more modern attention to margins and use of aromatase inhibitors, the difference in IBTR might be even less.

Thus, while lesser and lesser courses of radiation are possible, it is unclear that the inconvenience, morbidity, and expense can be justified. In women age 70 and older with small ER-positive tumors, the approach of endocrine therapy alone is compelling, and the National Cancer Center Network (NCCN) changed its guidelines in 2004 to make irradiation optional in women age 70 and above (44). Despite this, there was little change in the use of radiation in this older group

by 2007, 3 years after the initial publication of 9343 (45). But there is hope, because at NCCN hospitals, the rate of irradiation in women age 70 and above who meet the 9343 criteria has decreased in women age 70 to 74 (94% in 2000 to 88% in 2009) and women age 80 and above (80% in 2000 to 38% in 2009) (44). Further progress is needed. For older women with small (≤2 cm), ER-positive cancers, lumpectomy, selective axillary surgery, endocrine therapy, and no radiation appears to be a very reasonable approach to management.

Wide excision of the primary tumor alone in older women has resulted in local control rates ranging from 71% to 97% (41). In general, these results are inferior to those of other treatments, such as lumpectomy and breast radiation or lumpectomy plus endocrine therapy, but wide excision alone may be considered for patients with progressive localized breast cancer that is ER- and PR-negative and who have significant comorbidity, to minimize and potentially prevent complications of locally advanced breast cancer.

ENDOCRINE THERAPY ALONE AS PRIMARY TREATMENT

The use of tamoxifen alone as initial treatment for localized breast cancer was first studied in women who were not candidates for surgery or who refused surgical treatment; this approach is still appropriate in these settings. Subsequent randomized trials including a 2003 Cochrane analysis of 1,571 patients 70 and older fit for surgery and entered on seven randomized trials comparing tamoxifen to surgery showed that although primary endocrine therapy with tamoxifen was not as effective as surgery in preventing local recurrence, tamoxifen had no adverse effect on survival (46). The HRs for progression-free survival showed the benefit of surgery over endocrine therapy alone (0.55 and 95% CI, 0.39–0.77) and the time to tumor progression ranged from 18 to 24 months for all patients treated with tamoxifen as initial therapy. The Cochrane analysis, however, included trials that did not assess hormone receptor status and the time to tumor progression for patients on tamoxifen represents a worst-case scenario. Response durations of 10 to 50 months, however, remain the limiting factor to this approach for most patients, although in one series tumor regression can persisted up to 5 years in one-third of patients (47). For overall survival, the Cochrane analysis hazard ratio for surgery alone versus primary endocrine therapy was 0.98 (95% CI, 0.74–1.30) and for surgery plus endocrine therapy versus primary endocrine therapy was 0.86 (95% CI, 0.73–1.00). These survival data should not be surprising because tamoxifen is an extremely effective adjuvant therapy in hormone receptor-positive patients and likely compensates for the better local control gained with surgery.

In women with hormone receptor-positive breast cancer, response rates to neoadjuvant endocrine therapy are high and responses are usually evident within the first few months of starting therapy. However, further reduction in tumor size is frequent with longer durations of therapy. This latter observation is especially important for older women who present with advanced locoregional tumors not amenable to initial surgery. It is also likely that other factors known to predict the benefits of adjuvant endocrine therapy are likely to predict the likelihood of a response to neoadjuvant endocrine therapy, including lower tumor grade, a greater percentage of tumor cells displaying estrogen and progesterone receptors, and a lower proliferative index. A low 21-gene recurrence score obtained from a core biopsy may also be predictive of a response to neoadjuvant endocrine therapy (48).

In both the adjuvant and metastatic settings, aromatase inhibitors have proven superior to tamoxifen and this appears also to be true in the neoadjuvant setting. In a prospective randomized trial of 327 postmenopausal women with inoperable hormone receptor-positive tumors, complete and partial responses assessed by breast examination were 55% and 36%, and breast conserving surgery possible in 45% and 35% of patients treated with letrozole or tamoxifen, respectively (49). In another trial of 250 postmenopausal women with hormone receptor-positive primary breast cancer ineligible for breast-conserving surgery, tumor regression was noted in 60% and 41%, and breast-conserving surgery was successful in 48% and 36% of women randomized to letrozole or tamoxifen, respectively (50). These trials support the use of preoperative endocrine therapy, especially AIs, to improve a woman's chance for breast conservation after presenting with advanced locoregional disease. There is often concern that neoadjuvant endocrine therapy may be less effective than chemotherapy in causing tumor reduction. In one of the few randomized trials addressing this, neoadjuvant anastrozole or exemestane for three months was equally as effective as four cycles of paclitaxel and doxorubicin in causing tumor reduction and making patients candidates for breast conservation (51). Median time to clinical tumor response was similar (7 to 8 weeks); breast conservation rates were similar, pathologic complete response was seen in 6% of patients with endocrine therapy and 3% with chemotherapy, and disease progression while on treatment was 9% in both groups. As expected, toxicity was greater in the chemotherapy group.

In summary, primary endocrine therapy is not an ideal management approach for older women with hormone receptor-positive breast cancer who are fit for surgery, but it does offer those not able to undergo surgery or who refuse surgery the chance of disease control. The majority of older women with estimated survivals of greater than 5 years are likely to have tumor progression with endocrine therapy alone and should be encouraged to undergo surgery. Primary use of endocrine agents is only indicated for patients who refuse surgery or who have life expectancies limited to several years. For older patients who present with advanced locoregional hormone receptor-positive disease not amenable to surgery, neoadjuvant endocrine therapy should be considered; it is likely to be as effective as chemotherapy for reducing tumor size an making such patients candidates for surgery.

ADJUVANT THERAPY—GENERAL PRINCIPLES

As in younger women, the goal of adjuvant therapy in elders is to increase the chance for cure, and adjuvant therapy decisions should be based on risk of recurrence, estimated survival, and the potential benefits and toxicities of treatment. Adjuvant endocrine therapy is usually well tolerated. The decision to recommend chemotherapy is complicated by the fact that many older women have shortened survival due to existing comorbidity and are wary of the potential toxicities of treatment. The patient's life expectancy is a key factor in the adjuvant treatment decision because there is little role for adjuvant therapy in patients with life expectancies of 5 years or less. Life expectancy based on U.S. census data is factored into the treatment estimates provided by Adjuvant! (www.adjuvantonline.com) and can be estimated by other helpful tools (see reference (52) and www.eprognosis.org).

About 75% of elders with breast cancer have hormone receptor-positive and HER2-negative tumors and adjuvant endocrine therapy, regardless of nodal status, will offer them the greatest benefit. Although endocrine therapy can result

TABLE 84-3

Recommendations for Adjuvant Therapy in Women Older than 70 Years

Risk Category	*Definition*	*Treatment*
Node Negative and HER2 negative		
Minimal or low	<1 cm, ER and/or PR positive, grade I	No treatment or hormonal therapy
Moderate	>1 cm and <2 cm, ER and/or PR positive, grade I or II	- Hormonal therapy ± chemotherapy - If ER/PR positive and eligible for and willing to take chemotherapy, GEP is indicated to determine if chemotherapy is necessary.
High	>2 cm or grade II or III (any ER/PR)	- Hormonal therapy ± chemotherapy - If ER/PR negative, chemotherapy is indicated - If ER and/or PR positive and eligible for and willing to take chemotherapy, GEP is indicated to determine if chemotherapy is necessary
Node Positive and HER2 negative		
ER positive and/or PR positive	Any	- Hormonal therapy + chemotherapy - If minimal node involvement (1-3 nodes) and eligible for and willing to take chemotherapy, GEP is indicated to determine if chemotherapy is necessary
ER and PR negative	Any	Chemotherapy
HER2 positive	≥1 cm, any ER/PR	Consider chemotherapy and trastuzumab Hormonal therapy, if ER or PR positive

ER, estrogen receptor; PR, progesterone receptor. GEP, genetic expression profiling.

in toxicity, it is usually mild and not likely to affect function. The major decision is whether to offer chemotherapy, which can be associated with major toxicity. In one study of older patients with serious illness, 74% and 88% patients stated they would "rather die" than accept a treatment that caused loss of independence or cognitive function, respectively (53). Thus the decision to offer adjuvant treatment in older patients must strongly factor in the potential role of toxicity on functional status and quality of life. Our general recommendations for adjuvant therapy in women older than 70 years are outlined in Table 84-3 and are discussed below. Consensus recommendations and reviews for adjuvant therapy in elders have recently been published (54,55).

SELECTING ADJUVANT CHEMOTHERAPY

Adjuvant Endocrine Therapy for Hormone Receptor-Positive and HER2-Negative Tumors

The 2005 updated meta-analysis of adjuvant therapy trials by the Early Breast Cancer Trialists' Collaborative Group (EBCTCG) clearly shows the benefit of tamoxifen therapy and chemotherapy in improving relapse-free and overall survival in postmenopausal women with early-stage, hormone receptor–positive breast cancer (56). For such women 70 years and older 5 years of tamoxifen significantly decreased the annual risk of recurrence by 54% (standard deviation [SD] 13) and the annual risk of death by 34% (SD 13). Of note, these proportional reductions in breast cancer relapse and mortality were independent of nodal status, grade, tumor diameter, and chemotherapy use. A more recent 2011 EBCTCG analysis confirmed the benefits of 5 years of tamoxifen in women 70 years and older but noted a 0.6% combined risk of mortality from venous thromboembolism and endometrial cancer in women 55 years and older (57). This small but important risk should be factored in when considering tamoxifen in older women at low risk for recurrence.

Adjuvant endocrine therapy is discussed in Chapter 43. Although AIs may be a safer long-term choice for extended adjuvant therapy in elders, an extended duration of tamoxifen therapy may be an option for some older patients who cannot tolerate AIs, have a high risk of recurrence, and life expectancy of at least 5 years from completion of their endocrine therapy. The American Society of Clinical Oncology (ASCO) guidelines currently recommend that AIs be used as adjuvant therapy in postmenopausal women although no recommendations concerning the use of specific agents or schedules were made (58).

Unlike tamoxifen, AIs are not associated with endometrial cancer or thromboembolism but do increase the risk of fracture. In one study specifically looking at outcomes by age, women older than 70 years treated with letrozole did not have an increase in side effects when compared to placebo (59). As in younger postmenopausal women, the most common symptomatic toxicities of AIs are arthralgia and myalgia, which in some patients can be severe and lead to discontinuation of treatment. Older women who have osteoporosis at the time of endocrine therapy initiation may be best managed by starting with tamoxifen, which may improve bone density, and then switched to AIs 2 to 3 years later. Another option for women with severe osteopenia (T-score less than –2.0) or osteoporosis would be to start AIs and also to concurrently administer bisphosphonates or denosumab (60). In addition to preventing further bone loss, bisphosphonates may decrease risk of recurrence although this remains controversial.

Under-use of adjuvant endocrine therapy may put older patients with breast cancer at higher risk of disease recurrence and death. However, older women with hormone receptor-positive breast cancer with estimated survivals of 5 years or less who are frail or who have well-differentiated tumors ≤ 1cm are unlikely to benefit. A major issue in older patients taking endocrine therapy is compliance with treatment recommendations and a careful discussion of risks and benefits with patients and families is mandatory. In one study, women older than 80 years were half as likely as younger women to report a discussion about tamoxifen with their doctor (61). Also, from 15% to about 50% of older women discontinue tamoxifen before 5 years (62). Factors related to stopping tamoxifen early include toxicity, being older than 75 years, having increased comorbidity, and of major concern, having breast-conserving surgery without breast radiation. Compliance with aromatase inhibitor use is also a major issue with as many as half of patients discontinuing treatment by 4.5 years (63). Health-care providers must query older patients about compliance at every visit and continuously encourage patients to take their medications.

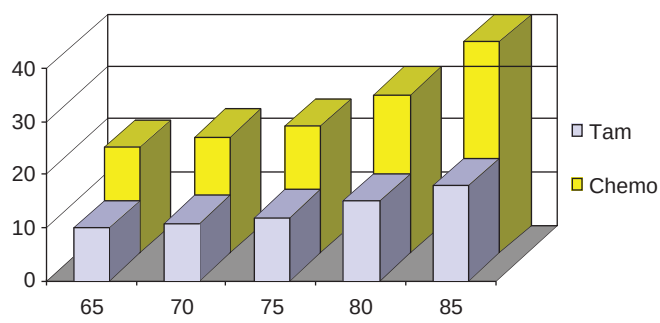
Chemotherapy in Older Women with Hormone Receptor-Positive, HER2-Negative Breast Cancer

For hormone receptor-positive, HER2-negative cancers, endocrine therapy is the mainstay of adjuvant treatment, but the major treatment decision is whether to recommend chemotherapy. The EBCTCG meta-analysis clearly showed that in women with hormone receptor–positive tumors, the combination of tamoxifen and chemotherapy was significantly better than the use of either modality alone (56). The proportional reductions in recurrence and death were 22% (SD 4%) versus 12% (SD 4%) for chemotherapy versus no adjuvant chemotherapy; 19% (SD 3%) versus 11% (SD 4%) for chemotherapy and tamoxifen versus tamoxifen alone; and 52% versus 47% for chemotherapy and tamoxifen versus chemotherapy alone. Of note, the EBCTCG meta-analysis included only about 1,000 women age 70 years or older entered in randomized trials comparing polychemotherapy with no chemotherapy. This sample size was insufficient to clearly define the benefits of chemotherapy in this oldest age cohort. However, the proportional benefits of chemotherapy for patients aged 70 years and older are likely to be similar to the benefits in postmenopausal women 50 to 69 years old. For patients aged 50 to 69 years, about 6 months of anthracycline-based chemotherapy reduced the annual breast cancer death rate by about 20%, irrespective of endocrine treatment.

The CALGB analyzed data from four randomized trials of adjuvant chemotherapy in 6,489 women with node-positive breast cancer, including three trials that included anthracyclines (64). These four trials compared different doses, schedules, and chemotherapeutic agents; patients receiving more treatment (higher doses of therapy or anthracyclines in addition to CMF regimens, or taxanes in addition to doxorubicin and cyclophosphamide) had superior relapse-free and overall survival compared with patients receiving less treatment. Similar to younger patients, those 65 years and older fared significantly better with more chemotherapy compared with less chemotherapy (31% risk reduction in relapse for those receiving more treatment; 95% CI for risk reduction, 9% to 47%). However, about 1% of older patients died of treatment-related toxicities (64). A recent meta-analysis of the EBCTCG evaluated the benefits of different polychemotherapy regimens for early breast cancer among 100,000 women in 123 randomized trials (65). This supported observations from prior trials that adding four cycles of a taxane to an anthracycline-based regimen leads to a significant reduction in breast cancer mortality (RR 0.86, SE 0.04, two-sided significance [$2p$] = 0.0005). Of note, there was no significant improvement in survival when longer or dose enhanced anthracycline-based regimens were compared to anthracycline regimens followed by taxanes (RR 0.94, SE 0.06, $2p$ = 0.33). In this meta-analysis proportional risk reductions were little affected by age, ER status, nodal status, tumor diameter, tumor grade, or tamoxifen use. However as in prior EBCTCG analyses involving chemotherapy, not enough patients 70 years were accrued and these data are not generalizable to older women.

Few older women with node-negative, hormone receptor-positive cancers will derive a meaningful survival benefit from chemotherapy. In addition, the natural history of hormone receptor-positive breast cancer in women treated with endocrine therapy indicates that the majority of relapses and the vast majority of cancer deaths occur after 5 years (56). Some older women with hormone receptor-positive cancer undoubtedly will benefit from chemotherapy, and those with estimated survivals exceeding 10 years should be considered for a gene-based assay (OncotypeDx and others) because some may have high 10-year risks of metastases and breast cancer death with endocrine therapy alone and may derive major benefit from chemotherapy (see Chapter 45). For women with one to three lymph nodes and low or low-intermediate recurrence scores, endocrine therapy alone may suffice, and a clinical trial randomizing women with hormone receptor-positive tumors and 1 to 3 positive lymph nodes (who will receive endocrine therapy) to chemotherapy or not is now in progress to confirm these observations (RxPONDER; NCT01272037). For all older women with node-positive tumors, the use of the web-based program Adjuvant! (www.adjuvantonline.com) can help in the chemotherapy decision process because benefits of treatment are based on estimated life expectancy and comorbidity. Although helpful, the potential benefits of newer more effective but toxic treatments provided by the program have not been validated independently and may overestimate treatment value.

Other estimates of the value of adjuvant chemotherapy in older women with hormone receptor-positive breast cancer may be helpful. Extermann and associates studied the threshold risk of relapse at which adjuvant tamoxifen and chemotherapy offered benefit to women up to age 85 years, including those with and without comorbidity (66) (Fig. 84-3). Using data from the 1992 overview analysis (67), these investigators examined the threshold risk of recurrence



Extermann et al, JCO 2000 12:1709

FIGURE 84-3 Ten-year risk of breast cancer relapse needed to improve mortality by 1% in patients with estrogen receptor–positive tumors.

for a 1% benefit in 5-year or 10-year relapse-free survival in older women with ER-positive tumors and for tamoxifen therapy, standard chemotherapy, or both. For tamoxifen, the threshold risks of relapse were 11% and 20% for a 1% benefit in 10-year survival for healthy and sick women at age 65 years while for age 85 years, the risks were 28% and 35% for a 1% benefit in 5-year survival for healthy and sick women, respectively (no 10-year survival benefit was seen in this age group). For chemotherapy, the threshold risk of relapse was 19% for a healthy 65-year-old patient and 62% for a sick 85-year-old patient. Although newer chemotherapy regimens are likely to lower the thresholds for treatment, the changes in these thresholds are likely to be very modest. This analysis further supports the view that chemotherapy benefits are likely to be very small in patients 75 years and older whose tumors are ER or PR receptor-positive.

The EBCTCG meta-analysis showed that six cycles of CMF and four cycles of standard AC were equivalent (RR 0.98, SE 0.05, $2p = 0.67$), but that anthracycline-based regimens with substantially higher cumulative dosage than standard AC (e.g., six cycles of CAF or CEF) were superior to standard CMF or four cycles of AC (65). Recent data suggests that four cycles of the non-anthracycline containing regimen docetaxel and cyclophosphamide (TC) are superior to four cycles of AC and result in superior disease-free and overall survival (68). At a median of 7 years follow-up, the difference in DFS and OS between TC and AC was significant with hazard ratios of 0.74 (95% CI, 0.56–0.98) and 0.69 (95% CI, 0.50–0.97), respectively, and the patients 65 and older did as well as their younger cohorts. The favorable hazard ratios for TC compared AC appear similar to the benefits seen for more intensive chemotherapy regimens in the EBCTCG analysis (65). The effect of the TC regimen on function has been retrospectively evaluated in 110 patients 70 years and older, many of whom had geriatric assessment (69); the regimen was reasonably well tolerated and 91% of patients received 4 or more cycles and 11% had dose modifications. This regimen currently represents a reasonable chemotherapy choice for many older women with hormone receptor-positive, HER2-negative breast cancer and avoids the use of anthracyclines.

Two instruments are available to predict chemotherapy toxicity in older patients. One, developed by the Cancer and Aging Research Group (CARG) (70), found 11 characteristics and clinical factors predictive of toxicity that were used to develop a score: a score of 3 was assigned for GI/GU cancer-type, delivery of standard-dose chemotherapy, hemoglobin less than 10 g/dL in women (<11 g/dL in men), creatinine clearance <34 mL/min, and 1 or more falls in the last 6 months; a score of 2 was assigned for age ≥73 years, use of poly-chemotherapy regimen, hearing impairment, and limited ability to walk 1 block; and a score of 1 was assigned if assistance was required in taking medications or for decreased social activity. Among 500 patients age 65 and older with stage I-IV cancer, at least one grade 3-5 toxicity occurred in 53% and there was 2% treatment related mortality. In the 1-19 point scale, higher scores indicated higher risk of grade 3-5 toxicity. Risk of grade 3-5 toxicity was 25% to 32% for scores of 1–5, 50% to 54% for 6–9, and 77% to 89% for 10–19. This model was better able to predict toxicity than the KPS (70). A second tool, the Chemotherapy Risk Assessment Scale for High-age patients (CRASH) score, uses both geriatric assessment tools and information classically used in clinical oncology practice to determine risk of hematologic and non-hematologic toxicity from chemotherapy (71). This tool, available online at www.moffitt.org/saoptools, is composed of two sub-scores, one predicting the risk of grade 4 hematologic toxicity and one predicting the risk of grade 3–4 non-hematologic toxicity.

Chemotherapy in Older Women with Hormone Receptor-Negative, HER2-Negative Breast Cancer

About 15% of older women present with hormone receptor-negative and HER2-negative (triple-negative) breast cancer. In this setting chemotherapy is of great value in node-positive and high-risk node-negative disease. Triple-negative breast cancer has a similar natural history in older and younger women (72), and a 2008 EBCTCG meta-analysis of women with estrogen-receptor-poor breast cancer showed a significant benefit for polychemotherapy in both women less than 50 years and those 50 to 69 years (73). The 10-year risks of recurrence and dying of breast cancer for those treated with polychemotherapy versus no chemotherapy (about six cycles of CMF or CAF) were 33% versus 45% and 24% versus 32% for those less than 50 years, and 42% versus 52%, and 36% versus 42% for those 50 to 69 years, respectively. Tamoxifen was of no benefit in these patients, and although there was no information on HER2 status, the vast majority of these patients are likely to have triple-negative tumors. The majority of these patients relapse within 5 years of diagnosis and, except for frail patients and those with a short life expectancy, the major decision is whether to use anthracycline or non-anthracycline chemotherapy. More aggressive treatment regimens using taxanes or longer durations for anthracycline-based therapy have resulted in better outcomes for patients on clinical trials and should be considered in healthy elders. Calculating treatment benefits from newer regimens using Adjuvant! (www.adjuvantonline.com) can be helpful in making treatment decisions, although there is not yet clinical validation of the benefits of these newer treatment regimens in older women.

Chemotherapy in Older Women with HER2-Positive Breast Cancer

For patients with HER2-positive tumors, the major consideration for therapy (in addition to endocrine therapy for those with hormone receptor-positive tumors) is the use of chemotherapy and trastuzumab. Older patients with small HER2-positive, node-negative, hormone receptor-positive tumors (T1a and T1b) are not likely to derive major benefit from chemotherapy and trastuzumab, while elders with hormone receptor-negative, HER2-positive tumors are likely to derive the greatest benefit from such treatment. Calculating the benefits of trastuzumab and chemotherapy in elders is challenging and at present Adjuvant! (www.adjuvantonline.com) does not provide for a simple assessment of treatment benefits. The Predict+ program (http://www.predict.nhs.uk/predict.shtml) has been validated in patients with HER2-positive tumors, incorporates age into treatment benefit estimates, and can of great help in determining the benefits of trastuzumab and chemotherapy in older patients (74). The use of trastuzumab or other anti-HER2-directed therapy without chemotherapy in lower risk, HER2-positive patients has not been studied and trials are being planned.

There is a greater risk of cardiac toxicity with trastuzumab in older patients and treatment requires careful monitoring. After 7 years of follow-up of National Surgical Adjuvant Breast and Bowel Project B-31, a randomized trial comparing anthracycline-containing chemotherapy with or without trastuzumab, 4.0% of 944 patients in the trastuzumab arm had a cardiac events compared to 1.3% of 743 patients who received chemotherapy alone. The majority of patients with cardiac toxicity recover after stopping trastuzumab, and only two cardiac events occurred more than 2 years after trastuzumab initiation (75). The authors have developed a

cardiac risk model from this trial that includes patient age that may be of major interest to clinicians caring for elders. In addition, data from another practice-changing randomized trial comparing chemotherapy with and without trastuzumab suggests that the non-anthracyline regimen of docetaxel and carboplatin combined with trastuzumab ("TCH") is as effective as anthracycline/trastuzumab regimens but less cardiotoxic (76). The TCH regimen should be considered for older patients with HER2-positive tumors. The use of beta blockers and ACE inhibitors can help reverse cardiac toxicity associated with trastuzumab (77); older patients with cardiac risk factors who are candidates for trastuzumab may benefit from cardiology consultation prior to initiation of treatment and may be considered for prophylactic use of these agents.

TREATMENT OF METASTATIC DISEASE

Selecting Therapy

Metastatic breast remains incurable. The goal of treatment in older women, like in younger women, should be to control symptoms, maintain function, and maximize quality of life. All women, regardless of age, should be managed using the principles outlined in Chapters 70–72. At least 75% of elders have metastases from a hormone receptor-positive primary lesion. These patients should be treated with endocrine therapy until there is clear evidence that the tumor is resistant to treatment. Endocrine agents should be used sequentially, and patients who have responded or had at least several months of stabilization to a specific agent may be rechallenged with the same agent, provided at least 6 months have lapsed since prior use. Once metastases are clearly refractory to endocrine therapy, older patients will be candidates for chemotherapy. For older patients with metastases but with good organ function, metastases that are not rapidly progressing, and with moderate or absent symptoms, treatment with single agent sequential chemotherapy is the best strategy. There is no compelling evidence that there is an optimal sequence of either endocrine therapies or chemotherapeutic agents and, for chemotherapy, we recommend starting treatment with the least toxic agents. Combination chemotherapy is associated with convincingly superior response rates and time to progression compared to single agents but is more toxic and does not lead to convincing improvement in survival. It should be considered for patients with rapidly progressive tumors where even modest progression would be life threatening. For patients with tumors that are HER2 positive, anti-HER2 directed therapy can substantially improve response to treatment and the duration of the response (see Chapter 72).

Older patients with lytic bone metastasis should be treated with bone resorption inhibitory drugs (bisphosphonates or denosumab). Since these agents are not associated with improved survival, there is no compelling reason to administer these drugs to asymptomatic or minimally symptomatic patients with blastic lesions only. Bisphosphonates and denosumab are effective at preventing skeletal-related events (SREs), bone pain, and hypercalcemia. This topic is discussed in detail elsewhere in this textbook (see Chapter 82). For patients with multiple painful bony metastases, treatment with radioactive pharmaceuticals such as strontium-89 and samarium-153 may result in major palliation with modest toxicity.

Endocrine Therapy

For patients with metastases that are detected while on adjuvant tamoxifen or whose cancer recurs greater than a year after stopping adjuvant aromatase inhibitors, initial endocrine treatment should be with an aromatase inhibitor. Large randomized trials have consistently shown that aromatase inhibitors (AI) are equally or more effective than tamoxifen in the metastatic setting (see Chapter 70). Although there is an increased risk for osteoporosis and fracture with long term AI use, in the metastatic setting osteoporosis is less problematic than in the adjuvant setting due to shortened life expectancy and the likelihood that many of these patients will have bone metastases and are also being treated with bisphosphonates or denosumab. Of note, a recent trial comparing anastrozole alone versus anastrozole and fulvestrant as initial therapy in 694 postmenopausal patients (median age of 65 years) with metastatic breast cancer showed both a significant improvement for the combination for both progression-free (15.0 months vs. 13.5 months, HR 0.80; p = .007) and overall survival (47.7 months vs. 41.3 months, HR 0.81; p =.05) (78). The major benefit was seen in the approximately 60% of patients who had no prior tamoxifen (PFS of 17.0 months for the combination vs. 12.6 months for anastrozole alone). A similar trial in 514 women showed no difference for the combination (79). The reasons for these differences are uncertain, and it is also uncertain if sequential use of an AI versus tamoxifen would be as effective because fewer than 41% of the patients on the Mehta trial (78) crossed over to fulvestrant after progression on anastrozole. At present the combination would appear to be a reasonable choice for the small percentage of older women who present with large volume and/or functionally impairing metastatic disease who have not had prior endocrine therapy. For the majority of older patients who develop metastases while on an AI, tamoxifen remains the treatment of choice.

About 30% to 60% of elders treated with first-line endocrine therapy have an objective response by RECIST criteria that can result in a dramatic improvement in symptoms and generally lasts for 9 to 12 months. Another 20% to 30% of patients have stable disease with no change in tumor size for at least 24 weeks. As in younger patients, higher response rates and long durations of response to endocrine therapy are more frequently seen in patients with longer disease-free intervals, those with only bone or soft tissue metastases, or a lesser number of metastatic sites. After tumor progression on initial treatment, subsequent response rates and durations of response are about half that for initial therapy. Optimal use of endocrine therapy is achieved by using agents sequentially until metastases progress. Those with metastases resistant to both tamoxifen and an AI can be treated with a different AI or fulvestrant, a selective estrogen receptor down regulator ("SERD"). Patients with very slow growing tumors refractory to these agents can be further treated with progestins (megestrol acetate and others), estradiol, and even glucocorticoids. Using endocrine therapy until metastases are convincingly refractory to such treatment allows for a delay in chemotherapy and maintenance of the highest quality of life.

A list of endocrine therapies and their potential toxicities are found in Table 84-3. A recent phase III trial (BOLERO-2) in 724 patients (median age 62 years) who had recurrence or progression of metastases on non-steroidal AIs (anastrozole or letrozole) compared the AI exemestane either alone or in combination with the mTOR inhibitor, everolimus (80). Median PFS was 6.9 months for the combination compared to 2.8 months with exemestane alone (HR 0.43; p <.001), but the combination was quite toxic and associated with increased stomatitis, fatigue, asthenia, diarrhea, cough, pyrexia, and hyperglycemia; 19% of those taking the combination withdrew from study, but quality of life was similar among both arms. Objective response rates were low in both groups—about 1%

for exemestane and 10% for the combination; mature survival data are not yet available. Of note, of 118 patients 70 years and older in the everolimus group, grade 3/4 toxicity was substantial with fatigue in 10%, anemia 10%, hyperglycemia 9%, stomatitis 8%, dyspnea 7%, pneumonitis 5%, neutropenia 3%, and hypertension 3% (81). These results are of interest, and consideration of this combination in older patients who meet the eligibility criteria for this trial is reasonable, although such patients should be carefully monitored for toxicity and should be advised of the high costs of everolimus.

Chemotherapy

The response rates and toxicity profiles of the standard chemotherapy regimens for metastatic breast cancer in older women who are functional and in reasonably good general health are similar to younger women. Chemotherapy for metastatic disease is discussed in detail in Chapter 71. The pharmacology of chemotherapeutic agents in older patients should be considered when selecting treatment because of the organ decline associated with increased age. The severity and duration of myelosuppression are modestly increased in older patients treated with chemotherapy, but this has not resulted in major differences in mortality related to neutropenia, sepsis, or bleeding. Nausea and vomiting may be less frequent in older patients, and psychosocial adjustment to chemotherapy appears better for older than for younger women. Models to help predict chemotherapy related toxicity have been discussed above (70,71). In older patients especially, sequential treatment with single agents is the strategy of choice. Only in the uncommon circumstance where urgent reduction in tumor burden is needed should combination chemotherapy be the initial choice.

There are many options for first-line chemotherapy. Capecitabine represents an excellent treatment choice for the older patient because it can be given orally and is rarely associated with myelosuppression or nausea and vomiting; it does not cause neuropathy. Starting at a lower dose and increasing the dose on subsequent cycles can avoid or minimize the hand-foot syndrome and diarrhea that can be dose limiting (82). Weekly paclitaxel has also been studied as first-line chemotherapy in elders and is highly effective but associated with a 15% occurrence of serious toxicities (83). Closely monitoring taxane-treated older patients for neuropathy is essential because even grade 1 or 2 neuropathy can adversely affect function. After tumor progression on the first chemotherapy regimen, response rates to subsequent "salvage" chemotherapy regimens are generally poor. Eribulin has been shown to be effective in elders with metastases (84), but it is also associated with neuropathy. Vinorelbine has also been evaluated in older patients; it had similar pharmacokinetics and a favorable toxicity profile when older patients were compared to younger women (85). Liposome-encapsulated doxorubicin is being tested in older patients because it is less cardiotoxic than other anthracyclines and easy to administer (86). Although a large number of biologic agents are currently in phase II and III trials, none except for those directed against HER2 tumors (see below) are FDA approved as monotherapy or in combination with chemotherapy.

Anti-HER2 Therapy

About 10% to 15% of elders have HER2-positive tumors. In the metastatic as in the adjuvant setting, the addition of trastuzumab to first-line chemotherapy has improved survival compared to chemotherapy alone (see Chapter 72). Elderly patients can tolerate trastuzumab well but require close monitoring for potential cardiac toxicity that increases with increasing age, especially in those with a history of cardiac disease or diabetes (87). Trastuzumab used as monotherapy can also be very effective and, except for cardiac risk, is associated with only minimal toxicity. Lapatinib, another anti-HER2-directed small molecule, can also increase response rates and duration of response when added to chemotherapy in trastuzumab-treated patients; its rate-limiting toxicity is diarrhea. In addition, when added to endocrine therapy with aromatase inhibitors, it is associated with increased response and progression free survival (see Chapter 72). It is uncertain however whether the combination of endocrine therapy and lapatinib is superior to endocrine therapy alone followed by lapatinib. The combination of lapatinib and trastuzumab has been shown to be extremely effective and well tolerated in patients with metastases refractory to trastuzumab. Other new anti-HER2 therapies, including pertuzumab and ado-trastuzumab-emtansine, have great potential but as yet there are no detailed data as to the tolerance of these agents in older women.

MANAGEMENT SUMMARY

Older age is a major determinant of life expectancy but is not an adequate independent predictor of treatment tolerance, disease outcome, or survival. It is essential to consider functional status, disability, and comorbidity in formulating an optimal management plan. In addition to careful screening for comorbid illness and its severity, we recommend making use of (i) available screening tools for geriatric syndromes, (ii) survival predictors, such as ePrognosis, and (iii) tools that determine risk of treatment toxicity, such as that created by CARG and the CRASH score. The composite of these proven tools in geriatrics, together with knowledge of breast cancer stage and biology, will aid older patients and their physicians in weighing the risks and benefits of surgical, radiation, and systemic therapies.

Screening

- Yearly clinical breast examination and monthly breast self-examination is recommended for all women.
- Yearly mammography is recommended up to age 75 years.
- Mammography every 2 or 3 years is recommended for women over age 75 years who have minimal limiting comorbid conditions.
- Compliance with mammography is best if it is recommended by the primary physician.
- In women with multiple comorbidities, the benefit of screening mammography should be weighed against estimated life expectancy.

Local Definitive Therapy

- No single approach for managing the primary lesion fits all older women. For older women with severe comorbidity and hormone receptor-positive tumors, treatment with endocrine therapy (tamoxifen or aromatase inhibitor) alone is reasonable. Otherwise, selection criteria for BCT and mastectomy do not differ on the basis of age.

- Preoperative endocrine therapy with tamoxifen or aromatase inhibitors may be tried in an effort to make breast-conserving therapy possible in patients with hormone receptor-positive tumors not initially amenable to breast conserving surgery.
- Sentinel node biopsy is appropriate for clinically node-negative tumors in women who plan to have a mastectomy, those with larger or hormone receptor negative tumors, or those where the outcome will impact use of chemotherapy.
- For women with small (T1), hormone receptor-positive tumors who undergo lumpectomy and where chemotherapy would not be seriously considered, sentinel node biopsy has little value.
- For women with hormone receptor-negative cancers, or T2 or greater hormone receptor-positive tumors, who will undergo lumpectomy, breast irradiation is recommended.
- Patients with clinically positive nodes who do not meet the criteria for the Z11 trial should undergo axillary node dissection (if patients are sufficiently healthy to undergo surgery), followed by breast radiation.
- For the patient with a T1, node-negative, hormone receptor-positive cancer, the use of endocrine therapy, with or without radiation (full course or abbreviated), should be discussed. Some patients are too frail for surgery when they present for treatment, and their tumors are ER and PR negative. Individualized treatment and frank discussions with these patients and their families are essential.

Systemic Adjuvant Therapy

- Adjuvant endocrine therapy should be considered in all older women with hormone receptor–positive tumors. Only older women with a very low risk of distant metastases (<10%) or severe comorbid illness should not be offered tamoxifen or an aromatase inhibitor.
- Adjuvant chemotherapy should be considered for older women whose risk of systemic breast cancer recurrence is sufficiently high and who are in good general health (estimated survival of at least 5 years).
- Chemotherapy is most beneficial in older women who have ER/PR negative or HER2-positive tumors. For older women with hormone receptor–positive tumors, however, there may be only a small added value to chemotherapy, even in patients with positive lymph nodes; the added value of chemotherapy in these patients should be estimated from available models (i.e., www.adjuvantonline.com) and new genetic tests may be helpful in selecting treatment (OncotypeDx and others).
- Trastuzumab and chemotherapy should be considered for older women with HER2-positive tumors.

Treatment of Metastatic Disease

- Endocrine therapy is the standard front-line treatment for almost all women with hormone receptor–positive metastatic breast cancer.
- There is no optimal sequence of endocrine therapy. Aromatase inhibitors tamoxifen and fulvestrant are the mainstays of treatment. Megestrol acetate, estrogens, or corticosteroids may be considered in selected patients.
- Patients who have responded to endocrine therapy can be rechallenged with the same agent or a similar agent (i.e., a steroidal aromatase inhibitor in a patient whose disease has progressed during treatment with a nonsteroidal inhibitor).
- Chemotherapy should generally be reserved for women with symptomatic disease who have progression of metastases during endocrine therapy.
- The sequential use of single chemotherapeutic agents is the preferred strategy.

CHAPTER 85

Breast Cancer in Younger Women

Ann H. Partridge, Aron Goldhirsch,
Shari Gelber, and Richard D. Gelber

CHAPTER CONTENTS

OVERVIEW

Breast cancer rarely occurs in young women. Of the hundreds of thousands of breast cancers diagnosed worldwide, fewer than 0.1% occur in women under age 20 years; 1.9% between ages 20 and 34; and 10.6% between ages 35 and 44 (1,2). Although fewer than 7% of women diagnosed with breast cancer are younger than age 40, more than 13,000 young women are diagnosed annually with invasive or noninvasive breast cancer in the United States alone, with thousands more diagnosed worldwide (3). Incidence rates in young women appear to be fairly stable over the past several decades in young women in the Western world, despite increases in mammography and reproductive and lifestyle trends (4). A suggestion is that rates are increasing among young women, particularly in less-developed countries, but this may be owing to improvements in awareness, diagnosis, and reporting (5,6).

Despite the relative rarity of breast cancer in young women, it is the leading cause of cancer-related deaths in women under age 40, and survival rates for young women with breast cancer are lower than for their older counterparts. The 5-year relative survival rate for women with breast cancer diagnosed before age 40 is 84% compared with 90% for women diagnosed at age 40 or older (3). The preponderance of evidence to date suggests that young age is an independent risk factor for disease recurrence and death, despite young women having conventionally received more intensive treatment than older women (7,8). Delays in diagnosis and the lack of effective screening in younger women may contribute to the poorer prognosis because they are more likely to present with larger tumors and more involved lymph nodes (9,10). However, survival differences also likely reflect biological differences in the type of breast cancer identified in young women. Young women are more likely to develop more aggressive subtypes of breast cancer with unfavorable prognostic features, and are less responsive to conventional therapy compared with disease arising in older premenopausal or postmenopausal women (11,12). Specifically, tumors in young women are more likely to be high-grade, hormone receptor (HR)–negative, and have high proliferation fraction and more lymphovascular invasion. Accumulating evidence suggests that young women are also more likely to develop more aggressive tumor molecular subtypes including greater proportion of triple negative and ERBB2 (formerly HER-2/neu) overexpressing tumors (13,14) (Fig. 85-1). Furthermore, studies suggest that the prognostic effect of age may vary by tumor phenotype, although additional research is clearly warranted (15,16).

Recent studies have sought to determine whether breast cancer arising in young women may represent a distinct biologic entity with unique patterns of gene expression and deregulated signaling pathways that may affect prognosis (17–19). However, at the present time, it is uncertain whether young age will remain an independent prognostic factor as we continue to elucidate further the distinct molecular biologic features of breast cancers arising in both young and older women.

Also, evidence suggests that biologic subtypes of breast cancer vary by race as a function of age (14,20). In a large, population-based study of breast cancer subtypes within age and racial subsets, the basal-like breast cancer subtype (ER–, PR–, ERBB2–, cytokeratin 5/6 positive, and/or ERBB1+) was more prevalent among premenopausal black women (39%) compared with postmenopausal black women (14%) and

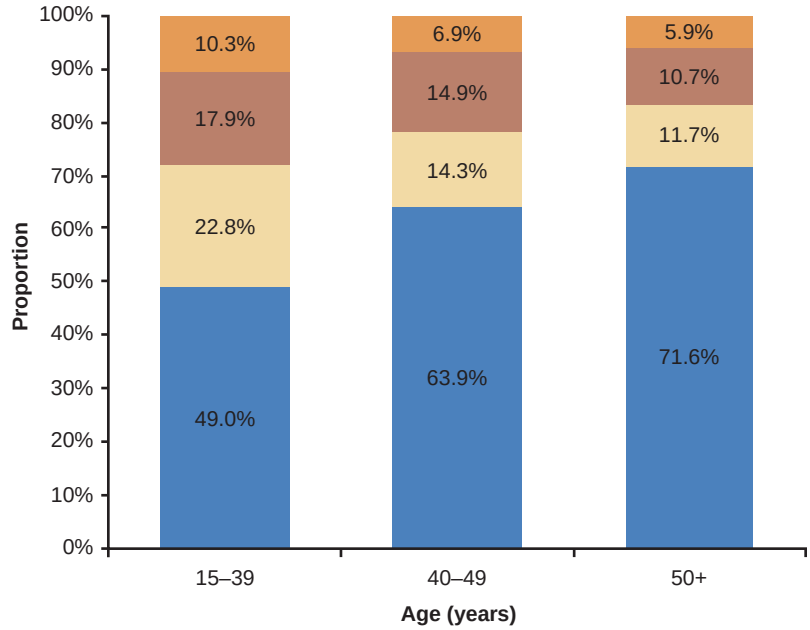

FIGURE 85-1 Proportion of breast cancer subtypes among California women by age group, 2005–2009. Hormone receptor (HR)–positive and ERBB2 negative (blue), HR+/ERBB2+ (red), HR–/ERBB2+ (green), and triple-negative (purple). (From Keegan TH, et al. Occurrence of breast cancer subtypes in adolescent and young adult women. *Breast Cancer Res* 2012;14:R55.)

nonblack women (16%) of any age ($p < .001$), whereas the better prognosis luminal A subtype (ER+ and/or PR+, ERBB2–) was less prevalent (36% vs. 59% and 54%, respectively). This higher prevalence of basal-like breast tumors and lower prevalence of luminal A tumors likely contributes to the poorer prognoses of young black women with breast cancer (20) (see Chapter 31, Prognostic and Predictive Factors: Molecular).

In addition to being at higher risk of dying from breast cancer, despite conventionally receiving more aggressive therapy, young women face a variety of problems unique to, or accentuated by, their young age. They are more likely to be diagnosed at a life stage when role functioning in the home and work can be threatened or disrupted by the diagnosis and treatment of breast cancer. Issues such as attractiveness and fertility may be of substantial importance. Young women are more likely to have young children for whom they are responsible, or desire to have biologic children following treatment. They also have an increased risk of harboring a genetic risk factor for breast cancer, and often suffer from a relative lack of information regarding treatment and survivorship issues compared with older patients. These concerns may contribute to the greater psychosocial distress seen in younger women at both diagnosis and in follow-up (21).

Research to date on breast cancer in young women is limited by generally small sample sizes and heterogeneous cut-offs used to differentiate between young and old. Although, age is a continuum and any cut-off is somewhat arbitrary. Many investigators have chosen up to age 35 or 40 to define breast cancer in younger women, recognizing that previous work focusing on premenopausal women is composed primarily of women in their 40s, owing to the higher incidence of the disease in older premenopausal women.

RISK FACTORS FOR EARLY-ONSET BREAST CANCER AND GENETICS ISSUES

Aside from female gender, increasing age is the strongest risk factor for developing breast cancer. Consequently, younger women are at much lower risk even when compared with older premenopausal women. An average woman has a 1 in approximately 1,800 risk of developing breast cancer in her 20s, 1 in 230 in her 30s, and 1 in 70 in her 40s (3). Family history is the primary risk factor for developing breast cancer at a young age, particularly when breast cancer has occurred in a first-degree relative at a young age. Although 5% to 10% of breast cancers are attributable to germline mutations such as *BRCA1* and *BRCA2* on chromosomes 17 and 13, respectively, another 15% to 20% of breast cancers are associated with the presence of gene polymorphisms and environmental factors (e.g., radiation; see later). By virtue of her age alone, a young woman diagnosed with breast cancer has a greater probability of carrying a *BRCA* mutation. In an unselected group of women under age 40 having surgery for early breast cancer, 9% harbored a deleterious *BRCA1* or *BRCA2* mutation (22). Other factors, including a personal or family history of ovarian cancer, bilateral breast cancer, or Ashkenazi Jewish ancestry, may increase that risk. The meaning of an unknown variant of the *BRCA1* or *BRCA2* genes may also vary by race (23). Young women with breast cancer should consider genetic counseling and testing for *BRCA1* and *BRCA2*, particularly if they have a family history of breast or ovarian cancer. Please see Chapters 17 and 18 for more details.

Some rare genetic disorders may predispose younger women to develop breast cancer. These include Cowden disease (*PTEN* gene mutation on chromosome 10 and associated with hamartomas, as well as with breast or thyroid cancer at a young age), and Li-Fraumeni syndrome (mutation of *TP53* gene on chromosome 17, with increased incidence of soft tissue and bone sarcomas, brain tumors, adrenocortical tumors, and breast cancers) (24) (see Chapter 17 for more detail). Young women exposed to ionizing radiation during childhood and the teenage years, such as survivors of pediatric Hodgkin disease treated with mantle field irradiation, are also at high risk of developing breast cancer (25). Despite preconceptions, most cases of breast cancers occurring in young women appear to be spontaneous and not clearly related to either carcinogens in the environment or family cancer syndromes (26). However, environmental and hormonal risk factors for breast cancer are not well characterized for younger women, but appear to be somewhat different than for older women. Although breastfeeding appears to be protective against breast cancer at any age,

pregnancy appears to have a dual effect on the risk of breast cancer. Large epidemiologic studies indicate that earlier age at first live birth has a long-term protective effect on the lifetime risk of breast cancer, yet it transiently increases the risk immediately following childbirth for 3 to 15 years postpartum (27–29). The excess transient early risk of breast cancer is most pronounced among women who are older at the time of their first delivery. Thus, pregnancy has a protective effect for postmenopausal breast cancer and is a risk factor for premenopausal breast cancer, particularly for older premenopausal women. The biologic mechanism for this is not well elucidated. Also contrary to what has been demonstrated in older women, weight gain and higher body mass index appear to be protective against the development of breast cancer at a younger age (30–32).

BREAST DIAGNOSTIC ISSUES FOR YOUNG WOMEN

Most lesions arising in the breasts of young premenopausal women will be benign (see Chapter 10, Benign Breast Disease). Mammography is often of limited value in this population because of high breast tissue density, and targeted ultrasound or magnetic resonance imaging can provide additional discriminatory information in the workup of a breast abnormality (33,34). Breast cancers may be more extensive in younger patients, although it is not clear whether they are at higher risk of multicentricity or bilateral disease, in the absence of a hereditary predisposition, and no evidence indicates that multifocality affects survival in this population (35,36).

TREATMENT ISSUES

Many clinical trials have divided patient populations based on menopausal status, or age greater or less than 50. Virtually no published clinical trials have focused on treatment issues for the youngest women. Trials reporting results of treatments for premenopausal women largely reflect outcomes for patients in their 40s. Thus, findings from studies that consider average results for premenopausal women may not be directly applicable to very young patients.

Local Therapy Issues

Partly owing to inadequate screening options for young women, breast cancer in young patients tends to be diagnosed at a more advanced stage, with more stage 2 and 3 disease diagnosed than in older women (9,12). Consequently, young women may more likely need or benefit from preoperative systemic therapy than older women, although available data in this area are limited (37). Despite the large benefit that young women obtain from an irradiation boost to the tumor bed, most studies continue to indicate that young age is a risk factor for local recurrence, for both invasive and noninvasive disease (38–40) (Fig. 85-2). No evidence suggests, however, that mastectomy in young women improves survival compared with breast conservation, likely because these women are also at increased risk of systemic recurrence (41,42). In a population-based Danish cohort of 9,285 premenopausal women with breast cancer, the incidence of local recurrence was 15.4% after breast-conserving therapy among the 719 women under age 35 compared with 3.0% in women ages 45 to 49, although no difference was found in the risk of death between the two age groups (42). Thus, young age alone is not a contraindication to breast conservation. Nonetheless, an increasing number of young women are opting not only for mastectomy, but for contralateral prophylactic mastectomy (43). Reasons for this trend are not completely clear, nor is there evidence that such aggressive surgical measures will improve outcomes. For some young women, local therapy decisions may be influenced by the presence or absence of a known genetic risk for new primary breast cancer (i.e., a *BRCA1* or *BRCA2* mutation). Thus, prompt genetic counseling and testing for young women at risk for harboring a deleterious genetic mutation should be considered, especially for women for whom the results would have an impact on local therapy decisions. Bilateral prophylactic mastectomy and oophorectomy are increasingly considered for young women with known *BRCA1* or *BRCA2* mutations, despite the current lack of clear benefits of such risk-reducing strategies in breast cancer survivors (44,45).

At present, no relevant data are available on the late effects of radiation therapy plus modern systemic therapy (including anthracyclines, taxanes, and trastuzumab) on cardiac functioning in young women. Moreover, other effects of radiation therapy in patients with very long life expectancy must be taken into account (46).

Attention to margin status may be particularly important for young women undergoing breast conservation treatment. In one evaluation including 37 women younger than age 35 with lymph node–negative breast cancer having breast-conserving therapy, local recurrence rates were 50.0% for women with positive margins compared with 20.8% for those with negative margins (47). In a more recent publication, women age 40 or younger with invasive disease had 10-year local recurrence-free survival of 84.4% with negative margins versus 34.6% with positive margins, whereas women over age 40 had local recurrence-free survival of 94.7% if margins were negative compared with 92.6% if margins were positive (48). These findings translated to a 10-year distant disease-free survival (DFS) of 72.0% for younger women with negative margins compared with 39.7% (relative risk [RR] = 3.4) for the younger age group with positive margins, whereas for older women, no significant difference was seen in DFS among those with negative compared to positive margins. There is also evidence that young women may benefit additionally from postmastectomy breast irradiation in the setting of one to three positive axillary lymph nodes (49). Despite the clear benefits, recent population-based data suggest that very young women may be less likely to receive adjuvant breast irradiation after breast-conserving surgery (50). Further research is needed to understand these trends.

Systemic Therapy Issues

Adjuvant treatment recommendations are based on tumor and patient characteristics predicting the risk of systemic recurrence and potential responsiveness to therapy, as well as the patient's preferences and values. Increasingly, treatments are tailored, regardless of age, to the phenotypic subtype of the tumor as assessed by conventional factors, such as grade, proliferation rate, estrogen and progesterone receptors, and ERBB2 expression. More recent application of genetic signature technology has provided additional predictive information regarding the degree of risk and responsiveness to therapy (see Chapter 31). However, most of the data on adjuvant treatment response was obtained during an era when details related to endocrine responsiveness were either incomplete or imprecise. Even today, endocrine responsiveness evaluation requires improved reporting of steroid hormone receptors and a better understanding of the role of ERBB2 overexpression and amplification (51). Currently it is recommended that the estimation of

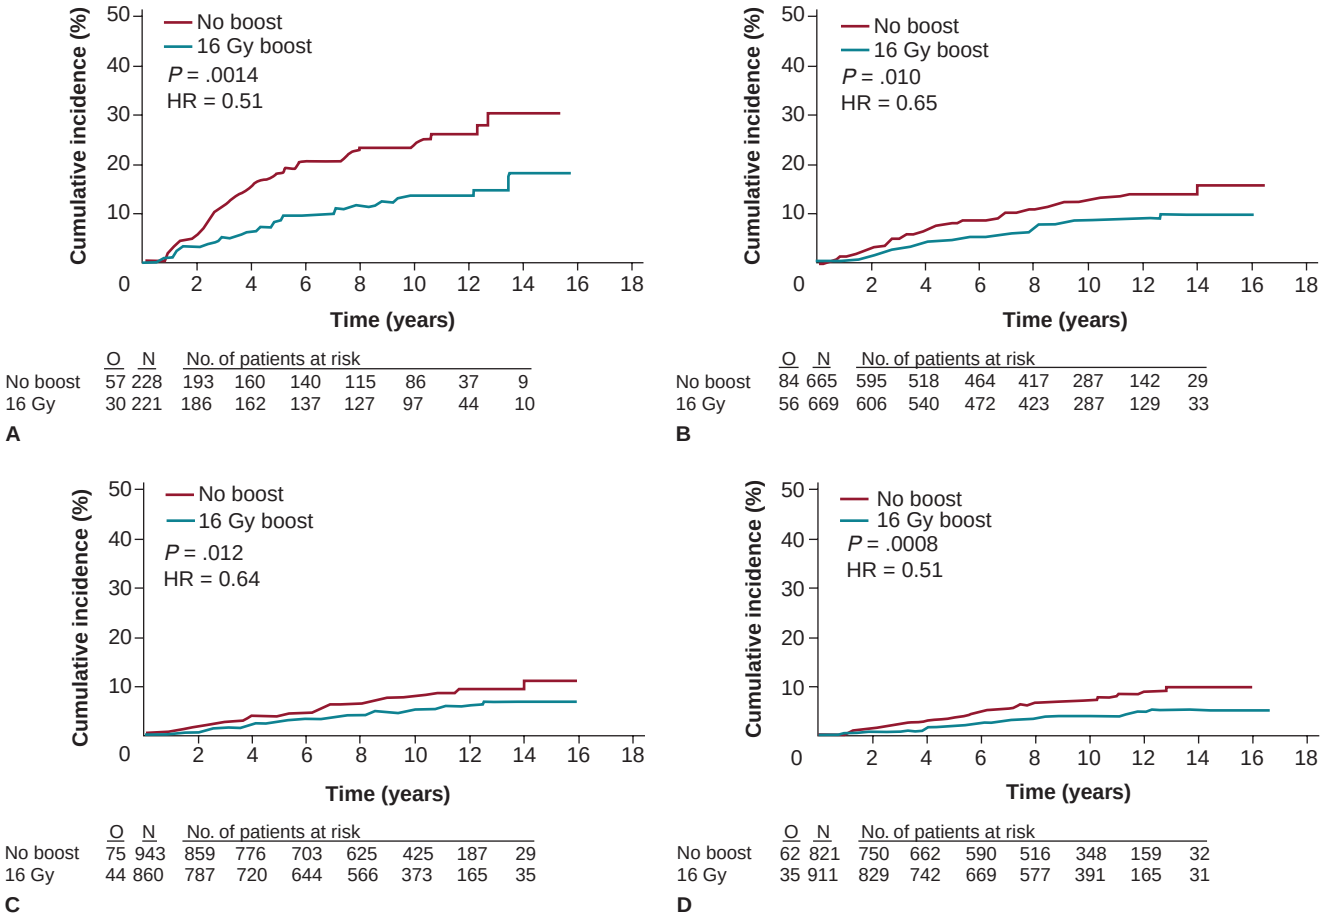

FIGURE 85-2 **Cumulative incidence of ipsilateral breast cancer recurrence according to age.** Age **(A)** ≤40, **(B)** 41 to 50, **(C)** 51 to 60, and **(D)** >60 years. (From Bartelink H, et al. Impact of a higher radiation dose on local control and survival in breast-conserving therapy of early breast cancer: 10-year results of the randomized boost versus no boost EORTC 22881-10882 trial. *J Clin Oncol* 2007;25:3259–3265, with permission.)

endocrine responsiveness should be the first consideration in tailoring adjuvant therapies for patients with breast cancer, regardless of age (52). Adjuvant chemotherapy has historically been used extensively in premenopausal patients because of its overwhelming beneficial effects on outcome (53). The incremental benefits of newer cytotoxic drugs and regimens, including the addition of the taxanes, dose density, and trastuzumab, appear to be present across age groups, although data for very young women are limited (54–58).

Adjuvant Systemic Therapy in Patients with Hormone Receptor–Negative Disease

For premenopausal women with hormone receptor (HR)–negative disease, adjuvant chemotherapy is a very important component of successful treatment. Only one trial, however, has prospectively tested the use of chemotherapy in women with HR-negative, node-negative disease (National Surgical Adjuvant Breast and Bowel Project [NSABP] B13) (59). Table 85-1 displays the relative risk of relapse for the chemotherapy-treated group compared with the surgery-alone group. No difference was found between the risk for very young patients compared with the older premenopausal patients, with a 38% reduction in the risk of recurrence from the use of chemotherapy. Novel biologic (e.g., anti-ERBB2-directed therapies, parp inhibitors) and chemotherapeutic regimens (e.g., platinum agents) that have shown promise in women with early and advanced disease may also be particularly relevant in the treatment of young women with breast cancer, given this population is more likely to develop more aggressive breast cancer subtypes and that they are more likely to harbor a BRCA1 or BRCA2 germline mutation.

Adjuvant Systemic Therapy in Patients with Hormone Receptor–Positive Disease: Chemotherapy and Endocrine Therapy

Controversy exists about the optimal management of young women with HR-positive breast cancer. Since the 1990s, adjuvant tamoxifen has been the mainstay of endocrine therapy for premenopausal women when the Early Breast Cancer Trialists' Collaborative Group (EBCTCG) overview, a large meta-analysis consisting of dozens of randomized trials, revealed a beneficial effect in women under age 50 similar to the benefit seen for older women (60). The first adjuvant systemic therapy for premenopausal women with breast cancer was ovarian ablation, but its use was almost abandoned in the mid-1970s when the benefits of adjuvant cytotoxic chemotherapy became clear. When the results of all trials of ovarian ablation were summarized by the EBCTCG meta-analysis, the beneficial effect of ovarian ablation appeared to be large in the absence of chemotherapy, whereas no

apparent advantage was seen when ovarian ablation was added to cytotoxic chemotherapy (61). More than 80% of the women in this chemotherapy-alone group experienced ovarian function suppression with the cytotoxic treatment, however, and the cohort was also a mixture of women with ER-positive and ER-negative disease (62). The International Breast Cancer Study Group (IBCSG) evaluated treatment outcome for very young women compared with older premenopausal women who received adjuvant chemotherapy alone. Very young premenopausal women (<35 years of age) with HR-positive tumors had a worse outcome compared with older premenopausal women, and compared with both older and younger women with HR-negative disease (63). This led to the hypothesis that the effects of cytotoxic chemotherapy on ovarian function, and the timing and duration of treatment-related amenorrhea, differ between older and younger premenopausal women. Very young women are much less likely to experience ovarian dysfunction with chemotherapy resulting in a poorer prognosis, particularly in the absence of additional endocrine therapy (64–67) (see Chapter 90, Reproductive Issues in Breast Cancer Survivors). To confirm the interaction between age and ER status in premenopausal women treated with chemotherapy alone, the IBCSG, NSABP, Eastern Cooperative Oncology Group (ECOG), and Southwest Oncology Group (SWOG) conducted a pooled analysis of 9,864 patients. Table 85-2 summarizes the results from all four cooperative groups. In each analysis, the relative risk of an event, estimated from a Cox proportional hazards regression model stratified by study and treatment group, was substantially higher for young patients with ER-positive tumors compared with the reference population of older patients with ER-positive tumors. This phenomenon was not observed for patients with ER-negative tumors. In recent years, it has become clear that in patients with HR-positive disease, the beneficial effects of cytotoxic agents are probably a result of a complex mixture of cytotoxic and endocrine effects of chemotherapy. IBCSG Trial VIII compared sequential chemotherapy followed by the gonadotropin-releasing hormone agonist goserelin with each modality alone in 1,063 pre- and perimenopausal

ER, estrogen receptor.

women with lymph node–negative breast cancer (68). Women were randomized to goserelin for 24 months (n = 346), six courses of "classic" CMF (cyclophosphamide, methotrexate, 5-fluorouracil) chemotherapy (n = 360), or six courses of classic CMF followed by 18 months of goserelin (CMF → goserelin; n = 357). (A fourth no-adjuvant treatment arm with 46 patients was discontinued early.) Of patients, 20% were age 39 years or younger and median follow-up was 7 years. Patients with ER-negative tumors had better DFS if they received CMF (5-year DFS for CMF = 84%, 95% confidence interval [CI], 77%–91%; 5-year DFS for CMF → goserelin = 88%, 95% CI, 82%–94%) than if they received goserelin alone (5-year DFS = 73%, 95% CI, 64%–81%). By contrast, for patients with ER-positive disease, chemotherapy alone and goserelin alone provided similar outcomes (5-year DFS for both treatment groups = 81%, 95% CI, 76%–87%), whereas sequential therapy (5-year DFS = 86%, 95% CI, 82%–91%) provided a statistically nonsignificant improvement compared with either modality alone, primarily because of the results among younger women (Fig. 85-3). The DFS results shown in Figure 85-3 according to treatment group illustrate that outcomes for older premenopausal women with ER-positive disease cannot be used to define appropriate treatment choices for younger women (in this example, ≤39 years). For some young patients, endocrine therapy alone may suffice, or a combined endocrine therapy approach may be optimal (69,70).

Tamoxifen

Tamoxifen, the most thoroughly studied selective ER modulator (SERM), has not been specifically investigated in very young patients. This drug typically increases the estradiol secretion from premenopausal ovaries. The updated EBCTCG meta-analysis of all randomized trials of adjuvant tamoxifen has revealed that 2 to 5 years of treatment has similar efficacy in all age groups, including patients less than 40 years of age (71). However, several analyses have suggested that the youngest women in various treatment groups seem to get less benefit from tamoxifen alone, which may be due in part to lower adherence to therapy in the very young (11,72,73). These findings suggest an opportunity to improve on treatment results for this patient population. It is also important to note that, although risks associated with tamoxifen (e.g., blood clot, stroke, and uterine cancer) tend to be much lower in younger patients than older patients, younger women are more likely to develop ovarian cysts because of high estradiol levels resulting in ovarian hyperstimulation while on tamoxifen (74,75). Nevertheless, tamoxifen substantially reduces the risk of breast cancer recurrence in women of all ages and recent data from the ATLAS trial demonstrating further improvement in mortality by extending tamoxifen to 10 years when compared to 5 years has opened up a new treatment option for young women who remain premenopausal after 5 years of tamoxifen and are therefore not candidates for aromatase inhibitor therapy (76).

Adjuvant Ovarian Ablation (Suppression) with or without Tamoxifen

The combination of ovarian suppression or ablation and tamoxifen has been tested in advanced disease and proved superior to either treatment alone (77). In a trial conducted in Asia, the combination of oophorectomy and tamoxifen compared with no adjuvant therapy resulted in an 11% absolute

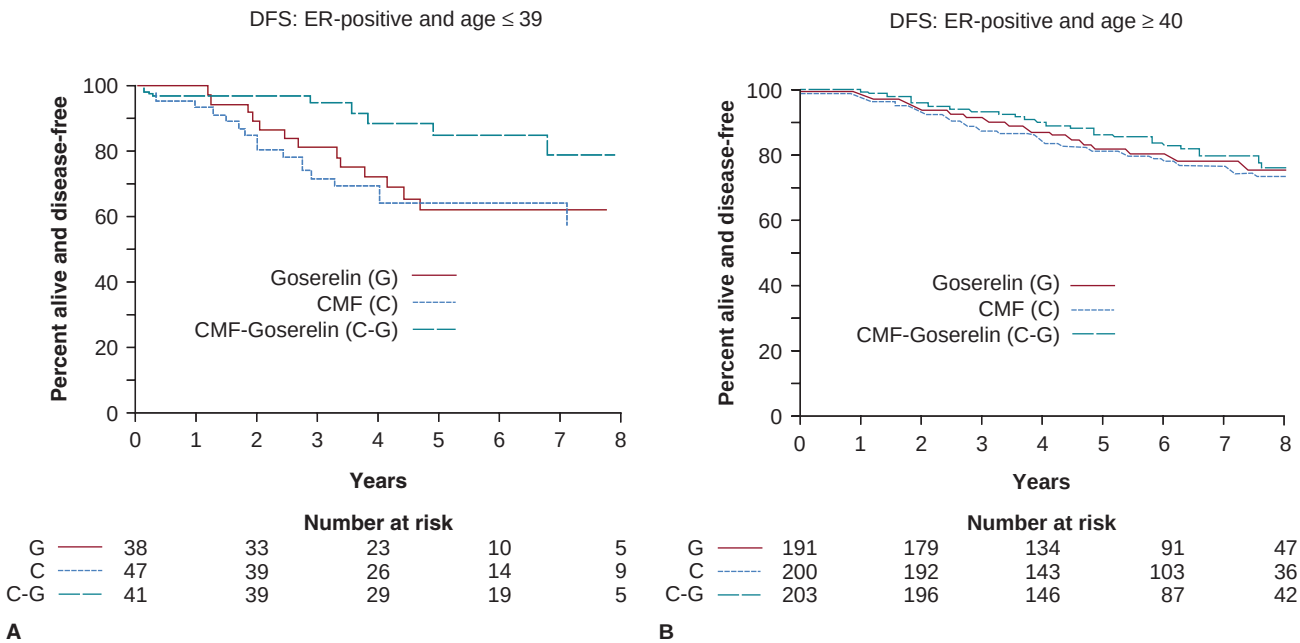

FIGURE 85-3 Kaplan-Meier plots of disease-free survival (DFS) for the ER-positive cohort enrolled in International Breast Cancer Study Group (IBCSG) Trial VIII comparing six courses of cyclophosphamide, methotrexate, and 5-fluorouracil (C), 24 months of goserelin (G), and six courses of C followed by 18 months of goserelin (C-G) at 7 years of median follow-up. Results for subgroups according to age less than 39 years **(A)** and age 40 years or more **(B)** are shown. (From International Breast Cancer Study Group (IBCSG). Adjuvant chemotherapy followed by goserelin versus either modality alone for premenopausal lymph node-negative breast cancer: a randomized trial. *J Natl Cancer Inst* 2003;95:1833–1846, with permission.)

benefit in DFS and an 18% benefit in overall survival (OS) at 10 years (78). In the subset of patients with ER-positive tumors, 10-year DFS probabilities were 66% in the treated group compared with 47% in the control group, corresponding to 10-year OS rates of 82% and 49%, respectively. In a subset analysis from this same study, ERBB2 overexpression appeared to have a favorable influence on response to adjuvant oophorectomy and tamoxifen in women with ER-positive disease (79).

Acceptance of ovarian function suppression, tamoxifen, or the combination may be a significant problem for premenopausal women in general and for younger patients in particular (80). Issues include objective and subjective symptoms of menopause, psychological distress, and adjustment to changes in personal and family plans. Chemotherapy seems easier to offer to younger patients because of its shorter duration and lesser degree of long-term effects on endocrine function than ovarian suppression, although evidence suggests most premenopausal healthy women would choose ovarian suppression over CMF chemotherapy, hypothetically (81). Long-term symptoms of acute ovarian suppression may be a particular problem for some patients. However, in an evaluation of 874 pre- and perimenopausal women in IBCSG Trial VIII (see previous section in this chapter), patients receiving goserelin alone showed a marked improvement or less deterioration in quality of life (QOL) measures over the first 6 months than those patients treated with CMF, yet no differences were seen at 3 years except for hot flashes (82). As reflected in the hot flashes scores, patients in all three treatment groups experienced induced amenorrhea, but the onset of ovarian function suppression was slightly delayed for patients receiving chemotherapy. Of note, in this study, younger patients (<40 years) who received goserelin alone returned to their premenopausal status at 6 months after the cessation of therapy, whereas those who received CMF showed only marginal changes from their baseline hot flashes scores, likely indicative of minimal ovarian dysfunction.

The Suppression of Ovarian Function Trial (SOFT) randomizing premenopausal women with HR-positive disease to tamoxifen, tamoxifen and ovarian suppression, or exemestane and ovarian suppression should further elucidate the role of ovarian suppression, and optimal endocrine therapy in young women with breast cancer. The complementary Trial of Exemestane and Tamoxifen (TEXT) randomizing premenopausal women with HR-positive disease to ovarian function suppression with either tamoxifen or exemestane will also clarify the role of aromatase inhibition for these patients. SOFT and TEXT have completed enrollment of over 5,700 patients and the overall primary endpoint disease-free survival event rate is 2% per year, about one quarter that originally anticipated. The first results of SOFT and TEXT are expected to be reported in 2014 (*www.ibscg.org*). The lack of acceptability resulting in premature closure of the Premenopausal Endocrine Responsive Chemotherapy Trial (PERCHE), a randomized trial evaluating the role of chemotherapy in the setting of combined endocrine therapy, will hamper the availability of more definitive evidence regarding the benefits and risks of chemotherapy in addition to endocrine therapy in very young patients. The fully enrolled TailoRx trial (*www.ecog.dfci.harvard.edu*) and the currently recruiting RxPonder trial (*www.swog.org*) may provide some information on the role of chemotherapy, but are likely to include very few young patients given the current attitude regarding need for chemotherapy in young women. Meaningful results for the very young HR-positive cohort will also require evaluation exclusively in patients who receive optimal endocrine therapy. The optimal duration and the timing of adjuvant endocrine therapy options in very young patients with HR-positive disease remain open questions.

BREAST CANCER DIAGNOSED DURING PREGNANCY

It is more likely that younger rather than older premenopausal women will be faced with concurrent pregnancy and the diagnosis of breast cancer, although the issues are similar, irrespective of age. Cytotoxic treatments have been safely administered, beginning in the second trimester, after the completion of organogenesis, although there are risks (83). Both trastuzumab and tamoxifen are contraindicated during pregnancy, due to risk of perinatal complications and teratogenicity, respectively. However, many babies have been born without obvious abnormality after *in utero* exposure to these agents (84,85), Issues regarding whether to maintain the pregnancy and the timing of breast cancer treatment are complex both from a medical and psychosocial standpoint (for additional details, see Chapter 65).

BREAST DISEASE IN ADOLESCENTS

Breast disease in adolescent females is fortunately uncommon, with most presenting lesions being benign, most commonly fibroadenomas (86,87). For most breast lesions in children and adolescents, open biopsy can be avoided (88). Breast cancer is very rare in this population. Because of this, neither the prognosis nor optimal management of the disease in this age group is clear. Available case series suggest that adolescents with breast tumors comprise a mix of histologic subtypes including cystosarcoma phyllodes and, more commonly, adenocarcinomas including invasive intraductal, invasive lobular, signet ring, and secretory adenocarcinomas (89,90). Treatment recommendations should be tailored to the specific histology, and attention to psychosocial issues, including adherence with therapy, is prudent in the care of teenagers with breast cancer.

BREAST CANCER IN CHILDHOOD CANCER SURVIVORS

Young women with a history of treatment for childhood cancer, in particular those treated with chest ("mantle") irradiation for Hodgkin disease, are at dramatically increased risk of early-onset breast cancer (91,92) (see Chapter 19 in this text). Treatment considerations in this unique subgroup may be complicated by previous systemic therapy, recommendations against further radiation therapy, and psychosocial issues.

TREATMENT OF YOUNG WOMEN WITH ADVANCED DISEASE

Very young women who present with metastatic disease are generally treated using an algorithm reflecting the general incurability of the disease, and employing ovarian function suppression together with other treatment options if the disease is endocrine-responsive (see Chapters 73 and 74 in this text). The sequential use of endocrine therapy followed at the time of disease progression by chemotherapy, similar to the conventional approach in older premenopausal and postmenopausal women, is reasonable, although this has not been specifically tested in younger patients. Young patients with metastatic disease may be particularly vulnerable to psychosocial distress, especially if they have young dependents (93).

QUALITY OF LIFE AND PSYCHOSOCIAL ISSUES

A growing body of evidence suggests that younger women with breast cancer are at increased risk of psychosocial distress compared with older women, both at diagnosis and follow-up (21). In a large prospective cohort study, women age 40 and younger who developed breast cancer experienced significant declines in their quality of life (QOL) compared with age-matched women without breast cancer (94). Adjusting for disease severity and treatment factors, young women who developed breast cancer had the largest relative declines in QOL following diagnosis compared with middle-age and elderly women who developed breast cancer. In a survey of women who were age 50 or younger at diagnosis and disease-free at 6-year follow-up, women generally reported high levels of physical functioning, but the youngest women (ages 25–34 at diagnosis) exhibited the greatest degree of psychosocial distress, particularly with social and emotional functioning as well as vitality (95). Young age at diagnosis as well as motherhood has also been associated with greater fear of recurrence, independent of disease characteristics (96,97) Many young women also feel isolated and lack information (98). When they attend breast cancer support groups, their issues are often substantially different from those of the older women. Others in their age cohort are planning for the future, whereas young women with breast cancer are facing a life-threatening and physically mutilating disease. Little information is available regarding work and life decisions made by these women. And although access to psychosocial support is associated with a better QOL in breast cancer survivors, these results have not been presented separately for the youngest patients and few psychosocial interventions have been evaluated in young women specifically (21,99).

FERTILITY AND PREGNANCY AFTER BREAST CANCER

Young women with breast cancer may face the risk of becoming amenorrheic with treatment, either temporarily or permanently, resulting in potential infertility, onset of menopausal symptoms, problems with sexual functioning, and exposure to long-term risks of early menopause. The risk of amenorrhea is related to increasing patient age and treatment received (100,101) (Fig. 85-4). For some young women, cessation of menses may be welcome and may improve outcomes for women with HR-positive disease. For many young women, however, the threat or experience of infertility may be devastating. Discussion of this important survivorship issue should commence early in the treatment decision process because some women may elect to try to preserve fertility through intervention or forgo some therapy (102). Young breast cancer survivors can be reassured that at the present time there is no clear increased risk of recurrence from having a biologic child (103). However, studies are limited by substantial biases, including the *healthy mother* bias, and concerns remain for some (104,105). Nevertheless, many young women are interested in pregnancy after breast cancer and an international effort is currently underway to evaluate the safety and efficacy of taking a break from tamoxifen therapy in order to try to have a biologic child. The Breast International Group (BIG) – North American Breast Cancer Groups (NABCG) Endocrine Working Group is developing a prospective trial for women 37 years old or younger at diagnosis of HR-positive breast cancer to assess pregnancy success following tamoxifen interruption after 18 to 30 months of treatment (coordinated by IBCSG) (*www.ibcsg.org*). Pregnancy after breast cancer is a very complex and personal decision for a woman who remains at risk for recurrent disease (for additional details, see Chapter 90, Reproductive Issues in Breast Cancer Survivors).

MENOPAUSAL SYMPTOMS AND SEXUAL FUNCTIONING

Menopausal symptoms and sexual dysfunction are common in breast cancer survivors (101). To date, most breast cancer survivors included in evaluations of sexual dysfunction have been over age 40, reflecting the demographics of breast cancer. Little information is available focusing on sexual dysfunction in very young breast cancer survivors, and no intervention studies have been conducted. Research has, however, identified risk factors for sexual dysfunction in breast cancer

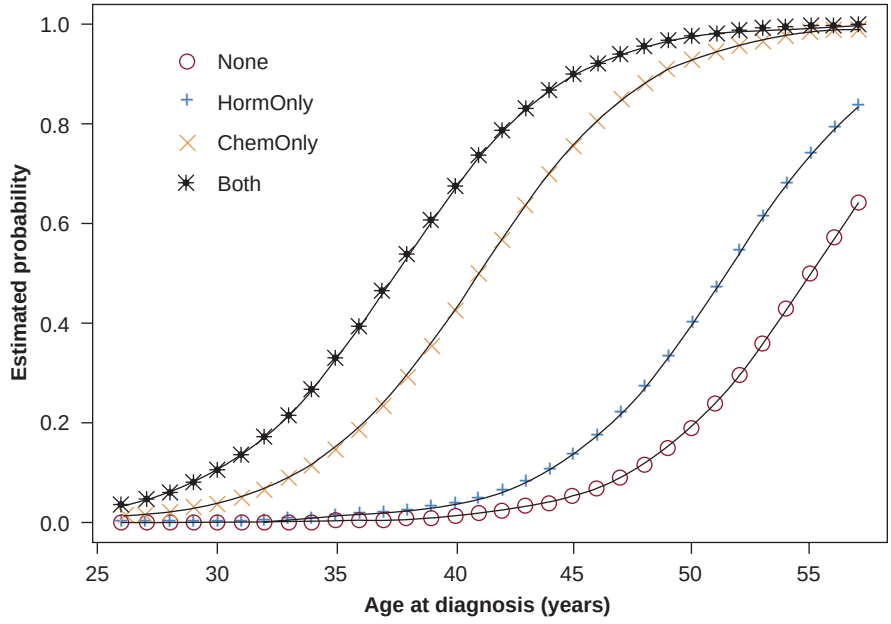

FIGURE 85-4 **Probability of menopause during the first year after diagnosis (according to a model).** (From Goodwin PJ, Ennis M, Pritchard KI, et al. Risk of menopause during the first year after breast cancer diagnosis. *J Clin Oncol* 1999;17:2365–2370, with permission.)

survivors including younger age, premature menopause, and the use of chemotherapy (106). The use of tamoxifen and type of breast surgery may also have an impact on sexual functioning, especially in young breast cancer survivors. In a survey of 371 women diagnosed with breast cancer age 40 and younger (mean age at diagnosis 33 years and mean age at follow-up 36 years) where 77% of these women were premenopausal at follow-up, many reported bothersome sexual functioning or menopausal-type symptoms (107). In particular, 46% of women reported hot flashes and 39% reported dyspareunia. Current ovarian suppression, menopausal status, baseline anxiety before the diagnosis, pregnancy after the diagnosis, prior chemotherapy, and lower perceived financial status were associated with more bothersome symptoms. Evidence indicates that intervention to improve menopausal symptoms and sexual functioning is effective, although limited research to date focuses on very young women (108).

CONCLUSIONS

When a very young woman is diagnosed with breast cancer, she may face several threats to her future health and well-being. Most concerning, a young woman with breast cancer is more likely than an older woman to have an adverse prognosis. The differential in prognosis by age may reflect, in part, biological differences between breast cancer that develops in a younger compared with an older woman. Prognosis may, however, also be affected by suboptimal therapy, particularly endocrine therapy, in the youngest patients who are least likely to lose ovarian functioning as a result of systemic therapy. Because of the relative rarity of breast cancer in young women, large pooled analyses and multinational clinical trials are necessary to address the many controversies and improve therapy for younger patients. Late health and psychosocial effects of breast cancer in young women should also be considered, and recent advocacy and public efforts to increase awareness of and support for young women with breast cancer should improve their outcomes (*www.cdc.gov/cancer/breast/*; *www.youngsurvival.org*).

MANAGEMENT SUMMARY

In general, treatment of the young patient with breast cancer is similar to other patients and is determined by the characteristics of the tumor and the patient, with some special considerations.

Local Therapy

- Consider preoperative systemic therapy for women with locally advanced disease or those with large tumors who desire breast preservation.
- Careful attention to margin status and boost irradiation after lumpectomy is warranted to minimize the higher risk of local recurrence associated with young age.

Systemic Therapy

- Consider the endocrine as well as the direct cytotoxic effects of chemotherapy.
- Optimize endocrine therapy, including consideration of adherence issues, given evidence for benefits in young women with hormone receptor–positive disease.

Psychosocial and Survivorship Issues

- Evaluate concerns about future fertility early on and refer for consideration of fertility preservation strategies as needed before systemic therapy.
- Consider genetic testing (e.g., *BRCA1* or *BRCA2* testing), early on if it would have an impact on a woman's treatment decisions.
- Provide psychosocial support, referrals, and informational resources (e.g., *www.youngsurvival.org*) given the increased distress often seen in young women with breast cancer.

CHAPTER 86

Breast Cancer in Minority Women

Katherine E. Reeder-Hayes,
Stephanie B. Wheeler, and Lisa A. Carey

CHAPTER CONTENT

INTRODUCTION: A FRAMEWORK FOR UNDERSTANDING BREAST CANCER DISPARITIES

The study of breast cancer in minority women is inevitably linked to the study of healthcare disparities. The Institute of Medicine has defined healthcare disparities as "racial or ethnic differences in the quality of healthcare that are not due to access-related factors or clinical needs, preferences, and appropriateness of intervention" (1). In the context of breast cancer, disparities occur when a group within the breast cancer population experiences unequal access to cancer screening and diagnostic care, inferior cancer treatment, lower rates of response to anti-cancer therapies, poorer short term outcomes such as treatment toxicities or complications, or poorer long-term outcomes including breast cancer recurrence and death. The determinants of breast cancer disparities are complex and include biologic, behavioral, socioeconomic, provider, and structural factors. Breast cancer disparities are seen in a number of vulnerable populations including elderly and poor women, but have been best documented among racial and ethnic minorities and particularly among black women. In this chapter, we will summarize the existing literature regarding racial disparities in breast cancer, explore the most pronounced disparities among other vulnerable groups, and discuss potential areas for intervention and future research.

African American women with breast cancer die at significantly higher rates than their white counterparts, and this racial gap in survival persists despite overall improvements in breast cancer mortality over time (2). This core fact has motivated much of the breast cancer disparities research in the United States over the past three decades. From this core finding, a number of questions immediately arise. These questions and their answers can be imagined as layers to be unearthed in the search for the roots of breast cancer outcome disparities. Are racial differences in breast cancer mortality best explained by differences in cancer stage at diagnosis, tumor biology, treatments received, response to treatment, subsequent experiences during survivorship, or a combination of these factors? These questions are the starting point for the study of breast cancer disparities.

Known differences in stage at presentation, tumor biology, receipt of treatment, response to therapy, and survivorship care are the basic elements contributing to breast cancer outcome disparities. Once these basic elements are established, we turn to understanding the factors underlying each element. For instance, do black women present at a later stage due to inherently more aggressive disease, less effective screening, or delays in diagnosis? Do black women receive different breast cancer treatments for equivalent disease across the spectrum of care, including diagnostic and staging evaluation, surgery, radiation, chemotherapy, and endocrine therapy? And do they respond to such treatments differently, in terms of both efficacy and toxicity?

Once the key drivers of breast cancer outcome disparities are defined, we can examine which factors may be amenable to change. As one example, a woman who presents with advanced breast cancer due to lack of screening may not have undergone breast cancer screening because she believes herself to be at low risk (behavioral factor),

because she cannot afford the cost of screening (socioeconomic factor), because her provider has not recommended screening (provider factor), or because there is no screening facility within a reasonable distance of her home (structural factor). This woman's story is an example of a basic element of breast cancer outcome disparity (advanced stage at presentation) potentially explained by a particular factor (lack of screening) which in turn may have a number of drivers at the patient, provider, or health system level. To the extent that these drivers vary by race, ethnicity, age or other patient characteristics, they contribute to health disparities. Complex interactions between factors are also to be expected in the study of health disparities. A conceptual model of the multilayered factors contributing to breast cancer disparities is presented in Figure 86-1.

OVERVIEW OF DISPARITIES IN BREAST CANCER

In the United States, new diagnoses of breast cancer are slightly more common in white women, but breast cancer mortality is higher among black women (2). In 2005–2009, the age-adjusted incidence rate of breast cancer was 127.3 per 100,000 women among whites and 121.2 per 100,000 among blacks, while age-adjusted death rates were 22.4 and 31.6 per 100,000 women among whites and blacks respectively (3). Although breast cancer incidence and mortality rates have declined for all racial groups over time, the gap between black and white patients has not closed and in fact appears to be widening (4). Figure 86-2 demonstrates the trends in breast cancer incidence and mortality among black and white women. Racial and ethnic trends in breast cancer incidence and mortality vary depending on age. Specifically, younger black women (those <50 years old) have a higher incidence of breast cancer compared to younger white women, but beginning around the time of menopause, incidence rates among white women surpass rates of black women, and remain higher throughout the older years (5,6). Although advanced stage at presentation will be discussed in this chapter and clearly contributes to poor breast cancer outcomes, a marked stage-specific survival gap remains after controlling for basic stage and hormonal status differences among newly diagnosed patients, as depicted in Figure 86-3. Race remains an independent predictor of poor survival after controlling for tumor size, grade, and year of diagnosis (7). In this chapter, we will examine in detail the major factors underlying disparities in breast cancer mortality—differences in stage at presentation, biology, receipt of treatment, treatment response, and survivorship care—and their drivers.

DISPARITIES IN PRESENTING STAGE

One well-documented contributor to higher breast cancer mortality among black women is advanced stage at presentation. Table 86-1 shows the percentage of women in the national Surveillance Epidemiology and End Results (SEER) database presenting with various stages of breast cancer between 2000 and 2009. Black women present more often than their white counterparts with regional or distant breast cancer, and less often with localized or early stage breast cancer (3). Given that cancer stage at diagnosis is a strong predictor of breast cancer survival (7), it is straightforward to understand why advanced presenting stage is associated with poor outcomes among black women. Less clear are the reasons why black women present at a later disease stage. Differences in screening patterns, diagnostic trajectory after a cancer is suspected, and risk of aggressive cancers that may arise in the interval between regular screenings may all contribute to late-stage diagnoses.

Screening Disparities

Modern mammography screening clearly reduces the risk of late-stage breast cancer diagnosis (8). Late-stage diagnosis of breast cancer in black women has historically been attributed to screening behaviors, specifically underuse of screening mammography or lack of diagnostic follow-up after an abnormal mammogram result (9). Overall use of screening mammography has risen over the past two decades, but the equivalence of mammography use among racial/ethnic groups is a subject of ongoing debate, with some studies showing equivalence and others suggesting that black women remain less likely to get mammograms at the recommended 1- to 2-year interval (9,10,11). Although screening is associated with early diagnosis among all racial groups, this association appears weaker in black women (12) and differential performance of mammography does not appear related to higher mammographic breast density among black women (13). This finding may instead be explained in part by the quality of mammography services received; one recent study found that black and Hispanic women were less likely than white women to have their mammograms at academic centers, facilities that used breast imaging specialists to interpret mammograms, and facilities with digital mammography (14). Provider factors also may contribute to disparities in receipt of mammography. Black women more often than white women cite lack of physician referral or recommendation for mammography as the reason they failed to receive the test (15).

Disparities in Diagnostic Workup

Completion of a diagnostic workup is an important step intervening between a screening or physical exam abnormality and initiation of treatment. Evidence suggests that racial disparities exist in the timeliness of diagnostic workup for breast cancer. Two studies in vulnerable populations have suggested that even among uniformly low income women, and after controlling for the effect of insurance status and income, black women experience longer delays between initial abnormal mammogram or exam findings and the final determination of a pathologic diagnosis (16,17). Large population-based studies confirm race as an independent predictor of diagnostic delays, with a greater disparity among women who present with physical symptoms compared to screening abnormalities (18,19). Cultural beliefs and attitudes, for example, the fear that cancer can be spread through the air during a diagnostic procedure, have been found to partially explain racial disparities in timeliness of diagnostic workup (20). Longer times between symptom onset and definitive pathologic diagnosis are associated with higher mortality (21).

RACIAL DIFFERENCES IN BREAST CANCER BIOLOGY

Persistent survival gaps between blacks and whites diagnosed at similar stages of illness (22) and with similar access to healthcare (23) have led researchers to suggest that breast cancer in black women may be fundamentally biologically different from that in white women. Early observations supporting this hypothesis include findings that, within a given stage, black women are more likely to have larger tumors and positive lymph nodes. However, McBride

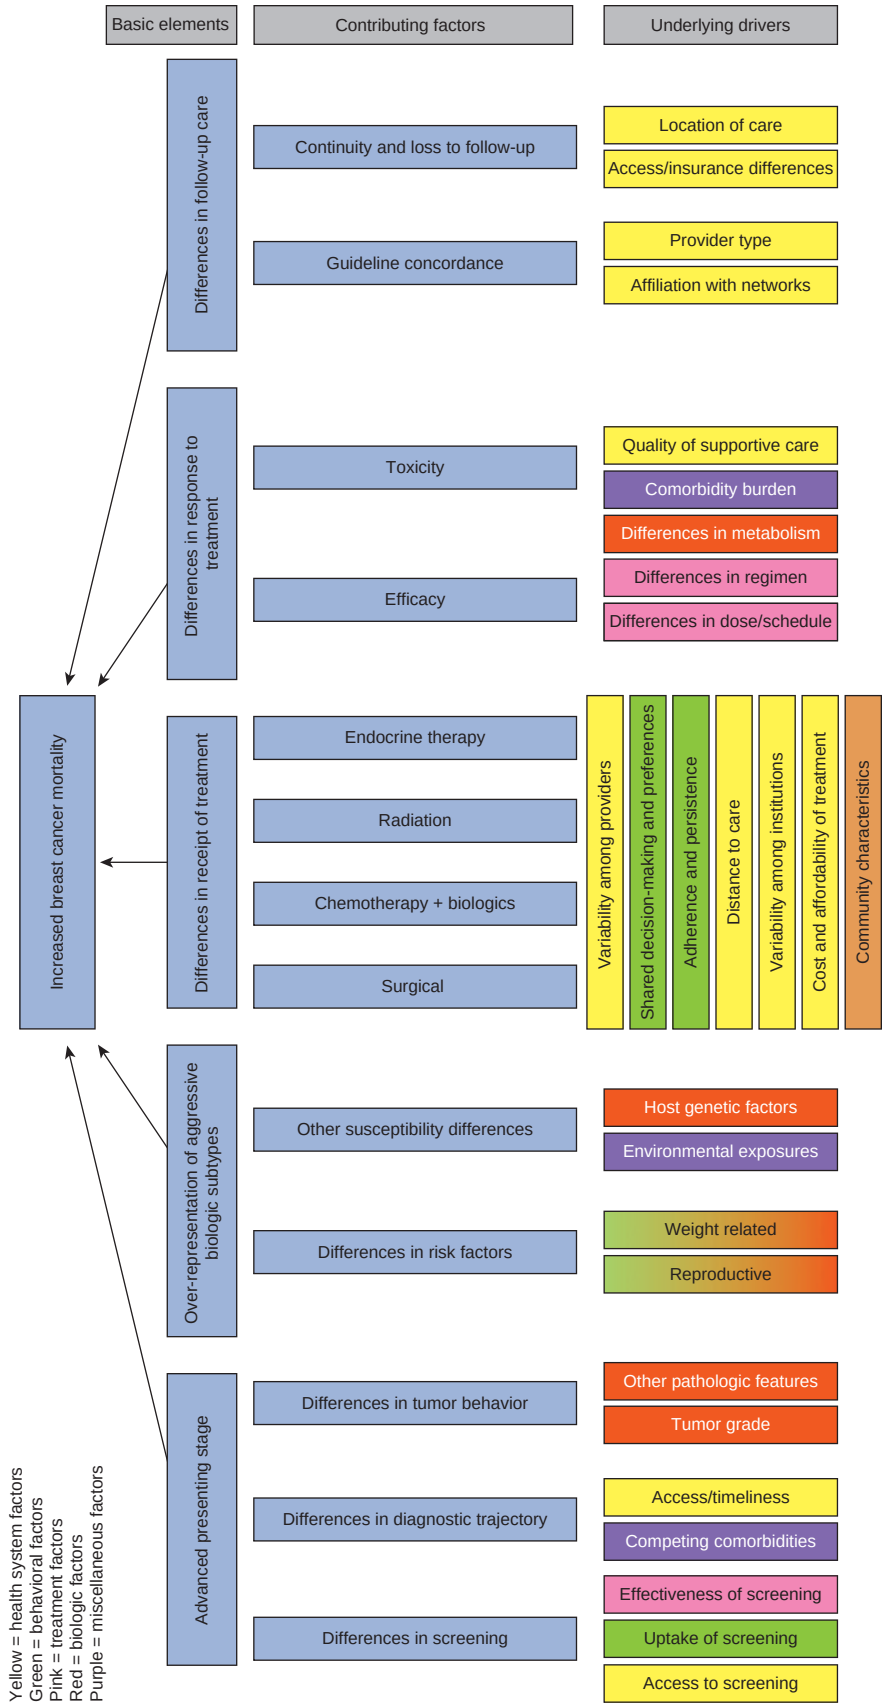

FIGURE 86-1 Key elements contributing to disparities in breast cancer mortality are pictured in *blue*. Underlying contributors are depicted in *yellow* (health system factors), *green* (behavioral factors), *pink* (treatment factors), *orange* (biologic factors), and *purple* (miscellaneous factors).

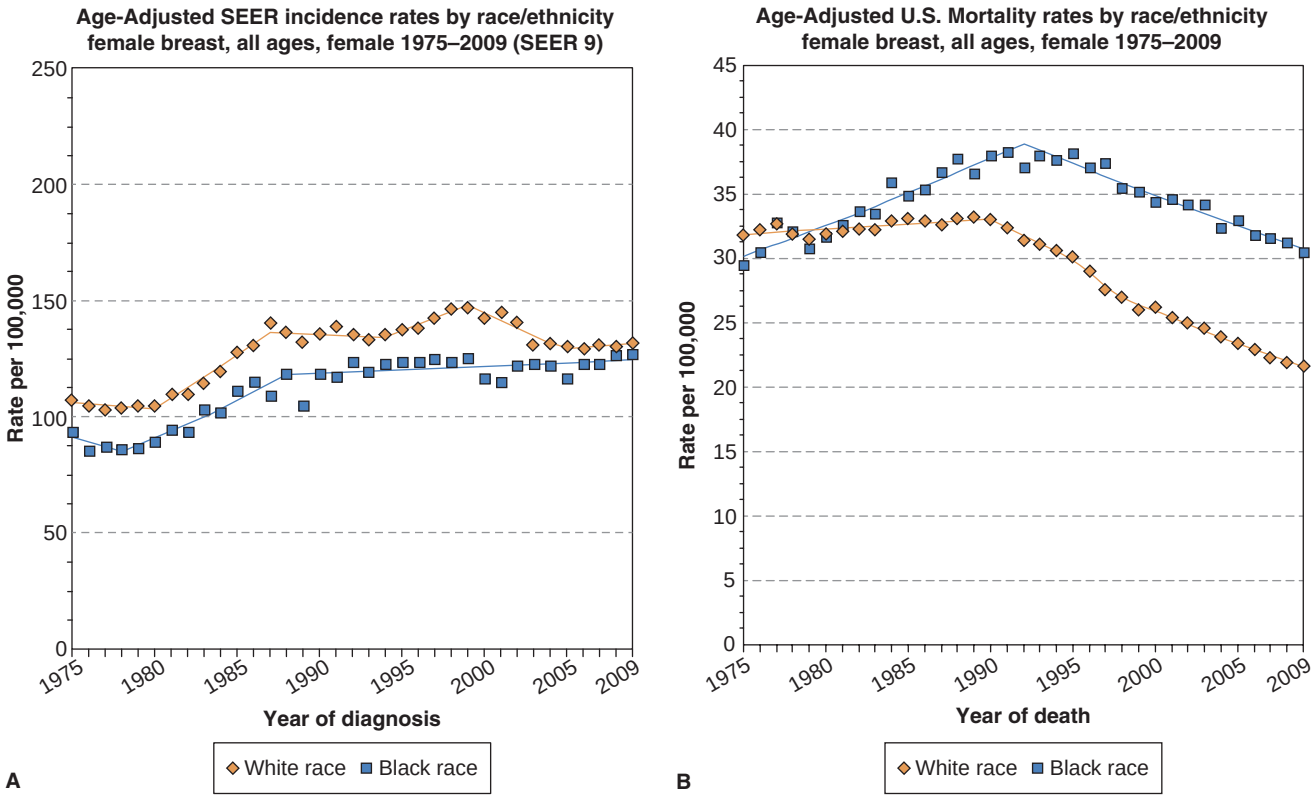

FIGURE 86-2 Age-adjusted incidence rates **(A)** and mortality rates **(B)** for U.S. women with breast cancers diagnosed from 1975 to 2005. White patients (*red lines*) have higher incidence but lower mortality than black patients (*blue lines*), and the mortality gap has increased over time. (Data from Fast Stats: an interactive tool for access to SEER cancer statistics. Surveillance Research Program, National Cancer Institute. http://seer.cancer.gov/faststats.)

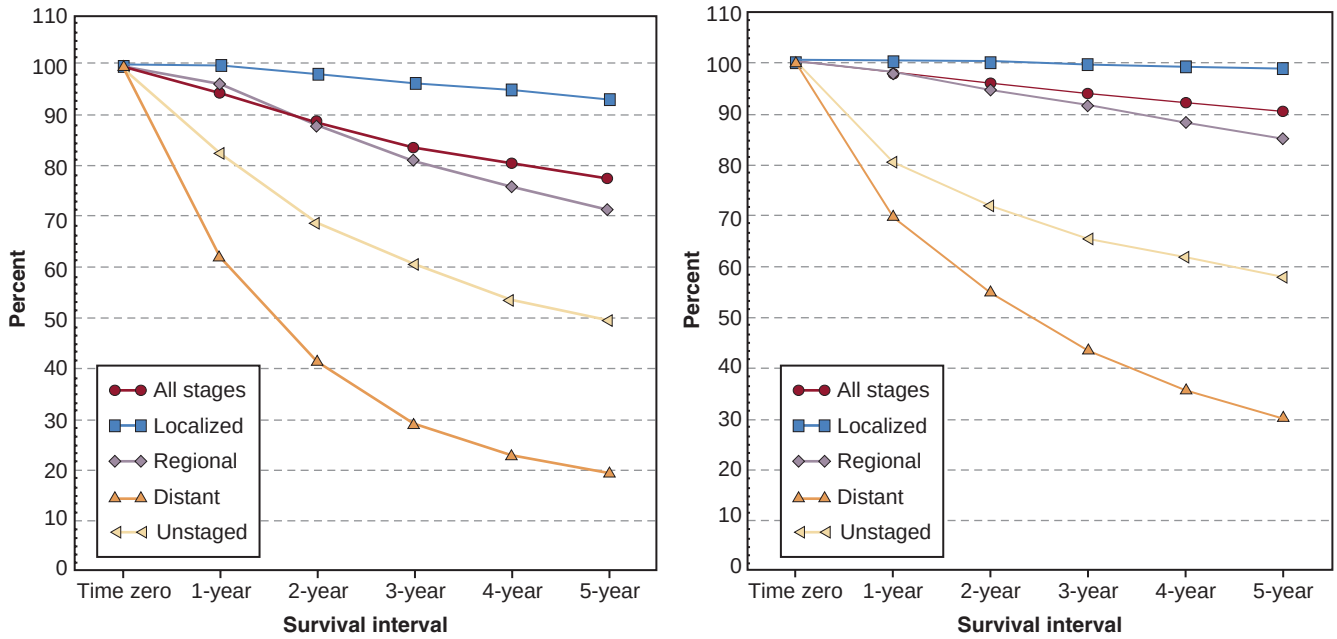

FIGURE 86-3 Relative 5-year survival of breast cancer patients by stage and race in United States SEER 9 (Surveillance Epidemiology and End Results) registries, diagnosed 1975–2005. Black patients are depicted on the *left*, white patients on the *right* hand graph. (Data from Fast Stats: an interactive tool for access to SEER cancer statistics. Surveillance Research Program, National Cancer Institute. http://seer.cancer.gov/faststats.)

TABLE 86-1

Percentages of Women in SEER 18 Registry Regions Presenting with Localized, Regional, and Distant Disease 2000–2009

	Localized	*Regional*	*Distant*	*Unstaged*
All	61.3%	31.1%	5.0%	2.6%
White	62.4%	30.4%	4.6%	2.5%
Black	52.0%	37.0%	8.1%	3.0%

Data from Fast Stats: an interactive tool for access to SEER cancer statistics. Surveillance Research Program, National Cancer Institute. http://seer.cancer.gov/faststats.

and colleagues found that controlling for such within-stage differences did not attenuate differences in mortality (24). Thus, racial differences in outcome among similar-stage women do not appear to be due primarily to more advanced disease among black women within each stage grouping.

Histologic features of breast cancers also vary by race and ethnicity. While differences in presenting stage largely disappear when mammography is received equally, black women still have significantly more high-grade breast cancers (10). Chen and colleagues found that after adjusting for age, stage, socioeconomic status, body mass index, reproductive history, insurance status, and location, black women with invasive breast cancer were more likely to have high grade nuclear atypia, high grade tumors, and more necrosis compared to white women (25). Black women are also more likely to have overexpression of cell-cycle regulators, such as Cyclin E, p16, and p53, and polymorphisms in nucleotide excision repair genes (26). All of these results provide a strong argument for biological differences between black and white women in breast cancer.

Perhaps the most striking example of biological differences between breast cancers in black and white women occurs in biologic "subtype," which refers to the profile of cell surface receptors expressed by the cancer, including estrogen receptors (ER), progesterone receptors (PR), and human epidermal receptor type 2 (HER2). Immunohistochemical analyses of tumors from women in the Carolina Breast Cancer Study (CBCS) and other population-based studies have found that a significantly lower proportion of black women have favorable prognosis ER or PR-positive, HER2-negative breast cancer compared to whites, and a correspondingly higher proportion of black women, particularly younger black women, have poor prognosis triple negative (ER-, PR-, and HER2-negative) breast cancer (27–29). Similar analyses of a West African cohort of breast cancer patients also found a high incidence of triple negative breast cancer (30). As molecular subtyping of breast cancers becomes more widespread, we expect that previously unappreciated biologic differences by race may also be found.

Recent studies have shed light on potential epidemiologic differences underlying racial differences in distribution of breast cancer subtypes. Reanalysis of the CBCS and other epidemiologic studies have suggested that the effect of traditional breast cancer risk factors, including reproductive history and weight-related factors, vary by biologic subtype (31,32). Some risk factors, including early age of menarche, centripetal obesity, or the protective effect of breast-feeding, are far stronger for basal-like breast cancer (the molecular correlate of triple negative breast cancer) than for hormone receptor-positive, HER2-negative breast cancer. Other factors actually appear to have opposite effects in different subtypes. For example, multiparity and young age at first full-term pregnancy, which have historically been identified as protective factors in breast cancer epidemiology, appeared protective only for luminal breast cancer (the molecular correlate of hormone receptor-positive breast cancer), while both appeared to be risk factors for basal-like breast cancer (31). These studies suggest that race-associated differences in lifestyle or hormonal exposures may partially explain variations by race in breast cancer subtype. Recent genome-wide association studies implicate novel risk variants for breast cancer in women of African ancestry as another contributor (33). It is clear, however, that biological factors cannot explain all of the racial disparity in morbidity and mortality because black women experience worse long term outcomes even when compared to white women with biologically similar disease (9,22,27).

DIFFERENCES IN RECEIPT OF TREATMENT

Background on Cancer Treatment Quality

Although presenting stage and biologic factors are important determinants of breast cancer prognosis and treatment, these factors do not fully explain racial disparities in outcomes. If minority women receive less-than-standard treatment, we might expect to see continuing differences in outcomes, even after controlling for stage at presentation and biologic differences. Differences in treatment are now the focus of many studies examining breast cancer disparities. A large body of research shows that racial disparities exist in overall receipt and timeliness of treatment as well as monitoring of treatment-related toxicities (34–37). Failure to receive appropriate treatment is an important cause of racial disparities in breast cancer mortality (38).

Evidence of Racial Variation in Quality of Breast Cancer Treatment

Evidence-based guidelines for the treatment of breast cancer (39) and metrics to evaluate breast cancer care quality (40) are widely available in the United States. Despite the existence and widespread dissemination of these guidelines and quality metrics, many patients—in particular, black women—do not receive high quality, guideline-concordant care. Studies of treatment disparities have focused on the receipt of mastectomy versus breast conserving therapy (BCT, defined as breast conserving surgery [BCS] followed by radiation therapy), receipt of radiation when breast conserving surgery is chosen, receipt of adjuvant chemotherapy, and receipt of endocrine therapy when appropriate. Some studies have also attempted to use aggregate measures of high quality breast cancer care. The ability to accurately measure these treatments and to adequately control for confounders of the race-treatment relationship, such as socioeconomic status and comorbidity, varies from study to study depending on the data source. We describe some of the most significant studies documenting treatment disparities, their findings, and limitations.

Using inpatient and outpatient medical records from six New York City hospitals, Bickell and colleagues found that 34% of black women and 23% of Hispanic women, compared to 16% of white women, failed to receive appropriate adjuvant therapy for early stage breast cancer. Appropriate treatment included radiation therapy after BCS, adjuvant chemotherapy after definitive surgery among patients with hormone receptor-negative tumors at least 1 cm in size, and

endocrine therapy among patients with hormone receptor-positive tumors at least 1 cm in size (34). In multivariate models, poor quality care was significantly associated with black or Hispanic racial/ethnic status, lack of medical oncologic referral, having more comorbid conditions, and lack of insurance. Black and Hispanic women were more than twice as likely to receive poorer quality care, after controlling for all other factors. Consulting with a medical oncologist attenuated but did not entirely eliminate the racial disparity (34).

Lund and colleagues examined first course of treatment among women diagnosed in 2000–2001 with invasive breast cancer in five Atlanta SEER counties (2008). In this analysis, black women were four to five times more likely to experience significant treatment delays. Black women also were less likely to receive cancer-directed surgery, radiation therapy after BCS, and endocrine therapy for hormone receptor positive tumors, after controlling for age, tumor size, stage, lymph node involvement, and ER/PR status (36). As with many observational studies, this analysis was limited by lack of information about treatments beyond the 4-month time window after diagnosis, inability to capture HER2 status, lack of information about comorbidities, and lack of information about provider and system-level characteristics.

In a study of newly diagnosed stage I and II breast cancer patients 65 and older using Surveillance Epidemiology and End Results (SEER)-Medicare data, investigators evaluated disparities in receipt of BCT, documentation of hormone receptor status, surveillance mammography during remission, and a combined measure of adequate care (41). In adjusted comparisons, Hispanic women were 33% less likely to receive adequate care, and black women were 23% less likely to receive adequate care, compared to white women. Black/white disparities actually worsened over time. Older women and those from rural areas were also significantly less likely to receive standard quality care, controlling for other factors. Banerjee and colleagues assessed receipt of BCT, endocrine therapy, and chemotherapy by conducting comprehensive medical record reviews of women diagnosed with breast cancer in Detroit at the Karmanos Cancer Institute and found that for local disease, white and black women received equivalent care, but for regional disease, black women were less likely to receive guideline-recommended endocrine therapy and chemotherapy. The authors did not find a racial disparity in receipt of BCT versus mastectomy, but they did note that women with Medicare or Medicaid insurance were more likely to receive mastectomy than those with private insurance. They also found that black women had far more comorbid conditions than white women, highlighting the need to control for comorbid illnesses in future analyses to avoid potential confounding (42). Because this study was limited to one institution in an area with many older, insured, black women of low socioeconomic status, the effect of variations in rural/urban residence, income and education, neighborhood racial composition, insurance status, and ethnic identity could not be easily assessed.

In a study by Freedman and colleagues (2009), SEER data from 1988 to 2004 were used to assess definitive local treatment (i.e., mastectomy or BCT) for early stage cancers. Over time, rates of mastectomy decreased as BCT diffused into practice; however, in adjusted models, rates of any definitive treatment remained lower for black and Hispanic women compared to white women, and no reduction of this disparity was observed over time (35). This analysis controlled for biologic tumor features, year of diagnosis, and region, but lacked information about employment, insurance status, and comorbidities, and did not control for possible organizational confounders.

Several studies have also found that black women more often experience delays in adjuvant therapy, which may affect longer-term health outcomes (18,37,43,44). One study using SEER-Medicare data explored variation in timing of receipt of radiation therapy after BCS and found that a substantial minority of breast cancer patients 65 years and older never received guideline-recommended radiation therapy after BCS. Further, among those women who did receive radiation therapy, black women more often experienced delays in initiation of therapy (37). After controlling for region-level resources, hospital facility-level factors, and patient-level factors, delayed initiation of radiation after BCS remained more common among black women compared to white women, although the Hispanic disparity resolved (37). Other studies have documented delays in time to first treatment among black women. Among young women with incident breast cancer (ages 20–54) in Atlanta, 22% of black women compared to 14% of white women experienced delays of greater than 3 months from diagnosis to first treatment. Access to care and poverty partially accounted for these delays, but significant racial differences in delays remained even after adjustment for all other factors (45).

Disparities also exist in the use of novel surgical techniques for breast cancer. Multiple studies have documented that black women are less likely to receive sentinel lymph node biopsy (SLNB), a less morbid but more technically challenging alternative to axillary lymph node dissection (46–48). This disparity does not appear to be explained by differences in clinical factors, insurance status, type of hospital, teaching status of hospital, or age. Despite increasing overall use of SLNB between 1998 and 2005, racial/ethnic gaps in receipt of SLNB have remained largely the same over time (48). Participation of the treating institution in cooperative research groups appears to promote use of SLNB roughly equally among black and white women (47).

Evidence suggests that after adjustment for known confounders such as hormone receptor status, stage, age, and insurance type, black women are equally likely to receive chemotherapy compared to non-Hispanic white women (49), and Hispanic women may actually be more likely than whites to receive adjuvant chemotherapy (49). However, other evidence suggests that black women more often delay or fail to complete adjuvant chemotherapy (50–52), have early dose reductions (53) or receive nonstandard chemotherapy regimens (54). Although completion of a full course of treatment is clearly important, clinically appropriate variation across patients in dosage, timing of cycles, and administration makes assessment of therapy completion difficult. As a result, it is sometimes difficult to determine whether such variation in chemotherapeutic administration is clinically valid or indicative of treatment disparity.

Initiation of trastuzumab-based adjuvant regimens, which has been standard of care for HER2-positive cancers since 2005, does not appear to differ by race, but completion of the prescribed year of infusional therapy is only half as likely among black women. Completion rates appear similar between non-Hispanic white and Hispanic women (52).

For hormone receptor positive patients, long-term endocrine therapy (ET) with tamoxifen or aromatase inhibitors is the cornerstone of adjuvant treatment to prevent recurrence. Unfortunately, evidence is beginning to emerge that many women either do not initiate ET or become nonadherent to therapy at some point after initiation, and this under-treatment is linked to higher mortality (55–58). Racial differences in ET adherence are an emerging topic of interest in breast cancer disparities, because differential initiation of, and adherence to, ET may explain noted racial heterogeneity in outcomes among hormone receptor positive patients.

Studies of endocrine therapy utilization generally examine initiation (beginning to take the medication), persistence (continuing to take the medication), and/or adherence (taking the medication at a percentage of the prescribed dose and schedule thought to be associated with acceptable efficacy, generally >80% of doses). In a uniformly insured cohort of Kaiser-Permanente patients, initiation of endocrine therapy in hormone receptor-positive patients was similar between black and white women, but significantly lower among Hispanics (59). Several studies in the Medicaid population have suggested that among low-income women, rates of ET initiation are uniformly low but not differential by race (60–62). Two studies of persistence to ET, one in a commercially insured population and one in Medicaid patients, suggest that race does not affect likelihood of continuing to take ET once a woman has started the medication (60,63). However, several studies suggest that among women continuing to take ET, black or non-white women are less likely to be adherent after adjustment for other factors. In the Kaiser-Permanente cohort mentioned above, black women were equally likely to persist in taking ET, but significantly less likely to be adherent to more than 80% of their doses (55). Similarly, Neugut and colleagues found lower odds of adherence among black women in a commercially insured cohort receiving medication via Medco pharmacies (63). In the Medicaid population, reports concerning adherence have been conflicting; one study in New Jersey patients found lower adherence among non-white women (58), while similar studies in New York, North Carolina, and South Carolina patients found no difference in adherence by race (60,62,64). Existing studies in this area have been limited by lack of population-based samples, lack of data on older women, and small minority sample sizes. More studies are needed with sufficient numbers of black women from a broader socioeconomic and geographic range in order to statistically support subgroup analyses by race of long-term ET adherence.

Potential Explanations for Racial Variation in Treatment

The role of comorbidities in explaining treatment and survival disparities between white and black women is very important. Higher rates of comorbidity among black women may explain some disparities in overall survival after breast cancer. However, Tammemagi and colleagues found that although comorbidity burden was partially responsible for racial disparities in overall survival, comorbidities did not explain differences in breast cancer-specific survival (65).

Beyond the obvious role of comorbidities in reducing life expectancy, higher comorbidity burden among blacks could lead to competing priorities in health care seeking-behavior. If, for example, a woman with uncontrolled diabetes and/or a serious disability has limited time and resources to attend healthcare appointments, she may prioritize certain health visits over others. Furthermore, if her functional status or mental health status is compromised by comorbid condition(s), these may additionally inhibit health-seeking behaviors for her cancer diagnosis, particularly if she feels she is at low risk for metastasis or death. Patient-level factors other than comorbid conditions may also help explain why different racial subgroups receive different treatments, including health literacy and personal preferences (66); insurance and socioeconomic status (67); cognitive and social network correlates (68); experience with/trust of the health care system; and fatalistic beliefs and health-seeking behavior (67).

Health system factors are also important potential explanations for why different subgroups of patients receive differential quality of care. Health services organization and structure are closely related to adoption of high quality, evidence-based practices and may play a role in explaining treatment disparities. The interplay between health system factors, community-level factors and patient-level factors can be complex. Characteristics of local communities, including population density, local resource capacity, and neighborhood racial/ethnic composition, may affect the types of organizations that locate in particular settings. In addition, patients' choice of residence, utilization of particular organizations or services, and access to well-trained health professionals may be influenced by their sociodemographic characteristics (69,70). As a result, access to medical innovations and new technology may be distributed unequally, influencing quality of care.

Generally, elements of the healthcare system are described in terms of provider-level factors (e.g., provider specialty, age, race/ethnicity, board certification), facility-level factors (e.g., type, size, profit status, procedural volume, teaching status), and system-level or structural factors (e.g., location, dispersion, and availability of health services, healthcare financing, technology investment, existence of quality monitoring systems). Several studies have investigated the effects of these factors on guideline-concordant practices in cancer care, but rarely are racial/ethnic and other patient-level variables considered in the context of the design and operation of the health system. One study showed that black cancer patients were more likely than white patients to be treated by physicians who lacked board certification, experience, and technical resources (71). Moreover, physicians treating black patients more often reported that they were unable to provide high quality care to their patients (71). Bao and colleagues have discussed the importance of distinguishing "within" physician differences from "between" physician differences, suggesting that the problem of one physician practicing poorly across all his/her patients is quite different from the problem of one physician providing worse quality care to certain patients, while providing better quality care to others (72). The exploration of these factors in the specific context of breast cancer care is described in the following paragraphs.

Despite strong evidence for racial disparities in breast cancer outcomes, few empirical studies have explicitly considered the modifying or confounding effect of health services factors on the relationship between race and breast cancer care. One publication by Jerome-D'Emilia and Begun using information from the National Cancer Database (NCDB) examined diffusion of BCS and highlighted the importance of hospital teaching status, regional supply of radiation oncologists, surgical volume, and ratio of specialists to generalists in predicting receipt of breast conserving surgery over time (73). After controlling for these health system-level factors, race did not have a significant effect on receipt of breast conserving surgery. In another study examining variation in timing of radiation therapy after BCS, researchers found evidence that characteristics of the health system, such as facility location, type/ownership, and institutional affiliations, play a role in determining timing of receipt of radiation therapy and that these factors, when omitted from analyses, likely confound the effect of race/ethnicity (37). For example, increasing distance to the nearest radiation facility generally was associated with lower odds of ever receiving radiation therapy, and distance to radiation facilities varied significantly by race. This study demonstrated that health system-level factors accounted for some, but not all, of the racial differences in timing of radiation therapy. However, racial/ethnic differences in *ever* receiving radiation therapy disappeared after controlling for health system factors and other potential confounders (37).

Access to insurance and ability to pay for treatment also may vary by race and lead to racial differences in outcomes. In general, uninsured/underinsured and low income women suffer serious problems of access to breast cancer care due to lack of ability to afford out-of-pocket deductibles and copayments, lack of reliable or free transportation, and competing demands. Long-term costs associated with breast cancer treatment can be staggering, which may affect receipt and completion of treatment. Uninsured or underinsured cancer patients are especially sensitive to high costs of care, and black women are more often uninsured or under-insured than white women. Regardless of insurance status, hidden costs of cancer care, such as transportation to treatment centers; loss of income due to diminished productivity or loss of work days; and out-of-pocket premiums, deductibles, and copayments can be especially burdensome to the cancer patient (74). Due to the difficulty of measuring person-level socioeconomic status and out-of-pocket expenses in large claims-based datasets, the effect of such factors on the relationship between race and breast cancer care is understudied.

Although racial disparities in breast cancer treatment are generally well-documented, more racially specific data are needed in some areas. With respect to stage IV or advanced breast cancer, many treatment options exist, and treatment options have rapidly changed over the years; more studies are needed to examine racial/ethnic, socioeconomic, geographic, and structural/organizational variation in the complex treatment of advanced disease. Additionally, racial differences may exist in receipt of post-mastectomy radiation therapy (indicated at a minimum for tumors greater than 5 cm or with multiple positive nodes). Punglia and colleagues examined receipt of radiation therapy after mastectomy in elderly women during the 1990s and found that trends in use differed significantly across practice settings, but more updated examinations by race are needed (75).

Differences in treatment can potentially explain a large portion of the racial and ethnic disparities in breast cancer, particularly among patients eligible for radiation and endocrine therapies. In many cases, however, racial differences in mortality remain even after controlling for treatments received, and racial differences persist in health systems with equal insurance coverage and access to care (23). These realities suggest a need to explore other factors that may contribute to poorer outcomes among minority breast cancer patients, including differences in treatment response and survivorship care.

DISPARITIES IN RESPONSE TO TREATMENT

Differences in Toxicity

One potential mechanism by which racial disparities in breast cancer can arise is through differential treatment toxicity in women of different races, leading to more frequent discontinuation, delay, or dose modification of treatment regimens. Such toxicity could be attributable to inherent race-based variations in susceptibility, or to differences in comorbid conditions that influence a woman's ability to tolerate cancer treatments. Both possibilities have been explored most thoroughly in the area of chemotherapy treatment.

Concerns have been raised for greater hematologic toxicity of chemotherapy among black patients due to lower baseline white blood cell counts (51). However, research suggests that hematologic toxicity of breast cancer chemotherapy is actually similar between blacks and whites (76), although more treatment modifications and dose reductions are seen in blacks. A single institution cohort study found lower baseline and posttreatment white blood cell counts among black women, and these lower counts were associated with reduced chemotherapy dose intensity due to dose reductions. Rates of serious chemotherapy-associated side effects including neutropenic fever and toxicity requiring a treatment delay did not appear to differ by race within a clinical trial population (77), though treatment delays for any reason were significantly more common in black women. The effect of toxicity-mediated disparities in treatment intensity on recurrence and survival outcomes is not yet understood.

Black women may also experience a disproportionate side effect burden from treatments other than chemotherapy. Black race has been reported as an independent risk factor for the development of lymphedema, or swelling of the arm after breast cancer surgery (78). Additionally, black and Hispanic women are more likely than white women to experience inadequate pain management and management of serious side effects of treatment (79).

Differences in Efficacy

On the whole, evidence suggests that black and white women receiving similar breast cancer treatment experience similar outcomes. Patients treated with neoadjuvant chemotherapy (chemotherapy given before definitive breast cancer surgery) have been a logical population in which to study this question, because pathologic findings at surgery provide a quantifiable patient-specific measure of response to chemotherapy. In a series of patients with triple negative breast cancer treated with neoadjuvant chemotherapy at MD Anderson Cancer Center, rates of pathologic complete response to chemotherapy and recurrence-free survival were similar among white and black women (80). However, in a larger MD Anderson cohort that included neo-adjuvantly treated patients of all biologic subtypes, black patients with hormone receptor-positive, HER2 negative disease did have significantly inferior recurrence-free survival after controlling for pathologic response to chemotherapy (81). This analysis was not able to control for receipt of, or adherence to, endocrine therapy. Similarly, a single institution study of a multiracial population of stage II–III patients treated at the University of North Carolina with anthracycline/taxane-based neoadjuvant chemotherapy found no difference in pathologic complete response between black and white patients, but significantly worse relapse-free and overall survival among blacks, especially those with hormone receptor-positive tumors (82). No significant difference in outcome was seen in patients with hormone receptor negative tumors, again raising the question of whether access or adherence to long-term endocrine therapy may influence disparities among women with hormone receptor-positive tumors.

Similar patterns of response have been observed in patients receiving adjuvant rather than neoadjuvant chemotherapy. A large cohort study of women participating in National Cancer Institute adjuvant chemotherapy trials found no racial disparity in outcomes among women with triple-negative and HER2+ cancers after controlling for receipt of therapy, but inferior outcomes among black women with hormone receptor-positive, HER2-negative cancers compared to whites (28). In a retrospective study of patients participating in Southwest Oncology group clinical trials, black women were more likely to discontinue or have delays in adjuvant chemotherapy, but even after controlling for these factors and other clinically relevant covariates, black women had inferior

disease free survival (77). No interaction between race and receptor subtype was found in this study, suggesting a consistent effect across breast cancer subtypes, but the strength of this finding is limited by a relatively small sample size.

In summary, the evidence suggests that response to chemotherapy in women with similar disease characteristics is comparable across races, and that observed differences in long-term breast cancer recurrence and survival outcomes after chemotherapy are most prominent in hormone receptor-positive subtypes, where outcomes may be affected by differences in use of endocrine therapy. It is also possible that within-subtype biologic differences explain worse outcomes among black women with hormone receptor-positive tumors, suggesting a need for more research focused on molecular characterization of these tumors.

DIFFERENCES IN SUPPORTIVE AND SURVIVORSHIP CARE

Potential racial differences in long-term sequelae of treatment and survivorship care of breast cancer survivors are dramatically understudied. Older studies suggested that black survivors might have more difficulty with resumption of daily tasks and long-term adjustment compared to whites (83), but research to substantiate or add detail to these findings is lacking. There is some evidence that minority women receive less adequate supportive care during the survivorship period. In one survey study, black and Hispanic women were less likely than whites to report talking with other survivors, and more likely to report wanting more contact with other breast cancer patients (84). Black and Hispanic breast cancer survivors in another survey of survivorship care were more likely to report an unmet survivorship-related need, such as menopausal symptoms, difficulty sleeping, or arm problems. Both cost/insurance and barriers and problems in communicating about needs with providers were cited by women as reasons for unmet needs (85). Overall health utilization among black women after breast cancer may also lag that of white women. In a large cohort study, black breast cancer survivors were less likely than their white counterparts to receive preventive healthcare services, such as influenza vaccination, lipid screening, and screening for other cancers, after adjustment for age, comorbidity and a variety of disease-related and socioeconomic factors (86). Although there is little research regarding the underlying causes of these disparities in survivorship care, it is reasonable to hypothesize that patient-, provider-, and structural-level factors affecting receipt of high quality care during initial treatment may have similar effects during survivorship.

SPECIAL ISSUES IN BREAST CANCER DISPARITIES

Women with Multiple Vulnerabilities

The problem of health disparities in breast cancer care and outcomes is not limited to racial disparities among black women compared to other groups. Organizational, structural, economic, and sociopolitical dynamics of the American health system contribute to complex racial/ethnic, socioeconomic, age-related, and geographic health disparities. Particularly vulnerable groups include the elderly, the uninsured and under-insured, low-income women, and women living in rural or under-resourced areas. Being in more than one of these subgroups likely corresponds with even higher risk of poor quality care and poor outcomes. Elderly, rural-dwelling, less educated, poor, disabled, and Hispanic and/or non-English speaking women all experience significant disparities in breast cancer detection and survival after diagnosis (87). Interactions among these patient-level factors may have an additive or multiplicative negative effect on health outcomes. For example, the issue of distance to care has been found to be more problematic for older women (88) and Hispanic women (37), perhaps suggesting that transportation to care is particularly problematic in these subgroups. High quality data as well as complex analytic methods are required to correctly understand interrelationships among multiple patient-level factors affecting the quality of breast cancer care.

It should be noted that the relationship between race and other factors that affect breast cancer risk and cancer care utilization is complex and that the needs or challenges of breast cancer patients of a given race may differ based on factors linked to, but distinct from, race. To cite one example, multiple studies have documented that use of adjuvant endocrine therapy is uniformly lower among Medicaid patients, who typically have low income and poor healthcare access, than has been reported in other patient populations, and this underuse is uniform across Medicaid patients of different races despite the over-representation of black women in Medicaid (58,60). In this case, socioeconomic vulnerability, not race, is likely the driver of underutilization and attenuates racial differences. Conversely, within-group heterogeneity in racial minorities is often understudied such that the variations in utilization within minority populations are masked. For instance, although Asian women in Northern California have been reported to initiate adjuvant endocrine therapy at similar rates compared to whites, further sub-group analysis identified that Chinese woman actually initiate endocrine therapy at lower than average rates, while other Asian subgroups including Japanese, Filipino and South Asian women initiate at average rates (59). Within-group heterogeneity in breast cancer also occurs within immigrant populations; U.S.-born Hispanic women have higher rates of incident breast cancer than foreign-born Hispanics, and higher socioeconomic status and residence outside an ethnic enclave have also been associated with higher breast cancer incidence, suggesting that these women may have changes in risk factors based on their length of residence in the United States (101). Paradoxically, U.S.-born Hispanic women have lower rates of advanced-stage breast cancer diagnosis than foreign-born women, but somewhat lower breast cancer-specific survival (102). These complex relationships illustrate that disparities in breast cancer among minority women are indeed multifactorial and likely will require equally complex solutions.

Breast Cancer Care in the Elderly

Age and breast cancer are closely and meaningfully correlated (5). The majority of breast cancer diagnoses occur in women older than 60, and the median age at breast cancer diagnosis is 62 years. Breast cancer incidence rises dramatically and nonlinearly with age and levels off around the time of menopause, a trend that is biologically explained by the important role of reproductive factors and ovarian estrogens in breast cancer etiology (6). Further, behavioral and morphologic characteristics of the cancer itself differ by age. As discussed earlier in this chapter, younger women tend to have more aggressive tumors and worse prognosis, whereas older women typically have more indolent disease with better prognosis (5). Important age-specific racial/ethnic trends in breast cancer incidence and mortality are also observed. Specifically, young black women (<50 years old) have a higher incidence of breast cancer compared to young

white women, but around the time of menopause, a crossover occurs and incidence rates among older white women surpass rates of older black women (6).

Age-related disparities in cancer treatment are well-documented in the literature, but the implications of such disparities are muddied by poor representation of elderly breast cancer patients in clinical trials (89). Due to insufficient accumulation of clinical trial evidence about the effects of radiation and chemotherapy in older women, cancer quality metrics have been limited to women younger than 70. Many experts agree that such an age-specification sets a low bar for quality, given observational evidence showing that older women benefit as much as younger women from these therapies (89). Studies have shown that women older than 70 are less often treated with chemotherapy and less often receive radiation therapy after breast conserving surgery (37,90), but the implications of this under-treatment are unclear and need further study. Importantly, randomized trials demonstrate that older women derive the same benefit from chemotherapy as younger women (91), and that women older than 65 treated with less aggressive, nonstandard adjuvant chemotherapy fare worse (89). Choice of treatment and supportive medications matter. In an older study of women over 70 treated with the first-generation chemotherapy regimen oral CMF, only 65% completed all 6 cycles; nonpersistence with treatment was associated with toxicity (92), highlighting the importance of side effect management in this vulnerable population.

Disparities in Research Participation

Black women enroll in clinical trials much less often than white women and thus may have poorer access to life-prolonging treatment offered by many cancer trials (93). As a result, diffusion of research-related innovations may be disproportionately benefiting certain women as compared to others. In addition, Mitchell and colleagues found that few breast cancer randomized trials reported or analyzed outcomes based on race/ethnicity, indicating a failure to report data that may help evaluate and overcome health disparities (94). Under-representation of elderly and minority women may also lead to under-recognition of toxicities that are race or age specific.

INTERVENTIONS TO ADDRESS BREAST CANCER DISPARITIES

The elimination of healthcare disparities is a national public health priority, and a number of interventions at the policy level have attempted to narrow breast cancer disparities. The national Breast and Cervical Cancer Early Detection Program (BCCEDP), begun in 1991, is one such program in which federal and state matching funds are allocated to provide cancer screening to low income women, and more recently to provide coverage for treatment in the event of a cancer diagnosis (95). Data from the early years of the program indicated a positive effect, with the greatest increases in mammography screening rates among black women in the under-65 age group (96). Rates of mammography among blacks continued to rise through the year 2000, and the age of the BCCEDP program at the state level was an independent predictor of higher mammography usage among white women, though the effect was not statistically significant for black and Hispanic women, likely due to smaller sample sizes (95).

A number of interventions at the patient- and provider-level have also been tested to increase use of screening mammography. A systematic review by Masi et al found that simple patient reminder-based interventions were not generally effective in raising screening rates in populations that included large numbers of black women and/or patients with low income or low educational attainment. Provider-targeted reminders, however, were more successful in improving screening rates in minority populations, and multifaceted interventions that addressed barriers such as transportation cost in addition to providing reminders and educational material have also been successful in minority populations (97,98). None of these interventions examined effects of the intervention on long-term outcomes such as breast cancer mortality, and such an evaluation is not likely to be feasible given the extended study timeframe required. Patient-level interventions to address disparities in diagnostic work-up or receipt of appropriate treatment have been tested less often than interventions to increase screening. In five studies of diagnostic testing interventions, Masi and colleagues found that some form of case management shortened the time from mammogram to diagnosis or biopsy among black (four studies) and Hispanic (one study) women (97). A more recent study of case management through a patient navigator among urban minority women with abnormal mammograms demonstrated improvements in time to diagnostic resolution, anxiety, and patient satisfaction with patient navigation compared to usual care (99). Similarly, a case management based intervention increased receipt of BCS with radiation therapy in a racially diverse cohort and eliminated disparities in rates of stage-appropriate treatment (100).

FUTURE DIRECTIONS

The decision by an individual patient and her providers to undertake a particular diagnostic and treatment path is complex. Treatment decisions leading to differential quality of care may arise from patient-level, provider-level, facility-level, and structural characteristics (37). Improving patient-level psychosocial or behavioral correlates of treatment disparities, such as health-seeking behavior and trust in the healthcare system, will require creative and sensitive interventions. Provider-level, facility-level, and structural correlates of treatment decision-making, however, should be distributed relatively similarly across patients. For example, access to specialists and facilities capable of providing modern procedures, such as sentinel lymph node biopsy or radiation therapy, should in theory be equally available to black, Hispanic, and non-Hispanic white patients, but this may not be true in reality. Of course, individuals can choose to forego guideline-recommended therapy, but as a rule, treatment options should be made equally available and accessible to all breast cancer patients with clinically similar tumors.

Clearly, race-specific genetic susceptibility to more aggressive cancers may not be affected by public health efforts; however, recognizing that there are racial differences in tumor biology may suggest the need for more tailored screening approaches or for focus on identifying environment-gene interactions that lead to strategies for cancer prevention. Additionally, health system/structural-level correlates of racial disparities in breast cancer outcomes such as access to insurance coverage may be slow to change over time, but are likely to improve with recently enacted health reform legislation. Health reform is an opportunity to redesign healthcare systems and policies in order to improve the quality of care for *all* breast cancer patients. The possibilities are numerous. For example, interventions designed to provide transportation to radiation therapy or chemotherapy appointments for racial/ethnic minorities and elderly women

without regular access to transportation could be tested and reimbursed by insurers should they prove effective in reducing barriers to access. Similarly, telemedicine strategies currently under study may be useful in building collaboration between tertiary centers and smaller community hospitals whose advanced breast cancer patients can benefit from inter-institutional tumor board meetings. Finally, greater emphasis on, and evaluation of, the training and use of patient navigators are needed to encourage early initiation of adjuvant therapy and to limit underuse of adjuvant therapy in racial/ethnic minorities and elderly patients.

Despite gains in our understanding of breast cancer disparities, many nagging questions remain regarding how to ensure optimal treatments and outcomes for all patients. Among these are questions about the best use of innovative gene expression profiles or detailed molecular studies in directing patient care, improvements in surgical and radiation techniques, optimization of adjuvant systemic therapies incorporating novel biologic treatments, whether structural interventions can improve receipt of guideline-concordant treatment by removing barriers to access, and whether behavioral interventions can increase initiation and long-term adherence to adjuvant therapy. As new treatment innovations emerge and new guidelines are developed, it will be increasingly important to monitor uptake and to ensure that vulnerable subpopulations have equal access to these evidence-based advances in care. The field of cancer disparities is evolving from one which builds observational evidence of differences in presentation, treatment, response, and survivorship to one which designs and tests novel interventions to remedy the underlying causes of these differences.

Finally, systems thinking could be used to build, parameterize, and validate models that help coordinate breast cancer care across diverse breast cancer patients, health facilities, and providers. Recognizing that the supply of oncologists and other cancer specialists is limited and that cancer prevalence may be increasing given the aging American population, optimal use of cancer resources is important. For example, earlier stage, uncomplicated breast cancer patients may be treated sufficiently well at lower volume, community-based facilities, whereas advanced stage patients with significant clinical complications or comorbidities may benefit from being treated at higher volume, academic medical facilities. Because there are fewer of the latter, we should seek to optimize patient allocation so that clinical expertise, technical resource capacity, transportation/travel, and case complexity can be delivered in the areas of greatest need. Such a systematic approach will ensure the best outcomes for all patients, regardless of race/ethnicity, age, or socioeconomic status. Creative optimization models drawing upon the methods used in industrial engineering and operations research may be useful in this context.

SECTION XIV

Issues in Breast Cancer Survivorship

CHAPTER 87

Nursing Care in Patient Management and Quality of Life

Karen Meneses and Deborah K. Walker

CHAPTER CONTENTS

Nurses have an integral role in the interdisciplinary management of patients from prevention, screening, and early detection through diagnosis, treatment, recurrence, and survivorship. This chapter is divided into patient care management along the cancer continuum with specific focus on patient management during the various therapeutic approaches to care. Each section emphasizes patient management related to education, symptom management, and psychosocial support.

PREVENTION, SCREENING, AND EARLY DETECTION

Prevention, screening, and early detection are important strategies in reducing the breast cancer incidence, particularly in high-risk women. The emphasis on lifestyle interventions along with routine screening has led to significant improvement in early detection of breast cancer.

Prevention

There are many risk factors for the development of breast cancer in women, but few can be modified. Table 87-1 lists risk factors. Lifestyle modifications are one area where nurses can be proactive and educate on strategies for risk reduction. Encouraging healthy nutrition, increased physical activity, weight management, and limited alcohol consumption are interventions that can reduce a women's risk of breast cancer (1–3). Although diet has not specifically been linked with an increased risk of breast cancer, obesity and weight gain have demonstrated an increased risk among postmenopausal women (4). Maintaining a healthy body mass index (BMI) through eating healthy and physical activity is important, not only for positive effects on body weight, but also for better psychological and quality-of-life outcomes (5). History of alcohol consumption is important to assess. As little as one drink per day of alcohol has been associated with an increased risk of breast cancer (6). Nurses involved in screening and early detection activities can educate on the risk of excess alcohol consumption, and recommend less than one drink per day (7).

Other prevention strategies for moderate- to high-risk women (i.e., *BRCA1* and *BRCA2*) include risk reduction surgery or using a selective estrogen receptor (ER) modulator such as tamoxifen. Risk reduction surgery may include a bilateral mastectomy and/or bilateral salpingo-oophorectomy. Surgery is usually recommended in women with either the *BRCA1* and *BRCA2* mutation or in women at high risk (8). Surgery may have a negative impact psychologically, so counseling is vital prior to the procedure. Counseling should include the risk and benefits of surgery and discussion of other options, if available (i.e., reconstruction).

In women 35 years or older, tamoxifen has be used to decrease the risk of a second primary contralateral breast cancer (9). Nurses can educate women about the benefits of tamoxifen that include reducing the risk of invasive and noninvasive breast cancer, and reducing risk of a new primary contralateral breast cancer (9). Symptom management education while on tamoxifen is also important, and should include hot flash management, risk of thromboembolic events, and increased risk for endometrial cancer (9).

TABLE 87-1

Risk Factors
Age—risk increases with age
Reproductive factors
Age at menarche—early increases risk
Age at menopause—late increases risk
Age of first live birth—late first pregnancy
Nulliparity—increases risk
History of benign breast disease
Oral contraceptive use
Current or prior use of hormone replacement therapy
Alcohol consumption
Increased body mass
Ionizing radiation to chest before the age of 30
Family history
Personal history of breast cancer—lobular carcinoma *in situ*

From National Comprehensive Cancer Network (NCCN). Fort Washington, PA: NCCN, Inc., 2012.

Educating women about risk factors is ideally done by the health care team. Patients often turn to their nurses for information. Nurses can share information about modifiable and nonmodifiable risk factors (i.e., age, family history, etc.). This knowledge would help nurses identify those at risk for breast cancer and provide help when they counsel about prevention strategies.

When addressing risk factors and prevention strategies with women, there is the potential for psychological concerns. Women may overinterpret their risk with resultant increase in anxiety or stress which may lead to ignoring symptoms or recommendations for screening. Alternatively, women may see improvement in overall health when they follow the recommendations for lifestyle modification and screening for breast cancer.

Screening and Early Detection

Recommendations for breast cancer screening vary slightly depending on the recommended guidelines that are followed. The general consensus among all recommendations is that not one screening modality should be used alone. Breast self-awareness, clinical breast exam, and mammography should be used together, along with clinical reasoning to screen individuals for breast cancer (7,10–12). Nurses should be familiar with the recommendations supported by their institution and educate women accordingly.

Breast biopsy is performed when an area of suspicion has been identified on diagnostic evaluation. Fine-needle aspiration, core needle, and excisional biopsy are commonly used methods (7). Patients should be educated about the specific method, recovery period, and when follow-up occurs. Fine-needle aspirations are typically done when there is a low suspicion for malignancy. It is the least invasive and can be performed in the office using a needle and syringe to aspirate contents of the mass. Recovery is quick and patient usually does not have any limitations. If the result is benign, follow-up occurs within a few months to monitor for reaccumulation of fluid.

Core needle biopsies are done more frequently to obtain large tissue samples for analysis. After local anesthetic, a large-gauge hollow needle is inserted into the suspicious area and several samples are obtained. During the sampling process a "clicking" sound may occur as the sample is retrieved. The patient may feel pressure during the procedure, but not major pain. Bruising may occur at the needle insertion site.

An excisional biopsy of the breast is invasive and may be done with a local anesthetic, under IV sedation, or rarely, general anesthesia. The patient should be informed accordingly regarding any restrictions prior to the type of procedure; for example, nothing to eat after midnight on the day before surgery. Because this procedure is invasive, patients may have a visible scar and/or a noticeable change in breast shape or size. This procedure can take about 1 hour with a recovery period of less than 2 hours. For a few days the patient can expect to be sore and have some swelling to the area. Patients should also be informed about the risk of infection from the invasive procedure and to call with fever, pain, erythema, or bleeding from the incision. Recovery is about 1 to 2 weeks for the incision to heal. Follow-up is needed in 10 to 14 days if sutures need to be removed.

Additionally, the nurse should provide education on breast self-awareness including the proper way to perform a self-breast exam (SBE). Although SBE is controversial and has not been shown to decrease breast cancer mortality (12), it is important that women become familiar with their breasts to help identify problems in between clinical examinations. The patients should also be given information to help them understand their own risk for developing breast cancer and the recommendations for ongoing surveillance. This information should be individualized and based on their medical and family history, as well as clinical exam findings. There are numerous online resources in both English and Spanish that can be used as education materials.

A review of a meta-analysis found that screening and early detection for breast cancer may cause fear and anxiety among individuals (13). Often individuals do not go for screening because they fear a mass might be found, they may have a recurrence, or a second breast cancer. To help alleviate some of those concerns, nurses should be proactive in offering recommendations and education on the use of screening as a tool to identify areas of concern early. Early identification may lead to early intervention and better outcomes.

PATIENT CARE MANAGEMENT OF LOCAL AND REGIONAL DISEASE

Education

Practice guidelines for the treatment of early-stage breast cancer are well publicized and are available to patients and their families (7). Patients who are best able to make decisions about treatment are those who can express and communicate their beliefs, feelings, and preferences, who actively listen to information shared by their oncology team, and who search out additional information or second opinions from trusted and respected sources (14). Likewise, clinicians who are best able to assist patients in making reasonable decisions about treatment are those who recognize that decision making is a process that occurs over time and who acknowledge patients' vulnerability in making decisions (15).

While there are numerous patient teaching materials available in print (e.g., books, pamphlets, and brochures), there has been a significant increase in electronic and

web-based education formats about breast cancer treatment (16). In addition, electronic support groups, face-to-face support groups, counselors, and individual networking efforts contribute to helping patients find information (see appendix for web sites). Clinicians can foster patient decision making by ongoing assessment of their patients' developmental stage, educational level, degree of anxiety, energy level, personal coping styles, past experiences, and family history. Nurses can help patients and their families discern what is useful during this stressful time and what can be used at a later date by knowing what resources are available in their institution, in the community, regionally, and nationally.

Preoperative Teaching

Specific preoperative teaching focuses on information about the procedure, incision and drain care, pain management, lymphedema prevention and management, and prosthetic devices (17). In the United States, length of hospital stay for mastectomy is about a day. Thus, preoperative teaching ideally begins in the surgeon's office. Patients generally find that a simple pamphlet, brochure, or video that illustrates the surgical experience beginning with admission, surgery, and recovery helps orient them to the surgical facility and procedures.

Patient teaching before surgery may include instructions about stopping use of any aspirin-containing products, vitamin E, and herbal preparations for at least 7 days preoperatively. Some postoperative pain medications contain opioids that can cause constipation; it is helpful for patients to drink several glasses of water before midnight the night before surgery. Similar to other surgical procedures, no solid food or drink may be ingested at least 6 hours preoperatively. On the day of surgery, patients may feel comfortable wearing a loose-fitting blouse with front tab buttons for ease of comfort, particularly when axillary node dissection is planned. Harris et al. recently evaluated guidelines for breast cancer rehabilitation with an emphasis on lymphedema and concluded that there is a pressing need to update the guidelines on upper extremity musculoskeletal impairments and lymphedema (18).

Symptom Management after Mastectomy

Incisional Wound and Drain Care

Nurses provide specific information about dressing changes, measurement and recording of drainage, monitoring for signs and symptoms of infection, and personal hygiene. Patients generally prefer a description of what their surgical incision will look like, and an appropriate visual diagram or photograph helps illustrate the anticipated results. Postoperatively, patients need instruction on drain care and how to minimize unnecessary pressure or prevent accidental dislodgement. Patients may feel mild to moderate discomfort and soreness. Having a family member or friend available to help them with physical care and personal hygiene and to monitor for potential postoperative complications (i.e., seroma, hematoma, increased pain or discomfort, or fever). Light foods such as clear broth or soup, fruit juices, and soft foods may help ease postanesthesia effects such as nausea. For general comfort, pillows to support the affected arm and back are helpful.

Pain Management and Comfort Measures

Postoperative pain varies widely, depending on individual and cultural characteristics, the surgical procedure, and pain medication relief (19). Some patients have relatively little discomfort with lumpectomy and require mild analgesics, whereas others may have pain after mastectomy and reconstruction that requires stronger analgesia. A plan for postsurgical pain management is best individualized between the clinician and patient with regular monitoring of pain relief.

Postoperative sensations and pain, such as muscle tightness, difficulty in lifting of the arm, and soreness around the shoulder, are to be expected (20). Support for the arm and shoulder during the first 24 postoperative hours and avoidance of active stretching or pulling until after the drains are removed are helpful. Gentle stretching exercises can usually begin soon after surgery (usually 48 hours) and should be individualized to reflect the extent of the operation, the presence of drains, and the preoperative capabilities of the patient. For patients who will receive radiation therapy as part of their treatment, regaining adequate range of motion is extremely important because the radiation treatment position requires the arm to be abducted at a 160-degree angle. Since lymphedema is a major side effect of treatment, the reader is referred to Chapter 40 for extensive information about the topic.

Prosthetic Fitting

Prosthetic fitting for women who have had mastectomy and reconstruction is generally done around the first postoperative follow-up appointment or when the incision has healed. However, women benefit from receiving specific information about how, when, and where to purchase a prosthesis and from having a temporary prosthesis in hand before hospital discharge. Many different prosthetics are available, such as soft forms and self-adhering forms, in a variety of colors and textures. There are also stylish and specially designed lingerie and bathing suits that can accommodate the prosthesis. Having a sample of a breast prosthesis and mastectomy bra to use during preoperative teaching is useful.

Care after Breast Reconstruction

After reconstruction, patients may start home exercises such as brisk walking, stationary bike riding, and gentle stretching exercises. Avoiding high-impact aerobics, jogging, and lifting weights above 5 to 10 pounds is recommended for several weeks after reconstruction (20). Patients should avoid the use of health spas and public swimming pools until after the incision lines and drain sites are healed (20). Although breast reconstruction approximates the look of the natural breast, it cannot duplicate the same look and feel (20).

Psychosocial Recovery

Detailed discussions of patients' psychological reaction and support programs are found elsewhere in the text. Specific preoperative discussions in which clinicians can engage with their patients include attending to the emotional impact of the initial diagnosis and treatment of breast cancer and acknowledging that the surgical experience marks the beginning of a long recovery period. Other psychosocial strategies include the following: helping patients to reframe their time sequence; reordering priorities about work, family, and social activities; and encouraging short-term thinking (e.g., practice 1 day at a time, practice thought-stopping that provokes anxiety, and think through the process of the events of the week and the time it takes to accomplish tasks).

PATIENT CARE MANAGEMENT DURING RADIATION THERAPY

Education

Teaching patients about radiation therapy ideally begins during the consultation visit, when the role of radiation therapy in the overall treatment plan, additional diagnostic

studies needed, and treatment planning are discussed. Patients may be apprehensive about starting radiation but generally are relieved to learn that side effects are well tolerated (21). Information about radiation treatment planning includes the rationale for simulation, the need to minimize radiation dose to vital organs such as the lung and heart, and the construction of immobilization devices to keep the limbs in consistent position during treatment. Patients must plan to spend sufficient time for the simulation procedure, must be prepared to feel some discomfort while lying on a hard simulation table, must understand that the radiation therapist will place a permanent tattoo or skin markings (e.g., the size of a freckle) directly on their skin surface to help reproduce the treatments on a daily basis, and must realize that simulation is *not* a radiation treatment.

After simulation is completed, patients receive an appointment to start treatment that will be given daily, 5 days a week. Patients find it helpful when the radiation oncology nurse gives information about a typical day or week's treatment so that they can obtain a mental picture of the experience. Patients also find it helpful to keep a diary of daily activities and appointments. Some patients prefer to bring a CD player or other device to listen to their relaxation tapes or music during treatment. The first treatment generally takes about 30 to 45 minutes; subsequent treatments take about 15 minutes. They may be disconcerted by the sounds emanating from the radiation treatment machine. Patients may need reassurance that although they are alone during treatment, the radiation therapists remain in contact with them by screen monitor and intercom. Radiation oncology departments are often located on the ground floor, with natural light, serene wall colors, and artwork. Soothing background music helps allay patients' anxiety.

Symptom Management during Radiation Therapy

Symptom management includes teaching about the potential side effects of radiation therapy, self-care measures to manage the side effects, and managing the overall radiation therapy experience. The acute physical side effects of radiation therapy are skin reactions and fatigue.

Skin Reactions

Radiation-induced skin effects range from slight peeling, dryness, tanning, itchiness, and breast tenderness and fullness to moist desquamation (21). The severity of skin reactions is related to radiation factors (i.e., total dose, fractionation, energy beam, bolus treatment, and volume of tissue treated), patient factors (e.g., breast size, age, nutritional state, presence of comorbid disease), and treatment factors such as previous or concurrent chemotherapy. Particularly susceptible areas of skin breakdown include the inframammary fold and supraclavicular areas.

Teaching patients self-care skin management during radiation ideally begins before or at the start of treatment. The radiation oncology team examines patients for acute side effects on a weekly basis and as needed as therapy progresses. In a recent update to evidence-based skin care management in radiation therapy for breast cancer, McQuestion indicates that there is insufficient evidence with respect to topical or oral agents in the prevention of skin reactions. Further, calendula cream may reduce the incidence of grade 2 or 3 skin reactions (21).

Cancer-Related Fatigue

Fatigue is recognized as one of the most prevalent symptom of cancer and its treatment (7). Fatigue can be a chronic problem that results from several causes (i.e., treatment and pathophysiologic, behavioral, and emotional factors). It occurs during treatment and persists even after treatment ends. Patients with cancer report that fatigue has a negative influence on quality of life: It can impair the ability to function or maintain daily routines (e.g., weakness, no energy), influence emotional reaction (e.g., sadness, irritability), and interrupt work schedules (e.g., poor attention or concentration). Although rest can restore a normal level of functioning in the healthy person, this restorative capacity is diminished in patients with cancer. Patients receiving radiation therapy report a usual pattern of fatigue that gradually rises by the third week of treatment and gradually declines after therapy ends. Some patients experience less fatigue on weekends, when radiation is not delivered.

The National Comprehensive Cancer Network (NCCN) practice guidelines for cancer-related fatigue (7) use a treatment algorithm of regular patient evaluation and a brief screening instrument. Basic cancer-related information is given after initial screening. A more focused evaluation is done when the patient has moderate or higher levels of fatigue. Patients are evaluated based on five factors known to be associated with fatigue: pain, emotional distress, sleep disturbance, anemia, and hypothyroidism. The presence of any of these factors requires treatment with patient reevaluation. If none of the factors is present or if the fatigue is unresolved, a more comprehensive assessment is recommended, including a thorough review of systems, review of medications, assessment of comorbidity, nutritional and metabolic evaluation, and assessment of activity level.

Specific causes of fatigue such as infection, fluid and electrolyte imbalances, or cardiac dysfunction are treated accordingly. Nonpharmacologic and pharmacologic treatment of the fatigue is considered when specific causes are not identified. Nonpharmacologic interventions may include a moderate exercise program to improve functional capacity and activity tolerance, restorative therapies to decrease cognitive alterations and improve mood state, and nutritional and sleep interventions for patients with disturbances in eating or sleeping. Pharmacologic therapy may include drugs such as antidepressants for depression or psychostimulants that have been reported to improve fatigue but are still investigational (7).

Patients may also experience problems with physical functioning, sleep, and attention. Effective management of cancer-related fatigue involves an informed and supportive oncology care team that assesses patients' fatigue levels regularly and systematically and incorporates education and counseling regarding strategies for coping with fatigue (7).

Psychosocial and Family Support

Radiation treatments require daily visits over a 4- to 5-week period that may require adjustment in work, family, and social patterns. Patients may need assistance in helping to reorganize work schedules to accommodate daily treatment. Strategies include scheduling radiation treatment at either the beginning or end of the workday, shortening the workday schedule when possible, or even taking a temporary leave of absence from work during radiation. Because of the daily imposition of the radiation treatment schedule, other patients may need assistance with home management and child care. Older patients or those with mobility problems may additionally require assistance in traveling to and from daily treatment.

PATIENT CARE MANAGEMENT DURING SYSTEMIC THERAPY

Education

Breast cancer treatment has become increasing complex. With a better understanding of the biology of breast cancer and the various types that have been identified (i.e., triple negative), new treatment strategies have been implemented. New drugs, new combinations, and the order in which the various treatment modalities are delivered is continuously being studied and implemented.

With these advances comes increased responsibility for the nurse in management of the patient with breast cancer. At a minimum the nurse should be familiar with treatment goals, the various drugs used in treatment (including the protocol), and potential side effects of the various drugs. This knowledge can help the nurse provide relevant patient education and appropriate nursing management.

Patients can receive therapies in the adjuvant, neoadjuvant, or metastatic setting, so goals may vary from cure, control or palliation. The therapies used in breast cancer treatment can also vary in side effects and toxicity, so education should be tailored to the patient and their individual response to treatment. The section will discuss a few selected symptom management strategies for breast cancer patient's being treated with endocrine therapy, chemotherapy and targeted therapy.

Endocrine Therapy

Tamoxifen and aromatase inhibitors (AIs) have similar side effect profiles with both classes of endocrine therapy showing similar effects on quality of life. Side effects include hot flashes and sexual dysfunction, such as vaginal dryness and dyspareunia, and sexual dysfunction. Increased bone turnover, reduced bone density, and increase in fractures are reported with AIs particularly among older women (22). Long-term adherence to endocrine therapy remains a challenge (23).

Chemotherapy

Symptom Management during Chemotherapy

The most common physical symptoms experienced are bone marrow suppression, nausea and vomiting, hair loss, fatigue, weight gain, mucositis, neurotoxicity, and menopausal symptoms. Managing vascular access devices (VADs) and decreasing risk of extravasation are also important aspects of clinical care.

Bone Marrow Suppression: Neutropenia is a dose-limiting toxicity of chemotherapy. The nadir is predictable and occurs about 10 to 14 days after treatment, with recovery occurring about 3 to 4 weeks later. Signs and symptoms of infection include fever, pain and tenderness, change in elimination of urine and stool, lethargy, myalgia, and malaise. Observed signs of infection are generally absent in moderate to severe neutropenia because of the lack of circulating neutrophils.

Ongoing and early assessment, identification, and patient education about the signs and symptoms of infection, hand washing, and meticulous personal hygiene are essential components in preventing and reducing neutropenia-related infections (7). The NCCN Myeloid Growth Factors Guidelines examined therapeutic efficacy and clinical benefit (7). The practice guidelines include risk assessment, prophylaxis of high-risk patients, and judicious use of myeloid growth factors.

Chemotherapy-Induced Nausea and Vomiting (CINV): With the widespread use of serotonin antagonists, nausea and vomiting are manageable side effects of chemotherapy. Chemotherapy-induced nausea and vomiting are categorized as acute (during treatment), delayed (more than 24 hours after therapy), and anticipatory (a classic conditioned response as a result of inadequate antiemetic therapy). The risks of nausea and vomiting are related to the type and dose of chemotherapy used and individual patient factors such as female gender, younger age, previous chemotherapy, and history of motion sickness. The emetogenic potential of chemotherapeutic agents is classified from high to low. Typical chemotherapeutic agents used to treat breast cancer, such as cisplatin, cyclophosphamide, doxorubicin, and methotrexate, have either moderate to high emetogenic potential. Although several antiemetic regimens are available, they must be individualized for each patient. Inadequate control of nausea and vomiting during treatment can lead to anticipatory nausea and vomiting, which is more difficult to manage.

Guidelines suggest that serotonin antagonists be used either alone or in combination with corticosteroids (7). These agents are highly selective for 5-HT_3 receptors and are best used with highly emetogenic chemotherapeutic regimens. The serotonin antagonists do not have the extrapyramidal reactions more commonly associated with dopamine antagonists. Other classes of antiemetics include dopamine antagonists (i.e., metoclopramide, phenothiazines, and butyrophenones), neurokinin 1 antagonist, corticosteroids, benzodiazepines, and cannabinoids.

Metoclopramide and dexamethasone have improved efficacy compared with the serotonin antagonists with delayed nausea and vomiting. Benzodiazepines have some efficacy in anticipatory nausea and vomiting.

Mucositis: Mucositis is a general term that refers to an inflammation of the mucosa (24). Agents that are considered highly stomatotoxic are the antimetabolites, anthracyclines, plant alkaloids, and taxanes. Patient factors that are considered to confer a higher risk of developing mucositis include older age, alcohol and tobacco use, poor oral hygiene, poor nutritional status, use of ill-fitting dentures, and compromised renal function (24–25).

Consistent use of an oral care regimen offers the best protection against mucositis. Pretreatment strategies to prevent and decrease the incidence of oral complications include a baseline oral assessment, treatment of preexisting dental disease, and patient education (25). Effective oral care protocols include a combination of a cleansing method, use of lubricants, measures to relieve pain and inflammation, and measures to prevent or treat infection (25).

Neurotoxicity—Acute Pain Syndrome: Patients receiving agents such as 5-fluorouracil, the taxanes, or eribulin mesylate are at risk of neurotoxic complications (26). Peripheral neuropathies present with loss of sensation that begins at the fingertips and spreads to the wrist and starts from the toes and spreads to the ankles. With additional therapy, progressive muscle pain, weakness, motor changes, and hypersensitivity to heat and intolerance to cold can occur (26).

Neurotoxicity associated with these agents includes numbness and paresthesias in the hands and feet that can worsen over time with treatment. Treatment of neurotoxicity has included changes in dose and timing (26). Smith et al. reported on the development and testing of the Neuropathic Pain Scale to assist practitioners in assessing neuropathy in clinical practice (27).

Arthralgia and Myalgia: Arthralgias and myalgias can occur in patients receiving taxanes (28). Symptoms are dose related, may be associated with mild discomfort, or more

severe discomfort and pain with higher doses. Effects occur 48 to 72 hours after infusion and can persist for up to 7 days. Effects occur primarily in large joints, but they can involve the whole body. Pharmacologic interventions, such as nonsteroidal analgesics or narcotics, are usually required. Nonpharmacologic interventions include warm baths, relaxation techniques, and massage therapy.

Alopecia: Alopecia includes body hair loss (e.g., eyelashes and eyebrows, axillary, and pubic hair). The literature continues to demonstrate that hair loss remains one of the most distressing side effects of chemotherapy (29). Although a mastectomy scar is devastating, hair loss can be publicly stigmatizing. Hair loss is often viewed as an assault to one's physical appearance, body image, self-esteem, and sexuality. Although patients may cognitively prepare for hair loss, the actual occurrence is most often a difficult emotional experience.

Different chemotherapy agents have the differential ability to induce hair loss based on their route of administration, dosing schedules, and peak blood levels. For example, doxorubicin is most commonly linked to alopecia. Patterns of doxorubicin-associated hair loss generally occur 2 to 3 weeks after initial treatment, with continued hair loss occurring over time. Conversely, taxane-associated hair loss often occurs dramatically and suddenly. Methotrexate and fluorouracil are associated with minimal hair loss. Oral cyclophosphamide is related to hair thinning, particularly at the crown.

Patient teaching should stress and reassure that hair loss is temporary. Useful interventions for hair loss and tips before hair loss occurs includes: cutting hair in a manageable and easy to maintain style before chemotherapy, using a mild protein-based shampoo and conditioner, using an electric hair dryer on the lowest setting, avoiding electric curling irons or curlers, and dye that can increase the fragility of hair, avoiding excessive brushing and hair combing, and purchasing a wig to fit one's normal hair color and style. After hair loss occurs, suggestions include: protect the exposed scalp from excessive temperature changes; use emollient or lotion regularly to moisturize the scalp, reduce scalp itching with an oatmeal-based colloidal soap, and scarves and turbans as an alternative to wigs.

Behavioral Symptoms: Behavioral symptoms during adjuvant chemotherapy and after treatment include changes in energy, sleep, mood, depressive symptoms, and cognition (30). Behavioral symptoms are related to a serious disruption in quality of life and can persist for many years after treatment. Treatment and cancer survivorship plans include information about the range of anticipated time that behavioral sequelae occur. Behavioral symptom management strategies include psychoeducational support, and cognitive-behavioral strategies.

Chemotherapy Administration Management

Evidence-based guidelines for the administration of chemotherapy have been issued jointly by the American Society of Clinical Oncology (ASCO) and the Oncology Nursing Society (ONS), and a separate statement by the Infusion Nurses Society (31). The most recent 2012 ASCO/ONS guidelines contain information about standards related to staffing, chemotherapy practice, chart documentation, chemotherapy orders, drug preparation, patient consent and education, chemotherapy administration, monitoring and assessment (31).

Preventing Extravasation

Extravasation is a serious complication, causing pain, swelling, erythema, paresthesias, and ulceration of tissue. Factors influencing the degree of extravasation include the type of vesicant, the dose, and the concentration (32). Chemotherapeutic agents are classified as either vesicants (drugs causing tissue damage if extravasated), irritants (drugs that cause redness and inflammatory reaction at the injection site without necrosis or ulceration), or nonirritants (33). The anthracyclines are the chemotherapeutic agents used in breast cancer that are classified as vesicants (32). Because vesicants cause extensive tissue damage, major efforts are made to prevent that complication. When extravasation occurs, antidotes differ depending on the chemotherapeutic agent (32–33).

Vesicants used in breast cancer include doxorubicin, epirubicin, and mitomycin; irritants include fluorouracil, mitoxantrone, and etoposide. Irritants are more readily metabolized, removed from the injection site, and excreted compared with vesicants. Assessment parameters to differentiate extravasation from irritation or flare reaction include pain, redness, ulceration, swelling, and blood return. Key strategies to prevent extravasation include: ensuring patency of the vein or central line, avoid infusing vesicants over joints, bony prominences, or antecubital fossa, avoid giving a vesicant in an area where lymphatic or venous circulation is poor (33). An extravasation kit and extravasation policy and procedures should be readily available in any area where chemotherapy is administered.

Hypersensitivity Reactions

Hypersensitivity reactions are rare, yet can occur within a few seconds after the start of taxane infusion. Hypersensitivity reactions range from a rash, erythema, flushing, or dyspnea to severe cardiopulmonary reactions (34). Since most hypersensitivity reactions occur within the first 10 minutes of paclitaxel infusion, the reaction is most likely caused by Cremophor EL which is associated with histamine release and hypotension. Premedication regimens of oral steroids, diphenhydramine, and cimetidine have decreased the incidence of hypersensitivity reactions.

Symptom Management of Targeted Therapies

Targeted therapies have a different side effect profile compared with chemotherapy. Trastuzumab, the first EGFR targeted drug indicated for the treatment of *HER2* overexpressing breast cancer can cause heart damage and must be used cautiously in patients receiving anthracyclines (35). Cardiac status is monitored regularly with MUGA or ECHO scans. Lapatinib is a small-molecule TKI indicated in advanced breast cancer setting. The drug is taken orally and can cause side effects such as diarrhea, acneiform skin reactions, and pain in hands and feet (36). Patients on herbal products such as St. John's wort should discontinue use while on lapatinib. Patients must contact their oncologist immediately with symptoms of dehydration. They are also restricted from eating grapefruit or grapefruit juice while on lapatinib.

Psychosocial Support during Chemotherapy and Targeted Therapy

Psychosocial response during chemotherapy varies. Patients need encouragement to pace their activities, to incorporate their treatment into their daily family and work routines, and most of all, to be encouraged to ask for and receive assistance. Many patients appreciate the support they receive from others who have been there or who are going through similar experiences. Others take comfort in their family and interpersonal relationships. Breast cancer patients also use electronic support through chat rooms and blogs (37). Most patients prefer to maintain a normal lifestyle during chemotherapy. They may continue to work

as long as they desire, but may request a treatment schedule that permits recovery from side effects on days off from work. Other patients may request that their chemotherapy treatment be given on weekends or evenings.

PATIENT CARE MANAGEMENT IN METASTATIC BREAST CANCER

Metastatic disease can present at initial diagnosis or can develop after adjuvant treatment of breast cancer. Despite screening efforts, women unfortunately can present with metastatic breast cancer (MBC). Although treatment for breast cancer has advanced over the years with many new therapies, metastasis can occur at any point following initial treatment. Patients may have a local recurrence to their chest wall or a distant recurrence in the bone, liver, lungs, or brain. When there is potential for disease recurrence, a biopsy must confirm the diagnosis (7). Treatment focus in MBC is to control the disease and any symptoms that the patient may be experiencing. Nurses can routinely assess about bone pain, neurologic changes, shortness of breath, and obtain patients weight to monitor for possible progression or recurrence of disease (38). Lab values can also indicate site-specific metastatic disease and should include liver function studies, alkaline phosphatase, and calcium.

Some of the same treatment options in the adjuvant setting are appropriate in the metastatic setting including endocrine therapy, targeted therapies, and chemotherapies. Treatment decisions are based on several factors including prior therapy, tumor type (e.g., triple negative or estrogen positive) performance status, toxicities, quality of life, patient preferences and patients' ability to adhere to a specific regimen. No matter what the therapy, treatment goals are to extend survival and improve overall quality of life. Patient management will depend on the therapy and be similar to management in the adjuvant setting, with a stronger focus on supportive care measures.

Bisphosphonate therapy is considered for patients with bone metastasis. Nurses' should monitor renal function, if indicated, each time the medication is administered, noting any signs of renal insufficiency. Calcium levels should be followed to ensure that levels do not drop to low. Hypocalcaemia should be corrected with calcium and vitamin D supplements. Osteonecrosis can occur in patients on bisphosphonates, so nurses should perform a good oral exam before initiation of treatment. Any invasive dental work should be avoided, as healing may be compromised.

Along with the health care team, the nurse should assess the psychosocial aspects of care with the patient, family, and/or significant other. Patients with MBC often experiences feelings of distress, anxiety and depression, fatigue, and even fear (39). These issues often may lead to a poor quality of life and should be discussed with interventions implemented to help alleviate some of their concerns. Referrals may need to be made for a more structured psychosocial evaluation. Education should be provided regarding the illness and symptoms they may experience, which may reduce their psychological symptoms.

PATIENT CARE MANAGEMENT IN LONG-TERM SURVIVORSHIP AND SURVEILLANCE

The end of primary treatment is associated with a decline in acute physical side effects (e.g., nausea and vomiting, hair loss, and bone marrow suppression) and a corresponding increase in physical late effects such as (e.g., infertility, menopausal symptoms, fatigue), and less frequent long-term effects (e.g., second cancers, lymphedema, osteoporosis) associated with a return to some semblance of order and routine. Breast cancer survivors describe psychosocial adjustment to living beyond breast cancer survivor. Periods of adjustment that include some level of psychosocial distress are common.

The Institute of Medicine recommended the use of survivorship care plans summarizing the type of cancer treatment, suggestions for management of late effects, cancer surveillance, and health maintenance (40). Yet, more than 5 years after the recommendations were released data indicate that less than half of oncology providers recently reported that they have implemented the guidelines (41). However, major breast cancer advocacy organizations such as Living beyond Breast Cancer, Komen Foundation, and others contain a wealth of practical information for management of late effects and offer webinars for updates.

Health promotion includes smoking cessation, nutrition, and physical activity. The American Cancer Society recently issued an update of its recommendations on nutrition and physical activity for cancer survivors (42). General recommendations for nutrition and physical activity are to maintain a healthy weight, be as lean as possible without being underweight, avoid excess weight gain, maintain regular physical activity, and limit alcohol intake. The American Cancer Society issued smoking cessation guidelines practical advice and the information is available at http://www.cancer.org/acs/groups/cid/documents/webcontent/002971-pdf.pdf.

Return to Work

Work issues can be major hurdles in adjustment after breast cancer (43). Breast cancer survivors may desire to continue working or may seek new work or professional employment after treatment ends. Worry about health insurance and benefits poses a high-priority concern. Several cancer advocacy organizations, particularly the National Coalition for Cancer Survivorship, have excellent pamphlets and books that discuss the insurance, employment, legal, and financial matters of high concern to cancer survivors that are well worth the cost of having copies in one's organization patient lending library.

SUMMARY

In summary, the human dimension of living through and beyond the breast cancer experience is more than management of acute physical side effects. It is the careful attention to *persons* with breast cancer, their unique personality, preference, choices, decisions, experiences, and insight that give meaning, shape, and form to the illness and disease. On a day-to-day basis, oncology nurses are a vital component to the oncology team by helping coordinate patient care, manage symptoms and psychosocial distress, manage the daily patient ebb and flow, evaluate quality-of-life outcomes, and add the critical dimension of caring to oncology care.

CHAPTER 88

Overview of Survivorship Issues

Ann H. Partridge and Larissa Nekhlyudov

CHAPTER CONTENTS

OVERVIEW

Cancer survivorship has been defined as the period of time from diagnosis through the balance of a person's life (1). However, most care and research in this area has focused on the post-early treatment phase, and broadly encompasses not only the physical, but the psychosocial and economic sequelae of the diagnosis and treatment of cancer for individuals, their families, and society. The vast majority of people diagnosed with breast cancer will become survivors in the short term and most also in the long term. Breast cancer survivors are the largest group of cancer survivors in the United States, comprising nearly a quarter of the recently reported 13 million cancer survivors; the number is expected to grow over the next decade (2). It is not surprising, therefore, that much of the survivorship research to date has focused on this population of women, resulting in a large and growing literature in this area. Yet, there remain significant limitations in our understanding of cancer survivorship care. This chapter presents the components of survivorship care for patients with a history of breast cancer, highlights evidence-based recommendations, and acknowledges areas of uncertainty.

The general goals of follow-up care for patients with breast cancer are to: (i) detect recurrence or new primary disease and reduce the risk of future breast cancer events including encouraging adherence to surveillance and chronic adjuvant therapy; (ii) monitor, prevent, and/or treat long-term, late effects related to diagnosis or treatment, including medical and psychosocial risks; (iii) provide breast cancer-related decision-making support (e.g., regarding duration of hormonal therapy, future fertility, or optimal contraception); (iv) educate and support patients to continue or adopt optimal health behaviors that may improve outcomes; and (v) assure that patients seek appropriate and timely non-cancer related care, such as management and prevention of comorbid medical conditions (see Fig. 88-1).

DETECTION OF DISEASE AND RISK REDUCTION

Breast cancer survivors are at risk for locoregional or distant disease recurrence, as well as new primary breast cancer in remaining breast tissue or the contralateral breast. The risk of locoregional or distant recurrence for an individual patient is dependent on a number of disease, treatment and patient characteristics. (See Chapter 28, Clinical and Pathologic Prognostic and Predictive Factors.) In follow-up care, providers should promote and facilitate the continuation of chronic treatment (e.g., adjuvant endocrine therapy) and/or other strategies such as surveillance mammography that have been proven to lead to reduced rates of recurrence and breast-cancer mortality. For the average breast cancer survivor, the risk of developing a second primary tumor in the contralateral breast is low, approximately 0.5% to 1% per year for the first five years (3). Even though this is higher risk than for the general population, because of competing risks and the lack of clear evidence that contralateral mastectomy improves outcomes, removal of the contralateral breast is not routinely recommended. Women with genetic mutations, for example, *BRCA1* or *2* mutation carriers are at dramatically increased risk of contralateral breast cancer; thus, screening for genetic risk is warranted where personal or family history suggests a potential mutation. In women who harbor a mutation or who have history suggestive of such, consideration of prophylactic efforts to reduce cancer risk in this high-risk population is standard. (see Chapter 17, Genetic Testing and Management of Patients with Hereditary Breast Cancer).

In order to detect recurrence or new primary disease, evidence-based guidelines recommend regular history and physical exam as well as mammography in follow-up but no additional screening for recurrence in the absence of prompting signs or symptoms (4). There is some controversy about the role of MRI in screening remaining breast tissue in survivors, particularly for women who are very young and/or have dense breast tissue. At the present time, while women who are at very high risk of developing new primary breast cancer (e.g., *BRCA1* or *2* mutation carriers) are recommended to undergo additional breast surveillance with MRI, while this is not recommended for women at average risk (5). Given research to date suggesting lack of benefit, no additional imaging or laboratory testing (i.e., tumor markers) are recommended (see Chapter 67, Surveillance of Patients Following Primary Therapy).

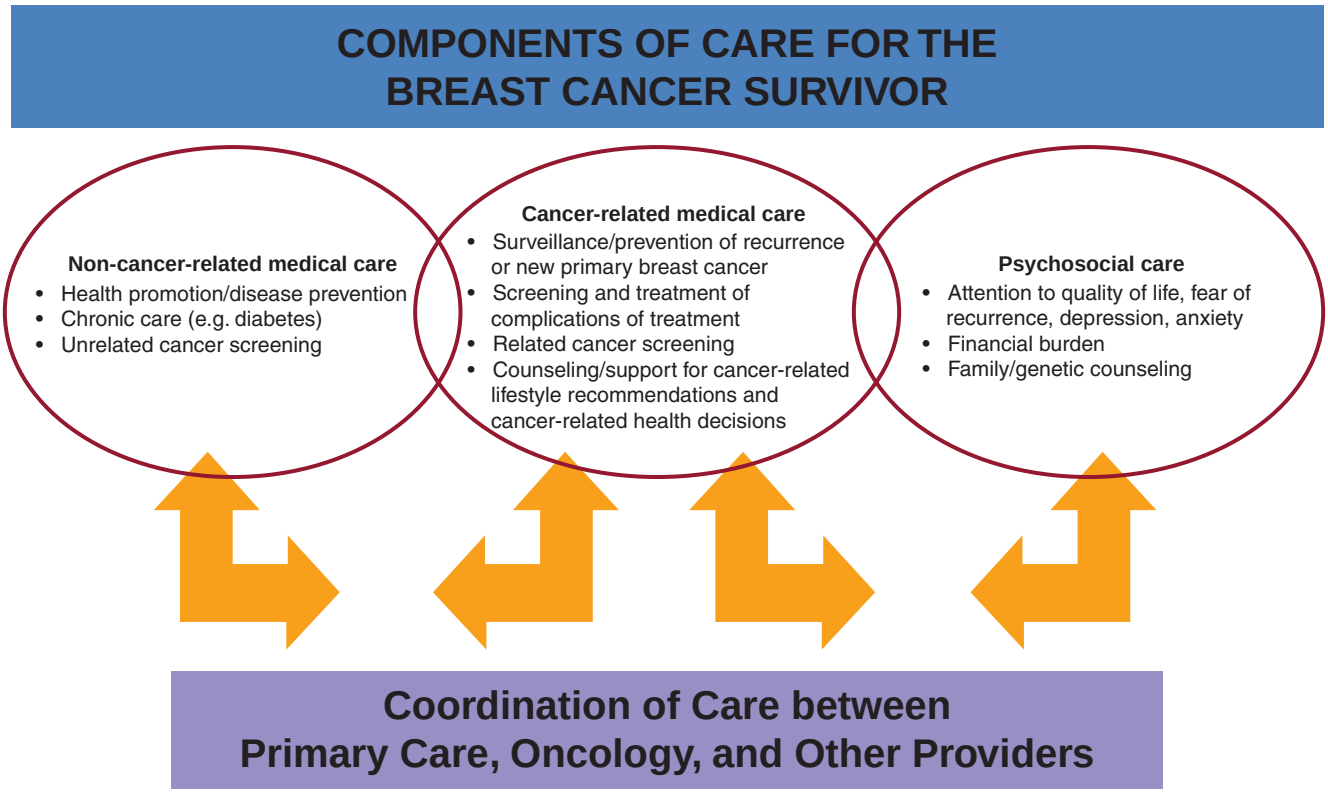

FIGURE 88-1 Components of care for the breast cancer survivor.

MANAGEMENT AND PREVENTION OF LONG-TERM, LATE EFFECTS

Breast cancer survivors may face a number of long-term and late effects from treatment. Long-term effects are problems that become apparent during treatment and persist (e.g., taxane-related neuropathy), while late effects are those that manifest after treatment has ended (e.g., osteoporosis due to premature menopause from chemotherapy or treatment-related leukemia). Figure 88-2 presents common long-term/late effects from breast cancer treatments as they relate to local therapy with surgery and radiation, and systemic therapy, including chemotherapy, biologic therapy, and hormonal therapy. Most patients receive multimodality treatment and clear attribution of problems can be difficult for some symptoms such as fatigue. Further, problems may be pre-existing and may be exacerbated by the diagnosis and treatment of breast cancer (e.g., obesity, diabetes, hyperlipidemia, arthritis). Regular screening for long-term/late effects in survivors as part of a standard history and physical, and prevention and palliation where appropriate is warranted to improve symptoms, quality of life, and potentially future risks and outcomes (see Chapter 49, Implications of Obesity in Breast Cancer; Chapter 51, Management of Menopausal Symptoms in Breast Cancer Survivors; Chapter 52, Long Term and Late Effects of Primary Curative Intent Therapy: Neurocognitive, Cardiac, and Secondary Malignancies).

Psychosocial distress, including depression, anxiety, and fear of recurrences, sexual dysfunction, financial, work and family stressors, and overall impairment of quality of life (QOL) may be one of the most insidious of the long-term, late effects on breast cancer survivors (see Chapter 89, Psychosocial Adaptation during and after Breast Cancer). In the year following a diagnosis of breast cancer, many women will experience difficulties, particularly as they transition to survivorship (1,6). And while there are substantial improvements in psychosocial morbidity over time, some women will experience long-term impairment, particularly those who have received prior chemotherapy (7). Given the evidence for benefits from psychosocial interventions, oncology and primary care providers should be attentive to these concerns in breast cancer survivors and provide support and refer patients to resources or specialists for additional counsel as needed.

BREAST CANCER RELATED DECISION SUPPORT

Patients with a history of breast cancer may face a number of issues in follow-up that are not related to breast cancer per se, but may have consequences for breast cancer risks. For example, young survivors who are interested in future fertility and pregnancy will desire oncology input regarding feasibility, risks, and timing both at diagnosis and in follow-up (see Chapter 90, Reproductive Issues in Breast Cancer Survivors). A history of breast cancer may also affect the risk-benefit ratio of various treatments for problems associated with menopause, in particular including menopausal symptoms, dysfunctional uterine bleeding, or diseases such as osteoporosis. It is incumbent on oncology providers to counsel survivors and coordinate with other specialists regarding these issues.

OPTIMIZING HEALTH BEHAVIORS

Lifestyle factors including diet, alcohol consumption, weight and weight gain, physical activity, as well as smoking have all been found to be associated with the risk of developing

LONG-TERM AND LATE PHYSICAL EFFECTS IN BREAST CANCER SURVIVORS

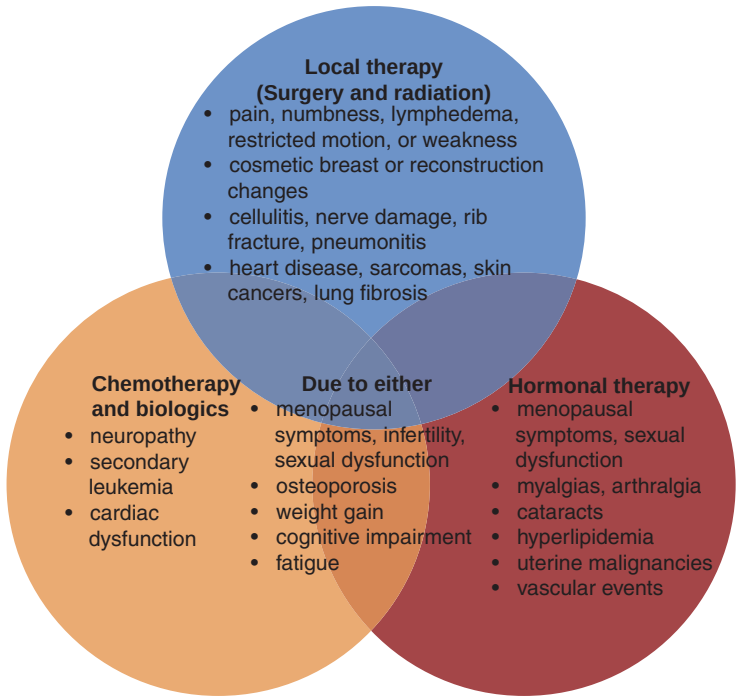

FIGURE 88-2 Long-term and late effects of breast cancer treatment.

breast cancer and increasingly, to prognosis after a diagnosis (8). Further, suboptimal health behaviors may have important consequences for the medical and psychosocial health of survivors (see Chapter 50, Life Style Issues in Breast Cancer Survivors). Although evidence is limited, an increasing number of intervention studies have revealed that improved health behaviors after a breast cancer diagnosis may promote improved quality of life including less fatigue, and possibly decrease risk of cancer recurrence (8). During the early survivorship period, breast cancer survivors may be particularly amenable to making positive health behavioral changes given the anxiety and stress associated with a diagnosis and desire on the part of the patient to improve their likelihood of a good outcome. However, providers should be aware that women may continue to pursue only limited activity, due to persistent symptoms and weight gain and should encourage incremental changes. Counseling survivors regarding optimal energy balance and the potential reduction of risks of recurrence, morbidity and/or mortality, and recommending exercise and weight management or reduction, as well as alcohol reduction and smoking cessation if appropriate, may capitalize on the "teachable moment" and help them to make lifestyle changes (9).

COORDINATION OF CARE AND NON-CANCER CARE MANAGEMENT

Breast cancer survivors are at risk for substantial morbidity, decreased survival, and impaired quality of life from both the cancer and from cancer treatment. Thus, attention to their unique issues in follow-up care is clearly warranted. However, previous research has revealed that there may be substantial gaps in the follow-up care of breast cancer survivors both for cancer and non-cancer-related health concerns (10). Breast cancer survivors are at increased risk of obesity and its related sequelae, such as hyperlipidemia and diabetes. Given the association between diabetes and poorer outcomes in women with a history of breast cancer, it is particularly important that survivors are counseled, monitored, and treated for metabolic syndrome-associated problems (11). Women with osteoporosis or those who may be at risk of developing osteoporosis due to chemotherapy and/or adjuvant aromatase inhibitors also need to be monitored for bone health and treated as necessary. As breast cancer survivors may be cared for by primary care providers in addition to the oncology clinician, it is important that optimal communication and coordination occurs. Various models of care, often encouraging the provision of treatment summaries and survivorship care plans have been promoted as methods to facilitate communication among providers across care transitions and improve access to, and receipt of, quality survivorship care (1). However, research supporting the feasibility of implementing these practices and their effectiveness in enhancing health outcomes is limited with one recent trial showing no beneficial effect of survivorship care plans on outcomes (12). Ultimately, the optimal approach for addressing the comprehensive health needs of the growing population of cancer survivors may be risk-based care as it involves a personalized, tailored systematic plan of periodic screening, surveillance, and prevention relevant to the cancer experience for a given individual (13).

MANAGEMENT SUMMARY

- Standard follow-up for women with a history of early stage breast cancer should include routine history and physical exam and elicitation of symptoms and mammography for remaining breast tissue.
- Attention to long-term and late physical and psychosocial effects of breast cancer is warranted to palliate symptoms and potentially prevent future problems.
- Education and counseling patients regarding optimal health behaviors and lifestyle modifications should be a standard part of breast cancer survivorship care.
- Breast cancer survivorship care requires good communication and coordination of care with primary and other subspecialty providers to assure recommended cancer surveillance and monitoring as well as optimal non-cancer related care.

CHAPTER 89

Psychosocial Adaptation during and after Breast Cancer

Kimberley L. Miller, Julia H. Rowland, and Mary Jane Massie

CHAPTER CONTENTS

INTRODUCTION

Breast cancer is the most common form of cancer among American women, with advances in detection and treatment leading to increases in disease-free survival. However, unlike treatment for other chronic diseases, many treatments for cancer are toxic and intensive, adversely affecting patients' physical, psychological, and social resources, both short and long term.

Because of improvements in screening technology that allow the diagnosis of breast cancer at earlier stages; new developments in treatment approaches; the greater use of preoperative systemic therapy, and increased awareness about potential late effects of chemotherapy and radiation, more women are confronted with a variety of treatment choices, emphasizing her role in the decision-making process and the critical role of patient-doctor and family communication in breast cancer care. The identification of genetic markers of breast cancer risk and the evaluation of chemopreventive agents adds to the psychological toll on unaffected women who are at increased risk for this disease. With the publication in 2008 of the Institute of Medicine's report, *Cancer Care for the Whole Patient: Meeting Psychosocial Health Needs*, a new standard has been set for oncology practice, one that acknowledges that the patient herselfis as important as, and at times more important than, the tumor in planning and delivering optimal care (1).

Although breast cancer is a major stressor for any woman, there is great variability in women's psychological responses. This chapter outlines the range of women's psychosocial responses to breast cancer and factors that may increase a woman's risk for poor adaptation. In addition, the role of family supports in adaptation, and concerns related to sexual functioning and posttreatment survivorship are addressed.

Although very little research has been done in male, compared to female, breast cancer, male breast cancer survivors have been found to have long-term deficits in physical and mental health status, compared to noncancer controls (2). There may be similarities in the challenges men and women face in coping with their cancers, however, there is a clear difference in that compared to women, men likely experience their cancer within the context of lower social awareness and higher social isolation. Male breast cancer is reviewed more fully in Chapter 61.

FACTORS THAT AFFECT PSYCHOLOGICAL IMPACT

A patient's psychological response to her disease is affected by her surrounding sociocultural environment, her underlying psychological characteristics, and medical factors (Table 89-1). Comprehensive care requires individualized attention to, and assessment of, each of these areas, as needed, throughout the illness trajectory.

Sociocultural Context and Psychosocial Issues in Decision-Making

The national visibility afforded to cancer has resulted in increasing attention to the patient's role in medical decision-making. As a result, women today have more information about, understanding of, and resources to manage their breast cancer illness and recovery than ever before. Although increasing patient awareness and understanding continues to be the goal, it is important to note that some women may feel they have "too much" responsibility in treatment decisions, up to 21% in one study (3), which was associated with poor baseline knowledge and 6-month decision regret. Thus, the need for physicians to tailor their communication and information-sharing with patients, especially those with low health literacy, is significant.

TABLE 89-1

Factors That Contribute to the Psychological Responses of Women to Breast Cancer

1. Current sociocultural context, treatment options, and decision-making
   a. Changes in surgical and medical management from a uniform approach, e.g., breast-conserving management; introduction of sentinel node biopsies and neoadjuvant therapy; more therapeutic options and acknowledged uncertainty
   b. Social attitudes
   c. Public figures openly sharing their breast cancer experience
   d. Autobiographic accounts of and "how to" guides for dealing with and surviving breast cancer in the popular press
   e. Ethical imperative for patient participation in treatment issues; legal imperative for knowledge of treatment options
   f. Variations in care by ethnicity, location, age
   g. Public awareness of treatment and research controversies; advocacy for more funding and lay oversight
2. Psychological and psychosocial factors
   a. Type and degree of disruption in life-cycle tasks caused by breast cancer (e.g., marital, childbearing, work)
   b. Psychological stability and ability to cope with stress
   c. Prior psychiatric history
   d. Availability of psychological and social support (partner, family, friends)
3. Medical factors
   a. Stage of cancer at diagnosis
   b. Treatment(s) received: mastectomy/lumpectomy and radiation (plus/minus immediate/delayed reconstruction), adjuvant chemotherapy, hormonal therapy
   c. Availability of rehabilitation
   d. Psychological (partner, support groups)
   e. Physical (reconstruction; arm mobility and lymphedema prevention)
   f. Psychological support provided by physicians and staff

Over the course of care, women face three major decision-making periods. The first is encountered at the time of initial discovery of a lump or symptom suspicious for breast cancer, at which time a woman must decide if further evaluation is needed. A woman's decision is informed by her access to, and cost of, specialized care; her age, her level of education or knowledge, her attitudes and beliefs about cancer; her personality and coping style; and the nature of the existing doctor-patient relationship (4). Delays in seeking care have been attributed to age (>65 years), a symptom other than a breast lump, not sharing the symptom with others, negative attitudes toward, or a poor relationship with, the healthcare professional, fear of cancer and related treatments, low perception of risk, less spirituality, and a willful ignorance of symptoms (4,5). Independent of health insurance, stage of diagnosis, and age, black and Hispanic patients have been shown to have higher risks of 30-, 60-, and 90-day treatment delay than white patients (6,7). Medicare beneficiaries may be at increased risk for delay in definitive treatment in particular (8). Language barriers, inadequate resources, and inaccurate beliefs may disproportionately affect Latina and African American women (9,10). In at least one study, treatment delays experienced among low-income women led to worse survival outcomes (11). If a delay in early detection has occurred, personal guilt or anger at her physician can interfere with a woman's adaptation to treatment. Reinforcing the value of care she is receiving may be important in her engagement in the recovery process.

The second major set of decisions is set in motion at the time of consultation with a surgeon about local treatment options, which may be followed by multiple consultations with other cancer specialists. Women may choose between mastectomy versus limited resection and irradiation, plus or minus immediate reconstruction. If systemic therapy is indicated, an additional cascade of decisions must be made. Differences in the types of breast cancer treatment received by a woman exist, based on geography, age, socioeconomic status, and race. For example, African American women with less education are at risk for receipt of non-guideline-concordant adjuvant chemotherapy regimens, potentially contributing to worse outcomes (12). Women living in rural areas, particularly those who are older, may be less likely to receive recommended radiation therapy in association with their breast cancer treatment (13). Breast-conserving therapy is more likely to be performed in academic settings, in the Northeast, and among younger women (14).

The time between diagnosis and initiation of treatment is one of the most stressful periods in the breast cancer experience. The emphasis on informed decision-making places a responsibility on the physician to be cognizant of the individual woman's physical and psychological needs and to tailor accordingly the discussion and recommendations made. At times, it may mean addressing a woman's demands for unrealistic treatment, acquiescing to another woman's desire to defer a final decision to her physician or significant other, or in some cases reassuring a woman that she need not reach a decision immediately but can research her options and come to an appropriate choice. During this time, she may opt to seek a second opinion to aid in her decision-making. As desire for information and preference about decision-making roles can change over time, asking about them periodically is important. Treatment information can be provided as printed or videotaped materials, and reputable websites may be recommended to patients and families. For women feeling overwhelmed or pressured to make a surgical decision, it may be helpful to postpone surgery and meet with a member of a psychosocial support team who could facilitate a discussion about underlying concerns and fears.

Psychological Variables in Adaptation

In 1980, Meyerowitz (15) delineated three broad areas of psychosocial impact of breast cancer: (a) psychological discomfort (anxiety, depression, and anger); (b) behavioral changes due to physical discomfort, marital or sexual disruption,

and altered activity level; and (c) fears and concerns related to body image, recurrence, or death. Although women diagnosed today have many more treatment options and resources for support, the psychological concerns remain the same (16). In addition to these variables, the life stage at which the cancer occurs, previous emotional stability (personality and coping style), and presence of interpersonal support also affect adaptation (see Table 89-2).

Age at time of diagnosis is important in considering a breast cancer patient's distress (17,18). Concerns about the threat to life and future health, as well as fears of potential disfigurement, disability, and distress associated with treatment, are common for women of all ages but may be heightened in younger women with breast cancer. In younger patients, beyond disruption to multiple active roles, there is the perception that they have more to lose due to the threat to their future, including the potential loss or delay in having or building a nascent career or family. Worse outcomes in quality of life and depressive symptoms have been shown to be more frequent and severe in breast cancer survivors aged 50 years or younger when compared with the general age-matched population of women without cancer and to older women (aged >50 years) with breast cancer (19). Concerns about premature menopause, menopausal symptoms, and infertility were common in younger women and have a role in the level of posttreatment distress. Additionally, the younger breast cancer patient often presents with more advanced disease and typically is treated more "aggressively" surgically, which further affects psychological adjustment. (See Chapter 85 on Breast Cancer in Younger Women.) Research has not focused as much on women older than 65, despite their representing almost half of current breast cancer survivors (20). Although one may assume an older woman's distress regarding her breast cancer may be buffered by her greater life experience and familiarity with medical settings, she may experience the diagnosis in the presence of other major losses and concurrent chronic medical conditions. Older women with breast cancer experience poorer health-related quality of life and lower psychosocial well-being than unaffected peers (21) and are at risk for significantly higher rates of decline in upper body function (22). This pattern, coupled with the observation that older women are significantly less likely to receive appropriate surgical care or rehabilitation (23,24), suggests that patients at both ends of the age continuum are at increased risk for problems in adaptation. Finally, although threats to body image, sense of femininity, and self-esteem may be greatest in younger women, particularly those who are single or without a partner, these threats are concerns of many older women as well (25). (See Chapter 84 on Breast Cancer in Older Women.)

Personality and coping styles affect adaptation to breast cancer. Women who are flexible and employ active problem-solving approaches have better moods and adaptation (26). Women who are able to draw on and use available social resources and support adapt better and may even live longer than women who do not (27). In contrast, women who are passive, helpless, hopeless, or pessimistic in the face of illness; are rigid in their coping style; and isolate themselves or reject help when it is offered adapt more poorly. Women who manifest persistent depressive symptoms in the face of cancer may be at risk not only for poor quality of life but also premature death (28,29) and should be considered promptly for professional psychological assessment and support. Women with a history of resolved major depression have been found to be at increased risk of developing greater depressive symptoms during treatment, which in turn predicts declines in physical functioning during chemotherapy, compared to those with no history of depression (30), highlighting the importance of identifying such women as early as possible and ensuring that adequate resources are in place for them. The relationship between attitude and cancer risk and/or survival remains an area of public interest and active research. Because breast cancer is so prevalent, is associated with significant negative psychological impact, and has inadequately defined causative factors, the possible role of psychological variables in vulnerability to breast cancer and its progression has been explored in medical studies. It also has received considerable attention from patients and the media. Stewart et al. (31) found that 42.2% of the 378 breast cancer survivors surveyed believed that stress caused cancer and 27.9% felt that stress reduction could prevent a recurrence, confirming work done 20 years earlier. Such beliefs can become an added psychological burden and lead some women to pursue unproven therapies. Although epidemiologic studies have failed to find an association between stress and breast cancer development (32) or survival (33), it is nonetheless important to mitigate chronic stress when it is identified. Education regarding the lack of evidence of stress causing cancer is an important component of integrated oncological care. Other important factors in adaptation are a patient's prior experiences with breast cancer and body image. Levels of psychological distress can be affected by the memory of a friend's or family member's suffering with breast cancer. Some women cannot tolerate the idea of loss or damage to a breast and may delay seeking consultation for a symptom, especially if their community views cancer as stigmatizing.

TABLE 89-2

Risk Factors for Poor Adaptation

1. Medical
   - More advanced disease
   - More intense or aggressive treatment
   - Other/multiple co-morbid medical conditions
   - Fewer rehabilitative options
   - Poor doctor/patient relationship
2. Personal
   - Prior psychiatric history
   - Past trauma history (especially physical or sexual abuse)
   - Rigid or limited coping capacity
   - Helpless/hopeless outlook
   - Low income/education
   - Multiple competing demands (e.g., work, child or other family care, economic)
   - Poor marital/interpersonal relationship
   - Younger age (<40) or older age (>80)
3. Social
   - Lack of social support (and/or religious affiliation)
   - Limited access to service resources
   - Cultural biases
   - Social stigma or illness taboo
4. Breast cancer specific
   - Prior breast cancer experience
     - Recurrence or second breast cancer
     - Loss of family or friends to breast cancer
   - High investment in body image, in particular breasts

Adapted from Weisman D. Early diagnosis of vulnerability in cancer patients. *Am J Med Sci* 1976;271:187.

A woman's sociocultural background can further influence her breast cancer experience. Although the interpretation of between-group differences in ethnicity often is confounded by variables such as income, education, and treatment (34), it is worth noting two historically understudied minority groups: lesbian breast cancer survivors and survivors living in rural communities. (For a full discussion of this topic, see also Chapter 86, Breast Cancer in Minority Women.)

Sexual orientation appears to have little effect on quality of life among breast cancer survivors (35). Some data suggest that lesbian breast cancer survivors may be more comfortable with body image and perceive greater social support than their heterosexual peers. However, they also may tend to experience more difficulty interacting with physicians (36). Survivors in rural areas are at greater risk for relationship problems, lack of support, and feelings of isolation (37). Finally, adjustment depends on the actual and perceived level of support, as well as the patient's ability to rely on that support (e.g., attachment security). For example, women who recalled childhood abuse were more likely to experience their surgeon as unsupportive (38).

Prolonged anxiety or depression is not an expected reaction to a cancer diagnosis (39).The common stress reactions around the time of diagnosis and onset of treatment usually can be evaluated and managed by the patient's physicians, nurses, or social worker. However, some women have greater problems and can benefit from psychological management by psychiatrists and psychologists, who often are collaborating members of the treatment team (Table 89-3).

If a patient's anxiety or insomnia interferes with functioning, low-dose anxiolytic medication (e.g., lorazepam [0.25 to 1.0 mg orally two to four times a day] or clonazepam [0.25 to 1.0 mg orally twice daily]) or a hypnotic (e.g., zolpidem [5 to 10 mg]) usually are effective. When anxiety and insomnia cannot be controlled with these medications or when surgical or medical staff observe symptoms of depression—such as frequent crying episodes, loss of interest and/or motivation, irritability, inability to concentrate, or remarks indicating hopelessness, helplessness, or suicidal thoughts—psychiatric consultation is indicated. Psychiatric consultants assess all of the factors contributing to a woman's distress, including any family or relational issues, combining psychopharmacological interventions with psychosocial support for the patient and family. The selective serotonin reuptake inhibitors (SSRIs; e.g., fluoxetine, paroxetine, sertraline, fluvoxamine, citalopram, escitalopram) and novel or mixed action antidepressants (venlafaxine, duloxetine, bupropion, mirtazapine) are considered first-line treatment because they are better tolerated in patients with comorbid depression and medical conditions. Venlafaxine currently is believed to be the antidepressant that should be prescribed to the depressed woman (or the woman with hot flashes) who is taking tamoxifen, due to its relative lack of impact on tamoxifen metabolism. (See Chapter 51 for information on management of hot flashes.)

TABLE 89-3

Women with Breast Cancer Who Should Be Considered for Psychiatric Evaluation

1. Those who present with current symptoms or a history of the following:
   - Depression or anxiety
   - Suicidal thinking (attempt)
   - Substance or alcohol abuse
   - Confusional state (delirium or encephalopathy)
   - Mood swings, insomnia, or irritability from steroids
2. Those who:
   - Have a family history of breast cancer
   - Are very young, old, pregnant, nursing, single, or alone
   - Are adjusting to multiple losses and managing multiple life stresses
   - Seem paralyzed with cancer treatment decisions
   - Fear death during surgery or are terrified by loss of control under anesthesia
   - Request euthanasia
   - Seem unable to provide informed consent

Medical Variables in Adaptation

The stage of breast cancer at diagnosis, treatment required, prognosis, and available rehabilitative opportunities constitute important medical variables that influence psychological adjustment. However, central to successful adaptation is a woman's relationship to her treating physicians and the degree to which they are sensitive to her individual concerns, communicate clearly, and monitor emotional and physical well-being. The length and intensity of current treatments and the recognition that women treated for breast cancer must be followed for extended periods of time have placed an added burden on healthcare providers. Depending on the setting, nurse clinicians or psychosocial clinicians may provide supportive care. Preliminary guidelines for psychosocial care across the cancer continuum have been developed, albeit for highly resourced comprehensive cancer centers, with adherence to, or adaptation of, these guidelines known to be quite low (40,41). Further, concerns about the cost of providing the recommended psychosocial and supportive care and who should pay for this continue to be significant barriers to optimal service delivery.

Surgery

Mastectomy Mastectomy is now performed in fewer than half of women diagnosed with early-stage breast cancer. Of late, however, there has been an increase in the number of women selecting ipsilateral mastectomy with contralateral prophylactic mastectomy (CPM), in part due to the greater use of pre-operative magnetic resonance imaging (MRI) (42,43). Further, for women who do undergo mastectomy, more will undergo breast reconstruction than previously, although data suggest that many mastectomy patients are not made aware of their reconstruction options. Considerable research exists on the impact of loss of one or both breasts on women's physical, social, and emotional functioning. Among the effects documented are feelings of mutilation and altered body image, diminished self-worth, loss of a sense of femininity, decreases in sexual attractiveness and function, anxiety, depression, hopelessness, guilt, shame, and fear of recurrence, abandonment, and death. Historic data indicate that women who are well adjusted before they have a mastectomy and whose disease is in an early stage can expect at 1 year to have a quality of life equal to that of unaffected peers. Today, a woman's persistent issues generally have less to do with the type of surgery received and more to do with her personal and social characteristics and the adjuvant therapy given. Issues related to the latter are discussed in the treatment-specific chapters and in the section Breast Cancer Survivors, later in this chapter.

Research suggests that, in addition to a number of medical factors (e.g., tumor size, location, and aggressiveness), several other characteristics may distinguish women who have mastectomy from those who receive breast-sparing surgery. These include older age, fear of irradiation, preferring to have no therapy beyond surgery, being black or Hispanic (or possibly low income), and among older women, living with extended or nonfamily members or in an assisted-living setting (10).

Contralateral Prophylactic Mastectomy Rates of CPM have increased dramatically in the past two decades, mostly in patients without any identified risk factors, such as genetic predisposition (*BRCA1/2* mutation) or a prior history of radiation (44). Independent predictors of CPM in a large retrospective analysis at a leading cancer center in the United States included white race, immediate reconstruction, family history of breast cancer, MRI at diagnosis, age younger than 50 years, noninvasive histology, and prior attempt at breast conservation (44).

Similar to all treatment decisions, the patient contemplating a CPM should be fully informed regarding her individual risk and given adequate time and information to make the decision, including the option to use a patient decision tool. An individualized approach includes incorporating a patient's personal values regarding risk aversion and anticipated regret into the ultimate treatment decision (45). A Cochrane review has found that there is insufficient evidence that CPM improves survival (46). However, those who chose bilateral prophylactic mastectomy (BPM) had lower levels of anxiety after BPM, compared to their baseline worry and to those who chose surveillance (46).

Breast-Conserving Therapy or BCT (Lumpectomy and Irradiation) A significant factor in what type of surgery is performed is the nature of the care that is available, including the availability of high-quality irradiation therapy. Further, restricted access to plastic surgeons can limit the availability of reconstructive options. Another factor determining choice is the knowledge and availability of genetic testing for mutations in *BRCA1* and *2*; patients with mutations now generally undergo bilateral mastectomy. Cultural and ethnic values also may direct or even dictate choice, although their role is poorly understood. Physician recommendation continues to exert the most significant influence on treatment choice for most women. Early reports suggested that women in BCT groups manifest a somewhat better overall adjustment than those in mastectomy groups (47). However, longer-term follow-up of more current cohorts of breast cancer survivors has failed to show differences in overall quality of life based on type of surgery alone (48). A consistent finding is that psychosocial variables are, for the most part, much stronger predictors of psychosocial outcomes than are medical factors (49). These latter studies further suggest that benefits to sexual function associated with BCT may be less than previously believed. Because BCT often is selected because it is perceived as less disfiguring than mastectomy, it is problematic when the surgical results do not meet expectations. A significant confound to examining the impact of surgery on women's quality-of-life outcomes is that younger women, known to be at increased risk for psychosocial problems in adapting to breast cancer, tend to elect to undergo BCT. These young patients also are more likely to receive adjuvant chemotherapy, which has a significant negative impact on sexual functioning. What we have learned is that BCT is not a psychosocial panacea; rather, it is a surgical and cosmetic option that may facilitate adaptation for many women. Two critical factors that continue to influence the surgical decision-making process are attitudes about cancer and irradiation. The thought of leaving tumor cells in the breast is intolerable for some women, who feel more secure with mastectomy. Other women fear irradiation or are unable to devote 6 weeks to daily irradiation treatments. Women undergoing irradiation are at risk for psychological distress, either related to treatment-associated fatigue, or persistent fears about their disease and the risk of recurrence. Providing a reassuring environment, orientation to expected side effects, and strong support promotes optimal adaptation. Most women who undergo radiation therapy experience initial anxiety related to the treatment, which diminishes after a few treatments, only to return toward the conclusion of therapy because of fear of tumor re-growth without treatment, and the loss of close medical surveillance. To ease this transition, patients should be made aware of the paradoxical increase in feelings of distress. Staff should remain available by telephone and through follow-up appointments.

When discussing women's reactions to irradiation, one additional factor that is important to consider is the risk for upper extremity lymphedema. Women who develop lymphedema are at high risk for problems in both psychological and social functioning (50). Fortunately, the proportion of women affected by this problem has decreased with the use of sentinel node biopsy. (See Chapters 40 and 42 for more details regarding lymphedema and radiation, respectively.)

Reconstruction Postmastectomy breast reconstruction is an important rehabilitative option pursued by a significant subset of women undergoing mastectomy. However, there is some evidence that reconstruction is not being routinely addressed in the surgical decision-making process. In their SEER-based sample, Alderman and colleagues found that only a third of patients reported that their general surgeon discussed this option with them during the decision-making process (51). Younger, more educated women with larger tumors were more likely to report that this discussion took place. Further, patients whose surgeon did cover this option were four times more likely to have a mastectomy. Relatively few studies have systematically examined the psychosocial impact of mastectomy alone compared with mastectomy plus reconstruction. Contemporary studies seek to evaluate psychosocial and sexual outcomes for women selecting each of the three different surgical options (lumpectomy vs. mastectomy alone vs. mastectomy with reconstruction). Parker and colleagues describe similar subtle differences in early adaptation among women undergoing each of the three different procedures, but note that few differences could be seen among groups 2 years after treatment (48). In general, aspects of quality of life other than body image are not better in women who have undergone BCT or mastectomy with reconstruction. In what remains the largest three-way comparison study, investigators found no differences in women's emotional, social, or role functions by type of surgery (52). Consistent with others' findings, women in the mastectomy with reconstruction group were most likely to report that breast cancer had a negative impact on their sex lives (45.4% vs. 41.3% for mastectomy alone, and 29.8% for lumpectomy). An important factor in women's sexual outcomes is that mastectomy with or without reconstruction results in permanent loss of sensation in the area. Further, as discussed in Chapter 42, the use of postmastectomy radiation therapy generally decreases the cosmetic results with reconstruction, particularly with implants. At the same time, the use of immediate breast reconstruction can compromise effective and safe delivery of postmastectomy radiation therapy.

Research suggests there are sociodemographic differences between women who do and do not undergo postmastectomy reconstruction. Women undergoing mastectomy with reconstruction generally are younger, better educated, have higher incomes, are more likely to be partnered, and have an earlier stage of disease (52,53). Women who are older, Hispanic, or born outside of the United States appear less likely to have reconstruction (54). Fewer African American women undergo reconstruction; this often may be due to economic and access barriers, but also potentially is related to lower interest in having reconstruction (55). Asian women also are less likely than white women to undergo reconstruction. There is some data to suggest that among sexual minority women (self-identified as lesbian or bisexual), there may be more decisional regrets among those who choose reconstruction versus mastectomy alone, leading to more adjustment problems (56). Regrettably, few efforts have been made to understand the psychological variables associated with who does and does not seek reconstruction, in particular in the present era in which autologous tissue procedures and immediate reconstruction represent standard options for care. Further, additional research is needed on the impact on women's satisfaction and functioning related to the extent of surgery performed and procedures used to achieve good symmetry.

In addition to local treatment choice (e.g., BCT vs. mastectomy with or without reconstruction), the impact on psychosocial function of the timing and type of reconstruction performed has been examined.

Timing of Reconstruction: Immediate versus Delayed Research with women undergoing immediate reconstruction has shown high levels of patient satisfaction with surgical results and less psychosocial morbidity than in those who undergo mastectomy alone, although as noted in earlier discussions, these differences diminish over time (57). Patients undergoing immediate reconstruction report being less depressed and anxious and experience less impairment of their sense of femininity, self-esteem, and sexual attractiveness than their peers who delay or do not seek reconstruction, but these initial differences in adjustment may be minimal and disappear over time. At least one study has suggested that satisfaction with technical aspects of the reconstructive outcome may be slightly lower among women undergoing immediate versus delayed reconstruction (59). This may reflect the fact that women with immediate reconstruction compare the result with their original breast, whereas those undergoing delayed surgery use the mastectomy site as their basis for comparison.

Type of Reconstruction: Implant versus Transverse Rectus Abdominus Myocutaneous Flap (TRAM) The research evaluating psychosocial outcomes for women undergoing reconstruction using TRAM surgery also has been an area of interest. No differences were seen between groups undergoing implant versus TRAM surgery in satisfaction with the appearance or feel of their breasts or the overall impact of breast cancer on their sex lives, although there was a consistent tendency for the women with TRAM reconstructions to report greater comfort and satisfaction (59). This pattern is consistent with others' findings and the observation that timing of reconstruction may be more influential than type of procedure on women's long-term adaptation (57). However, women who had an implant were significantly more worried about having a problem with their reconstruction (59). Longer-term follow-up of cosmetic outcomes for implant recipients would appear to confirm these fears. Clough et al. (60) report that overall cosmetic outcome was rated as acceptable in 86% at 2 years but had declined to 54% by 5 years in their study sample. Further, 23% of the 334 women in their study underwent implant exchange (excluding those with expanders). A similar pattern was not observed among TRAM reconstructions, in which assessment of cosmetic outcome remained stable over time (60).

Regardless of the type of reconstructive surgery proposed or selected, women need to be well informed about what to expect, including the cost of the surgery, length of time under anesthesia, number of procedures required, cosmetic results achievable, and safety of the techniques used. This may be accomplished through providing patients written materials, including images of reconstructed breasts, as well as referring them to a previously reconstructed patient for more details. Wider availability of video and online tools for decision-making is beginning to provide a unique way to educate women about choices that allows them to tailor the information they receive.

Adjuvant Chemotherapy

A recent systematic review has shown that, of the three breast cancer treatments (surgery, radiation, or chemotherapy), chemotherapy-treated patients have the highest level of anxiety, reaching its peak just before the first infusion, mediated by age and trait anxiety (61). Anticipation of chemotherapy can be difficult, highlighting the importance of patient education by the medical team. Women fear the transient acute sequelae of chemotherapy (e.g., nausea and hair loss). With greater public awareness, fear of chemotherapy's persistent effects (e.g., fatigue, pain, memory problems, sexual dysfunction, sleep disturbance, depression) also can cause major concern (62). Clinical experience suggests that most women cope with the short-term adverse psychological effects by focusing on delayed benefits (e.g., reassurance that they have done everything possible to eradicate their disease). However, clinicians need to be aware that, for some women, declines in health-related quality of life during treatment increase risk for discontinuation of chemotherapy (63). Monitoring for problems and addressing them promptly are important in ensuring adherence to the planned course of care.

Nausea and vomiting, once common side effects of adjuvant chemotherapy and feared and dreaded by patients, now are well controlled with pharmacologic and behavioral interventions (64,65). However, other side effects such as hair loss, weight gain, poor concentration, premature menopause, and fatigue affect psychological adjustment and warrant special attention and early discussions with patients. Information about wigs, the cost of which often is covered by insurers, along with referral to the American Cancer Society's *Look Good…Feel Better* program can help reduce appearance-related distress.

The cause of weight gain with chemotherapy remains unclear. Because of the added insult to self-esteem posed by significant weight gain, as well as data suggesting that obesity leads to worse prognosis (66), greater attention is being paid to diet and exercise. The introduction of exercise programs during chemotherapy is feasible, well tolerated (67), and of benefit in controlling weight gain, improving functional and cardiac status, and potentially enhancing quality of life. (See Chapter 50 for a broader discussion of lifestyle interventions.)

Difficulty with attention, concentration, memory, and processing speed also is reported by many women undergoing chemotherapy. These troubling neurocognitive effects, which also may be chemotherapy-dose related, are the focus of active research (see also Chapter 53 on side effects of systemic therapy). The symptoms may be associated with

the stress of illness, antiemetic drugs, hormonal changes secondary to chemotherapy-induced menopause, and principally with treatment-induced alterations in neurochemical and brain function (68). In some women, this effect may be mediated by a genetic predisposition (69). Important in this literature is the finding that women's complaints about cognitive compromise are not consistently associated with neuropsychological test performance (68). Understanding the true impact of therapy on cognition is challenging as we lack good measures for its role in women's day-to-day functioning. Nevertheless, if cognitive dysfunction is found to persist over time or as some studies suggest worsen this troubling side effect may become a dose-limiting factor in treatment decisions and care (70).

A further troublesome effect of chemotherapy in premenopausal women is premature menopause. (See Chapter 51 Management of Menopausal Symptoms in Breast Cancer Survivors.) The threatened or actual loss of fertility and acute onset of menopause anticipated with adjuvant chemotherapy often cause distress in the woman who is premenopausal at diagnosis. Iatrogenic acute estrogen deficiency may, in a small number of patients, be associated with psychiatric syndromes, depression in particular (71). The hot flashes, night sweats, and vaginal dryness and atrophy caused by chemotherapy-induced menopause can produce severe physical discomfort, including dyspareunia. Although instruction on the use of vaginal lubricants can be helpful, thinning of the vaginal mucosa still may result in irritation on intercourse. Though controversial, use of topical vaginal estrogen may be recommended for women experiencing severe dyspareunia. Studies indicate that the levels of circulating estrogens observed with this intervention are not expected to alter breast cancer recurrence patterns (72).

Hot flashes are among the most common acute and long-term side effects of breast cancer treatment. This symptom is seen secondary to chemotherapy-induced premature menopause, secondary to exposure to tamoxifen or raloxifene, or consequent to cessation of hormone replacement therapy (HRT) following diagnosis. Hot flashes can be profoundly debilitating for some women. Cognitive behavioral therapy (CBT), physical exercise (PE), and these two interventions combined have a beneficial effect on menopausal symptoms and physical functioning, with CBT specifically reducing both the frequency and perceived burden of hot flashes and night sweats (73). The challenge with the CBT group was adherence to the program due to the time commitment required, emphasizing the need for thoughtful, individualized planning with each potential participant. Clonidine, venlafaxine, paroxetine, fluoxetine, mirtazapine, and gabapentin are nonhormonal agents that have demonstrated efficacy in small controlled and uncontrolled trials in reducing hot flashes and should be considered in patients unwilling or unable to take hormonal therapies (74). Some evidence suggests there may be greater patient preference for venlafaxine over gabapentin, although both have similar efficacy (74,75). However, there is an accumulating body of evidence that several SSRI antidepressant drugs, especially fluoxetine and paroxetine, might interfere with tamoxifen metabolism by inhibiting the CYP2D6 enzyme. Venlafaxine minimally affects CYP2D6 activity and, therefore, is the first-line treatment for the tamoxifen-treated depressed patient who is experiencing hot flashes (76). Soy-based phytoestrogens, on the other hand, appear to provide little relief of hot flashes compared to placebo (77). A further effect of chemotherapy is loss of libido, which likely is associated with a reduction in circulating androgens. For many women, loss of desire is the most difficult sequela to treat.

A final troubling side effect of systemic therapy is fatigue. Increased use of multidrug adjuvant therapies that are both more dose-dense and more intense is leading to more women complaining of prolonged fatigue (78). Some studies with duration of follow-up measured in years following treatment completion have found that 15% to 20% of patients may experience fatigue as a chronic effect of treatment (79,80), whereas others have found a near resolution in fatigue levels as soon as 12 months after treatment completion (81). Noted clinically, the prevalence, etiology, and treatment of post-treatment fatigue continue to be areas needing further research. Introduction of molecularly targeted agents, alone or in combination with chemotherapy (e.g., Herceptin), also will increase the need for longitudinal outcome data among treated women, especially given early reports of troubling side effects even with these supposedly less toxic therapies (82). Although overall level of functioning and quality of life among long-term disease-free breast cancer survivors remains high many years after primary therapy, past systemic adjuvant treatment was associated with persistent poorer performance in physical activity and function, pain, and general health (83,84). These findings should be taken into account when counseling women about treatment choice, particularly when disease is limited.

As critical as it is to prepare women well for the commencement of treatment, it is equally important to anticipate and plan for emotional reactions to ending treatment, when fears of recurrence peak. In this regard, women who go on to adjuvant hormonal therapies may gain a sense of relief knowing that they still are doing something active to prevent recurrence. Other factors also contribute to anxiety (see Table 89-4). In recognition of the many persistent effects of modern breast cancer treatment, some clinicians routinely advise women anticipating the end of treatment to allot as many months for their recovery as were spent being treated for their cancer. Two booklets that form part of the National Cancer Institute's *Facing Forward* series, *Life After Cancer Treatment*, and *When Someone You Love Has Completed Cancer Treatment*, provide useful information for the woman and her family about what to expect after initial therapy ends.

Adjuvant Hormonal Therapy

Recommendations regarding the optimal duration of treatment with tamoxifen are unclear, with recent studies suggesting up to10 years may be optimal (85). Although these potential survival and recurrence benefits bring great hope to patients, they also warrant a deeper discussion with the patient regarding the long-term psychological and sexual

TABLE 89-4

Challenges Related to Ending Treatment

1. Fear that the cancer will return
2. Concern about ongoing monitoring (e.g., whom to call if a problem/symptom arises)
3. Loss of a supportive environment (including relationships with staff and fellow patients)
4. Diminished sense of well-being due to treatment effects (often feeling less well than when treatment was initiated)
5. Social demands: "re-entry" problems (dealing with expectations of family and friends that the breast cancer patient will quickly be back to "normal" and resume full function equivalent to pre-illness levels)

impact of this therapy. Once used mostly with postmenopausal patients, tamoxifen now is routinely given to premenopausal women with hormone receptor-positive breast cancer as part of their adjuvant therapy. Thus, when tamoxifen is recommended to a young childless woman who had hoped to regain fertility after 5 years of treatment, she may now have to face the possibility of never having her own biological children.

Some older women find that the associated increase in hot flashes with tamoxifen (or an AI) is a limiting factor in its use. By contrast, some younger patients report that tamoxifen provides relief from the vaginal dryness and decreased libido that accompany chemotherapy-induced premature menopause. Problems with tamoxifen-related hot flashes are more common among women who have a history of moderate to severe hot flashes with menopause and a history of estrogen therapy use. It is important to note that a small subset of women become depressed with use of tamoxifen, which can require temporary or even permanent discontinuation of its use (86). The impact of tamoxifen exposure on brain function also has come under examination (87,88). Rates of discontinuation or nonpersistence of use of tamoxifen, whether due to problems with drug side effects or some other reason, may be higher than believed, ranging from 31% to 73% in a recent systematic review (89). (See Chapter 44 for a discussion of appropriate monitoring for these potential complications.)

Relatively less is known about the psychological and sexual impact of the newer class of hormonal agents, the AIs (90,91). These agents have been associated with troubling joint and muscle pain symptoms. One report found that as many as 10% of women had discontinued AI use because of these side effects (92). The impact of these newer therapies on women's sense of well-being as well as adherence patterns among breast cancer survivors with respect to long-term adjuvant hormonal use are areas warranting future research.

RECURRENT AND ADVANCED DISEASE

With more women living longer after treatment for breast cancer, the numbers of those treated subsequently for recurrent local and distant disease have grown. Despite the physical burden of recurrence, during the year after diagnosis women show steady improvement in psychological functioning, reflecting the adaptive capacity of survivors (93). The distress associated with recurrence can come in many forms and affect multiple quality-of-life domains. Compared with disease-free survivors, women with recurrent breast cancer report poorer physical functioning and perceived health, more impairment in emotional well-being, more problems in relationships with family and healthcare providers, and less hope. Even when disease is localized, significant levels of psychiatric morbidity may occur (93). Women with recurrent disease, whether local or distant, are a particularly vulnerable group for whom active psychosocial intervention is warranted. Family members of these women also experience high levels of emotional distress and may require support.

Supportive care for patients with advanced breast cancer is aimed at comfort and control of symptoms. Different metastatic sites, especially bone, lungs, and brain, present special supportive problems. As discussed in the Interventions section later, participation in support groups may improve quality of survival significantly in this group of women, although the effect of such groups on length of survival appears limited (94).

Advanced care often is provided at home with support from the family or in a hospice setting (see Chapter 73). Central to the success of a home care program is continuity of care with physicians and staff and continued support of family and friends. Psychiatric consultation should be considered when distress (anxiety and depression) is not responsive to the usual supportive measures. Depression and expression of desire for hastened death may present in these settings (95). A management approach that combines psychological support with use of antidepressants and anxiolytics often is helpful. Agitated behavior associated with metabolic encephalopathy, resulting often from hypercalcemia, brain metastases, or narcotic or steroid side effects, may require use of an antipsychotic medication.

Because pain is such a common and feared experience of people living with advanced stages of disease, attention to its management is critical to care. Patients with cancer who experience pain are more likely to exhibit higher levels of mood disturbance and functional disability than those who have little or no pain. Spiegel and Bloom (96) found that for women with metastatic breast cancer, beliefs about the meaning of the pain in relation to the illness predicted level of pain better than site of metastasis. Attitudinal barriers to compliance with medical treatment, including stoicism and fear of narcotic addiction, are common. Thus, addressing the meaning and response to pain from the perspective of the patient is as important as providing an explanation of proposed control techniques.

INTERVENTIONS

The use and variety of psychosocial and behavioral interventions applied in the cancer setting in general and in breast cancer care in particular continue to grow (97). Cancer is one of several chronic illnesses that precipitate the need for, and use of, mental health services (98). Young age at diagnosis, being a younger survivor (younger than 65 years), being formerly married, and having a chronic comorbid illness all are associated with increased use of mental health services in the context of cancer, although as many as one in six survivors may fail to receive mental health services because of cost (100).

Though varying greatly by type (e.g., individual vs. group), orientation (e.g., behavioral vs. cognitive vs. supportive), mode of delivery (in person vs. remote), duration (time limited vs. open ended), and timing (e.g., before, during, or after treatment), as well as target populations served (early vs. advanced, younger than 40 years vs. older, partnered vs. single, or mixed), the fundamental purpose of interventions developed is to provide each woman with the skills or resources necessary to cope with her illness and improve the quality of her life and health. The various types of psychosocial and behavioral interventions used in the cancer setting and their efficacy in improving targeted outcomes are well reviewed elsewhere (99,100). The vast majority of these interventions have been developed specifically for patients with breast cancer or have included patients with breast cancer. A detailed review of the use of different interventions in the care of patients with breast cancer is beyond the scope of this chapter. However, three points must be made regarding the use of such programs in the overall care of patients with breast cancer and their families.

First, researchers have found that patients who received an intervention designed to improve knowledge or coping or reduce distress did better than those who did not. Specifically, those receiving some form of individual or group intervention experienced less anxiety and depression,

had an increased sense of control, had improved body image and better sexual function, reported greater satisfaction with care, and exhibited improved medication adherence (100,101). Significant attention needs to be paid to the development and delivery of psychosocial care models if we are to understand who needs what, delivered by whom, and when in the course of care (102). Further, understanding the economic impact of these programs or services in terms of delivery, changes in healthcare utilization, and out-of-pocket expenses may be critical if we are to expect their broader uptake into routine practice.

Second, use of psychosocial interventions continues to grow, especially in the setting of breast cancer. Use of these services reflects not only patient demand for supportive care, but also growing recognition that addressing psychosocial issues may improve outcomes for patients. At one point, it was hoped that such interventions would result in life extension. The current consensus is that psychosocial interventions do not prolong survival (103,104), but help women "live better," although there are provocative data to suggest that women in the highest medical and psychological risk groups may realize a survival benefit (105). Social well-being in the first year after diagnosis has been found to be a prognostic factor in recurrence and mortality (106,107), although interventions to improve social well-being have not led to improved survival (27). Decreasing depressive symptoms through supportive expressive group therapy over the first year has been shown to be associated with prolonged survival (53.6 months vs. 25.1 months) (108). In breast cancer, because so many women do well or live for longer periods even with more advanced disease, the incremental benefit to survival conferred by receipt of these interventions may be harder to detect.

Provocative, but admittedly preliminary, research in the area of psychoneuroimmunology and cancer suggested that psychological variables (e.g., perceived stress, mood) might modify disease outcomes (109). However, efforts to design interventions to address this interface have produced mixed results. Despite the growing number of trials reported, meta-analyses provide only modest evidence that psychosocial or behavioral interventions reliably alter immune parameters (110). Because of their key role in breast cancer, better understanding of the impact of psychosocial interventions on endocrine functioning and disease outcomes warrants further pursuit.

Third, although it might be argued that an individually tailored intervention should result in the best outcome for any given patient; this may not be feasible, suitable, or even desirable in all cases. Increasing evidence shows that participation in group activity offers a uniquely supportive and normalizing experience, with a small number of older studies finding that groups were as effective as individual sessions in reducing patient distress. Use of communication technologies, including the Internet, teleconferencing, and telephone (111), may be used to provide group support and represent the new frontier in intervention research. These technologies address issues of isolation and allow for anonymity. In addition to providing medical information, the Internet may offer a unique vehicle to improve access to information and social support and reduce isolation (112–114).

Research suggests that four key elements are vital to achieving optimal outcomes for all cancer survivors: (a) access to state-of-the-art cancer care; (b) active coping, in particular active participation or engagement in one's care, even if this means delegating decision-making; (c) use of social support (although it is recognized that the perception that this is available may be sufficient) (115); and (d) having a sense of meaning or purpose in life. Many of the psychosocial and behavioral interventions developed in cancer are designed to foster or reinforce some or all of these core needs. However, access to these remains a problem. Clinician awareness about, and referral of, patients to even such well-established programs as the American Cancer Society's Reach to Recovery is variable (116). Key to the development of an effective intervention is the recognition that, for many women, cancer represents a transitional event. As defined by Andrykowski et al. (117), cancer is "a traumatic event that alters an individual's assumptive world with the potential to produce long-lasting changes of both a positive as well as negative nature." As such, the primary goal in any intervention is to help minimize the negative and enhance the positive impact of the breast cancer experience on the woman's recovery and well-being.

SPECIAL ISSUES

In the remaining sections, the special issues related to the care of other family members, the role of sexual quality of life in rehabilitation, and the well-being of long-term breast cancer survivors are reviewed.

Role and Care of the Family

The quality and quantity of individuals' social connections is linked not only to mental health status, but also to both morbidity and mortality (118). Not surprisingly, social support has been found to be integral not only to positive adjustment, but also to length of survival (119,120) in women with breast cancer. When people are ill, they tend to feel less in control and less confident, especially when they must rely on others. At the same time, serious illness of any kind increases the ill person's need for closeness to others to counteract feelings of insecurity and vulnerability. Absence of social support or the loss of a significant person who withdraws during the patient's illness becomes an additional stressor that may be more painful emotionally than the illness itself.

Active family involvement helps to meet the emotional and practical needs of the patient, while providing meaningful roles and related functional goals toward which the patient can strive. Despite the recognized importance of the role of partners and family in caring for women with breast cancer, this subject remains the focus of only a modest number of studies. Further, even less is known about family adaptation long-term, as the majority of studies conducted have examined the acute or early post-treatment period. Once treatment ends, family members must adapt to the interpersonal and financial changes brought on by cancer, deal with their loved one's lingering effects of illness, and learn to live with potential uncertainty about the future. Family caregivers may experience lower quality of life, more fear of cancer recurrence, and less support than their loved one with cancer does (121). In this study, the strongest predictors for survivors' quality of life were family stressors, social support, meaning of the illness, and employment status, whereas the strongest predictors for family caregivers' quality of life were fear of recurrence and social support. Of note, the quality of life of the survivor and caregiver contributed independently to the quality of life of the other person.

Partners' adaptation, similar to patients', varies over time, as do the sources of distress they face. For example, during treatment, concerns may focus on whether the therapy is working and how to cope with the side effects of treatment and manage a household; whereas after treatment fear of recurrence and trying to make sense of the experience may produce distress. Further, there is a significant correlation

between a patient and her partner's patterns of coping, and these couples' levels of distress are higher than those of couples not facing cancer (122). Predictors of partner distress include: high burden of the illness and caregiving demands, more limited resources available, recency of the marriage, older age, less education, lack of or dysfunctional communication style, heightened fear for the wife's well-being, worry about job performance, and the partner's own baseline level of adjustment (122). One study examining cultural differences found that Asian American women (specifically those of Chinese and Japanese descent) were expected to be self-sacrificing and nurturing of husband and family regardless of illness, whereas European American women were allowed to be more dependent (123). Further, Asian American women emphasized a goal of harmony over intimacy—whereas European American women embraced the reverse—and in communication preferred the nonverbal versus the verbal communication style valued by European American women.

When observed or reported, high emotional distress in a partner or family caregiver warrants immediate attention. Left unaddressed, high anxiety in the partner/caregiver can have a negative impact on the breast cancer patient's adaptation over time; impair the ability of the partner/caregiver to provide optimal patient care; and result in changes in a partner's/caregiver's immune system that can result in adverse health consequences (124). Research on interventions to promote coping conducted with dyads or family caregivers documents significant albeit modest benefits. These include reduction in caregiver burden and improvements in caregiver coping, self-efficacy, and quality of life; coupled with decreased patient symptoms, reduced mortality, and improved patient physical and mental health (124–126). Reflected in these reviews is that many of these interventions seek to promote teamwork and mutual support, foster open communication, encourage caregiver self-care, and enhance education about the illness experience. Although more research in this promising adjunct to quality care is needed, interventions currently exist that would benefit "at risk" couples.

An experience of breast cancer may bring couples closer together and typically does not result in partner abandonment. A history of prior marital discord may put a couple at risk, however. Cancer is very "permission giving" to many survivors. The woman who uses this event to examine her satisfaction with a preexisting partnership may, if she finds it lacking or emotionally dissatisfying, decide to make a major life change and exit the relationship. In a similar vein, desire to reduce the stress in her life, felt by many women to be a causal factor in risk for cancer, may precipitate a drive to make major life changes.

It is critical to remember that support is a two-way street; the source of the problem may arise in the provider of support (family member) and/or in the recipient, and commonly involves both. The impact of cancer can be as devastating to a family member as to the patient herself, and sometimes worse. Whereas the woman can obtain support from multiple sources and control her anxiety by focusing on just getting through treatment, partners often receive less attention and report feeling uncertain as to what to do and helpless in their role as observers. It is helpful for staff to acknowledge the difficult task faced by family members, provide opportunities for them to talk about questions and reactions both with the patient and alone, and ensure that backup supports are available and that efforts are made to give family members relief, especially if care is going to be complex or long term. It also is important to permit family members to limit care to those areas in which they are most comfortable and effective.

Once thought to be traumatic for children, current literature suggests that the experience of cancer in a parent may be more modest in impact. This may be due to greater public dialogue about cancer, greater openness among families dealing with this crisis, and broader availability of resources to help families cope (127,128). Behavioral problems, conflicts with parents, and other symptoms of emotional distress can increase during parental illness. Increased risk of a child internalizing (which can be reflected by feelings of guilt, worry that he/she caused the cancer, and symptoms of depression) is present. A number of factors may affect a child's response to maternal breast cancer, including disease severity, family function and environment, family and child coping reactions (in particular maternal depression if this occurs), and parent and family characteristics, in particular their communication/expressiveness. Relationships to a child's age and gender were inconsistent across studies, although there was a suggestion that adolescent daughters may be more vulnerable when their mother has breast cancer (129).

The monitoring of all dependent children, especially when the mother's breast cancer is advanced, is important. The opportunity for parents to discuss how and what to tell their children about the mother's illness early in the course of care also is important and should include advice on tailoring these conversations to meet the appropriate developmental needs of their offspring. Specific interventions to help a mother and her children cope with illness may be helpful (130). A number of books addressing this topic and an NCI publication, *When Someone in Your Family Has Cancer,* may be useful in this process. Teachers and school counselors can assist in monitoring the child's behavior and response to this family stressor. This task may be more difficult when the offspring is an adolescent. Finally, concern about what impact breast cancer may have on a mother's survival may be complicated by worry about its meaning for an offspring's future well-being. With the growth of high-risk genetic clinics, attention has focused on the overall psychological adjustment and quality of life of female first-degree relatives of patients, which may impact their adherence to such screening programs, an issue addressed in greater detail in Chapter 17. Whereas the information needs of women treated for breast cancer are well documented, those of their family members bear further study.

Quality of Life and Sexual Functioning

The impact of disease and treatment on women's sexual functioning, once rarely discussed or addressed, has garnered significant research attention in recent years. Interest in this important topic is both a function of compelling advocacy by women for greater attention to these issues, and consequent to the large number of women for whom treatment causes significant problems in this valued area of function.

The literature documents a range of changes in women's sexual function after breast cancer, including disruptions in normative sexual processes (e.g., sexual desire, arousal, lubrication, and orgasm), and diminished sexual activity and pleasure. Most of these effects are secondary to exposure to adjuvant chemotherapy and hormonal therapy, with adverse consequences of surgery conferring a more limited impact (e.g., changes in body image, interference with function due to lymphedema or persistent postoperative pain syndromes) (131). AIs, increasingly used in the management of postmenopausal breast cancer survivors, are associated with increased vaginal and vulvar symptoms. In those for whom these side effects are severe, a switch to tamoxifen

may be preferred over adding local or systemic estrogens to the AI regimen (132). In addition to exposure to adjuvant therapies, risk factors for problems in sexual function include poor partner communication, sexual function problems in the partner, depression in either partner, or younger age. Compared to their older counterparts, younger women have distinct concerns about chemotherapy-induced premature menopause and loss of fertility that contribute to their distress; they also report more problems with weight gain and physical inactivity that, in turn, can negatively affect their sense of femininity and attractiveness (133). Because of strong cultural taboos around discussion of women's health issues, young African American women in particular may fail to receive desired education and counseling around the sexual impact of cancer on their well-being (134).

Overall, sexuality declines after initial diagnosis. When breast cancer recurs, although most couples strive to maintain intimacy, further decline may be noted (135). In metastatic breast cancer patients and their partners, sexual problems have been found to be associated with increased depressive symptoms (136). Furthermore, high levels of mutual constructive communication and low levels of demand-withdraw communication may protect against depressive symptoms associated with sexual problems in patients but not in their partners, emphasizing the need for future interventions that target communication patterns in couples.

The range of psychological reactions to cancer that threaten sexual function include threats to (a) sexual identity and self-esteem, such as disturbances of mood, gender, and sexual identity and body image; (b) personal control over body functions, such as disease-related symptoms that interfere with or inhibit sexual functioning; (c) intimacy, such as loss of social contacts that have potential for intimate physical expression, the disintegration of established patterns of achieving physical pleasure and intimacy, or myths related to contagion; and (d) reproductive function, such as the direct impairment of fertility or the fear of recurrence with pregnancy. In addition to these psychological reactions, some women experience less joy and vigor, as well as an underlying uncertainty about their health and the vulnerability of their bodies to further assault. The emotional distress, pain, fatigue, and insult to the patient's body image and self-esteem caused by the diagnosis and treatment of breast cancer can damage sexual functioning, even among individuals who had a strong and satisfying sexual relationship before illness. Despite heightened sensitivity to sexual issues, in practice, provision of effective sexual interventions remains highly variable. Further, research to guide the delivery and evaluate the impact of care in this area is limited.

A central challenge to addressing sexual dysfunction when it occurs is avoidance of this sensitive topic by both provider and patient. In addition to the discomfort most people feel when discussing sex, practitioners must contend with limited time, and at times, privacy to raise these issues, lack of awareness that sexual problems are being encountered, or when present, knowledge about local resources to address them. Currently, this last barrier is dissipating as education about effective therapies for problems such as vaginal dryness, hot flashes, painful intercourse, and lack of desire becomes more broadly acknowledged and available.

Whereas breast cancer survivors appear to attain maximum recovery from the physical and emotional trauma by 1 year after surgery, a number of specific problems persist beyond 1 year, in particular those amenable to sexual rehabilitation (e.g., body image, lubrication, orgasm). A multimodal approach to women's sexual rehabilitation is recommended. This includes use of pharmacologic, nonpharmacologic, and psychosocial interventions as appropriate (137,138). Special training in sex therapy techniques is not a prerequisite for discussing sexual dysfunction; only information about and willingness to refer women for help with these issues is needed. For women still in their childbearing years, there are now American Society of Clinical Oncology (ASCO) guidelines about asking and for referring these individuals for fertility preservation options and counseling (139). (See Chapter 90 Reproductive Issues in Breast Cancer Survivors for a discussion of management of fertility and breast cancer.) Because sexual problems tend to worsen, not improve, over time, sexual rehabilitation needs to start early. Ideally, this should occur before treatment starts for those patients for whom specific impairment of sexual function can be anticipated (e.g., premature menopause in the premenopausal or perimenopausal woman). Raising the topic of sexual function early, by letting the patient know it is an appropriate focus of concern and that the healthcare provider is willing to discuss it, opens the door for future dialogue in this area, and normalizes their distress. It also is important to respect a woman's privacy, and as such, it may be helpful to identify a single staff member to initiate such conversations, often the primary nurse. When specific questions arise, the nurse needs to know what the patient has been told and by whom in order to focus questions for patients, direct their inquiries to the appropriate staff member, clarify or reinforce information provided, and serve as an advocate for the patient. Above all, this designated member should know about resources for help in this area and, as needed, coordinate input with that of others.

BREAST CANCER SURVIVORS

With their numbers expected to grow in years to come (140), more attention is being focused on cancer survivors and the experience of living through and beyond their illness and its treatment (141). Although women vary widely in their response to diagnosis and treatment, most return to lives that are as full as, and often richer personally, than before their illness. Although some women reduce work hours or leave jobs following a cancer diagnosis, either by choice or because of disability, by 12 to 18 months postdiagnosis most patients have returned to work (142). Besides being a vital source of income and often of needed healthcare coverage, work also can be an important source of social support and self-esteem as well as distraction from illness during treatment. Those in manual labor jobs (which often includes women with lower education and income) may experience more limitations, but most find that employers are accommodating of their needs (143), suggesting that many of the myths about cancer's adverse impact on survivors' job performance are beginning to be dispelled. Somewhat troubling, however, is the longer term picture. Continued follow-up of breast cancer survivors suggests they may be at risk of later morbidity that reduces their numbers in the workforce relative to women without a cancer history. Morbidity may be due to treatment-related effects (e.g., lymphedema, decreased functional capacity, cognitive problems) or disease recurrence (142). Population-based data suggest that over time, carrying a cancer history puts survivors at greater risk for experiencing problems in their physical (24.5%) and mental (10.1%) health compared with 10.2% and 5.9% of adults without cancer, respectively (144). Given these findings, a growing case is being made for the need to revisit the idea of rehabilitation after cancer (145). As part of this, assessment of work status and counseling

around work-related issues, with referral for help in negotiating workplace issues as needed, are important in aiding women's continued employment as desired.

Striking to many clinical researchers involved in the conduct of long-term follow-up studies is the enormous resilience evidenced by women; post-traumatic growth as a benefit that may occur after facing a life-threatening illness (146). The growing interest in cancer survivorship, as reflected in the number of programs offered by the NCI-designated cancer centers designed specifically to address survivors' needs posttreatment, is testament that survivors' call to action is being heard (http://cancercenters.cancer.gov/documents/Survivorship%20Appendix%20D.pdf). Services provided focus on two main areas: (a) surveillance, and (b) health and well-being after treatment.

Follow-Up Care and Surveillance Posttreatment

Although concern about disease recurrence may diminish over time, for most breast cancer survivors, this never fully goes away. The degree of worry may fluctuate and be triggered by a variety of sources, including continuing physical problems after treatment (see Table 89-5). Fear of recurrence in the survivor can have an adverse effect on family quality of life; the reverse also is true, with family members' fears negatively influencing the quality of life of the survivor. When activated, fear may lead to disruptive behavior such as heightened body monitoring, anxiety well in advance of a doctor visit, and worry about the future; or in some instances severely disabling reactions including hypochondriac-like preoccupation with health at one extreme, or avoidance and denial at the other, inability to plan for the future, and despair. Interventions are being developed to help women cope successfully with uncertainty (147). Although other interventions that effectively reduce distress and improve a sense of well-being might be expected to result in decreased worry about disease recurrence, this remains to be tested.

Part of this persistent anxiety may be attributable to the fact that breast cancer survivors understand that their cancer could recur at any time after treatment and that medical follow-up must continue for life. Data support the appropriateness of this concern. As women live longer after their initial breast cancer diagnosis, they are at higher risk than women with no cancer history of developing a second cancer, most often a second breast cancer (148). In this context, it is important to note that not all women posttreatment for breast cancer consider or think of themselves as "survivors." Although some women embrace this language and are proud of their status, others reject being so labeled. Still others fear that calling themselves survivors before 5 years might invite a recurrence. More important is that each woman treated recognizes the need for follow-up for life. Decision-making around follow-up care itself represents the third major decision point in the breast cancer patient's illness pathway.

TABLE 89-5

Triggers for Fear of Recurrence

1. Routine follow-up visits and tests
2. Anniversary dates (e.g, date of diagnosis, end of cancer treatment, birthday)
3. Worrisome or "suspicious" symptoms
4. Persistent treatment-related side effects (especially fatigue or pain)
5. Change in health (e.g., weight loss, fatigue)
6. Illness in a family member
7. Death of a fellow survivor/prominent cancer survivor
8. Times of stress
9. Idiosyncratic triggers (e.g., "learned responses" such as the smell of alcohol due to association with receipt of chemotherapy; sight of the treatment center)

Although the value of survivors receiving a treatment summary and plan for future care at the end of treatment has been recognized, the type of follow-up care that should be provided to which survivors and at what periodicity is a major topic of debate (see Chapter 67, Surveillance of Patients following Primary Therapy and Chapter 88 on survivorship). Increasingly, it is recognized that women need to be followed for surveillance of recurrent disease as well as adverse long-term or persistent and late-occurring sequelae of treatment, and psychosocial adjustment, although who should be responsible for this latter aspect of care in particular is unclear (149). Ganz and Hahn provide guidance on how to implement comprehensive care plans for breast cancer survivors transitioning to recovery (150). Among the questions for the future will be to determine where this care is best delivered and by whom: in primary care, specialty clinics, or some combination of these. Research also will be needed on the cost, both economic and with respect to women's sense of well-being, of the models developed for follow-up care.

An important take-home message in all of the research discussed in this last section is that a cancer diagnosis represents for many a "teachable moment" for healthcare providers along with breast cancer survivors themselves, a moment currently being missed by many oncology practitioners (151). The crisis of cancer often creates a window of receptivity during which healthcare professionals can provide patients with educational messages about, and support for, pursuing healthy lifestyle choices. Although these activities, if adopted, may not alter length of breast cancer survival, they do carry the potential to significantly reduce individual risk for treatment-related or other chronic illness-related morbidities and potentially other cancers. To take full advantage of this opportunity to intervene, it will be vital to understand what women identify as important for them to address (e.g., weight, diet, stress, exercise, and tobacco/alcohol use), the types of information and resources needed to promote and maintain change in these identified areas, and how to most effectively deliver these interventions. Encouraging breast cancer survivors to take control of what they can in their lives may enable them to live with better health in, and less fear of, the future.

Health Behavior after Cancer

One of the newest topics in breast cancer follow-up care is the role of health promotion (see also Chapter 51). This is being spurred largely by survivors' interest in, and growing requests for, informed guidance about what they can do to reduce their risk of cancer-related morbidity and mortality. Many breast cancer survivors already report taking better care of themselves in the wake of cancer, with particular focus on adopting healthier lifestyles, reducing stress, eating better, and exercising regularly. In our research with long-term (≥5 years after diagnosis) breast cancer survivors, the areas in which the experience of cancer had the most positive impact were diet, exercise activities, and religious beliefs. The greatest negative impact was felt in the domains of love life and, for younger survivors, work life or career and financial situation (84).

Two areas receiving significant research attention with respect to their impact on women's health outcomes are stress management and physical activity interventions. As noted earlier, many women believe that the stress in their lives can precipitate or exacerbate breast disease. For these survivors, reducing stress is seen as potentially lifesaving. Researchers at the University of Miami's Mind Body Center have developed a standardized 10-week training program that equips women with the cognitive and behavioral skills necessary to identify, analyze, and manage stress (152).

A second avenue to stress reduction is staying active during, or becoming physically active after, cancer treatment. There is increasing evidence demonstrating the association of obesity with: (a) greater risk of contralateral breast cancers (153); (b) development of postmenopausal breast cancer (154); (c) poorer prognosis in early stage disease, with increased recurrences, including distant recurrences (155); and (d) poorer response to adjuvant therapy (156), highlighting the importance of addressing weight control and levels of physical activity (energy balance) in the total care of the breast cancer patient. Often begun during treatment, research shows that physical activity can improve mood (reduce anxiety and depression), enhance cardiovascular function, control weight, improve body image and self-esteem, reduce nausea and fatigue, and potentially alter immune function (157). To date, two observational studies (158,159) and one randomized clinical trial (160) have found a survival benefit for women who became or remained moderately physically active after breast cancer treatment.

As the evidence of their benefits for survivors mounts, lifestyle changes are being recommended posttreatment (161). Although U.S. population-based data suggest that survivors may be more active than their peers without a cancer history, both groups remain well below the recommended levels of daily activity; smoking and dietary practices also lag behind recommended patterns (162). Use of complementary and alternative medicine (CAM), reported by many patients during active cancer treatment, also is seen in the posttreatment setting. Studies suggest that CAM use is more common among younger, better educated women with good health insurance. Reports of poorer psychological functioning among patients with cancer using CAM remedies (163) suggest that some women may be self-medicating for depressive symptoms.

Reducing alcohol exposure also is common in this population. A study investigating postdiagnosis alcohol consumption in 9,329 breast cancer patients over a median 10-year follow-up revealed no association with recurrence or all-cause mortality (164). However, regular drinking, defined as more than three drinks per week, was associated with a higher risk of recurrence but not mortality in postmenopausal women (164). Surprisingly, because few survivorship studies inquire about smoking, we have very little information on women's practices in this regard. Data from the National Health Interview Survey (NHIS) indicate that although overall smoking rates are lower in survivors than adults without a cancer history (19.7% vs. 23.8%), many cancer survivors continue to smoke after treatment. Such behavior appears to be of particular concern among younger survivors (19- to 40-year-olds), in whom the rate of smoking posttreatment (40.5%) was significantly higher than estimates for their cancer-free peers (27.1%) (162). Although limited to date, research points to a positive association between current smoking and breast cancer mortality (165). Given this picture and breast cancer survivors' heightened risk for cardiovascular problems, it is important to remember that it is never too late to realize a health benefit by quitting smoking. Those caring for breast cancer survivors should ask about this behavior and intervene as appropriate.

CONCLUSION

Breast cancer has a unique, and at times complex, psychological impact, with variable emotional responses developing in women and ranging in severity and their impact on functioning. Increasing treatment options have empowered women—and for some, overwhelmed them—emphasizing the need for individualized approaches and treatment discussions with all women. Broader dissemination of information from psychological studies of adaptation to the available treatment options can help in efforts to determine the best treatment to meet patients' physical and emotional needs. Addressing the psychosocial and psychosexual needs of patients with breast cancer improves quality of survival and may even enhance length of survival from other, comorbid conditions and events, even if not from cancer. As newer therapies are introduced, research on their immediate and delayed psychosocial impacts is needed. Finally, with the increasing demand for their involvement in care, special attention must be directed to the psychological well-being of the immediate relatives of women with breast cancer, especially their partners and offspring.

In closing, clinicians should be reminded that their relationship with a given patient remains paramount above all of the considerations outlined previously. A physician's communication style, behavior, attitudes, and beliefs can dramatically affect a woman's experience. Toward this end, it is important for the healthcare professional to view him- or herself as part of the treatment. By acquiring and honing the communication skills necessary to engage a patient in her own care, while being respectful and observant of her needs, clinicians can increase the opportunity to minimize psychological trauma, enhance treatment adherence, and obtain the best possible outcome for each woman treated.

MANAGEMENT SUMMARY

- Although most women diagnosed and treated for breast cancer do well psychologically and socially, one fourth of women with breast cancer have psychological symptoms that warrant psychiatric intervention.
- Clues to identifying women with psychological distress include previous treatment for depression or anxiety, symptoms of depression and anxiety that seem out of the "normal" range, and psychological symptoms that worsen over time.
- Diagnosis and treatment of breast cancer causes psychological distress for all women; recovery from physical and emotional symptoms usually occurs gradually during the 12 months after the completion of cancer treatment. Patients should be told that asking for psychological help is a sign of strength, not weakness.
- Psychological and social support services should be offered to all women (the availability of support services varies depending on the location and type of practice).
- Brief, easily scored distress screening tools could be used periodically across the course of care to help identify women who are most in need of psychological treatment.

- Psychological support comes in many forms and is delivered by many professionals. Available psychosocial support members should be encouraged to become active participants in a multidisciplinary team.
- Symptoms of anxiety and insomnia during the diagnostic, pretreatment, and treatment phases often can be rapidly and effectively treated with low-dose anxiolytics and hypnotics.
- Symptoms of depression should be evaluated by a psychiatrist or a psychologist; safe and effective antidepressants are available for women who are being or have been treated for breast cancer.
- Women who are receiving dexamethasone should be informed that it can cause psychological symptoms (anxiety, depression, mood swings); women should be asked to report these symptoms if they occur because they can be treated rapidly and effectively.
- Family members' responses to a woman's illness are important to her adaptation. These should be monitored and support provided if there are signs of distress.
- The oncologist can play an important role in encouraging the patient's early resumption of sexual activity after breast surgery or chemotherapy. The patient's partner should be encouraged to attend diagnostic planning and follow-up visits. Sometimes partners need referral for psychological support so they can better support the patient.
- Menopausal symptoms are highly distressing for many women. Mood swings, irritability, insomnia, and hot flashes can be treated effectively with a variety of medications. Some patients experiencing these symptoms benefit from referral to a psychiatrist for evaluation.
- Women value communication with their physicians. The most satisfied patients are those who feel they were compassionately warned about potential side effects of treatment.
- Be aware that some women emotionally "sail" through treatment and then develop symptoms of distress; symptoms develop in some of these women at the anniversary of their diagnosis or during the following year. Women should be asked during their 3-month posttreatment and 1-year follow-up visits how they are doing emotionally and referred as appropriate.
- Psychological symptoms such as anxiety are common at the conclusion of cancer treatment. Women feel vulnerable and less protected when not being seen regularly by their radiation or medical oncologist. Women should be provided with information on what to expect when treatment ends.
- It is useful to provide each woman with a survivorship care plan that includes a written summary of the treatments received and recommendations for follow-up care. This can help breast cancer survivors negotiate the transition to recovery and plan appropriately for future healthcare needs.

ACKNOWLEDGMENTS

The authors would like to gratefully acknowledge Isabel Sulimanoff's assistance in the preparation of this manuscript.

CHAPTER 90

Reproductive Issues in Breast Cancer Survivors

Kathryn J. Ruddy and Elizabeth S. Ginsburg

CHAPTER CONTENTS

INTRODUCTION

Breast cancer is one of the most commonly diagnosed malignancies in women of childbearing age. Approximately 10% of women diagnosed with breast cancer are younger than 45, translating to over 23,000 women in the United States yearly and many thousands more worldwide (1). Thanks to improvements in the treatment of breast cancer and an increasing focus on survivorship issues, combined with the sociodemographic trend of delaying childbearing, many young breast cancer survivors are interested in future fertility (2–4). A recent meta-analysis found that concerns about infertility contributed to high levels of distress in young women with breast cancer (5). Breast cancer treatment can diminish or destroy a woman's reproductive potential due to direct gonadal toxicity or due to the natural waning of fertility while she is receiving therapy. However, many young women remain premenopausal and fertile for at least some period of time after breast cancer treatment, and some are interested in interventions to increase the chance that they will be able to conceive (6).

Because of the intricate relationship between breast cancer and hormones, fertility and reproductive issues in this population are complex. Reproductive factors are associated with the risk of developing breast cancer, and hormonal manipulations and medications are a mainstay of breast cancer treatment. Chemotherapy recipients who experience treatment-related amenorrhea have a better prognosis than women who continue to menstruate throughout chemotherapy (7). Nevertheless, for some young women with breast cancer, the threat or experience of infertility may be particularly distressing (6,8). Fertile Hope is an advocacy organization that supports fertility preservation for cancer patients; its founder proclaimed about her cancer diagnosis on www.fertilehope.org, "The thought of being sterile was almost as devastating as my cancer diagnosis itself." Some women are also interested in avoiding potential ill-health effects of premature menopause, including hot flashes, vaginal dryness, bone thinning, cardiovascular problems, and mental health issues (9,10).

EFFECT OF BREAST CANCER TREATMENT ON OVARIAN FUNCTION

Fertility may be adversely affected in several ways in young women with breast cancer. First, the time required to receive systemic breast cancer treatment may be months (e.g., conventional cytoxic chemotherapy) or years (e.g., adjuvant tamoxifen). During treatment, while pregnancy is contraindicated due to risks of teratogenicity, ovarian function and fertility are naturally declining due to aging. (see Fig. 90-1). The average age of menopause in the United States is 51 years, but fertility wanes many years before cessation of menses for most women, so many breast cancer patients diagnosed in their late 30s or 40s will be unable to conceive by the time they complete five to ten years of treatment with tamoxifen.

Second, adjuvant chemotherapy is directly toxic to the ovary, reducing fertility and potentially inducing premature menopause. The degree of damage to the ovaries will determine whether amenorrhea is temporary or permanent. Chemotherapy induces apoptosis in dividing cells in the ovary including maturing follicles (11). Because alkylating agents like cyclophosphamide are not cell-cycle specific, they may also directly kill oocytes and pregranulosa cells of primordial follicles. There is mixed evidence regarding whether chemotherapy given during the follicular phase of the menstrual cycle is more injurious to ovarian function than chemotherapy given at other times (12,13). Chemotherapy-associated premature menopause is thought to occur in 10% to 90% of patients receiving chemotherapy depending on the regimen given, the age of the patients, and the definition of menopause. Most studies are limited by the use of chemotherapy-related amenorrhea (CRA) as a

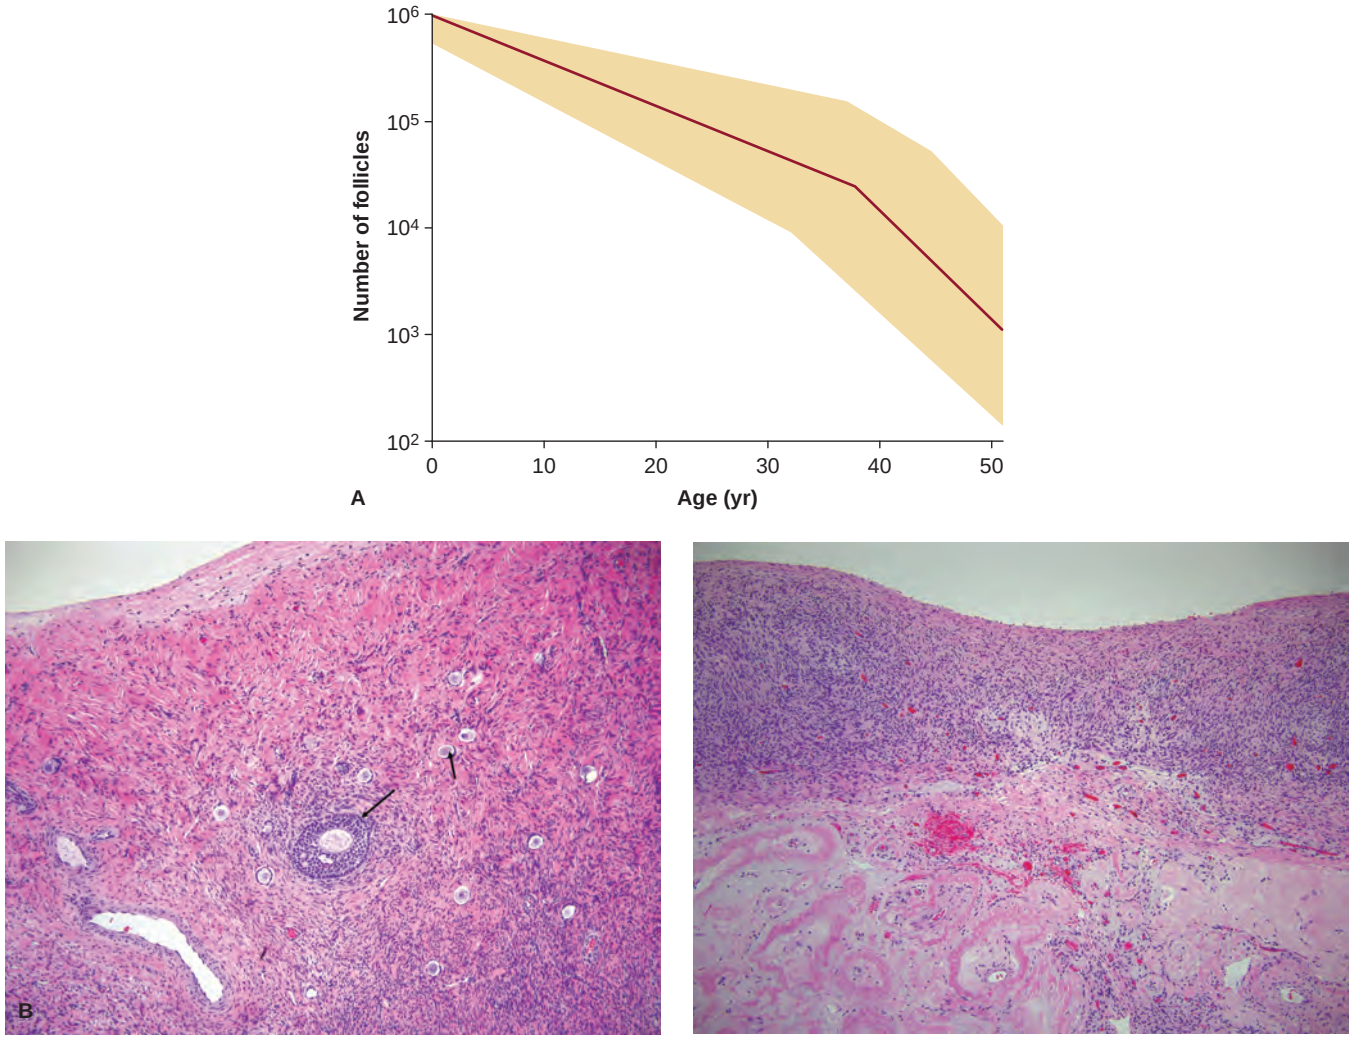

FIGURE 90-1 Natural decline in oocytes over time from birth to menopause. **(A)** depicts the decline in human ovarian oocytes by age (Data from Faddy et al. (74)). **(B)** shows histologic specimens of a premenopausal ovary containing follicles (*arrows*) and postmenopausal ovary without follicles. The expanse of tissue is the ovarian medulla, which does not contain many follicles even in the premenopausal state. (Adapted with permission from Lobo RA. Potential options for preservation of fertility in women. *N Engl J Med* 2005;353:64–73. (Ref. 73); Courtesy Q3 of Cynthia A. Jimenez, MD.)

surrogate for menopause and infertility. Treatment regimens vary substantially, and follow-up is heterogeneous and relatively short. CRA may be temporary, especially in very young women; older women are more likely to have permanent amenorrhea. Chronically anovulatory women may remain fertile even if they are not having menstrual cycles, but, on the other hand, ongoing menses are a poor surrogate for fertility, especially as women age, due to waning egg quality.

Available data confirm that risk of CRA is related to increasing age and increasing cumulative dose of cytotoxic chemotherapy, in particular, alkylating agents (14). A recent study of more than 2,000 pre- and perimenopausal women randomized to docetaxel-doxorubicin versus concurrent docetaxel-doxorubicin-cyclophosphamide or sequential doxorubicin-cyclophosphamide followed by docetaxel found that the women in the non-cyclophosphamide containing group had significantly less likelihood of CRA (15). Younger age was also significantly protective against CRA. Likewise, an earlier prospective longitudinal survey of 595 U.S. women with breast cancer diagnosed at age 25 to 40 undergoing adjuvant chemotherapy confirmed that menstrual cycles were less likely to persist at 1 year among women treated with regimens containing higher cumulative doses of cyclophosphamide (i.e., cyclophosphamide-methotrexate-5-fluorouracil [CMF] or 5-fluorouracil-doxorubicin-cyclophosphamide rather than doxorubicin-cyclophosphamide, doxorubicin-cyclophosphamide-paclitaxel, or doxorubicin-cyclophosphamide-docetaxel) (OR 0.37, 95% CI, 0.37–0.67) (16) (see Fig. 90-2). Rates of menstrual bleeding six months after completion of chemotherapy were also strongly related to patient age, with approximately 85% of women age <35 years having ongoing menses, 61% in women ages 35 to 40, and <25% in those age >40 (see Fig. 90-3). Recent evidence suggests that the addition of the taxanes to anthracycline-based adjuvant chemotherapy confers little or no increased risk of CRA, although data are mixed (17–20). Table 90-1 summarizes the risk of CRA with common adjuvant therapy regimens by age (14).

Even among women who remain premenopausal after cytotoxic therapy, menopause may ensue earlier than would have been expected in the absence of chemotherapy. An analysis of

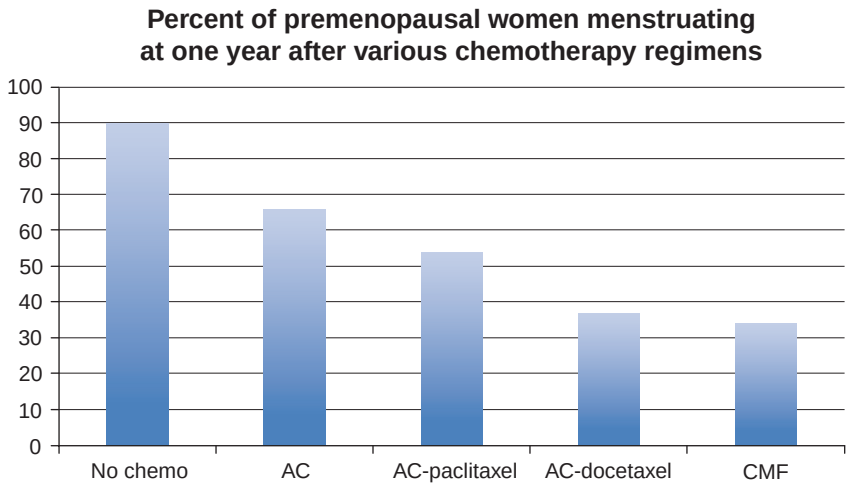

FIGURE 90-2 Menstrual bleeding by chemotherapy regimen received. (Data from Petrek JA, Naughton MJ, Case LD, et al. Incidence, time course, and determinants of menstrual bleeding after breast cancer treatment: a prospective study. *J Clin Oncol* 2006;24:1045–1051.) (Ref. 16)

the International Breast Cancer Study Group (IBCSG) Trials V and VI revealed that 227 women who were menstruating and disease free at 2 years after diagnosis and treatment with 6 to 7 cycles of CMF had earlier menopause compared to controls (21). For a woman who was 30 years old at time of diagnosis and menstruating 24 months after 6 cycles of CMF, there was a 37% risk of menopause only 3 years later (at age 35) and an 84% risk at age 40. Other studies have also shown that ovarian reserve is diminished even in young women who remain premenopausal after chemotherapy for breast cancer (22–24). Hormonal treatments appear to primarily impact fertility due to delayed child-bearing, allowing natural waning of ovarian function (25).

CONSIDERATIONS FOR WOMEN WHO DESIRE TO HAVE A FUTURE BIOLOGICAL CHILD

Many young women with breast cancer struggle with the competing interests of optimizing personal survival and wishing to have a future biological child (26). Some choose to modify their expectations regarding future biological children, often considering alternatives such as adoption

TABLE 90-1

(though adoption can be more difficult when a person has a history of cancer). For others, minimizing treatments or pursuing interventions aimed at fertility preservation, or a combination of these, may be appropriate.

Approach to a Patient Concerned about Fertility

The American Society of Clinical Oncology (ASCO) has published recommendations regarding fertility preservation considerations for cancer patients (27). For women with breast cancer, data regarding the efficacy and safety of strategies for fertility preservation are somewhat limited. These limitations may impede discussions about these issues, referrals to reproductive specialists, and enthusiasm for available techniques (28). Lack of awareness by healthcare providers regarding the importance of fertility issues may also be an obstacle to optimal care (29). The first step in counseling breast cancer patients regarding fertility is to assess each patient's desire for a future biological child (see Fig. 90-4). The second step is to describe the risk of premature menopause and/or infertility associated with various treatment options so that a patient can make informed decisions about treatments and about fertility-sparing strategies. Some women may elect to forego some therapy if the incremental benefit is modest and the risk of subsequent infertility is high (6).

Fertility Preservation Strategies

For those who desire a future biological child and need systemic therapy that will put them at risk for premature menopause, fertility preservation strategies are available. While studied in other cancer populations, there is limited enthusiasm for using oral contraceptives during chemotherapy in young women with newly diagnosed breast cancer due to concerns that exogenous hormones may worsen prognosis (30). Ovarian suppression with gonadotropin-releasing hormone (GnRH) agonists (e.g., leuprolide acetate) is widely available and can be administered during cytotoxic chemotherapy to attempt to reduce the gonadotoxicity of the treatments by halting ovarian cycling. However, the results of several randomized studies have been mixed with regard to the efficacy of this strategy (31–34). Cryopreservation of oocytes and ovarian tissue, the former of which usually entails ovarian stimulation prior to treatment, are also options where available. Oocyte cryopreservation is widely used internationally and recently had its experimental label removed in the United States by the American Society of Reproductive Medicine (35–38). Oocyte cryopreservation by experienced centers is now nearly as effective as embryo cryopreservation in young women and is particularly appealing to patients who do not have a male partner and do not wish to use donor sperm. Ovarian tissue cryopreservation in theory could allow preservation of hundreds of primordial follicles (containing immature eggs) prior to chemotherapy without ovarian stimulation and the associated concerns about high hormone levels, and without treatment delay, other than to remove the ovarian tissue. However, this method suffers from substantial technical limitations (39), and there have been fewer than 20 published reports of live births to date (40,41). This technique is also associated with theoretical concerns about the reintroduction of cancer cells via the reimplanted ovarian tissue though a recent small study showed no metastatic cells in 51 biopsies of cryopreserved ovaries from patients with breast cancer (42). Research to enable *in vitro* maturation and *in vitro* fertilization of oocytes from these ovarian tissue

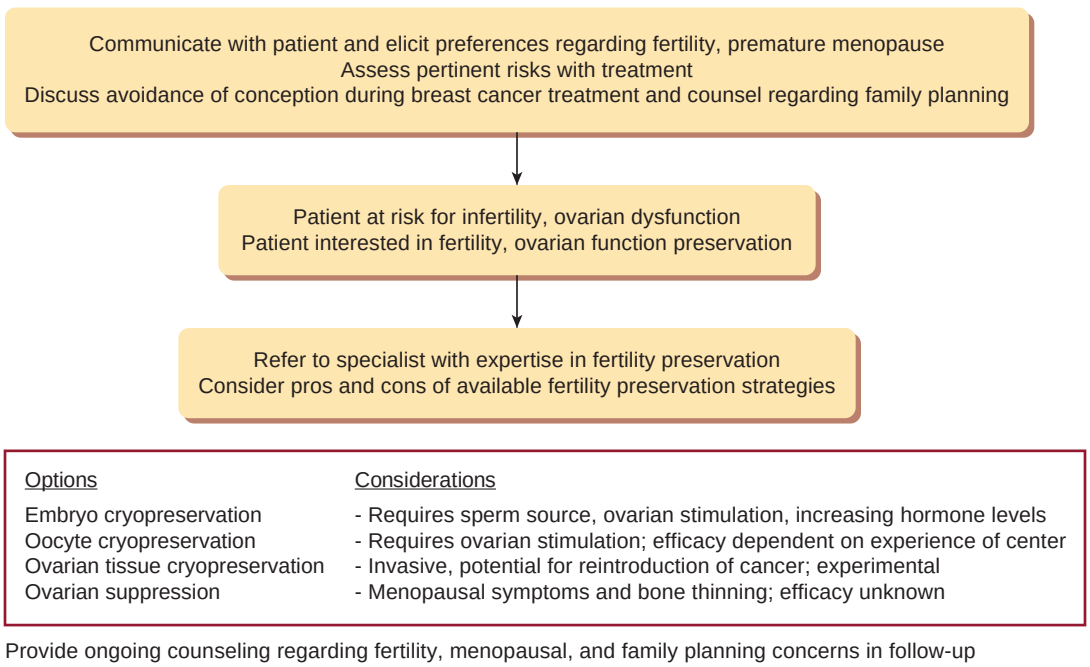

FIGURE 90-4 Management summary for premenopausal women with breast cancer regarding issues. (Adapted from Lee SJ, Schover LR, Partridge AH, et al. American Society of Clinical Oncology recommendations on fertility preservation in cancer patients. *J Clin Oncol* 2006;24:2917–2931.) (Ref. 27)

fragments is ongoing. Cryopreservation of embryos following *in vitro* fertilization (IVF) is a standard procedure with a relatively high success rate in infertile women, with an approximately 20% to 40% live birth rate per transfer of 2 to 3 thawed embryos depending on maternal age, as described at www.sart.org.

Ovarian Stimulation for Egg Retrieval

In women with breast cancer, there has been concern that ovarian stimulation for cryopreservation of oocytes or embryos, with the associated supraphysiologic estradiol and other hormone levels, might increase the risk of cancer recurrence, particularly in the setting of hormone receptor-positive disease. Estradiol levels during traditional stimulated IVF cycles can be greater than 2,000 pg/mL, while levels average less than 300 pg/mL in the normal menstrual cycle. Because natural cycle IVF (not using ovarian stimulation) has much lower oocyte and embryo yield compared to stimulated cycles, alternative stimulation strategies have been investigated. Tamoxifen and letrozole have been used for ovarian stimulation in women with recently diagnosed early breast cancer prior to IVF, and preliminary results are reassuring in that no effect on recurrence is evident (43,44). When letrozole is used during ovarian stimulation, estradiol levels are not substantially higher than in natural menstrual cycles (45). The 2- to 6- week period required for this procedure prior to beginning systemic breast cancer treatment may not be prudent in some disease settings (e.g., inflammatory breast cancer) though this is reasonable for many patients, usually in the interval between surgery and the start of chemotherapy.

ASSESSMENT OF OVARIAN FUNCTION AND FERTILITY AFTER BREAST CANCER

Many survivors are interested in understanding their reproductive potential, but assessment of fertility and even menopausal status after treatment for breast cancer can be complicated and imprecise. Interruptions in menstrual cycles are not sensitive or specific for infertility. Temporary amenorrhea is common after chemotherapy, even in women who later resume menstrual functioning, and hormonal treatments make the presence or absence of menses a less accurate reflection of reproductive potential. In a prospective cohort of 595 premenopausal women age 20 to 40 at the diagnosis of early breast cancer, the proportion experiencing monthly bleeding decreased from 90% to 40% following the first dose of chemotherapy (16). The rates of monthly bleeding rose to 55% over the next 15 months but then slowly declined to 35% at 5 years after diagnosis. Women who were taking tamoxifen were 15% less likely to be menstruating at 1 year after beginning therapy, presumably due to temporary ovarian dysfunction during treatment.

Hormonal biomarkers may clarify how likely a woman is to be able to conceive. Even within the normal ranges of follicle-stimulating hormone (FSH), there may be a correlation between higher levels and poorer chance of conception (46). Women with decreased ovarian reserve often have shorter menstrual cycles due to accelerated follicle development. FSH levels on the third day of menses >10 mIU/mL, resulting in E2 levels >75 pg/mL, cause early ovulation, which is associated with reduced fertility. Inhibin levels and anti-mullerian hormone (AMH) levels may also clarify fertility status. Inhibin A is primarily secreted during the luteal phase, while inhibin B is primarily secreted during the follicular phase. Levels of both decrease during gonadotoxic chemotherapy but may increase to the normal range in those who eventually resume menses (47). AMH levels fall after exposure to chemotherapy for breast cancer (23), and even survivors who resume menses have prolonged reductions in AMH that may herald reduced fertility (48). AMH is produced by early-stage ovarian follicles and, therefore, demonstrates ovarian reserve as reflected by the pool of remaining primordial follicles (49). One recent study showed that AMH >1.2 ng/mL is predictive of more successful egg harvesting in breast cancer patients (50). In addition, vaginal ultrasound can be used to measure the antral follicle count (AFC) on the third day of the menstrual cycle, which is predictive of response to *in vitro* fertilization and potential fertility (51).

However, hormonal manipulation can have a major impact on the values of these biomarkers. Estradiol can be 4 to 5 times higher, and FSH can be markedly suppressed on tamoxifen. Due to the presence of common simple ovarian cysts induced by tamoxifen, AFC while on tamoxifen may not accurately reflect ovarian reserve. AMH is produced in very early follicles and is not influenced by menstrual cycle phase, so it may be the best indicator of ovarian reserve in a woman who has been on tamoxifen although there is only limited research to date in this area (52).

FAMILY PLANNING AND BIRTH CONTROL AFTER BREAST CANCER

Hormonal methods of contraception generally are not recommended for breast cancer survivors because of concerns about a potential effect on breast cancer outcomes, including new primary disease. Barrier methods of contraception or nonhormonal intrauterine devices (IUDs) can be considered to prevent unwanted pregnancy, which can be particularly onerous for young survivors (53).

While there is no clear evidence that ovulation induction or IVF increases the risk of breast cancer (and in fact, the Two Sister Study suggested that women who had received fertility drugs such as clomiphene were at lower future risk of breast cancer) (54), there has been concern that IVF may increase risk of breast cancer in a person with a personal or family history of the disease. IVF has been conducted in cancer survivors, although response to stimulation and subsequent embryo yield have been suboptimal (55).

IMPACT OF PREGNANCY AFTER BREAST CANCER ON ONCOLOGIC OUTCOMES

There has been concern that pregnancy after breast cancer may worsen prognosis, especially among women with hormone receptor-positive disease. To date, the effect of pregnancy after a diagnosis of breast cancer on rates of relapse and survival has not been reported prospectively. Evidence from several retrospective studies on pregnancy following breast cancer suggests no impaired survival or increase in recurrence rate, but these studies are all limited by significant biases (56–60). Table 90-2 presents recent studies evaluating survival among breast cancer survivors who have had a subsequent pregnancy compared to survivors who have not had a pregnancy. Although not all studies reach statistical significance, they all suggest that women who have had a pregnancy

TABLE 90-2

Recent Studies Evaluating Safety of Pregnancy After Breast Cancer

Study	*No. of Breast Cancer Survivors with Subsequent Pregnancy*	*No. of Controls*	*Relative Risk (95% CI) of Recurrence or Death*
Gelber (2001) (56)	94	188	0.44 (0.21–0.46)
Mueller (2003) (57)	438	2,775	0.54 (0.41–0.71)

after breast cancer may actually have a lower risk of recurrence and death. In a recent meta-analysis including data from 14 studies, it was concluded that the 1,244 women who became pregnant after breast cancer had a 41% lower risk of death than the 18,145 young breast cancer patients who did not (61). While these data are reassuring, all studies may be confounded by the "healthy mother" effect (i.e., survivors who are healthier and less likely to develop a recurrence at baseline may be more likely to become pregnant, perhaps in part due to the advice of their physicians) (62). Nonetheless, it is possible that there is a beneficial biological effect from the immunologic changes or high hormonal levels of pregnancy. High-dose estrogen and progestins are effective treatments for breast cancer, and they have demonstrated an antitumor effect in *in vitro* and animal models, possibly due to signaling via the insulin growth factor pathway (63). Ongoing prospective studies may help to elucidate further the risks and benefits of pregnancy after breast cancer.

A common recommendation is for breast cancer survivors to wait at least 2 years after treatment before attempting a pregnancy in an effort to get them beyond the period of highest risk of recurrence. However, the available data have not revealed that an earlier pregnancy impairs disease outcomes. Given that many women with breast cancer are at risk of recurrence long beyond the first few years after diagnosis, and given that fertility wanes with age, some women elect not to wait a substantial period of time to become pregnant after diagnosis. For women with hormone receptor-positive disease, five to ten years of tamoxifen therapy is often recommended, during which time pregnancy is contraindicated. This approach is problematic for many women, given the concerns about declining fertility, and some may elect to forgo completion of a course of tamoxifen to try to become pregnant sooner rather than later.

PRACTICAL ISSUES PERTAINING TO PREGNANCY AND LACTATION AFTER BREAST CANCER

There are a range of medical and psychosocial issues that impact whether a breast cancer survivor who is interested in future fertility ultimately becomes pregnant. There are limited data on fertility and pregnancy outcomes among women with a history of breast cancer. Findings from select populations of young women with breast cancer suggest that approximately 5% to 15% of young breast cancer survivors will become pregnant at least once after their diagnosis (59,64). Three large studies including nearly 4,000 total offspring of childhood cancer survivors, excluding clearly hereditary cancers, revealed no statistically significant increase in cancers or malformations (65). Some BRCA1 or BRCA2 mutation carriers will consider *in vitro* fertilization with embryo biopsy and preimplantation genetic testing or prenatal genetic testing once they are pregnant (66). Women who have been treated with cytotoxic agents in the past may be at increased risk of peripartum complications (e.g., cardiomyopathy due to prior anthracycline and trastuzumab), but data are scarce. Future research in this area is warranted, and women with a history of breast cancer treatment should consider receiving "high risk" obstetrical care during a pregnancy.

Breast cancer survivors who have a baby may be interested in breast-feeding (53). The degree to which local therapy has affected the normal breast anatomy will dictate the ability of that breast to produce milk. Women who have had a mastectomy can lactate from the opposite breast. Milk production may be limited by the lack of the second breast, and substantial asymmetry may result between the engorged, lactating breast and the contralateral chest wall or reconstructed breast during the period of lactation. For women who have undergone breast conserving therapy (BCT), resection of a centrally located tumor, particularly if affecting the nipple-areolar complex, is more likely to impair lactation. Radiation therapy can cause lobular sclerosis and atrophy within breast tissue, which may also limit milk production (67). Asymmetry may be a problem in this situation as well, with the treated breast producing less milk. In a multicenter, retrospective review of 53 women who became pregnant after BCT, one-third had some lactation from the affected breast. Many of these women reported low milk output or the baby preferring the untreated breast, and only 25% of women were able to successfully breast-feed from the treated breast (68). While it is evident that lactation works as primary prevention against breast cancer, there have been no efforts to evaluate the benefits of lactation in breast cancer survivors, in part because so few survivors have successfully breast-fed.

MANAGEMENT SUMMARY

- Young women with early stage breast cancer have a strong desire to not only decrease their risk of recurrence but to continue to live satisfying lives.
- Some feel that the ability to have a biological child in the future is important to their quality of life.
- Discussions about fertility should be tailored to each patient's preferences, taking into account the baseline risk of her disease, risk reduction from recommended therapy, as well as risk of infertility from treatment.
- Because of the time-sensitive nature of treatment initiation as well as of most fertility preservation strategies, early referral to a fertility specialist is prudent for those interested (27).
- For some patients, a combination of fertility preservation strategies may be optimal, while many will elect to forgo any such intervention.
- Regardless, shared and informed decision-making not only about conventional risks of treatment (e.g., nausea, hair loss, fatigue) but also about the possibility of treatment-related infertility is likely to lead to more realistic expectations and better psychosocial outcomes for young breast cancer survivors.
- Healthcare providers should also educate patients about effective and safe contraception during and after their breast cancer treatment.

CHAPTER 91

Cost and Cost Effectiveness Considerations

Bruce E. Hillner

CHAPTER CONTENTS

Cancer care costs have been growing faster than the overall rates of health care, especially over the last 20 years. The combination of the 2008 worldwide recession and the recent U.S. debate over healthcare reform has focused attention on the rising costs of new cancer therapies. U.S. costs for breast cancer care were estimated to exceed $16 billion in 2010 (1) and are the highest overall of any cancer type.

The spiraling costs of new cancer therapies are increasingly recognized by cancer professional organizations such as ASCO (2)and ACS, but what to do about them is another hurdle without consensus. Since 2008, the greatest source of discussion focusing on breast cancer costs is likely to have been around the FDA. decision to revoke the approval of bevacizumab. Those discussions were usually a mix of concern about the bevacizumab's costs (~$88,000 per year of treatment) and/or an implicit cost-effectiveness analysis ("it's not worth it") given the uncertainties of any overall benefit (3).

In this chapter, I will review the literature published since 2008 that addresses the costs and cost-effectiveness of breast cancer assessment and treatments for the initial care, adjuvant therapies, and advanced/recurrent disease as well as highlight where these reports by inference give guidance to quality of care indicators.

For this review, I searched Medline for publications from January 2008 to late 2012 with the following search characteristics: breast neoplasm/economics, an abstract (except for editorials), English languages, and excluded reports addressing prevention, strategies for high-risk women, and screening (principally mammography). The individual report abstracts were reviewed for relevance to U.S. clinical practice, thereby excluding many reports from limited resource countries. Table 91-1 lists the categories used to structure this review.

COST ANALYSIS VOCABULARY

Before jumping into the review, because most readers of this book are not knowledgeable about the methodology used in these reports, the following brief section discusses the key terms as a platform for the chapter.

There are five common categories of cost studies used in assessing healthcare. The first category, *cost of illness* studies, are studies that describe the financial burden or consequences of illness but do not make any comparison to other conditions. A *cost comparison* report explicitly addresses the relative costs of two (or more) approaches or populations. A comparison report will specify what cost elements and time frame are being compared and defers to the reader to make any inferences.

Cost minimization reports either explicitly or implicitly assume no difference in the benefit (or harm) incurred between two different approaches. By comparing the costs incurred, the lowest cost strategy will be, by definition, preferred as it has the lowest cost. The recent American Board of Internal Medicine Foundation Choosing Wisely® (www.choosingwisely.org) campaign fits the definition of cost minimization. Each specialty was asked to identify five tests or procedures commonly used whose common use and clinical value are not supported by the literature. The ASCO list for cancer included the following breast cancer topic: avoid advanced imaging in staging early breast cancer as well as in the surveillance of asymptomatic individuals' post-initial treatment (4).

Cost-effectiveness analyses (CEA) and *cost-utility analyses* (CUA) estimate the additional cost per unit of benefit associated with the use of a given intervention as compared to the alternative. The intervention of interest can be of any type: prevention, screening, diagnosis, treatment, or symptom control. CEAs consider either a specific health effect

Summary Costs

(e.g., disease free survival) without assigning a specific value to it or use years of life. A CUA is a specific type of cost-effectiveness analysis that combines mortality and morbidity into a single multi-dimensional measure called a quality adjusted life year (QALY).

The result of a CEA is usually expressed as a ratio of the difference in cost between the two competing strategies divided by the difference in benefit. A CEA is of most interest when the new intervention is more effective and more costly than the reasonable alternative strategy. The lower the ratio of the additional cost of the new intervention to gain the additional benefit, the more appealing to society as a whole it is to add the intervention to current medical approaches.

For the interested reader, several sources of standards and checklists for best practice reporting of CEA studies are available (5–7). In this chapter, three recurring concerns will be pointed out: —i) In cost minimization studies, was it appropriate to assume the two strategies are equally effective? ii) Were the data used to guide the efficacy estimates accurate, representative, and credible? and iii) Was the default strategy representative of current patterns of care in a particular location and during those years?

LIFETIME COSTS

Accurate, current estimates of the cost of illness incurred for breast cancer treatment are hard to identify. In the United States data sources have shifted from single centers to claims analyses have been predominantly of three different groups—patients insured by Medicaid (poor and relatively young), patients insured by self-insured employers (wealthier, young) and the elderly (usually with a linkage of Medicare claims with registry data from SEER).

TABLE 91-2

NCI 2010 Estimates of U.S. Costs for Breast Cancer Care

Phase of Illness	*Age <65*	*Age >65*
Initial year	$27,700	$23,100
Continuing care (per year)	$2,200	$2,200
Last year of life	$94,300	$62,900

Modified from Mariotto AB, Yabroff KR, Shao Y, et al: Projections of the cost of cancer care in the United States: 2010–2020. *J Natl Cancer Inst* 2011;103:117–128.

Mariotto and colleagues from the NCI (1) have recently updated their national projection of costs for 2010 and projected to 2020 associated with care for 15 different cancer types including breast cancer (1). Table 91-2 shows their projections for breast cancer. The higher costs for women younger than 65 years were based on studies from integrated managed care organizations (in the 1990s) that showed costs for younger patients (of all cancer types) were 20% higher in the initial year and 50% higher in the last year of life than for Medicare beneficiaries. In my opinion, especially for younger women, the initial management costs are likely a substantial under-estimation as the type and frequency of more-expensive adjuvant chemotherapies are more common in younger women. In either case, their first year costs (local surgical therapy, axillary staging/dissection, and adjuvant therapies) were estimated at $25,000 to $30,000, continuing care after the first year at $2,200, and for those developing recurrent disease, the average costs in the last 12 months of life were $63,000 to $94,000.

The challenges in doing cost-of-illness studies in breast cancer were addressed in two excellent reviews (8,9). The review (n = 29) reports of U.S. costs of illness studies published between 1984 and 2007 covered a broad range ($20,000 to $100,000 per lifetime) (8), were predominantly from an insurer/third party payer perspective, predominantly of early stage disease, and did not include many, or most, of the expensive innovations of the last decade (e.g., IMRT, CSFs, 3rd generation chemotherapy). These limitations, or under-estimations, from either inaccurate or outdated sources have an often important hidden impact when added to most economic evaluations because these need to project the future. Fortunately, there have been recent reports of new, large, detailed analyses of U.S. metastatic disease costs that will be discussed later.

DIAGNOSTIC PROCEDURES

The increased use of stereotaxic core biopsy has reduced the rates of open surgical biopsy throughout the world. Between 2000 and 2005, in the Netherlands, surgical biopsies were reduced from 54% to 10% of the total diagnostic costs associated with screen detected breast cancers (10). A Swedish audit of fine-needle aspiration (FNA) cytology compared to core needle biopsy (CNB) found a difference; FNA had lower rates of definitive diagnosis, more additional needle biopsy, or surgical biopsy prior to definitive surgery (11). An Austrian budget impact audit of CNB compared to open surgical biopsy found a 30% total cost reduction per lesion and obviated the need for open surgical procedure in 60% of women (12).

For these non-palpable lesions, the current standard of wire localization (WL) to guide surgical excision appears to be evolving. WL is unfortunately associated with positive margins due to migration. Radioactive seed localization that permits equal or superior localization and is associated with lower re-excision may be another major cost-reduction tool if the results from experienced centers using it become generalizable (13). To date, no cost consequence studies of radioactive seeds were identified.

Ongoing uncertainty persists concerning the role of breast MRI in the initial staging. The cost of a dedicated breast MRI is high and the downstream costs of pursuing false-positives are well known. Changes in primary surgical treatment were noted in 8% to 33% of women in a recent meta-analysis, yet without randomized, prospective assessments the benefit value cannot be determined (14).

STAGING THE AXILLA

The rapid acceptance of the use of axillary sentinel lymph node detection to guide managing axillary lymphadenectomy was reinforced by several cost-minimization reports from around the world. The French reported a prospective national, multi-institutional, cost comparative analysis found an ~12% reduction in costs (15) while a large, single center, Italian series found cost savings of 10% to 26%. The potential role of axillary ultrasound in obviating the need for SLN for patients with bulky enlarged nodes has intuitive appeal but prospective, comparative studies are needed (see Chapter 38) (16).

RADIATION THERAPY

Alternatives to the traditional 6-week course of whole breast radiation following breast-conserving surgery have obvious cost of care implications with uncertain relative cost-effectiveness. The first alternative is more expensive with uncertain reductions in local control. Intensity-modulated radiation therapy (IMRT) has been rapidly adopted in the United States, increasing from <1% of women in 2001 to 11.2% in 2005 among the U.S. elderly, with a doubling of costs compared to whole breast radiation (Medicare payments $15,230 for IMRT vs. $7,180 for whole breast) (17).

Shorter courses using hypo-fractionation, accelerated partial breast, or targeted intra-operative radiotherapy are all less costly. Hypo-fractionated whole-breast radiotherapy (WBR) (over 3 weeks) in Australia was estimated to reduce total treatment costs by 24% (18). The major uncertainty is whether these shorter courses lead to inferior outcomes in terms of local recurrences. Another factor is whether patient selection is appropriate. The economic consequences of accelerated partial-breast irradiation (PBI) as an alternative to WBR or IMRT are still uncertain, especially in light of a recent report stating that about one-half of Medicare patients receiving PBI did not receive the level of care recommended by the American Society for Radiation Oncology consensus guidelines (19).

PROGNOSTIC AND PREDICTIVE FACTORS

The challenges associated with obtaining Medicare coverage for innovative diagnostics (e.g., molecular imaging, genomic profiling, circulating tumor cells) are well illustrated by the many year battle prior to recent Medicare coverage of Oncotype Dx and Mammaprint. Fifteen reports were found addressing the cost consequences of genomic predictions. As reviewed in detail in Chapter 48, the current patient subgroups for which these tests should be used are cancer that are ER+ with axillary node negative and possibly one-three node positive women eligible for chemotherapy. Pricing in 2012 for Oncotype Dx and Mammaprint are almost identical at $4,200.

The economic consequences have been assessed by hypothetical decision models using Markov chains to estimate projected costs from the societal perspective in Canada, Europe, Israel, Japan, and the United States Hornberger et al compared and summarized these economic assessments in a 2012 review (20). In sum, each gene profiler is superior to authoritative guidelines, Adjuvant!, or current practice. We are unaware of any direct comparisons of Oncotype Dx to Mammaprint. The incremental cost-effectiveness ratios, or cost-savings results, varied with the pre-test recurrence risk (node-negative, positive, or both), the costs of chemotherapy used (especially dose-dense), time horizon, and comparator (Adjuvant! was the second best). For example, in a U.S. managed care setting, Oncotype showed costs savings and the incremental costs were <$30,000/QALY. These assays are the first of their kind and suggest that the best care is less care.

ADJUVANT THERAPY—ENDOCRINE THERAPY

Several reports addressed the question of adherence to hormonal aromatase inhibitors (AI) in U.S. women using administrative pharmacy benefit claims. Neuget et al. assessed mail order prescription records from January 1, 2007, to December 31, 2008 for women older than 50 years (21). They used two distinct, useful definitions—"non-persistence" was defined as a prescription supply gap of more than 45 days without subsequent refill and "non-adherence" was a medication possession ratio of less than 80% of eligible days. This study of 8,100 women age 50 to 64 years and 14,000 age >65 found non-persistence in 21% and 24% and non-adherence in 11% and 9% by age group, respectively. As expected, higher co-payment amounts were associated with both types of gaps. A similar type of analysis that assessed the first year following an initial claim for an AI found non-adherence (using the same definition as Neuget) was 23% over the year in 13,600 commercially insured women. Co-payments >$30 per prescription, younger age, and higher co-morbidity was associated with non-adherence (22). In a one-state Medicaid cohort (n = 1,538) adherence was even lower (58% at one year) and more troubling was that hormonal therapy of any kind was not promptly initiated within one-year (68%) in an analysis of linked pharmacy claims and state cancer registry (23).

Numerous cost-effectiveness assessments of different AIs and schedules were reviewed in the previous edition of this book!. A unique analysis reviewed economic analyses of AIs in breast cancer published between 1999 to 2008 (n = 32) and categorized the conclusions of the reports and pharmaceutical company sponsorship (n = 26). Only one of the 26 (4%) pharmaceutical company-sponsored studies reported unfavorable cost-effectiveness of an AI, which was a competitor's product, whereas two of four (50%) non-pharmaceutical company-sponsored studies concluded AIs are not cost-effective in certain clinical scenarios (p < .05). Seven pharmaceutical company-sponsored studies conducted a comparison among several AIs; all 7 studies reported favorable conclusions for the sponsoring company's products (24).

ADJUVANT THERAPY—CHEMOTHERAPIES

Twelve different cost-effectiveness analyses were reported that all addressed the use of docetaxel in node-positive disease and used either the BCIRG001 (TAC vs. FAC) or the PACS 01 trial (FEC-D vs. FEC) as the efficacy source for their projected CE ratios. For more detailed discussion of these findings see Chapter 44. What is most notable is that these analyses were from such a divergent group of countries (Canada, Korea, Spain, U.K., China, France, Japan, and Iran). With the exception of Iran, where the toxicities may have been overweighted, all reports using modeling of future anticipated benefits, found that the docetaxel regimens were "cost-effective." For example, the British assessment, using a 10-year timeframe, projected that TAC with growth factor support had an incremental cost/QALY of 20,400 pounds (25) and the French assessment of FEC-D found an incremental cost/QALY of 9,700 euro (26). Relatively low, favorable incremental cost-effectiveness ratios were associated with pharmaceutical support of the study. One noteworthy, indirect economic analysis for four regional Ontario cancer centers noted that FEC-D, in routine practice, was associated with febrile neutropenia in 23% of women. The costs of FEC-D should assume primary prophylaxis with growth factors for all women (27). These economic analyses, given the febrile neutropenia concerns, support the apparently worldwide adoption of these combinations.

Growth Factors

In most Western countries in 2013, the most expensive element of more aggressive third generation adjuvant therapies, or dose-dense therapies, is granulocyte colony-stimulating factors (CSFs). Several industry supported cost-effectiveness models were reported showing benefits from primary prophylaxis with peg-filagrastim in support of a highly myelo-suppressive regimen (28,29). These models inherently hinge upon superior efficacy of the new therapy. Hershman has recently reported that U.S. oncologists were early adopters of dose-dense therapy leading to an explosion in the use of CSFs in Medicare recipients since 2003 (30). However, with longer follow-up and subsequent trials, the benefits of dose-dense treatment in estrogen receptor positive disease are now more uncertain (31,32). It is now thought that substantial savings could occur if dose-dense therapy were restricted to women with ER-negative, luminal B-type cancers.

Trastuzumab

Several results of ongoing follow-up of the pivotal adjuvant trials of trastuzumab have economic consequences—the benefits are durable well beyond the initial follow-up years, treatment for two years versus one year provides no additional benefit (33), and the late development of congestive heart failure is uncommon (34). The drug is very effective and the concerns about the dire financial consequences of this expensive drug have not come to pass. While the price paid per unit of trastuzumab varies from country to country, adjuvant trastuzumab has been widely adopted in most economically advanced countries. It is also reassuring that the favorable incremental cost-effectiveness ratios reported by numerous independent teams were found in a 2011 review to be of high methodological quality (35). One noteworthy report suggested that by 2016 the use of adjuvant trastuzumab in the United States would yield a ratio of adjuvant vs. metastatic trastuzumab of 3:1 due to it's efficacy in preventing metastatic recurrences (36). A new concern, at least in the United States, is that women of color and/or low education were found in a NCCN database to less often complete full duration (>9 months) of therapy (37).

EMPLOYMENT CONSEQUENCES

The adverse impact of the initial, and adjuvant treatment of, early stage breast cancer on employment is generally recognized. In general, the impact is greater in blue-collar, self-employed, lower-wage, and non-Caucasian women (38). Even in Canada, a study of 962 women from eight hospitals found they lost an average of 27% (median) of their projected annual wages in the first year of treatment (39). Two similar studies of commercially insured women addressed short-term disability. Each study had >800 patients. The first observed an average of 35 days of absenteeism and 51 days of short-term disability and the second 60 days of disability (40,41). In the latter report, however, there was no difference between years 2 and 4 and breast cancer survivors stayed with their employer longer.

PAYING FOR QUALITY CARE

One unique 2004 report from Los Angeles examined the use of financial incentives related to performance on quality measures reported by medical or radiation oncologists and surgeons associated with a population-based cohort of patients with breast cancer (42). In this survey of 350 providers, about 20% reported financial incentives based on patient satisfaction and 15% based on guideline adherence, predominantly for services through a network-model HMO.

SECOND AND THIRD LINE METASTATIC THERAPY

The few cost-effectiveness reports of second or third line therapies all found relatively high CE ratios. The Swiss addressed continuing or stopping trastuzumab (and adding capecitabine) at the time of progression when treating *HER2*+ metastatic disease and found a gain of ~0.3 QALY at ~100,000 euros/QALYs (43). The alternative of switching to lapatinib (plus capecitabine) was projected to have a gain of only 0.12 QALYs at $166,000 per QALY (44). A third report of an economic companion study including quality of life estimates of the licensing trials comparing ixabepilone plus capecitabine vs. capecitabine for metastatic disease progressive after anthracyline and taxane treatments adds about $31,000 in cost and is associated with about one-month of quality adjusted survival (45). We had the opportunity to write the accompanying editorial highlighting that efficacy does not necessarily translate into cost-effectiveness (46).

Brain Metastases

The direct medical care costs for brain metastases were addressed in two reports. A U.S. commercial insurer database from 2002 to 2004 identified 779 incident brain metastases patients whose costs of care and/or utilization indicators compared to non-brain metastatic breast cancer were about double—mean twelve-month payment of ~$100,000 vs. $47,900 (47). A French national database analysis of all patients admitted in 2008 for brain metastases and who previously had received target anti-*HER2* therapy found 2,100

women whose annual hospital treatment costs were 22,500 euros (48).

Metastatic Disease

Three European reports tracked deaths from metastatic cancer using either a region (Uppsala, Sweden) or single centers (Great Britain and France) (49,50,51). While these reports provide summary estimates for costs by site of care (inpatient vs. outpatient), they do not provide the units consumed (e.g., hospital days, chemotherapy days, radiation days). The Swedish audit of 53 patients—ER+ 60%, *HER2*+ 25%, mean 26 months and median survival 19 months—suggest a representative disease severity distribution. Totals costs were estimated at 93,700 euros (95% CI 78,500–109,600) in 2006 currency. The British estimate included 30% local recurrences and little trastuzumab use; therefore, their estimates are artificially low at 25,200 pounds per patient. The French report of 290 women from 2005 to 2008 is more detailed. This cohort's survival from diagnosis of metastatic disease was an average of 25 months and a median survival of 18 months. They stratified costs into the following categorizes –50% for outpatient chemotherapy, 38% for inpatient care, 15% for palliative care, and only 4% for radiotherapy. Total costs were 36,500 euros in 2008 currency.

Several large multi-year detailed analyses of American insurer data of employed women with claims-inferred metastatic breast cancer provide a much-needed cost-of-illness summary (52–54). These reports all used a similar approach—a HIPPA compliant, de-identified administrative claims payment record for women with employee-sponsored health insurance. The index date for presence of metastatic disease was defined by the first one or two dates of claims with a diagnosis of secondary malignant neoplasm (ICD 196.xx) plus breast cancer (ICD 174.xx). Each used total payments including patient deductibles, copays, and/or coinsurance. One analysis stratified therapies by drug-inferred type (hormonal, *HER2*, cytotoxic, and no systemic therapy), a second on payments from the first chemotherapy claim without concurrent hormonal therapy or trastuzumab claims, and the last on inferred hormone receptor positive disease based on hormonal therapy (oral or infusion) without concurrent chemotherapy.

Table 91-3 shows the results from 7,700 women (with an average age at index of 52 years, and average follow up of 2.2 years) meeting the above definition of metastatic cancer between 2003 and 2009. Stratified by inferred treatment types the cohort included 41% hormonal only therapy, 9% *HER2* treatment with trastuzumab, 29% with at least three months of cytotoxic chemotherapy claims, and 20% with none or less than three months of these cancer-directed therapies (53). Costs were reported as payments per patient per month (PPPM). The average PPPM was $9,800 and, at the average 2.2 years of claims, equates to a lifetime cost of $250,000 per woman! For the three active therapy categories, inpatient hospital costs accounted for 20% to 33% of costs versus about 50% in women receiving no active therapy. Anti-cancer therapy, including anti-emetics, bisphosphonates, and red or white cell growth factors accounted for about 20% in the hormonal only therapy group, 25% in the chemotherapy group, and 49% in the *HER2* group. The average size of the expenditures for all forms of outpatient diagnostics (blood and imaging) of >$20,000 per woman and radiation therapy (for presumed bone or brain metastases) of ~$9,000 were surprisingly high.

Table 91-4 shows the results from the analysis of 1,444 women from their first chemotherapy claim without hormonal or *HER2* therapy (52). This report of care between 2000 and 2006 is useful as it gives resource use averages separate from aggregated payments. During these years, hospitalization became an infrequent event and is likely even lower in 2012—1.7 lifetime admissions for an average of 10.7 days (including end of life) and accounted for only 25% of overall payments. The volume of outpatient unique

TABLE 91-4

Payments for 1,444 Women with Metastatic Disease Receiving Chemotherapy

Category		*Costs, 2006 fl $*
Total Payments		128,600 (95% CI, 118,400–137,600)
Hospitalizations—n, days	1.7, 10.7	**25,400«**
Outpatient Services, total		**37,900**
Office Visits, n	59	2,900
Diagnostic Radiology	*	7,200
Therapeutic Radiology	*	5,000
Other Outpatient Service		17,500
Medications, Total		**65,300**
Chemotherapy		31,600
G-CSF		5,000
ESAs		5,600
Anti-emetics		2,700
Bisphosphonates		2,800
Other meds		17,550

Costs rounded to nearest 100.
«Professional charges for inpatients were not separately reported
*An additional 25 days for hospital outpatient services (such as therapeutic radiology).
Modified from Vera-Llonch M, Weycker D, Glass A, et al. Healthcare costs in women with metastatic breast cancer receiving chemotherapy as their principal treatment modality. *BMC Cancer* 2011;11:250.

visits is the real news—an average of 59 lifetime outpatient visits plus an additional 25 days to hospital outpatient services as well as 6 days of home health or hospice. Overall, medication costs accounted for about 50% of overall care ($65,300 per woman) costs of which about one-half was for cytotoxic chemotherapy. The last report estimated costs incurred for women only receiving hormonal therapy as well as after they transitioned to receiving chemotherapy (54). In this cohort, the combined drug costs after starting chemotherapy accounted for about 2/3 of overall costs.

PALLIATIVE AND END OF LIFE CARE

No reports were found that specifically assessed breast cancer patient patterns or costs of their end of life care. The reader is directed to an analysis of end-of-life care in the U.S. elderly of beneficiaries with cancer from 2003–2007 involving about 215,000 cancer decedents of whom 5.6% had breast cancer (55). Key findings were a commonly high intensity of care in the last month of life (e.g., 30% death in hospital, 64% hospitalized) and late hospice used (median 8 days before death). The intensity for younger women who have been through all available effective therapies is likely even higher.

How to address the societal problem of patients (and their families) having unrealistic expectations and the failure of physicians to be more forthright in their prognosis and resistance to giving futile cancer-directed therapy are beyond the scope of this chapter. The reader is directed to the further discussion of this in Chapter 73 by Jennifer Cheng and Thomas Smith as well as their recent commentary (56).

SUMMARY

Oncology practitioners and their professional organizations are increasingly aware of the need to address the spiraling escalation of cancer care costs. As a broad generalization, most attention has focused on routine measurement and improvement in quality of care metrics without attending to the associated costs. Targets for substantial cost savings need to stratify between initial therapies versus recurrent disease. Obvious targets are for shorter, simpler radiotherapy of the primary site, less (or more targeted) use of adjuvant chemotherapy requiring colony-stimulating factors, sequential monotherapies for advanced disease, and in all situations less imaging. The breast cancer scientific community has been the leader in innovative basic and translational science. The breast cancer practitioner community needs to be leaders in a new dimension of competency—stewardship of financial resources and for practicing in a cost-conscious fashion (57). Stewardship of resources or for practicing in a cost-conscious fashion (57). If not, further erosions of our professional independence, patient choice, access to care, and fewer new therapeutic options will prevail.
